Preface

These proceedings contain abstracts for the talks and posters of the 24th Asian Quantum Information Science conference, AQIS'24, held from August 26th to August 30th, 2024, at Hokkaido University, Sapporo, Japan.

AQIS, the successor to the EQIS conferences held in Japan from 2001 to 2005, has been the foremost Asian conference series converging all aspects of quantum information science, the burgeoning interdisciplinary field across quantum physics, computer science, mathematics, and information technologies, which includes theoretical and experimental research in all of the following areas: quantum computation and simulation, from algorithms and complexity to circuit design; quantum programming languages and semantics; quantum information theory; quantum cryptography, communication, and more general network tasks; quantum gate design and architecture; quantum technologies and related fields such as quantum foundations, quantum metrology, many-body quantum (thermo)dynamics, and quantum space-time.

This year's program comprises 7 invited talks, 55 contributed talks (12 long and 43 regular talks), and 218 posters. In response to the Call for Papers, we received record-breaking 312 submissions for talks by the deadline of May 20th. Of these, 55 contributed talks (i.e., the acceptance rate is less than 18%) were selected via intensive reviews within a limited period of time, followed by serious discussions between all members of the Program Committee.

We would like to thank the invited speakers and all authors who submitted abstracts of papers for consideration. We would also like to thank the AQIS'24 conference chair, Prof. Akihisa Tomita; the conference Steering Committee, chaired by Prof. Jaewan Kim; and the Organizing Committee, chaired by Prof. Shigeru Yamashita. Lastly, we would like to express our deep gratitude to all the members of the Program Committee, who accomplished difficult tasks with great perseverance and dedication within such a limited period.

Quantum processes with indefinite input-output direction

Abstract. At the fundamental level, the dynamics of quantum particles and fields is time-symmetric: their dynamical equations are invariant under inversion of the time coordinate, possibly in conjunction with the change of other physical properties, such as charge and parity. At the operational level, the time-symmetry of the fundamental equations implies that certain quantum devices are bidirectional, meaning that the role of their inputs and outputs can be exchanged. Here we characterize the largest set of operations that can in principle be implemented on bidirectional devices, and show that this set includes operations in which the role of the input and output ports of the given devices becomes indefinite. An example of such an operation, called the "quantum time flip," achieves input-output indefiniteness by adding quantum control to the direction in which a single device is used. We show that quantum operations with indefinite input-output directions can in principle achieve information-theoretic advantages over all possible operations with definite time direction, and can lead to an extrmely strong form of indefinite causal order.

Color code decoder with improved scaling for correcting circuit-level noise

Seok-Hyung Lee[1] * Andrew Li[1] Stephen D. Bartlett[1]

[1] *Centre for Engineered Quantum Systems, School of Physics, The University of Sydney, Sydney, NSW 2006, Australia*

Abstract. Two-dimensional color codes are a promising candidate for fault-tolerant quantum computing, as they have high encoding rates and transversal implementation of logical Clifford gates. However, decoding color codes presents a significant challenge due to their complex structure. We introduce an efficient color-code decoder that tackles these issues by combining two matching decoders for each color, generalized to handle circuit-level noise by employing detector error models. Our simulations reveal that this decoding strategy nearly reaches the best possible scaling of logical failure ($p_{\text{fail}} \sim p^{d/2}$), where p is the physical noise strength, which significantly outperforms the best matching-based decoders.

Keywords: Quantum error correction, Color code, Decoder

1 Introduction

Two-dimensional (2D) color codes [1, 2], visualized in Fig. 1, are a family of stabilizer quantum error-correcting codes that can be realized with local interactions on a 2D plane, and provide a promising pathway for implementing fault-tolerant quantum computation. Compared to surface codes [3, 4], color codes have several noteworthy advantages: (i) They have higher encoding rates for the same code distance [5], (ii) all the Clifford gates can be implemented transversally [1], and (iii) an arbitrary pair of commuting logical Pauli product operators can be measured in parallel via lattice surgery [6]. In addition, the well-studied Steane code is a small instance of a color code, and recently a number of fault-tolerant operations including transversal logic gates and magic state injection have been demonstrated using color codes [7–11].

For these desirable features to be exploited for fault-tolerant quantum computing in practice, we need better decoders for color codes. Surface codes benefit from the many advantages of a decoding approach based on 'matching', which is a standard method to handle errors in codes that can only have *edge-like* errors (namely, elementary errors violate at most two checks). Matching-based decoders can operate both efficiently and near-optimally, and are readily adapted to handle noisy syndrome extraction circuits. In color codes, an elementary error, which is a single-qubit X or Z error, is generally involved in three checks, and so a matching decoder cannot directly be used. Moreover, considering realistic circuit-level noise makes decoding more difficult because the color code syndrome extraction circuits are more complex than for the surface code. As a result of these deficiencies, existing decoders for the color code do not perform as well as expected either in terms of error thresholds or for sub-threshold scaling of the logical failure rate.

Several approaches to decode errors in color codes have been proposed. The most widely studied methods are the projection decoder and its variants [12–16], which can achieve thresholds of around 8.7% for bit-flip noise [12] and around 0.47% for circuit-level noise [16]. However, they have a fundamental limitation that the logical failure rate p_{fail} scales like $p^{d/3}$ below threshold [14, 16, 17], not $p^{d/2}$, where p is a physical noise strength and d is the code distance. Such a drawback may significantly hinder resource efficiency of quantum computing; roughly speaking, it demands 9/4 times as many qubits than the case with an optimal decoder if other factors are the same. The Möbius decoder [17] is another matching-based decoder, which achieves a higher threshold of 9.0% under bit-flip noise and, more importantly, a better scaling of $p_{\text{fail}} \sim p^{3d/7}$. The decoder has subsequently been improved to accommodate circuit-level noise and general color-code lattices [18].

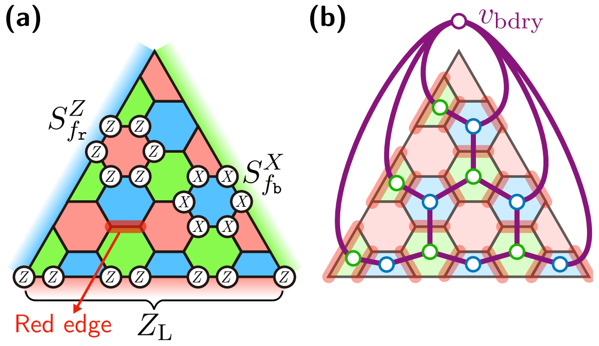

Figure 1: **(a)** Triangular 2D color code with code distance $d = 7$ based on a hexagonal lattice. Each vertex hosts a qubit and each hexagonal face is associated with a pair of Z-type and X-type checks. Logical operators X_L and Z_L are supported on one of the three boundaries. **(b)** Red-restricted lattice. Vertices and edges are shown as blue/green circles and purple lines, respectively.

In this work, we propose a matching-based color-code decoder, which we call the *concatenated minimum-weight perfect matching (MWPM) decoder*, that demonstrates exceptional sub-threshold scaling of the logical failure rate in regimes of interest for fault-tolerant quantum computing. Our decoder functions by 'concatenation' of two matching decoders per color, for a total of six

matchings. We demonstrate that this decoder can be generalized to handle circuit-level noise by using the concept of *detector error model*. Notably, the logical failure rates of the concatenated MWPM decoder below threshold is shown to be well-described by the scaling $p_{\text{fail}} \sim p^{d/2}$ for both bit-flip and circuit-level noise models. Thanks to this improvement, its sub-threshold performance significantly surpasses the projection decoder. Compared to the Möbius decoder, our decoder has a similar scaling factor against d but achieves approximately 3–7 times lower logical failure rates for circuit-level noise when $10^{-4} \lessapprox p \lessapprox 5 \times 10^{-4}$.

Technical description of our work is presented in Ref. [19].

2 Concatenated MWPM decoder

We first describe the 2D variant of the concatenated MWPM decoder that is applicable only when every syndrome measurement is perfect. Let us consider the 2D color code on a lattice $\mathcal{L}_{\text{2D}}$, which may have boundaries. The decoder to predict X errors in a single round can be briefly depicted as follows (see Fig. 2 for an example):

1. **(First-round MWPM)** Input violated blue and green Z-type checks to the MWPM algorithm on the red-restricted lattice $\mathcal{L}^*_{\neg\mathtt{r}}$, which returns a set of edges of $\mathcal{L}^*_{\neg\mathtt{r}}$. This set corresponds to a set $E^{(\mathtt{r})}_{\text{pred}}$ of red edges of $\mathcal{L}_{\text{2D}}$, each of which is predicted to contain one X error. See Fig. 2(a).

2. **(Second-round MWPM)** Input $E^{(\mathtt{r})}_{\text{pred}}$ and violated red Z-type checks to the MWPM algorithm on the 'red-only lattice' $\mathcal{L}^*_{\mathtt{r}}$, which is constructed according to the connection structure of red edges and faces in $\mathcal{L}_{\text{2D}}$. The algorithm returns a set of edges of $\mathcal{L}^*_{\mathtt{r}}$, which correspond to a set of vertices $V^{(\mathtt{r})}_{\text{pred}}$ of $\mathcal{L}_{\text{2D}}$ that are predicted to have errors. See Fig. 2(b).

3. Repeat the above two steps (together referred to as the *red sub-decoding procedure*) while varying the color to green and blue, obtaining $V^{(\mathtt{g})}_{\text{pred}}$ and $V^{(\mathtt{b})}_{\text{pred}}$. Select the smallest one V_{pred} among $V^{(\mathtt{r})}_{\text{pred}}$, $V^{(\mathtt{g})}_{\text{pred}}$, and $V^{(\mathtt{b})}_{\text{pred}}$ as the final outcome.

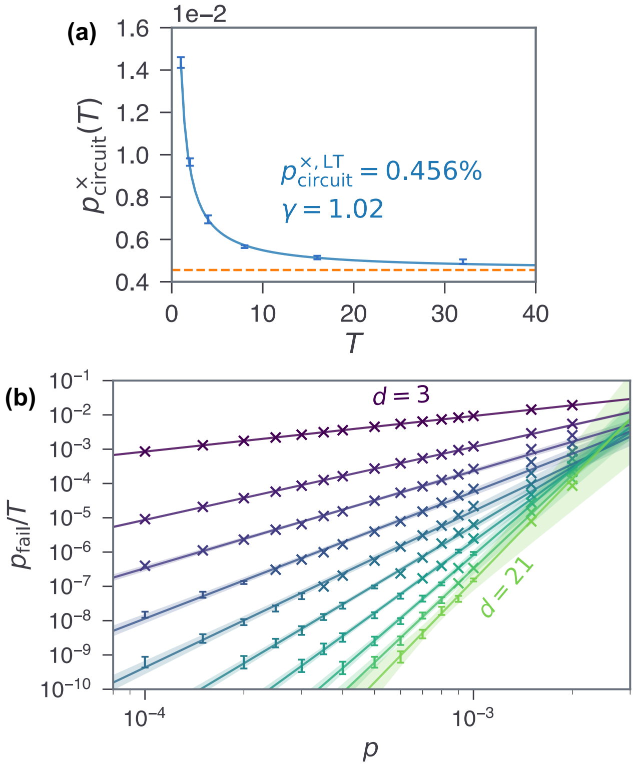

Figure 3: **Numerical analysis of the concatenated MWPM decoder under circuit-level noise.** **(a)** Noise threshold $p^{\times}_{\text{circuit}}(T)$ as a function of the number T of QEC rounds, which converges to $p^{\times,\text{LT}}_{\text{circuit}} \approx 0.456\%$. **(b)** Logical failure rate per round p_{fail}/T against p for various code distances d when p is sufficiently lower than the threshold.

Figure 2(c) presents a set of residual errors after correction, which is equivalent to a stabilizer thus does not

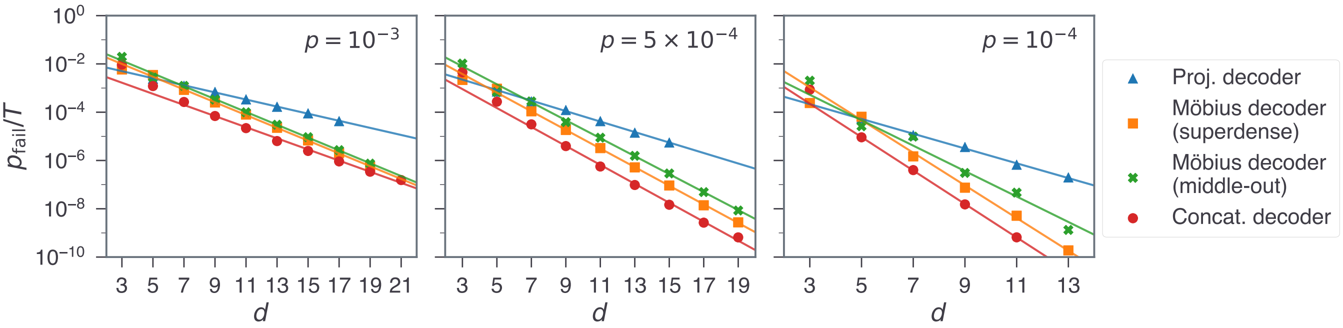

Figure 4: **Comparison of three matching-based decoders under circuit-level noise.** Logical failure rates per round p_{fail}/T are estimated by using three different decoders: projection [14], Möbius [17, 18], and concatenated MWPM decoders. The data for the projection and Möbius decoders are from Ref. [14] and [18], respectively.

cause a logical failure. Z errors can be predicted by decoding X-type check outcomes in an analogous way.

The above scheme cannot handle realistic noise (including measurement errors) that is relevant to fault-tolerant quantum computing. We thus adapt the decoder to a circuit-level noise model, where each preparation/measurement gives an orthogonal outcome with probability p and each unitary gate is followed by a depolarizing noise channel with strength p. We employ detector error models [20] for this, which are lists of independent error mechanisms specifying their probabilities and the set of detectors (i.e., products of measurement outcomes that are deterministic when noiseless) and logical observables damaged by them. We generalize the three steps of the concatenated MWPM decoder using detector error models and employ the *Stim* library [20] to implement and analyze the decoder.

3 Performance analysis

For assessing the performance of the decoder, we consider T rounds of the logical idling gate of the triangular color code with code distance d under circuit-level noise with strength p. The results are summarized in Fig. 3(a) and (b), which are respectively for near-threshold and sub-threshold regimes. From Fig. 3(a), we estimate the long-term threshold of the decoder (when $T \to \infty$) as 0.456%. From Fig. 3(b), we obtain an approximation of the logical failure rate p_{fail} as a function of T, p, and d when $p \lessapprox 0.1\%$: $p_{\mathrm{fail}} \approx (0.0093) \times (p/0.0032)^{0.50d-0.60}$.

Notably, the concatenated MWPM decoder has a significant advantage in terms of the scaling of the failure rate over d and p. Namely, $p_{\mathrm{fail}} \sim p^{0.5d}$ for our decoder within our simulation range of $d \le 31$, while it is $\sim p^{d/3}$ for the projection decoder [14] and $\sim p^{(3/7)d}$ for the Möbius decoder [17, 18]. The impact of this improvement is numerically presented in Fig. 4, which compares the performance (in terms of p_{fail}/T) of the concatenated MWPM decoder with those of these two decoders. The figure shows that the projection decoder significantly underperforms the other two due to its suboptimal scaling against d. The scaling against d is comparably similar for the other two decoders (when $p \lessapprox 5 \times 10^{-4}$); however, the concatenated MWPM decoder achieves logical failure rates that are approximately 3–7 times lower than the Möbius decoder.

More numerical results are presented in our technical description [19]. In particular, we observe that choosing an optimal CNOT schedule is very important as the logical failure rates of the best and worst schedules differ by more than twice.

4 Remarks

In this work, we introduced the concatenated MWPM decoder processed by the concatenation of two rounds of MWPM per color, which is applicable not only to simple bit-flip noise but also to realistic circuit-level noise. The decoder is based on the idea that the outcome obtained from decoding on a restricted lattice can serve as additional 'virtual syndrome data', which undergo a subsequent decoding round in conjunction with remaining syndrome data.

We numerically analyzed the performance of the decoder in various aspects: We considered both bit-flip and circuit-level noise models and investigated near-threshold and sub-threshold behaviors of the logical failure rate p_{fail}. We found that the decoder has the thresholds of 8.2% for bit-flip noise and 0.46% for circuit-level noise, which are comparable with those of previous matching-based decoders such as the projection decoder [12–16] and Möbius MWPM decoder [17, 18]. Remarkably, we verified that the decoder approaches a scaling of $p_{\mathrm{fail}} \sim p^{d/2}$, where p is the noise strength and d is the code distance, at least within our simulation range ($d \lessapprox 31$ for bit-flip noise and $d \lessapprox 21$ for circuit-level noise). As a consequence, it outperforms previous matching-based decoders in terms of their sub-threshold failure rates across both bit-flip and circuit-level noise. We therefore anticipate that our decoder enhances the practicality of employing color codes in quantum computing, which has been considered less viable than surface codes due to its logical failure rate performance despite its advantage in resource efficiency [6]. We distributed a python module implementing the decoder on Github [21] so that other researchers can use it.

Abstract. Measurement-induced state disturbance is a main challenge in obtaining quantum statistics at multiple time points. We introduce a novel method, namely snapshotting quantum dynamics, for extracting temporal quantum statics from intermediate measurements at each time point. This allows us to extract temporal quasi-probability distributions and correlation functions for various time orderings. We experimentally demonstrate the proposed protocol using a $^{171}\mathrm{Yb}^{+}$and $^{138}\mathrm{Ba}^{+}$dual-species trapped-ion system. The nonclassicality of multi-time QPDs is observed by their negativity and complex values, which clearly indicate a contribution of quantum coherence in the dynamics.

Keywords: quantum statistics, quantum correlation function, quasi-probability, trapped-ion system

1 Introduction

A striking difference between quantum and classical mechanics arises from the understanding of measurements. In quantum mechanics, the uncertainty principle asserts that defining a joint probability distribution of statistical properties of non-commuting variables is impossible, prohibiting a description of quantum physics using classical probability theory. The same principle is applied when performing sequential measurements during the quantum state's evolution. The double-slit experiment serves as an illustration of this phenomenon: attempting to extract path information causes the final interference patterns to disappear. Consequently, one cannot attain a classical joint probability distribution that simultaneously describes both the which-path information and the particle's final position. The destructive and irreversible effect of measurements on a quantum system raises an ongoing question: Is it possible to extract the system's information throughout quantum dynamics while minimizing the impact of measurement on subsequent events? In this work, we show that dynamical quantum information can be reconstructed from intermediate measurement outcomes aided by classical post-processing, where the statistics at the latter time are not affected by the measurement at the formal time. We provide a schematic protocol for doing this, which we named snapshotting quantum dynamics.

Technical details are in the Appendix (see also [1]).

2 Snapshotting quantum dynamics

The main idea of snapshotting quantum dynamics (see Fig. 1) is to consider a joint quasi-probability distribution between time points based on the Kirkwood-Dirac (KD) distribution [2, 3]. For example, when a quantum state ρ_{t_1} at time t_1 evolves under a quantum channel $\mathcal{N}_{t_1\to t_2}$, we define the joint measurement statistics at two times t_1, t_2 with outcomes x_1, x_2 as

$$\begin{aligned} p(x_1, x_2; t_1, t_2) &= \mathrm{Tr}\left[\mathcal{N}_{t_1\to t_2}\left(\rho_{t_1}\Pi_{x_1}\right)\Pi_{x_2}\right] \\ &= \mathrm{Tr}\left[\left(\mathcal{M}_{x_2}\circ\mathcal{N}_{t_1\to t_2}\circ\mathcal{M}_{x_1}\right)\rho_{t_1}\right], \end{aligned}$$

where $\mathcal{M}_x(\rho) \equiv \rho\Pi_x$. Such a joint distribution is not a classical probability distribution as it can have negative or non-real values, often referred to as quasi-probability distribution. Nevertheless, the KD distribution preserves the marginal statistics at each time, i.e., $\sum_{x_2} p(x_1, x_2; t_1, t_2) = \mathrm{Tr}\left[\rho_{t_1}\Pi_{x_1}\right]$ and $\sum_{x_1} p(x_1, x_2; t_1, t_2) = \mathrm{Tr}\left[\mathcal{N}_{t_1\to t_2}(\rho_{t_1})\Pi_{x_2}\right] = \mathrm{Tr}\left[\rho_{t_2}\Pi_{x_2}\right]$. We can further generalize this to N-time points as

$$\begin{aligned} &p(x_1, x_2, \cdots, x_N; t_1, t_2, \cdots, t_N) \\ &= \mathrm{Tr}\left[\left(\mathcal{M}_{x_N}\circ\mathcal{N}_{t_{N-1}\to t_N}\circ\cdots\circ\mathcal{N}_{t_1\to t_2}\circ\mathcal{M}_{x_1}\right)\left(\rho_{t_1}\right)\right]. \end{aligned}$$

Our key observation is that these quasi-probability distributions can be obtained from sequential measurement at each time. This can be done by decomposing $\mathcal{M}_x(\rho)$ into a linear combination of weighted Kraus operators as

$$\mathcal{M}_x(\rho) = \sum_m \gamma_{xm} K_m \rho K_m^\dagger$$

with some complex-valued coefficients γ_{xm} (see also Fig. 2).

As Kraus operators with outcomes m can be realized by ancilla-assisted measurements, one can reconstruct the N-time quasi-probability distribution from the intermediate outcomes by averaging over them with the complex value weight as

$$p(x_1, x_2, \cdots, x_N; t_1, t_2, \cdots, t_N) = \mathbb{E}\left[\prod_{i=1}^{N}\gamma_{x_i m_i}\right].$$

Marginal distributions

Figure 1: Schematic procedure for snapshotting quantum dynamics. Various types of information on quantum dynamics are obtained simultaneously through classical post-processing of the intermediate measurement outcomes. These include the multi-time QPD with the correct marginal probabilities at the respective time points, as well as both time-ordered and out-of-time-ordered correlation functions.

Here, $\mathbb{E}[\cdot]$ denotes averaging over all possible sequential measurement outcomes $(m_1, \cdots, m_N)$, which can be understood as the observed trajectories of the quantum dynamics, following the distribution $p^{\mathcal{K}}(m_1, \cdots, m_N) = \mathrm{Tr}[(\mathcal{K}_{m_N} \circ \mathcal{N}_{t_{N-1} \to t_N} \circ \cdots \circ \mathcal{N}_{t_1 \to t_2} \circ \mathcal{K}_{m_1})(\rho_{t_1})]$.

An important consequence of the proposed protocol is that the quasi-probability contains the information of both time- ordered and out-of-time-ordered quantum correlations. In other words, one can obtain the multi-time correlation functions,

$$C(t_1, t_2, \cdots, t_N) = \langle A(t_1) A(t_2) \cdots A(t_N) \rangle,$$

even for the cases where the time-ordering $t_1 \leq t_2 \leq \cdots \leq t_N$ is not satisfied.

As a special case, our approach offers a novel scheme to obtain the out-of-time-ordered correlator (OTOC) throughout quantum dynamics, which has been widely adopted as a quantifier of quantum information scrambling throughout complex quantum dynamics [4]. The OTOC of a quantum system under unitary dynamics U_τ is defined as the absolute square of the commutator between two operators V and W,

$$C_{\mathrm{OTOC}} \equiv \langle [W(\tau), V(0)]^\dagger [W(\tau), V(0)] \rangle, \tag{1}$$

where $V(0) = V$ and $W(\tau) = U_\tau^\dagger W U_\tau$. We note that the OTOC is essentially a linear sum of four-point functions

Figure 2: (a) Ancilla-assisted measurement for realizing Kraus operators. By performing z-, y- and x-basis measurements on the ancilla, the system state is updated depending on the measurement outcome. (b) The quantum circuit to obtain the QPD $p(x_1, \cdots, x_N)$ for a qubit system. $\mathcal{N}_{t_{N-1} \to t_N}$ describes the dynamics of the system from t_{N-1} to t_N. The ancilla-assisted measurement is performed at each time t_i with the outcome m_i. The system state is updated to $\rho^{\mathcal{K}}_{t_N}(m_1, \cdots, m_N)$ when the measurement outcomes read $(m_1, \cdots, m_N)$, which happens with probability $p^{\mathcal{K}}(m_1, \cdots, m_N)$.

containing both time-ordered and out-of-time-ordered correlation functions. Even though C_{OTOC} in Eq. (1) contains terms with reversed time ordering, C_{OTOC} can be obtained from the sequential measurement outcomes (m_1, m_2, m_3) at three-time points (t_1, t_2, t_3) under the unitary dynamics $U_{t_1 \to t_2} = U_\tau$ and $U_{t_2 \to t_3} = U_\tau^\dagger$ as

$$C_{\mathrm{OTOC}} = \mathbb{E}\left[\prod_{i=1}^{3} \gamma_{m_i}^{\mathrm{OTOC}}\right], \tag{2}$$

with some complex coefficients $\gamma_{m_i}^{\mathrm{OTOC}}$.

Compared to interference-based schemes for obtaining the OTOC [5, 6], our scheme offers the advantage that an ancilla state is required to remain coherent only for a short time during each ancilla-assisted measurement. We highlight that the time-reversal unitary is applied only once in our scheme. This can be contrasted with the weak measurement-based schemes [7, 8], which possess the same advantage as our scheme in ancilla coherence time but require two time-reversals [7, 8].

3 Experimental demonstration

We experimentally demonstrate the proposed scheme using dual-species trapped-ion system. $^{171}\mathrm{Yb}^+$and $^{138}\mathrm{Ba}^+$ions are used as the system qubit and the ancillary qubit for measurement, respectively. We apply two different rotations to the system qubit for two different time intervals (see also Fig. 3). We successfully reconstructed the three-time quasi-probability distribution of the dynamics, whose negative and non-real values indicate the non-classical contributions of coherence. From the quasi-probability distribution, two- and three-point correlation functions for the Pauli Z operator are evaluated, which nicely match the theoretical predictions (see Fig. 3). We also verify that the classical post-processing of our protocol successfully cancels out the impact of measurement when compared to the projective measurement case (see Fig. 4).

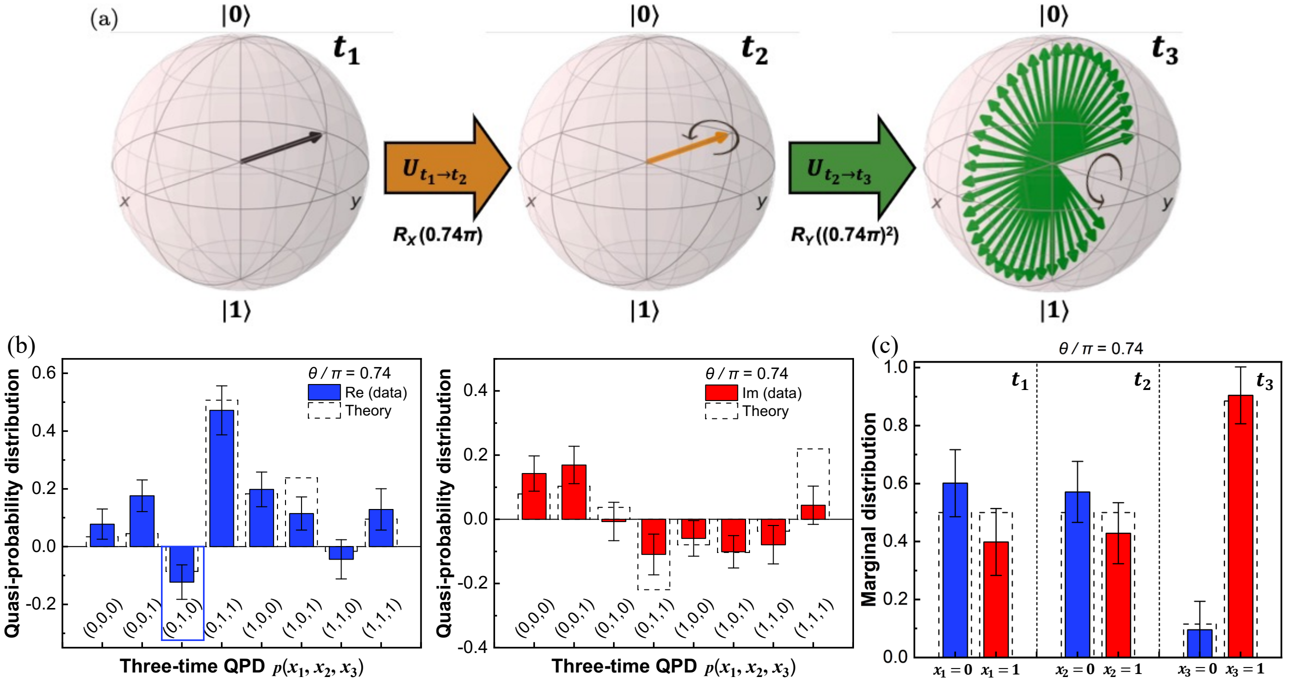

Figure 3: (a) The unitary evolution of the system qubit: the operator $U_{t_1\to t_2} = R_X(\theta)$ rotates the initial state around the x-axis, and the operator $U_{t_2\to t_3} = R_Y(\theta^2)$ further rotates the system state around the y-axis. (b) The three-time QPD $p(x_1, x_2, x_3)$ reconstructed from the observed trajectories by classical postprocessing. The negativity of the real QPD is verified for $p(x_1 = 0, x_2 = 1, x_3 = 0)$ (in blue-dashed-line boxes). (c) The marginal distributions for t_1, t_2, and t_3 under the unitary dynamics show the snapshotting of the state evolution.

4 Remarks

Our protocol provides a systematic approach to extracting quantum statistics from intermediate measurement outcomes aided by classical post-processing. Our method is applicable to any quantum system and dynamics, serving as a valuable experimental tool for exploring the quantum statistics of both open and closed quantum systems. The potential applications include obtaining various critical quantities based on correlation functions, such as OTOC, in quantum many-body systems.

Measurement-induced state disturbance is a major challenge in obtaining quantum statistics at multiple time points. We propose a method to extract dynamic information from a quantum system at intermediate time points, namely snapshotting quantum dynamics. To this end, we apply classical post-processing after performing the ancilla-assisted measurements to cancel out the impact of the measurements at each time point. Based on this, we reconstruct a multi-time quasi-probability distribution (QPD) that correctly recovers the probability distributions at the respective time points. Our approach can also be applied to simultaneously extract exponentially many correlation functions with various time-orderings. We provide a proof-of-principle experimental demonstration of the proposed protocol using a dual-species trapped-ion system by employing $^{171}\mathrm{Yb}^{+}$ and $^{138}\mathrm{Ba}^{+}$ ions as the system and the ancilla, respectively. Multi-time measurements are performed by repeated initialization and detection of the ancilla state without directly measuring the system state. The two- and three-time QPDs and correlation functions are reconstructed reliably from the experiment, negativity and complex values in the QPDs clearly indicate a contribution of the quantum coherence throughout dynamics.

INTRODUCTION

A striking difference between quantum mechanics and classical mechanics arises from understanding the measurements. In quantum mechanics, the uncertainty principle asserts that it is impossible to define a joint probability distribution of statistical properties of non-commuting variables, thus prohibiting a description of quantum physics using classical probability theory. This leads to the introduction of quasi-probability distributions (QPDs), a prototypical example of which is the Wigner function [1] describing quantum phase space. Another important class of QPDs is the Kirkwood-Dirac (KD) distribution [2, 3], which can be applied to any two incompatible sets of measurement operators. The non-classical features in these QPDs, characterized by negative [1, 4] or even non-real values [2, 3], have been investigated within the realms of quantum foundations [5, 6], closely connected to quantum contextuality [7–12], and recently recognized as a resource in quantum computing [13–18] and quantum metrology [19–22].

The same principle is applied when performing sequential measurements during the evolution of a quantum state. The double-slit experiment serves as an illustration of this phenomenon: attempting to extract path information causes the final interference patterns to disappear. Consequently, one cannot obtain a classical joint probability distribution that simultaneously describes both the which-path information and the final position of the particle. The absence of the classical probability description of quantum mechanical processes gives rise to the nonclassicality of temporal correlation described by the Leggett-Garg inequality [6] and the no-go theorem for defining work observables in quantum thermodynamics [23]. Meanwhile, with recent advances in quantum information science, there has been an increasing demand to study multi-time quantum statistics to explore exotic features of quantum dynamics, such as information spreading throughout quantum dynamics [24, 25]. Recently, it has also been shown that monitoring the dynamics of a quantum system at multiple time points can witness entanglement [26].

On the other hand, a major challenge arises when attempting to access these quantum correlations over time in experiments. As observed from the double-slit experiment, direct measurements performed on a quantum state wash out quantum coherences so that they can no longer contribute to the subsequent dynamics. The destructive and irreversible effect of measurements on a quantum system raises an ongoing question: Is it possible to extract information of the system at intermediate points in time throughout quantum dynamics while minimizing the impact of the measurement on subsequent events? The most widely adopted method is the use of weak measurements [27–32] (see Refs. [33–38] for experimental realizations) to gain little information with little disturbance of the system [39–41]. Over the years, various quantum measurement schemes [30, 31, 42] beyond weak measurement have been proposed to extract temporal quantum correlation functions. Alternative approaches have also been explored, including those utilizing long-time entanglement between the system and the ancilla [43–46], as well as methods involving multiple copies of quantum states for each trial [23, 47, 48].

In this work, we propose a novel method to extract dynamical information from a quantum system through ancilla-assisted measurements at intermediate time points, which we term *snapshotting* quantum dynamics. After collecting the ancilla measurement outcomes, they are properly weighted to cancel out the impact of the measurements at each time point, enabling us to obtain multi-time QPDs with correct marginal probabilities at the respective time points.

Our method shares an advantage with sequential weak measurements [31, 36–38], requiring a short interaction time between the system and the ancilla. However, the main difference lies in the ability of our protocol to completely cancel out the measurement effect through classical post-processing, without approximating the system state in the weakly interacting regime.

Another important feature of the proposed protocol is that exponentially many quantum correlation functions can be obtained simultaneously from the N-time ancilla measurement outcomes. This provides a useful methodology for obtaining multiple temporal quantum statistics without changing the experimental settings. In particular, the obtainable correlation functions include the out-of-time-ordered correlator (OTOC), a quantifier of quantum information scrambling [24, 25], which has also been studied in the context of QPDs [46, 49, 50].

We provide a proof-of-principle experimental demonstration of snapshotting to reconstruct multi-time QPDs. We employ a dual-species trapped-ion system consisting of $^{171}\mathrm{Yb}^{+}$ and $^{138}\mathrm{Ba}^{+}$ ions. We realize the required repeated ancilla-assisted measurements through interactions between $^{171}\mathrm{Yb}^{+}$ and $^{138}\mathrm{Ba}^{+}$ ions by performing in-circuit detection (ICD) and in-circuit initialization (ICI) [51–55]. The experimentally reconstructed QPD up to three-time points correctly reveals the marginal distribution at each time, and the correlation functions extracted from them match the quantum mechanical prediction well with the full contribution of coherence. To the best of our knowledge, this is the first direct experimental realization of a quantum mechanical temporal joint distribution beyond two-time points without process tomography.

Marginal distributions

FIG. 1. Schematic procedure for snapshotting quantum dynamics. Various types of information on quantum dynamics are obtained simultaneously through classical post-processing of the intermediate measurement outcomes. These include the multi-time QPD with the correct marginal probabilities at the respective time points, as well as both time-ordered and out-of-time-ordered correlation functions.

QPD FOR MULTIPLE TIME POINTS

Suppose a quantum state is ρ_{t_i} at t_i and evolves in time. The quantum state at a certain time t_j can be expressed as

$$\rho_{t_j} = \mathcal{N}_{t_i \to t_j}(\rho_{t_i}), \tag{1}$$

where $\mathcal{N}_{t_i \to t_j}$ is a completely positive trace-preserving quantum channel describing the evolution from time t_i to t_j. To obtain the information of the quantum state at time t_i, one may perform measurements given by a set of projection operators $\Pi_{x_i} = |x_i\rangle\langle x_i|$ satisfying $\sum_{x_i} \Pi_{x_i} = \mathbb{1}$, which leads to the outcome distribution of x_i at time t_i, $p(x_i; t_i) = \mathrm{Tr}[\rho_{t_i} \Pi_{x_i}]$. After the measurement is performed, the state collapses to $|x_i\rangle\langle x_i|$. Such a projective measurement incurs a critical issue when obtaining quantum statistics for more than two sequential time points. For example, the joint distribution of outcomes by performing projective measurements at times t_1 and t_2 can be written as $p^{\text{proj.}}(x_1, x_2; t_1, t_2) = p(x_1; t_1)\mathrm{Tr}[\mathcal{N}_{t_1 \to t_2}(|x_1\rangle\langle x_1|)\Pi_{x_2}]$. However, the marginal distribution at time t_2 obtained from the joint distribution $p^{\text{proj.}}(x_1, x_2; t_1, t_2)$ does not match the statistics without the measurement at time t_1, i.e., $\sum_{x_1} p^{\text{proj.}}(x_1, x_2; t_1, t_2) \neq p(x_2; t_2)$. This invokes the so-called measurement problem that the wavefunction collapse induced by the measurement cannot be explained as a direct consequence of the Schrödinger equation [56–58]. Consequently, the joint distribution of projective measurement outcomes becomes unsuitable for providing a complete description of quantum dynamics.

To address such a problem, one can introduce a two-time joint distribution,

$$\begin{aligned} p(x_1,x_2;t_1,t_2) &\equiv \mathrm{Tr}[\mathcal{N}_{t_1\to t_2}(\rho_{t_1}\Pi_{x_1})\Pi_{x_2}] \\ &= \mathrm{Tr}[(\mathcal{M}_{x_2}\circ\mathcal{N}_{t_1\to t_2}\circ\mathcal{M}_{x_1})(\rho_{t_1})], \end{aligned} \tag{2}$$

where $\mathcal{M}_x(\rho) \equiv \rho\Pi_x$. We note that $p(x_1,x_2;t_1,t_2)$ is well-normalized, $\sum_{x_1,x_2} p(x_1,x_2;t_1,t_2) = 1$, and correctly indicates the marginal distribution, $\sum_{x_1} p(x_1,x_2;t_1,t_2) = p(x_2;t_2)$. However, $p(x_1,x_2;t_1,t_2)$ can have complex values, i.e., being a QPD, and can be understood as the KD distribution [2, 3] of the two different measurement operators Π_{x_1} and $\mathcal{N}^\dagger_{t_1\to t_2}(\Pi_{x_2})$ [59]. Such a distribution has been recently rediscovered to provide a useful mathematical formalism to explore the concept of work and the fluctuation theorems in quantum thermodynamics [23, 46, 49, 59–63].

The QPD based on the KD distribution was also generalized to multiple-time points [22, 49]. In this paper, we define N-time QPD as

$$\begin{aligned} &p(x_1,x_2,\cdots,x_N;t_1,t_2,\cdots,t_N) \\ &\equiv \mathrm{Tr}[(\mathcal{M}_{x_N}\circ\mathcal{N}_{t_{N-1}\to t_N}\circ\cdots\circ\mathcal{M}_{x_2}\circ\mathcal{N}_{t_1\to t_2}\circ\mathcal{M}_{x_1})(\rho_{t_1})]. \end{aligned} \tag{3}$$

When the quantum state at each time point commutes with the measurement operator, i.e., $[\rho_{t_i},\Pi_{x_i}] = 0$ for all t_i, the distribution coincides with the classical joint distribution obtained from sequential projective measurements. Consequently, nonclassical values, i.e., negative or non-real values in the QPD capture the coherence of the system state within the measurement basis by witnessing the non-commutativity between the state and the measurement operator (see, e.g., Refs. [10–12, 64] for more detailed analysis). Throughout the manuscript, we will also use a simplified notation $p(x_1,x_2,\cdots,x_N) = p(x_1,x_2,\cdots,x_N;t_1,t_2,\cdots,t_N)$ when the time sequence is trivial from the context.

An important property of the N-time QPD is that it correctly reproduces marginal distributions, satisfying

$$\sum_{x_k} p(x_1,\cdots,x_N) = p(x_1,\cdots,x_{k-1},x_{k+1},\cdots,x_N) \tag{4}$$

for any $k = 1,2,\cdots,N$, where $p(\cdots,x_{k-1},x_{k+1},\cdots) \equiv \mathrm{Tr}[(\cdots\circ\mathcal{M}_{x_{k+1}}\circ\mathcal{N}_{t_{k-1}\to t_{k+1}}\circ\mathcal{M}_{x_{k-1}}\circ\cdots)(\rho_{t_1})]$ is a joint QPD without performing a measurement $\mathcal{M}_{t_k}$ at time t_k. This is known as the Kolmogorov consistency condition in classical probability theory [65]. In other words, the N-time QPD incorporates all the information from the k-time QPDs $p(x_{i_1},x_{i_2},\cdots,x_{i_k};t_{i_1},t_{i_2},\cdots,t_{i_k})$ for any sub-time sequences with $1 \le i_1 < i_2 < \cdots < i_k \le N$. In particular, the marginal distribution of the QPD at a single time t_i, $p(x_i)$, becomes real and non-negative, correctly indicating the probability distribution of the measurement outcome x_i at time t_i.

We also note that the N-time QPD cannot simply be expressed as a product of two-time QPDs, since it does not obey the Markov chain property [65], i.e., $p(x_1,\cdots,x_N) \neq p(x_N|x_{N-1})\cdots p(x_2|x_1)p(x_1)$ with $p(x_k|x_{k-1}) = \frac{p(x_{k-1},x_k)}{p(x_{k-1})}$. We highlight that the quantum channel $\mathcal{N}_{t_k\to t_{k+1}}$ for each time interval is Markovian, hence the non-Markovianity arises from the effect of $\mathcal{M}_{x_k}$.

SNAPSHOTTING QUANTUM DYNAMICS

The primary challenge in dealing with QPDs is that experimental reconstruction is not straightforward due to the presence of negative or non-real values. For the N-time QPD defined in Eq. (3), this stems from the fact that $\mathcal{M}_{x_i}(\rho_{t_i}) = \rho_{t_i}\Pi_{x_i}$ at each time t_i is a non-physical process that does not yield a Hermitian matrix. Our key observation to overcome this issue is that $\mathcal{M}_x$ can be alternatively expressed as a weighted sum of $\mathcal{K}_m(\rho) \equiv K_m\rho K_m^\dagger = p^{\mathcal{K}}(m)\rho_m^{\mathcal{K}}$, which can be interpreted as the result of a generalized measurement with outcome m [66]. The probability of the outcome is given by $p^{\mathcal{K}}(m) = \mathrm{Tr}[\mathcal{K}_m(\rho)] = \mathrm{Tr}[\rho K_m^\dagger K_m]$, and the state after the measurement becomes $\rho_m^{\mathcal{K}} = \frac{K_m\rho K_m^\dagger}{p^{\mathcal{K}}(m)}$. The measurement operators compose a set of Kraus operators $\{K_m\}$, satisfying $\sum_m K_m^\dagger K_m = \mathbb{1}$.

More explicitly, we aim to prove the following expression,

$$\mathcal{M}_x(\rho) = \sum_m \gamma_{xm}\mathcal{K}_m(\rho), \tag{5}$$

with complex-valued coefficients γ_{xm}. The complex coefficients can be implemented via classical post-processing by weighting the measurement outcomes differently, which will be discussed in more detail. For example, the projection onto the computational basis of a qubit system, $\Pi_x = |x\rangle\langle x|$ with $x = 0,1$, can be decomposed into

$$\rho\Pi_x = \frac{\rho - Z\rho Z + 4\Pi_x\rho\Pi_x - i(-1)^x S\rho S^\dagger + i(-1)^x S^\dagger\rho S}{4}, \tag{6}$$

where $S = |0\rangle\langle 0| + i|1\rangle\langle 1|$ is the phase gate. We further note that any Kraus operators can be realized by ancilla-assisted measurements [66]. For the qubit case in Eq. (6), the CNOT gate between the system and the ancilla followed by the ancilla measurement in the x-, y-, and z-bases leads to the set of Kraus operators, $\{K_m\} = \left\{\frac{\Pi_0}{\sqrt{3}}, \frac{\Pi_1}{\sqrt{3}}, \frac{S^\dagger}{\sqrt{6}}, \frac{S}{\sqrt{6}}, \frac{\mathbb{1}}{\sqrt{6}}, \frac{Z}{\sqrt{6}}\right\}$ (see Fig. 2(a)).

This observation can be further generalized to any d dimensional quantum system as follows:

Theorem 1. *For any set of projectors $\{\Pi_x\}_{x=0}^{d-1}$ acting on a d-dimensional quantum state ρ, one can always construct a set of Kraus operators $\{K_m\}$ from ancilla-assisted measurement and find coefficients γ_{xm} satisfying Eq. (5). The Kraus operators are determined by the informationally complete measurement on a d-dimensional ancilla state after its interaction with the system.*

FIG. 2. (a) Ancilla-assisted measurement for realizing Kraus operators. By performing z-, y- and x-basis measurements on the ancilla, the system state is updated depending on the measurement outcome. (b) The quantum circuit to obtain the QPD $p(x_1, \cdots, x_N)$ for a qubit system. $\mathcal{N}_{t_{N-1}\to t_N}$ describes the dynamics of the system from t_{N-1} to t_N. The ancilla-assisted measurement is performed at each time t_i with the outcome m_i. The system state is updated to $\rho^{\mathcal{K}}_{t_N}(m_1, \cdots, m_N)$ when the measurement outcomes read $(m_1, \cdots, m_N)$, which happens with probability $p^{\mathcal{K}}(m_1, \cdots, m_N)$.

The proof of Theorem 1 with more details can be found in Methods.

Now, we introduce a protocol for snapshotting quantum dynamics via intermediate measurements. As an illustrative example, we show that the two-time QPD $p(x_1, x_2; t_1, t_2)$ can be obtained by ancilla-assisted measurements at times t_1 and t_2 as follows. At time t_1, we interact the state ρ_{t_1} with the ancilla and measure the ancilla state. For the ancilla state's outcome m_1, the system state is updated to $\rho^{\mathcal{K}}_{t_1}(m_1) = \frac{\mathcal{K}_{m_1}(\rho_{t_1})}{p^{\mathcal{K}}_{t_1}(m_1)}$ with probability $p^{\mathcal{K}}_{t_1}(m_1) = \mathrm{Tr}[\mathcal{K}_{m_1}(\rho_{t_1})]$. Subsequently, the system evolves to $\rho^{\mathcal{K}}_{t_2}(m_1) = \mathcal{N}_{t_1\to t_2}\left(\rho^{\mathcal{K}}_{t_1}(m_1)\right)$ from time t_1 to t_2. We then perform the second measurement at time t_2. When the outcome is m_2, the system state is updated to $\rho^{\mathcal{K}}_{t_2}(m_1, m_2) = \frac{\mathcal{K}_{m_2}(\rho^{\mathcal{K}}_{t_2}(m_1))}{p^{\mathcal{K}}_{t_2}(m_2|m_1)}$ with conditional probability $p^{\mathcal{K}}_{t_2}(m_2|m_1) = \mathrm{Tr}[\mathcal{K}_{m_2}(\rho^{\mathcal{K}}_{t_2}(m_1))]$ for a given first measurement outcome m_1. The joint probability of the sequential measurement outcome (m_1, m_2) becomes $p^{\mathcal{K}}(m_1, m_2) = p^{\mathcal{K}}_{t_1}(m_1)p^{\mathcal{K}}_{t_2}(m_2|m_1) = \mathrm{Tr}[(\mathcal{K}_{m_2} \circ \mathcal{N}_{t_1\to t_2} \circ \mathcal{K}_{m_1})(\rho_{t_1})]$. We note that this joint probability is a classical probability distribution that can be obtained directly from the outcome statistics.

We emphasize that the QPD $p(x_1, x_2)$ and the classical joint distribution $p^{\mathcal{K}}(m_1, m_2)$ are linked through Eq. (5) in the form of $p(x_1, x_2) = \sum_{m_1, m_2} \gamma_{x_1 m_1}\gamma_{x_2 m_2} p^{\mathcal{K}}(m_1, m_2)$. Therefore once the probability distribution $p^{\mathcal{K}}(m_1, m_2)$ is obtained from the measurement outcomes, $p(x_1, x_2)$ can be reconstructed via classical post-processing by the weighted sum of these probabilities.

As shown in Fig. 2(b), it is straightforward to repeat this protocol for multiple time points, which leads to the following expression of the N-time QPD:

$$\begin{aligned} p(x_1, \cdots, x_N) &= \sum_{m_1, \cdots, m_N} p^{\mathcal{K}}(m_1, \cdots, m_N)\left[\prod_{i=1}^{N} \gamma_{x_i m_i}\right] \\ &= \mathbb{E}\left[\prod_{i=1}^{N} \gamma_{x_i m_i}\right], \end{aligned} \tag{7}$$

where $\mathbb{E}[\cdot]$ denotes averaging over all possible sequential measurement outcomes $(m_1, \cdots, m_N)$, which can be understood as the observed trajectories of the quantum dynamics, following the distribution $p^{\mathcal{K}}(m_1, \cdots, m_N) = \mathrm{Tr}[(\mathcal{K}_{m_N} \circ \mathcal{N}_{t_{N-1}\to t_N} \circ \cdots \circ \mathcal{N}_{t_1\to t_2} \circ \mathcal{K}_{m_1})(\rho_{t_1})]$.

We note that the number of observed trajectories to be collected to reconstruct quantum statistics $p(x_1, \cdots, x_N)$ is greater than that for classical statistics $p^{\mathcal{K}}(m_1, \cdots, m_N)$ with the same precision. More precisely, the number of trajectories M_{traj} to estimate $p(x_1, \cdots, x_N)$ for each time point within a fixed precision ϵ with probability $1 - \delta$ scales as $M_{\mathrm{traj}} = \frac{2(\max_{x,m}|\gamma_{xm}|)^{2N}}{\epsilon}\ln(2/\delta)$ from Hoeffding's inequality [67]. Our protocol can also be applied to local projectors of multi-qubit systems with the same sampling overhead. We also provide a systematic algorithm to find the optimal coefficient γ_{xm} to reconstruct the joint probability with the minimum number of measurement outcomes (see Methods).

The resource requirement of the proposed protocol can be compared to other schemes for obtaining the KD distribution, while explicit comparisons between these protocols are challenging due to their different natures (see also Refs. [49, 59] for an overview). Compared to the two-point measurement-based scheme [42], which requires the measurement of multiple measurement distributions to infer the KD distribution, our protocol only requires a single measurement distribution $p^{\mathcal{K}}(m_1, m_2)$. The main difference compared to the weak measurement-based schemes [30, 31] is that our protocol does not need to implement a weak coupling between the system and the ancilla to ensure that the system is undisturbed. While the schemes [68, 69] entailing strong measurements for two-time points share a similar structure with our protocol, our protocol provides a straightforward multi-time generalization. Another scheme based on characteristic function estimation [43] requires classical post-processing of the inverse Fourier transform, while our protocol has a relatively simple post-processing with pre-determined coefficients $\gamma_{x_i m_i}$. The interference-based scheme [46] requires overlapping measurement and tomography of a quantum state in some occasions, both of which are not required in our scheme. A recently proposed quantum circuit model based on the block-encoding [70] could have a lower sampling cost than our protocol, but its application is limited to unitary dynamics and requires the implementation of the inverse unitary channel.

Taking into account the physical constraints, our protocol has a short time of system-ancilla coherence during a measurement process at each time, which has an advantage over interferometric schemes [43, 46] that require a long time of system-ancilla coherence throughout the entire protocol. While applying measurements in sequential times could also be a challenging task, it has been realized on various physical platforms [36, 48, 71–74]. We also note that such intermediate measurement has been an active research area, as being an essential technique for quantum information processing, such as syndrome detection for quantum error correction [66].

In the following section, we discuss that the classical post-processing of the sequential measurement outcomes leads to a unique feature of our approach, which allows the simultaneous extraction of exponentially many correlation functions.

EXTRACTION OF MULTI-TIME CORRELATION FUNCTIONS

While the N-time QPD provides valuable information about the marginal distribution at each time, its utility can even go beyond that. We demonstrate that correlation functions with different time-orderings can be obtained simultaneously from the N-time QPD. The quantum correlation function of an observable A throughout unitary quantum dynamics given by $U_{t_i \to t_j}$ is defined as

$$C(t_1, \cdots, t_N) \equiv \langle A(t_1) \cdots A(t_N) \rangle \equiv \mathrm{Tr}[\rho_{t_0} A(t_1) \cdots A(t_N)], \tag{8}$$

where $A(t_i) = U^{\dagger}_{t_0 \to t_i} A U_{t_0 \to t_i}$ is an observable in the Heisenberg picture. If the time sequence is given in increasing order, i.e., $t_1 \le t_2 \le \cdots \le t_N$, the correlation function is called time-ordered, otherwise it is called out-of-time-ordered.

Using the eigenvalue decomposition of the observable, $A = \sum_x a_x \Pi_x$, the time-ordered correlation function can be expressed in terms of the QPD as

$$C(t_1, \cdots, t_N) = \sum_{x_1, \cdots, x_N} a_{x_1} \cdots a_{x_N} p(x_1, \cdots, x_N). \tag{9}$$

Furthermore, as the N-time QPD contains any k-time QPD with $k \le N$, all lower order correlation functions can also be obtained from $p(x_1, \cdots, x_N)$. For example, one can simultaneously obtain a complete set of time-ordered correlation functions $\{C(t_1), C(t_2), C(t_3)\}$, $C(t_1, t_2), C(t_2, t_3), C(t_1, t_3)\}$, and $C(t_1, t_2, t_3)$ from the three-time QPD $p(x_1, x_2, x_3)$.

More surprisingly, the snapshotting method can be utilized to obtain a family of out-of-time-ordered quantum correlation functions, summarized by the following observation.

Observation 1. *All correlation functions $C(t_{\mu_1}, \cdots, t_{\mu_j}, t_{\mu_{j+1}} \cdots, t_{\mu_k})$ with $\mu_1 \le \mu_2 \le \cdots \le \mu_{j-1} \le \mu_j$ and $\mu_j \ge \mu_{j+1} \ge \cdots \ge \mu_{k-1} \ge \mu_k$ for some $\mu_j \le N$ can be simultaneously deduced from the distribution of observed trajectories $p^{\mathcal{K}}(m_1, \cdots, m_N)$.*

This can be shown by expressing the correlation function as $C(t_{\mu_1}, \cdots, t_{\mu_j}, \cdots, t_{\mu_k}) = \mathrm{Tr}[A(t_{\mu_{j+1}}) \cdots A(t_{\mu_k}) \rho_{t_0} A(t_{\mu_1}) \cdots A(t_{\mu_j})]$, with two monotonically increasing sub-time sequences $t_{\mu_1} \le t_{\mu_2} \le \cdots \le t_{\mu_j}$ and $t_{\mu_k} \le t_{\mu_{k-1}} \le \cdots \le t_{\mu_{j+1}}$. The correlation function is then expressed in terms of $p^{\mathcal{K}}(m_1, \cdots, m_N)$ by noting that $\rho_{t_i} A$, $A \rho_{t_i}$, and $A \rho_{t_i} A$ can be simultaneously decomposed as a linear sum of $\mathcal{K}_{m_i}(\rho_{t_i})$ at each time t_i (see Methods for detailed discussions). We highlight that our approach allows a systematic protocol to obtain both time-ordered and out-of-time-ordered correlation functions from a single set of measurement data $p^{\mathcal{K}}(m_1, \cdots, m_N)$, without changing the setting for each correlation function. For example, in the three-time case, one can additionally access the out-of-time-ordered correlation functions $C(t_3, t_2, t_1)$, $C(t_2, t_3, t_1)$, and $C(t_1, t_3, t_2)$. The number of correlation functions that can be obtained from the N-time distribution $p^{\mathcal{K}}(m_1, \cdots, m_N)$ scales exponentially as $\approx 2^N$, since there are two choices for $A(t_i)$ to be placed either on the left or on the right sides of the quantum state ρ_{t_i} at each time t_i. The out-of-time-ordered QPDs can also be obtained in the same way by taking $A(t_i) = \Pi_{x_i}(t_i)$.

As a special case, our approach offers a novel scheme to obtain the OTOC throughout quantum dynamics, which has been widely adopted as a quantifier of quantum information scrambling throughout complex quantum dynamics [24, 25]. The OTOC of a quantum system under unitary dynamics U_τ is defined as the absolute square of the commutator between two operators V and W,

$$C_{\mathrm{OTOC}} \equiv \langle [W(\tau), V(0)]^{\dagger} [W(\tau), V(0)] \rangle, \tag{10}$$

where $V(0) = V$ and $W(\tau) = U^{\dagger}_{\tau} W U_{\tau}$. We note that the OTOC is essentially a linear sum of four-point functions containing both time-ordered and out-of-time-ordered correlation functions. For example, if both V and W are Hermitian and unitary, $C_{\mathrm{OTOC}} = 2(1 - \langle W(\tau) V(0) W(\tau) V(0) \rangle)$. Even though C_{OTOC} in Eq. (10) contains terms with reversed time ordering, $p^{\mathcal{K}}(m_1, m_2, m_3)$ obtained from the three-time snapshotting method enables us to evaluate its value described as follows (see Methods):

Observation 2. *C_{OTOC} can be obtained from the sequential measurement outcomes (m_1, m_2, m_3) at three-time points (t_1, t_2, t_3) under the unitary dynamics $U_{t_1 \to t_2} = U_\tau$ and $U_{t_2 \to t_3} = U^{\dagger}_{\tau}$ as*

$$C_{\mathrm{OTOC}} = \mathbb{E}\left[\prod_{i=1}^{3} \gamma^{\mathrm{OTOC}}_{m_i} \right], \tag{11}$$

with the Kraus operator described in Theorem 1 and some complex coefficients $\gamma^{\mathrm{OTOC}}_{m_i}$.

Compared to interference-based schemes for obtaining the OTOC [45–47, 75, 76], our scheme offers the advantage that an ancilla state is required to remain coherent only for a short time during each ancilla-assisted measurement. We highlight that the time-reversal unitary is applied only once in our scheme. This can be contrasted with the weak measurement-based schemes [46, 49, 77], which possess the same advantage as our scheme in ancilla coherence time but require two time-reversals [46, 49, 77]. On the other hand, the stability of the protocol against imperfect implementations of the time-reversal unitary [78, 79] remains open for quantitative comparison with an interference-based scheme without time reversals [46, 47]. We also note that our scheme works for any diagonalizable operators V and W, nor on the target state ρ.

EXPERIMENTAL REALIZATION

We experimentally demonstrate the proposed protocol with trapped ions. A crucial part of the protocol is the repeated measurement (ICD) and initialization (ICI) of the ancilla without influencing the system, which are also core technologies for quantum error correction. In trapped-ion systems, the ICD and ICI can be achieved by adopting ion shuttling [80–84] or multiple types of qubits [53, 85–92]. Here, we employ two different species trapped in a single trap, $^{171}\mathrm{Yb}^{+}$and $^{138}\mathrm{Ba}^{+}$ions [90, 93, 94], which are used for the system qubit and the ancilla qubit, respectively. Both trapped ions are controlled by lasers with different wavelengths so that they can be controlled independently with minimal influence on each other [90].

In the experiment, the system qubit is encoded in the hyperfine levels of the $S_{1/2}$ manifold of the $^{171}\mathrm{Yb}^{+}$ ion, $|F=0, m_F=0\rangle = |0\rangle_{\mathrm{Yb}}$ and $|F=1, m_F=0\rangle = |1\rangle_{\mathrm{Yb}}$ with a splitting of 12.6428 GHz. The ancilla qubit is encoded in Zeeman levels of the $S_{1/2}$ manifold of the $^{138}\mathrm{Ba}^{+}$ ion, $|s_j=1/2\rangle = |0\rangle_{\mathrm{Ba}}$ and $|s_j=-1/2\rangle = |1\rangle_{\mathrm{Ba}}$ with an energy splitting of 16.2 MHz. Raman transitions are used to individually manipulate the $^{171}\mathrm{Yb}^{+}$ and $^{138}\mathrm{Ba}^{+}$ ion-qubits with 355 nm and 532 nm lasers, respectively. For the entangling operations for both qubits, we simultaneously apply the 355 nm and 532 nm laser beams with appropriately chosen frequencies (see Methods).

We implement the quantum circuit in Fig. 2 to reconstruct the multi-time QPD for a qubit system. The experimental realization for the essential parts of the circuit is shown in Fig. 3. At the beginning of the protocol, we optically pump the system qubit to $|0\rangle_{\mathrm{Yb}}$, then prepare the state of ρ_{Yb} by using a single-qubit rotation performed by applying 355 nm Raman laser beams. As depicted in Fig. 3(a), the Raman lasers have a frequency difference that matches the transition frequency of the $^{171}\mathrm{Yb}^{+}$ion-qubit. This frequency matching allows the Raman lasers to drive unitary evolutions, specifically single-qubit rotations, on the $^{171}\mathrm{Yb}^{+}$ion-qubit, At time t_1, we perform the ancilla-assisted measurement as illustrated in Fig. 3(a). The measurement procedure consists of initializing the ancilla qubit, applying a CNOT gate, and detecting the ancilla qubit state, where the first and third steps are regarded as the ICI and ICD. We perform the CNOT gate by using the Mølmer-Sørensen (M-S) gate [95] and single-qubit operations shown in Fig. 3(b). The z-basis measurement of the $^{138}\mathrm{Ba}^{+}$ ion is realized by fluorescence detection after shelving $|0\rangle_{\mathrm{Ba}}$ to $D_{5/2}$ manifold. The x- and y-basis measurements are realized by rotating the axis of the $^{138}\mathrm{Ba}^{+}$ ion state before the z-basis measurement. We repeat the protocol by applying the next unitary evolution on the system qubit, followed by the ancilla-assisted measurement. We simplify the final measurement by using a projection measurement on the system qubit of $^{171}\mathrm{Yb}^{+}$ ion in the basis $m_N \in \{|0\rangle, |1\rangle\}$, since no further measurements are performed after that.

FIG. 3. Experimental realization of unitary evolution and ancilla-assisted measurement with $^{171}\mathrm{Yb}^{+}$-$^{138}\mathrm{Ba}^{+}$ trapped-ion system. (a) A unitary operation $U_{t_{N-1}\to t_N}$ is performed by applying Raman laser beams to the system qubit represented by the pink ball. The ancilla-assisted measurement is realized with the following three steps: (i) initialization of the $^{138}\mathrm{Ba}^{+}$ qubit represented by the blue ball to $|0\rangle_{\mathrm{Ba}}$ by optical pumping (OPT), (ii) application of a CNOT gate between two qubits through an entangling operation, and (iii) measurement of the ancilla qubit with fluorescence detection (DET). (b) The CNOT gate consists of an M-S gate and four single-qubit rotations. The M-S gate can be described as $\exp(-i\frac{\pi}{4}X\otimes X)$, where X is the Pauli operator. The single-qubit rotation is defined as $R(\theta,\phi) = \begin{pmatrix} \cos(\frac{\theta}{2}) & -ie^{-i\phi}\sin(\frac{\theta}{2}) \\ -ie^{i\phi}\sin(\frac{\theta}{2}) & \cos(\frac{\theta}{2}) \end{pmatrix}$. (c) The final time measurement can be performed by direct measurement in basis $m_N \in \{|0\rangle, |1\rangle\}$ on the system qubit.

As a concrete example, we reconstruct the three-time QPDs with the initial state $\rho_{\mathrm{Yb}} = (|1_x\rangle\langle 1_x|)_{\mathrm{Yb}}$ at time t_1, where $|1_x\rangle_{\mathrm{Yb}} = (|0\rangle_{\mathrm{Yb}} - |1\rangle_{\mathrm{Yb}})/\sqrt{2}$. The unitary evolution from time t_1 to t_2 is described as $U_{t_1\to t_2} = R_X(\theta) = e^{-i\frac{\theta}{2}X}$, and the evolution from t_2 to t_3 is described as $U_{t_2\to t_3} =$

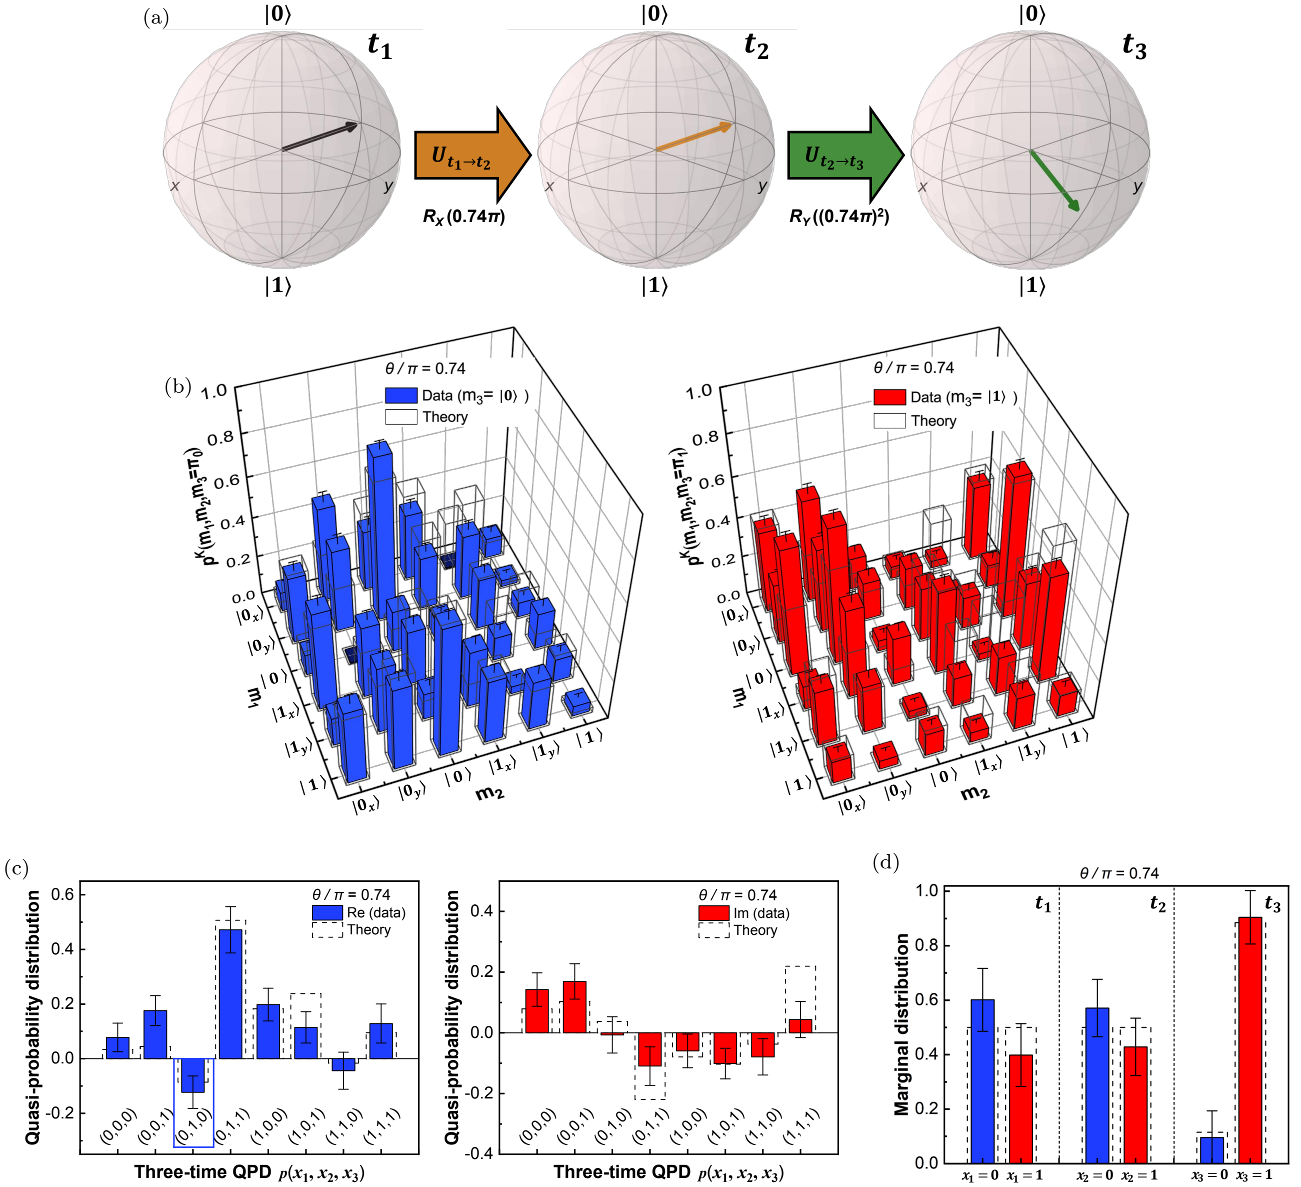

FIG. 4. The experimental reconstruction of the three-time QPD and marginal distribution by the ancilla-assisted measurement for $\theta/\pi = 0.74$. (a) The unitary evolution of the system qubit is shown in the Bloch representation. The operator $U_{t_1\to t_2} = R_X(\theta)$ rotates the initial state around the x-axis, and the operator $U_{t_2\to t_3} = R_Y(\theta^2)$ further rotates the system state around the y-axis. (b) The normalized observed trajectories from the measurements at t_1, t_2, and t_3 are represented by the 2D bar charts, where $m_1, m_2 \in \{|0_x\rangle, |0_y\rangle, |0\rangle, |1_x\rangle, |1_y\rangle, |1\rangle\}$. The bar charts on the left and right represent the observed trajectories of $m_3 = |0\rangle$ and $m_3 = |1\rangle$, respectively, which are the measurement results of t_3. (c) The three-time QPD $p(x_1, x_2, x_3)$ reconstructed from the observed trajectories by classical processing. (i) The left blue bars indicate the real parts of the reconstructed three-time QPD, and the negativity of the real QPD is verified for $p(x_1 = 0, x_2 = 1, x_3 = 0)$ (in blue-dashed-line boxes), which is −0.123(±0.060). (ii) The right red bars indicate the imaginary parts of the reconstructed three-time QPD. (d) The marginal distributions for t_1, t_2, and t_3 under the unitary dynamics $U_{t_1\to t_2}$ and $U_{t_2\to t_3}$ show the snapshotting of the state evolution. The distributions are marginalized over all the other time points of the QPDs. For all figures, error bars indicate standard deviations (STDs), and theoretical expectations are shown as dashed bars (see Methods for details).

$R_Y(\theta^2) = e^{-i\frac{\theta^2}{2}Y}$. Since the unitary evolution from time t_1 to t_2 is a rotation around the x-axis, the system state remains the same if no measurement is performed at time t_1. However, if a measurement is made on the z-basis at time t_1, the state collapses to $|0\rangle$ or $|1\rangle$ and then rotates under the evolution $U_{t_1\to t_2}$. This scenario illustrates how measurements can significantly influence the subsequent dynamics of a quantum system. From time t_2 to t_3, the unitary evolution rotates the system qubit around the y-axis with angle θ^2, which leads to non-trivial behaviors of the QPDs and correlation functions beyond sinusoidal functions of θ. The three-time QPD is then expressed as

$$\begin{aligned} &p(x_1,x_2,x_3)\\ =&\mathrm{Tr}\left[U_{t_2\to t_3}U_{t_1\to t_2}\rho_{t_1}\Pi_{x_1}U^\dagger_{t_1\to t_2}\Pi_{x_2}U^\dagger_{t_2\to t_3}\Pi_{x_3}\right]\\ =&\langle 1_x|x_1\rangle\langle x_1|e^{i(\theta/2)X}|x_2\rangle\langle x_2|e^{i(\theta^2/2)Y}|x_3\rangle\langle x_3|\\ &e^{-i(\theta^2/2)Y}e^{-i(\theta/2)X}|1_x\rangle, \end{aligned} \tag{12}$$

where $\Pi_x = |x\rangle\langle x|$ with $x\in\{0,1\}$.

Figure 4 shows the experimental results for the above procedure. The distribution of observed trajectories from three-time measurements, $p^{\mathcal{K}}(m_1,m_2,m_3)$, for the case of $\theta = 0.74\pi$ is shown in Fig. 4(b). At t_1 and t_2, we have the measurement results in the x-, y- and z-basis and only the z-basis measurement results for time t_3. As shown in the circuit of Fig. 2(b), x-, y- and z-basis measurements of the ancilla yield six measurement outcomes, $m_i\in\{|0_x\rangle,|1_x\rangle,|0_y\rangle,|1_y\rangle,|0\rangle,|1\rangle\}$. We post-select the data with only dark state outcomes to avoid heating of the vibrational modes (see Methods). We repeat each measurement configuration 100 times, for a total of 3600 measurements.

From the distribution of observed trajectories in Fig. 4(b), the three-time QPDs $p(x_1,x_2,x_3)$ are reconstructed as shown in Fig. 4(c). The quasi-probability of $p(x_1=0,x_2=0,x_3=0)$, as an example, is obtained directly from the relation of Eq. (7), $\sum_{m_1,m_2,m_3}\gamma_{0m_1}\gamma_{0m_2}\gamma_{0m_3}p^{\mathcal{K}}(m_1,m_2,m_3)$, where γ_{0m} can be calculated from Eq. (6). In our actual reconstruction, we perform an optimization procedure to obtain a proper $\gamma_{x_im_i}$ for all experimental data (see Methods). Some data points in Fig. 4(c) deviate from the theoretical expectations by more than one standard deviation. This is because several observed trajectories shown in Fig. 4(b) deviate from the ideal values. However, these deviations are mainly due to technical imperfections rather than fundamental problems. We discuss experimental limitations related to fluctuations of experimental control parameters in the last section before the conclusion section of the paper (see Methods for further details). Despite these deviations, our experimental results reveal the essential features of the QPDs, which are different from classical probability distributions. Classically, the joint probabilities at multiple time points can only have positive values. However, as shown in Fig. 4(c), the negative value for $p(x_1=0,x_2=1,x_3=0)$ and the imaginary values are observed for most cases.

The three-time QPDs enable us to evaluate the correct probability distribution of the system state during its unitary evolution. By taking the marginals of the QPDs, we recover the probability distribution at each point in time, which is not influenced by the previous measurements. As shown in Fig. 4(d), the measurement results at times t_1, t_2, and t_3 are consistent with those distributions where no measurements were performed before. The clear difference with and without previous measurements can be seen in the probability distribution at time t_3. If projective measurements were performed at time t_1 or t_2, the distribution of the measurement results at time t_3 should be 0.5 for each basis, which is not the case as shown in Fig. 4(d).

We can obtain any combination of two-time QPDs from the three-time QPDs and observe nonclassical features as shown in Fig. 5. The two-time QPDs are straightforwardly obtained from the three-time QPD by taking its marginals, $p(x_1,x_2) = \sum_{x_3}p(x_1,x_2,x_3)$, $p(x_1,x_3) = \sum_{x_2}p(x_1,x_2,x_3)$, and $p(x_2,x_3) = \sum_{x_1}p(x_1,x_2,x_3)$. We note that it is not always possible to do the reverse, that is, the reconstruction of the three-time QPDs from two-time QPDs, even with all possible combinations. Some data points in Fig. 5 deviate from the ideal values by more than their standard deviations. Despite these deviations, we observe imaginary and negative values in two-time QPDs as shown in Fig. 5, which indicate the coherence of the state with respect to the measurement basis [10–12, 64].

Imaginary and negative values in two-time QPDs are shown in Figs. 5(a-b) and Figs. 5(b-c), respectively. For the unitary evolution of the single-qubit state, the occurrence of imaginary and negative values in two-time QPDs can be understood from the relationship between the representation of the quantum state and the rotation axis in the Bloch sphere when the state contains coherence. For $U_{t_1\to t_2}$, the initial quantum state is represented on the x-axis, and the rotation axis for the unitary evolution is also aligned along the x-axis in the Bloch sphere. In this case, the QPDs reveal imaginary values, as shown in Fig. 5(a). For $U_{t_2\to t_3}$, the quantum state is on the x-axis of the Bloch sphere, but the axis of rotation is along the y-axis, perpendicular to the state. In this case, the QPDs reveal negative values, as shown in Fig. 5(c). In Fig. 5(b), the process contains parallel and perpendicular relations, resulting in imaginary and negative QPDs.

We also obtain quantum correlation functions from the observed trajectories. For different values of θ, time-ordered three-time correlation functions (Fig. 6(d)) and all combinations of two-time correlation functions (Fig. 6(c)) are deduced from the three-time QPDs. We also reconstruct out-of-time-ordered correlation functions based on Observation 1. We present $C(t_3,t_2,t_1)$ with the reversed time-ordering and $C(t_1,t_3,t_2)$ with an increasing-decreasing time-ordering in Figs. 6(e) and (f), respectively. The solid lines are from theoretical calculations, where their explicit forms can be found in Methods. The bands in Fig. 6 indicate the standard deviation (STD) of the experimental data. Although certain data points exhibit deviations exceeding the error bars, the overall trends observed in the data are generally consistent with the theoretical predictions.

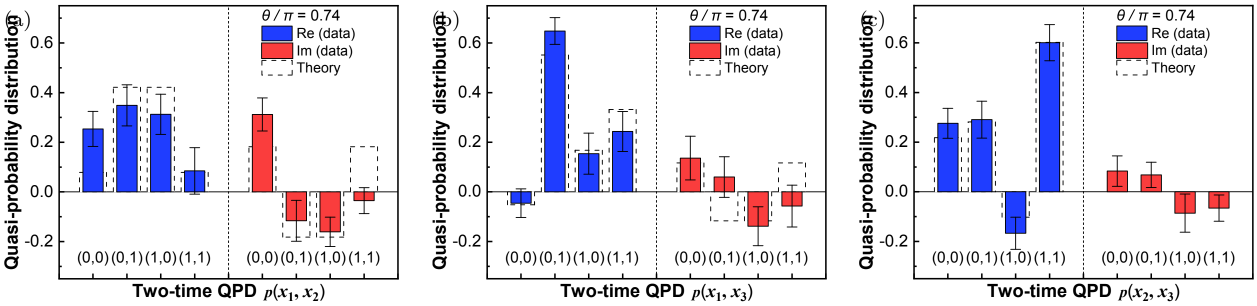

FIG. 5. The two-time QPDs obtained from the three-time QPDs. The blue and red bars indicate the real and imaginary parts of the QPDs. (a) The two-time QPD $p(x_1, x_2)$ from the unitary evolution $U_{t_1\to t_2}$. (b) The two-time QPD $p(x_1, x_3)$ from $U_{t_1\to t_3}$. (c) The two-time QPD $p(x_2, x_3)$ from $U_{t_2\to t_3}$. For all figures, the error bars indicate the STD, and the theoretical expectations are shown as dashed bars (see Methods for details).

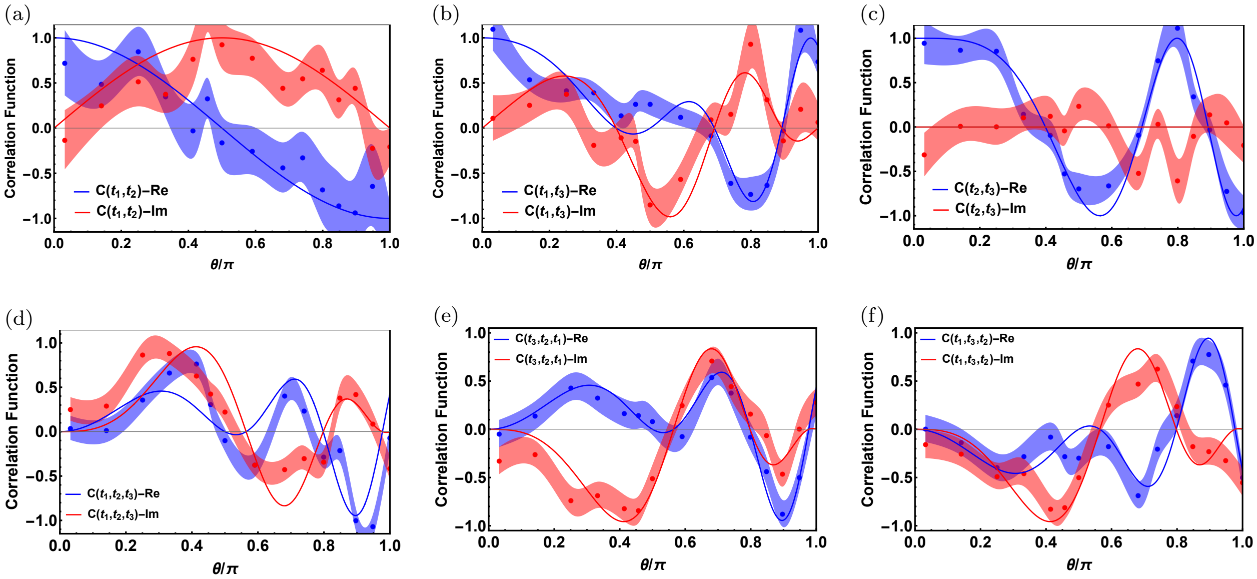

FIG. 6. The results of the two- and three-time correlation functions. Here, blue and red colors indicate the real and the imaginary parts of the correlation functions, respectively. Experimental data and theoretical expectations are shown as dots and solid lines, respectively. (a-c) The two-time correlation functions reconstructed from the three-time QPDs. (d) The time-ordered three-time correlation function reconstructed from the three-time QPDs. (e-f) $C(t_3, t_2, t_1)$ with the reversed time-ordering and $C(t_1, t_3, t_2)$ with an increasing-decreasing time-ordering respectively.

The majority of the experimental deviations stem from technical imperfections in controlling experimental parameters rather than fundamental issues in the underlying theoretical framework. Fluctuations in the parameters of the M-S gates are primarily responsible for the observed experimental deviations. In particular, more than 90% of the data points that deviate from theoretical predictions in Fig. 4(b) can be explained by fluctuations in the rotation angle of the M-S gates and the relative phase between two successive gates (see Methods). In the analysis, the amounts of the fluctuations in rotation angle and relative phase are required to be 0.03π (corresponding to 11.8% fluctuations) and 0.04π (approximately 4.4% fluctuations), respectively. We investigate the performance of the M-S gate using quantum process tomography, but we highlight that this data is not used for obtaining the joint distribution. The related details and other experimental imperfections are discussed in Methods.

Figure 7 indicates the fidelity $F(p, p_{\text{exp.}}) = \sum_{x_3} \sqrt{p(x_3)p_{\text{exp.}}(x_3)}$ between the theoretical distribution at time t_3 without intermediate measurements, $p(x_3) = \text{Tr}[\rho_{t_3}\Pi_{x_3}]$, and the marginal distribution of the QPD, $p_{\text{exp.}}(x_3) = \sum_{x_1,x_2} p_{\text{exp.}}(x_1, x_2, x_3)$, obtained from the experimental data. The marginal distribution obtained experimentally at time t_3 is closer to the ideal distribution compared to the case when intermediate projective measurements are performed at times t_1 and t_2.

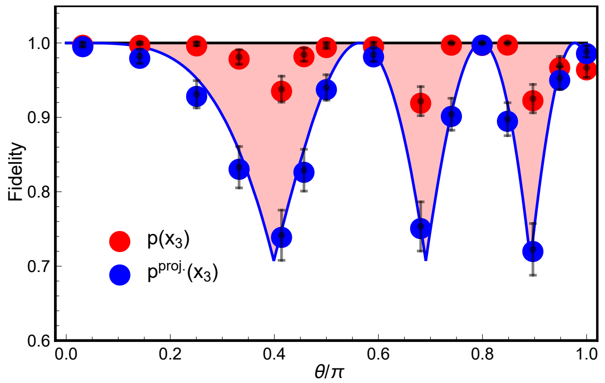

FIG. 7. Fidelity between the distributions for the z-basis measurement at time t_3. The error bars represent the standard error of the mean. Red dots refer to the fidelity between the marginal distribution from theory ($p(x_3)$) and the experimentally obtained three-time QPD ($p_{\text{exp.}}(x_3) = \sum_{x_1,x_2} p_{\text{exp.}}(x_1,x_2,x_3)$). The black line refers to the fidelity of 1 when the two distributions are equal. The blue line refers to the theoretical fidelity between $p(x_3)$ and $p^{\text{proj.}}(x_3)$ when projective measurements are performed at times t_1 and t_2. The blue dots refer to the corresponding experimental result.

CONCLUSION AND OUTLOOK

We have introduced a novel protocol named *snapshotting* to extract quantum statistics at multiple times from ancilla-assisted measurements and demonstrated it experimentally using the $^{171}\text{Yb}^{+}$-$^{138}\text{Ba}^{+}$ trapped-ion system. The key features of our approach are that the measurement effect can be entirely canceled out through classical post-processing of the ancilla measurement outcomes and that the measurement requires only a short-time system-ancilla interaction at each immediate time point. By snapshotting quantum dynamics, the QPD at multiple time points and various types of quantum correlation functions can be simultaneously obtained from a single distribution of observed trajectories. We highlight that this method is applicable to any quantum system and dynamics, serving as a valuable experimental tool for exploring the quantum statistics of both open and closed quantum systems.

The potential applications of the proposed protocol include exploring quantum dynamics in many-body physics. In principle, when considering local observables, the number of samples required to reconstruct QPDs and correlation functions does not scale with the size of the system or the number of qubits. This property is promising for obtaining various critical quantities based on correlation functions, such as OTOC, in quantum many-body systems [24, 25]. As the KD distribution itself has recently been recognized as an essential tool for investigating information scrambling and quantum thermodynamics [46, 49, 50, 59], its direct reconstruction from experimental data will open a new avenue for experimentally testing of the nonclassical phenomena arising from quantum dynamics.

METHODS

Proof of Theorem 1

Let us consider a slightly more general scenario such that the operators $A = \sum_{x=0}^{d-1} a_x \left|x\right\rangle\left\langle x\right|$ and $B = \sum_{x=0}^{d-1} b_x \left|x\right\rangle\left\langle x\right|$ diagonal in the same basis $\{\left|x\right\rangle\}_{x=0}^{d-1}$ are acting on the left and right sides of a d-dimensional quantum state, respectively, given as

$$\mathcal{E}_{B,A}(\rho) = B\rho A = \sum_m \gamma_m(B,A)\mathcal{K}_m(\rho), \tag{13}$$

where $\mathcal{K}_m(\rho) = K_m\rho K_m^\dagger$. We note that A and B is not required to be Hermitian. Theorem 1 in the main text to obtain the QPD $p(x_1, x_2, \cdots, x_N)$ is a special case with $A = \Pi_x = \left|x\right\rangle\left\langle x\right|$, $B = \mathbb{1}$, and $\gamma_{xm} = \gamma_m(\mathbb{1}, \Pi_x)$.

We then construct a set of Kraus operators $\{K_m\}$ to satisfy the condition in Eq. (13):

Proposition 1. *For the operators $A = \sum_x a_x \left|x\right\rangle\left\langle x\right|$ and $B = \sum_x b_x \left|x\right\rangle\left\langle x\right|$ diagonal in the same basis $\{\left|x\right\rangle\}$, there always exist $\gamma_m(B,A)$ satisfying Eq. (13) for a set of Kraus operators $\{K_m\}$ with*

$$K_m = \sum_{x=0}^{d-1}\left(\frac{\langle\phi_m|x\rangle}{\sqrt{\alpha}}\right)\left|x\right\rangle\left\langle x\right|,$$

where $\{\left|\phi_m\right\rangle\left\langle\phi_m\right|\}$ is a set of informationally complete projectors and satisfies $\sum_m \left|\phi_m\right\rangle\left\langle\phi_m\right| = \alpha\mathbb{1}$.

Proof. For the diagonal operators $A = \sum_x a_x\Pi_x$ and $B = \sum_x b_x\Pi_x$, let us rewrite Eq. (13) as

$$\begin{aligned}\mathcal{E}_{B,A}(\rho) &= B\rho A \\ &= \left(\sum_{y=0}^{d-1} b_y\Pi_y\right)\rho\left(\sum_{x=0}^{d-1} a_x\Pi_x\right) \\ &= \sum_{x,y=0}^{d-1} a_x b_y \Pi_y\rho\Pi_x \\ &= \sum_{x,y=0}^{d-1}\left\langle x\right|\left(\sum_{x',y'=0}^{d-1} a_{x'}b_{y'}\left|x'\right\rangle\left\langle y'\right|\right)|y\rangle\Pi_y\rho\Pi_x \\ &= \sum_{x,y=0}^{d-1}\langle x|O(B,A)|y\rangle\Pi_y\rho\Pi_x,\end{aligned} \tag{14}$$

where we define $O(B,A) = \sum_{x,y=0}^{d-1} a_x b_y \left|x\right\rangle\left\langle y\right|$. We note that any operator O can be expressed in terms of the informationally complete projectors $\{\left|\phi_m\right\rangle\left\langle\phi_m\right|\}$ as $O =$

$\sum_m c_m^O |\phi_m\rangle \langle\phi_m|$ with some complex coefficients c_m^O. This leads to an alternative expression

$$O(B,A) = \sum_m c_m^{O(B,A)} |\phi_m\rangle \langle\phi_m|.$$

By substituting this form into Eq. (14), we obtain

$$\begin{aligned}&\mathcal{E}_{B,A}(\rho)\\ &= \sum_m \sum_{x,y=0}^{d-1} c_m^{O(B,A)} \langle x|\phi_m\rangle\langle\phi_m|y\rangle \Pi_y \rho \Pi_x\\ &= \sum_m \alpha c_m^{O(B,A)} \left(\sum_{y=0}^{d-1} \frac{\langle\phi_m|y\rangle}{\sqrt{\alpha}}\Pi_y\right) \rho \left(\sum_{x=0}^{d-1} \Pi_x \frac{\langle x|\phi_m\rangle}{\sqrt{\alpha}}\right)\\ &= \sum_m \gamma_m(B,A) K_m \rho K_m^\dagger\\ &= \sum_m \gamma_m(B,A) \mathcal{K}_m(\rho),\end{aligned} \tag{15}$$

where we take $K_m = \sum_{y=0}^{d-1} \frac{\langle\phi_m|y\rangle}{\sqrt{\alpha}}\Pi_y$ to satisfy the normalization condition $\sum_m K_m^\dagger K_m = \mathbb{1}$ and define $\gamma_m(B,A) = \alpha c_m^{O(B,A)}$. □

To complete the proof of Theorem. 1, we show that these Kraus operators can be realized by the ancilla-assisted measurements. To this end, we introduce a d-dimensional ancilla state, initially prepared in $|0\rangle_R$. After applying the CSUM gate, a generalized CNOT gate, $U_{\mathrm{CSUM}} = \sum_{x,y=0}^{d-1} |x, x\oplus y\rangle \langle x,y|$ followed by the ancilla measurement with respect to the set of informationally complete projectors $\{|\phi_m\rangle\langle\phi_m|\}$, the Kraus operators for each measurement outcome become

$$K_m = \sum_{x=0}^{d-1}\left(\frac{\langle\phi_m|x\rangle}{\sqrt{\alpha}}\right)\Pi_x = \frac{\langle\phi_m|U_{\mathrm{CSUM}}|0\rangle_R}{\sqrt{\alpha}}. \tag{16}$$

For a d-dimensional system, a set of informationally complete projectors $\{|\phi_m\rangle\langle\phi_m|\}$ has at least d^2 elements. For example, the measurement set discussed in the main text, $\{|\phi_m\rangle\} = \{|0\rangle, |1\rangle, |0_y\rangle, |1_y\rangle, |0_x\rangle, |1_x\rangle\}$ has 6 elements, which is more than $d^2 = 4$, thus being overcomplete. However, this measurement set is easier to realize in experiments since all the projectors are the eigenvalues of the Pauli matrices.

Theorem 1 can be extended to local operators A and B of a multi-qudit system. This can be achieved by replacing Π_x with $\mathbb{1}\otimes\cdots\otimes\mathbb{1}\otimes\Pi_x\otimes\mathbb{1}\otimes\cdots\otimes\mathbb{1}$, where the projection is only applied to the target qudit. Consequently, K_m only acts on the target qubit while maintaining the same form as in Eq. (16), ensuring that the corresponding ancilla-assisted measurement requires only the interaction between the ancilla state and the target qudit. Since the coefficient $\gamma_m(B,A)$ for the local operators A and B remains the same as in the single-qudit case, the protocol does not scale with the size of the system as long as A and B act on a single-qudit.

We also note that there can be various choices of weight vectors $\gamma_m(B,A)$ that satisfy Eq. (13) for a given set of Kraus operators $\{K_m\}$. In this case, the optimal choice would be to minimize $|\gamma(B,A)|_{\max} := \max_m\{|\gamma_m(B,A)|\}$ as the number of samples to collect for a fixed precision scales with $|\gamma(B,A)|^2_{\max}$ from Hoeffding's inequality [67]. More precisely, the optimization problem can be formalized as follows:

$$\begin{aligned}\text{for given}: &\quad A,\ B,\ \{K_m\} &(17)\\ \text{minimize}: &\quad |\gamma|_{\max} = \max_m\{|\gamma_m|\} &(18)\\ \text{subject to}: &\quad B\otimes A^T = \sum_m \gamma_m K_m \otimes K_m^*. &(19)\end{aligned}$$

By vectorizing the density matrix ρ in Eq. (13), we note that Eq. (19) is equivalent to the condition that Eq. (13) holds for any ρ.

For $A = \sum_{x=0}^{d-1} a_x |x\rangle\langle x|$ and $B = \sum_{x=0}^{d-1} b_x |x\rangle\langle x|$ and the measurement operators described in Eq. (16), the condition in Eq. (19) is reduced to

$$\boldsymbol{T}\boldsymbol{\gamma} = \alpha\boldsymbol{\xi}, \tag{20}$$

where $[\boldsymbol{T}]_{x+yd,m} = \langle\phi_m|y\rangle\langle x|\phi_m\rangle$, $[\boldsymbol{\gamma}]_m = \gamma_m$, and $[\boldsymbol{\xi}]_{x+yd} = a_x b_y$. From numerical optimization for the measurement set $\{|\phi_m\rangle\} = \{|0\rangle, |1\rangle, |0_y\rangle, |1_y\rangle, |0_x\rangle, |1_x\rangle\}$ with $\alpha = 3$, which leads to $\{K_m\} = \left\{\frac{\Pi_0}{\sqrt{3}}, \frac{\Pi_1}{\sqrt{3}}, \frac{S^\dagger}{\sqrt{6}}, \frac{S}{\sqrt{6}}, \frac{\mathbb{1}}{\sqrt{6}}, \frac{Z}{\sqrt{6}}\right\}$, we obtain $\gamma_{\max} = \max_{x,m}\{|\gamma_m(\mathbb{1},\Pi_x)|\}| \approx 1.775$. This is a more efficient decomposition than that in Eq. (6) which yields $\gamma_{\max} = 3$.

Derivation of Observation 1

From the cyclic property of the trace, the correlation function can be rewritten as

$$\begin{aligned}&C(t_{\mu_1},\cdots,t_{\mu_j},\cdots,t_{\mu_k})\\ &\quad= \mathrm{Tr}[A(t_{\mu_{j+1}})\cdots A(t_{\mu_k})\rho_{t_0} A(t_{\mu_1})\cdots A(t_{\mu_j})].\end{aligned}$$

Then we note that both $t_{\mu_1} \le t_{\mu_2} \le \cdots \le t_{\mu_j}$ and $t_{\mu_k} \le t_{\mu_{k-1}} \le \cdots \le t_{\mu_{j+1}}$ are monotonically increasing time sequences, which leads to the following expression:

$$\begin{aligned}&C(t_{\mu_1},\cdots,t_{\mu_j},\cdots,t_{\mu_k})\\ &\quad= \mathrm{Tr}[(\mathcal{E}_{B_N,A_N}\circ\mathcal{U}_{t_{N-1}\to t_N}\circ\cdots\circ\mathcal{U}_{t_1\to t_2}\circ\mathcal{E}_{B_1,A_1})(\rho_{t_1})],\end{aligned}$$

where $\mathcal{U}_{t_i\to t_j}(\rho) = U_{t_i\to t_j}\rho U^\dagger_{t_i\to t_j}$ and we take $(B_i,A_i) = (\mathbb{1},A)$ when $A(t_i)$ is applied to the right side, $(B_i,A_i) = (A,\mathbb{1})$ when $A(t_i)$ is applied to the left side, and $(B_i,A_i) = (A,A)$ when $A(t_i)$ is applied to the both sides.

Since each $\mathcal{E}_{B_i,A_i}$ can be expressed as a linear combination of the actions of the Kraus operators $\{K_m\}$ from Proposition 1, we obtain the following form,

$$C(t_{\mu_1},\cdots,t_{\mu_j},\cdots,t_{\mu_k}) = \mathbb{E}\left[\prod_{i=1}^N \gamma_{m_i}(B_i,A_i)\right],$$

by averaging over all possible observed trajectories following the distribution $p^{\mathcal{K}}(m_1, m_2, \cdots, m_N) = \mathrm{Tr}[(\mathcal{K}_{m_N} \circ \mathcal{U}_{t_{N-1}\to t_N} \circ \cdots \circ \mathcal{U}_{t_1 \to t_2} \circ \mathcal{K}_{m_1})(\rho_{t_1})]$.

We highlight that the correlation functions with different time sequences $(t_{\mu_1}, \cdots, t_{\mu_k})$ are obtained by only replacing the coefficients $\gamma_{m_i}(B_i, A_i)$, which can be easily done in classical post-processing using the same data used to obtain $p^{\mathcal{K}}$.

Obtaining C_{OTOC} from intermediate measurements

Let us express the OTOC for the two operators $W(\tau) = U_\tau^\dagger W U_\tau$ and $V(0) = V$ as

$$\begin{aligned}
C_{\mathrm{OTOC}} &= \langle [W(\tau), V(0)]^\dagger [W(\tau), V(0)] \rangle \\
&= \langle W^\dagger(\tau) V^\dagger(0) V(0) W(\tau) \rangle - \langle V^\dagger(0) W^\dagger(\tau) V(0) W(\tau) \rangle \\
&\quad - \langle W^\dagger(\tau) V^\dagger(0) W(\tau) V(0) \rangle + \langle V^\dagger(0) W^\dagger(\tau) W(\tau) V(0) \rangle \\
&= \mathrm{Tr}[V U_\tau^\dagger W U_\tau \rho U_\tau^\dagger W^\dagger U_\tau V^\dagger] \\
&\quad - \mathrm{Tr}[V U_\tau^\dagger W U_\tau \rho V^\dagger U_\tau^\dagger W^\dagger U_\tau] \\
&\quad - \mathrm{Tr}[U_\tau^\dagger W U_\tau V \rho U_\tau^\dagger W^\dagger U_\tau V^\dagger] + \mathrm{Tr}[W U_\tau V \rho V^\dagger U_\tau^\dagger W^\dagger] \\
&= \mathrm{Tr}[(\mathcal{E}_{V,V^\dagger} \circ \mathcal{U}^{-1} \circ \mathcal{E}_{W,W^\dagger} \circ \mathcal{U} \circ \mathcal{E}_{\mathbb{1},\mathbb{1}})(\rho)] \\
&\quad - \mathrm{Tr}[(\mathcal{E}_{V,\mathbb{1}} \circ \mathcal{U}^{-1} \circ \mathcal{E}_{W,W^\dagger} \circ \mathcal{U} \circ \mathcal{E}_{\mathbb{1},V^\dagger})(\rho)] \\
&\quad - \mathrm{Tr}[(\mathcal{E}_{\mathbb{1},V^\dagger} \circ \mathcal{U}^{-1} \circ \mathcal{E}_{W,W^\dagger} \circ \mathcal{U} \circ \mathcal{E}_{V,\mathbb{1}})(\rho)] \\
&\quad + \mathrm{Tr}[(\mathcal{E}_{W,W} \circ \mathcal{U} \circ \mathcal{E}_{V,V^\dagger})(\rho)],
\end{aligned}$$

where we denote $\mathcal{U}(\rho) = U_\tau \rho U_\tau^\dagger$ and $\mathcal{U}^{-1}(\rho) = U_\tau^\dagger \rho U_\tau$, respectively.

One can then construct the intermediate measurements $\{K_{m_1}^V\} = \{K_{m_3}^V\}$ and $\{\mathcal{K}_{m_2}^W\}$ from Proposition 1 to express $\mathcal{E}_{\mathbb{1},\mathbb{1}}$, $\mathcal{E}_{\mathbb{1},V^\dagger}$, $\mathcal{E}_{V,\mathbb{1}}$, and $\mathcal{E}_{V,V^\dagger}$ as a weighted sum of $\mathcal{K}_{m_1}^V$ or $\mathcal{K}_{m_3}^V$, and $\mathcal{E}_{W,W^\dagger}$ as a weighted sum of $\mathcal{K}_{m_2}^W$. From this, all the four terms in C_{OTOC} can be obtained simultaneously from $p^{\mathcal{K}}(m_1, m_2, m_3) = \mathrm{Tr}[(\mathcal{K}_{m_3}^V \circ \mathcal{U}^{-1} \circ \mathcal{K}_{m_2}^W \circ \mathcal{U} \circ \mathcal{K}_{m_1}^V(\rho)]$.

Experimental setup

As shown in Fig. 8(a), we use a dual-species trapped-ion system, which traps one ^{171}Yb$^+$ ion and one ^{138}Ba$^+$ ion in a four-rod trap, to perform the ancilla-assisted measurements. The ^{171}Yb$^+$and ^{138}Ba$^+$ ions serve as the system and the ancilla qubits, respectively. The two ions have different energy structures and require different initialization and detection lasers. Therefore, operations on the ^{171}Yb$^+$ ion do not affect the ^{138}Ba$^+$ ion and vice versa. Therefore, it is possible to perform the ICD and ICI, where ^{138}Ba$^+$ ion-qubit is detected or initialized without affecting the other qubit [90], which is the essential property for the ancilla-assisted measurement. We perform single-qubit rotations and the two-qubit M-S gate by using 355 nm and 532 nm Raman laser beams for ^{171}Yb$^+$and ^{138}Ba$^+$ ions, respectively, as shown in Fig. 8(b).

Two- and three-time QPDs simulation data

Quantum process tomography of M-S gate

To quantitatively characterize the effect of imperfect M-S gates on the protocol, we perform quantum process tomography of the M-S gate. For quantum process tomography, we first prepare the system to one of the 16 states $|i\rangle \otimes |j\rangle$, where $|i\rangle$, $|j\rangle \in \{|0\rangle, |1\rangle, |1_x\rangle, |0_y\rangle\}$, then apply an M-S gate operation and then measure the system on one of the nine measurement bases $\{xx, xy, xz, yx, yy, yz, zx, zy, zz\}$. Using the maximum likelihood method[94, 96–98], we reconstruct the process matrix from the measurement results as shown in Fig. 11. Compared to the ideal M-S gate, the process matrix has a fidelity of 93.16%. The process matrix has a mean fidelity of 94.51%±1.18%, the average fidelity of the output state over all possible input states[94, 97, 99], which is consistent with the fidelity of the Bell state of 94% ± 2%.

We analyze the raw data, that is, 72 different observed trajectories shown in Fig. 4(b) with the result of quantum process tomography of the M-S gate. In our numerical analysis, fluctuations in the rotation angles of the M-S gate and relative phases between successive M-S gates can explain the deviations of the experimental results from the theoretical predictions. A parameterized M-S gate can be described as $\mathrm{MS} = \exp(-i\theta_{\mathrm{M}}(\sin(\phi_{\mathrm{M1}})Y + \cos(\phi_{\mathrm{M1}})X) \otimes (\sin(\phi_{\mathrm{M2}})Y + \cos(\phi_{\mathrm{M2}})X))$, where θ_{M} represents the rotation angle that should be $\pi/4$ for the ideal gate, and ϕ_{M1} and ϕ_{M2} represent the phases that determine the rotation axis for the ^{171}Yb$^+$and ^{138}Ba$^+$qubits, respectively, which should be zero for the ideal gate. For each trajectory, we numerically adjust the rotation angles and relative phases of the M-S gate process matrix so that the numerical calculation agrees with the experimental result. Then, we collect the adjusted rotation angles and relative phases for all observed trajectories. Among a total of 72 measurement results of $p^{\mathcal{K}}(m_1, m_2, m_3)$, more than 90% deviations in the data can be explained by fluctuations in the rotation angle of the M-S gate and relative phases between two gates. The distributions of the adjusted parameters are as follows. The rotation angles are overall shifted by 0.001π with a standard deviation of 0.03π, corresponding to approximately 11.8% fluctuations. The relative phases are shifted by 0.01π with a standard deviation of 0.04π, corresponding to 4.4%. Here, we note that phase fluctuations are only considered for the ^{171}Yb$^+$qubits.

To illustrate the experimental imperfections, we investigate the dependence of the contrasts of the two-time correlation functions on the infidelities of the M-S gates by using the experimental M-S gate process matrix. As

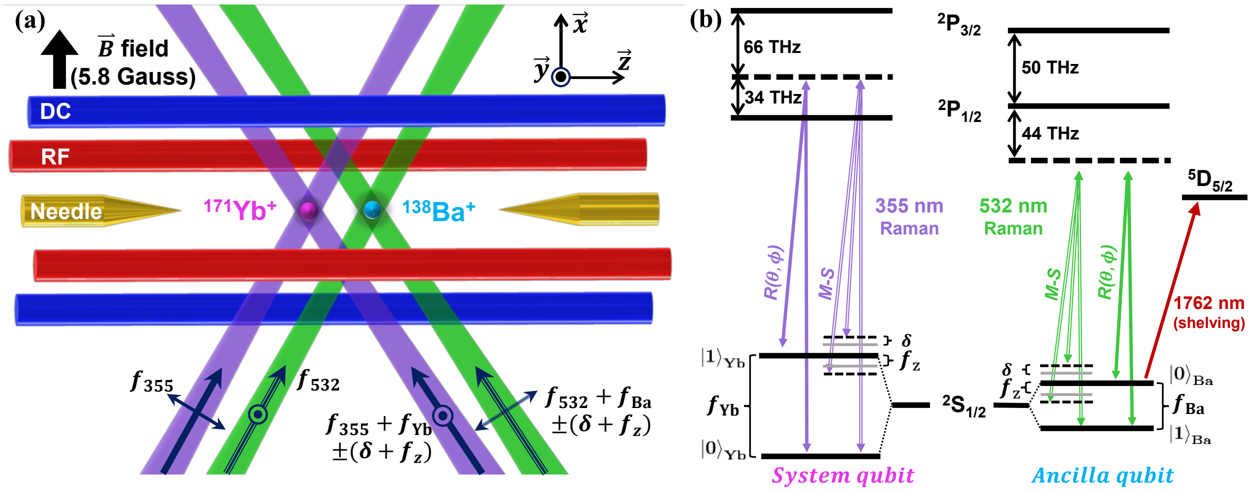

FIG. 8. Experimental setup. (a) ^{171}Yb$^+$ and ^{138}Ba$^+$ ions trapped in a four-rod trap. A magnetic field of 5.8 Gauss is applied along the x-axis. To realize the M-S gate between two ions, the ^{171}Yb$^+$ ion is controlled by illuminating a pair of 355 nm lasers (purple) with a frequency of f_{355} and $f_{355}+f_{\rm Yb}\pm(\delta+f_z)$, where $f_{\rm Yb}$ is the qubit splitting of the ^{171}Yb$^+$ qubit. The ^{138}Ba$^+$ ion is controlled by illuminating a pair of 532 nm lasers (green) with a frequency of f_{532} and $f_{532}+f_{\rm Ba}\pm(\delta+f_z)$, where $f_{\rm Ba}$ is the qubit splitting of the ^{138}Ba$^+$ ion-qubit, f_z is the frequency of the axial OOP (out-of-phase) mode, and δ is the laser detuning from the sideband of the OOP mode. Raman laser directions are represented by thick arrows, and the polarization is represented by thin arrows and dots. (b) Energy levels and related lasers for the ^{171}Yb$^+$ and ^{138}Ba$^+$ ions. The hyperfine qubit of the ^{171}Yb$^+$ ion and the Zeeman qubit of the ^{138}Ba$^+$ ion serve as the system qubit and the ancilla qubit, respectively. Single-qubit rotations are realized by resonant Raman transitions. The two-qubit entangling operation is realized by applying a bichromatic Raman laser for both ions. The 1762 nm laser is the shelving laser used for ^{138}Ba$^+$ ion-qubit detection.

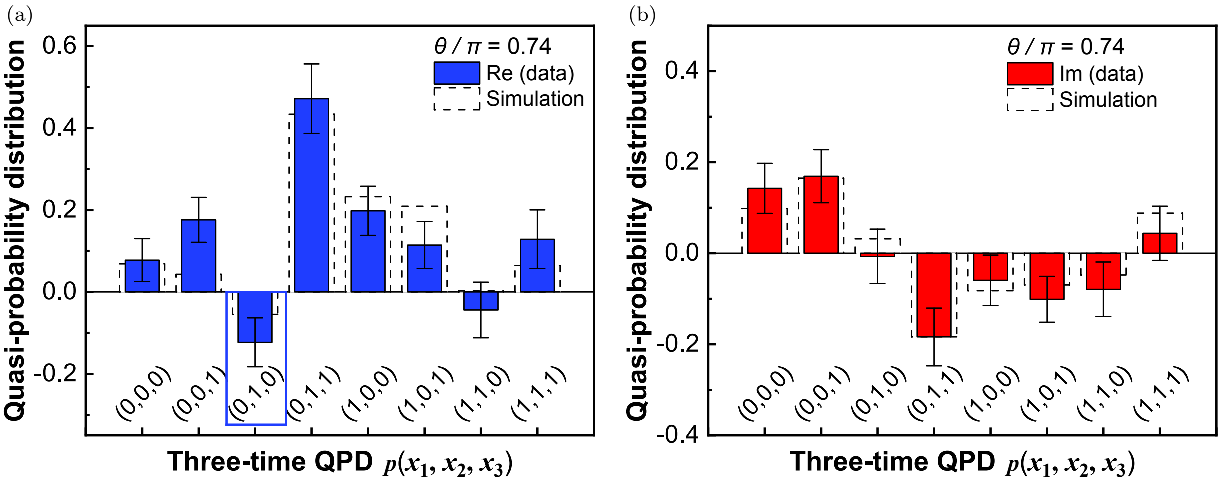

FIG. 9. Three-time QPDs simulation data

shown in Fig. 12(a), for the two-time correlation functions, the contrast of the real part decreases more than the contrast of the imaginary part. Here, we increase the infidelity by multiplying the operation of the M-S gate and assume that it increases linearly with the number of gates. Since multiplying the ideal CNOT gate twice equals an identity operator, we add two M-S gates at each step to increase the gate infidelity while maintaining the measurement scheme. Three-time measurements are also investigated using the experimental M-S gate process matrix. As shown in Fig. 12(b), the three-time correlation functions are simulated taking into account the process matrix infidelity. The experimental and simulated data with infidelity agree better than the ideal theory data, indicating that the infidelity of the M-S gate is one of the main causes of deviation. The major imperfections come from the rotation angle of the M-S gate. To be an ideal CNOT gate, the angle of the M-S gate should be

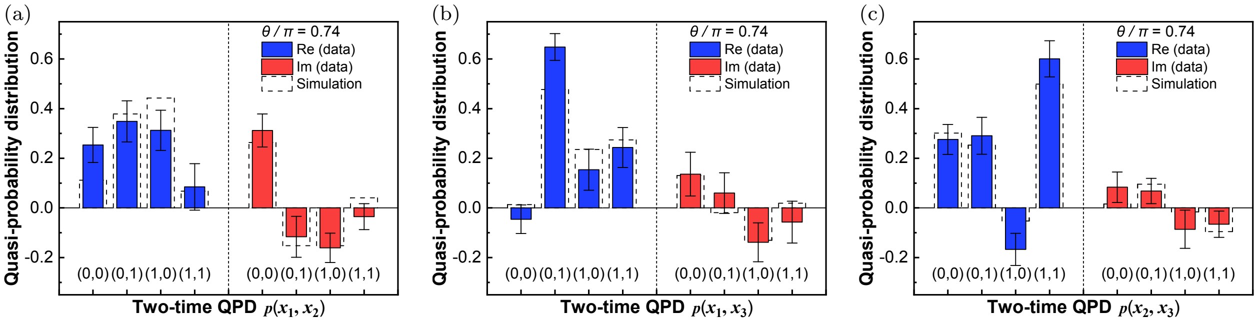

FIG. 10. Two-time QPDs simulation data

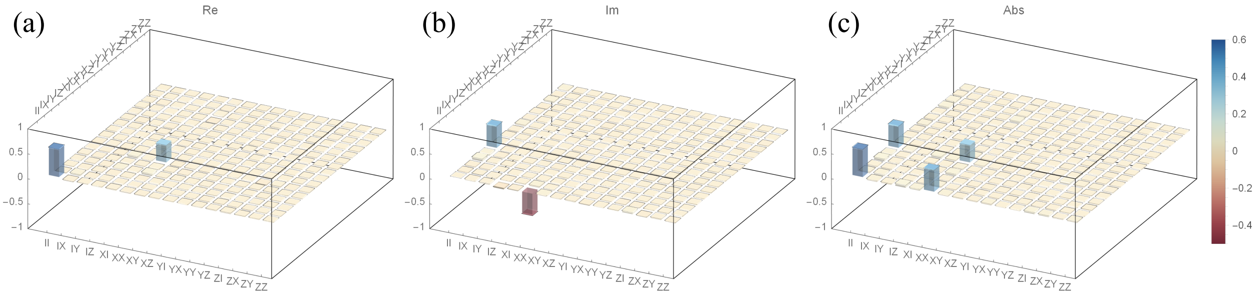

FIG. 11. The experimental process matrix of the M-S gate. (a-c) represent the real part, the imaginary part, and the absolute value of the process matrix, respectively.

$\pi/4$, but in our experiment, the angle is about 10% less than the ideal value. This angle imperfection explains well the disagreement in the imaginary parts for small θ values.

Further deviations can arise from phase fluctuation problems between successive M-S gates. The M-S gate can be described as $\exp\left(-i\frac{\pi}{4}X_{\text{Yb}}X_{\text{Ba}}\right)$, where X_{Yb} and X_{Ba} are Pauli operators σ_x of the $^{171}\text{Yb}^+$ and $^{138}\text{Ba}^+$ ion qubits. We need to control the laser phases for the M-S gate to make the gate work as $X_{\text{Yb}}X_{\text{Ba}}$ and not on other axes. For example, in the three-time correlation functions of Fig. 12(b), the second time point can be explained by the drift of the 0.1π phase for the $^{138}\text{Ba}^+$ ion qubit.

Post-selection detection and error analysis

Figure 13 shows the detailed process of the $^{138}\text{Ba}^+$ ion fluorescence detection. In this detection process, we first use a 1762 nm laser to shelve the $|0\rangle_{\text{Ba}}$ population to $\text{D}_{5/2}$, and then apply a 493 nm laser to drive the transition between $\text{S}_{1/2}$ and $\text{P}_{1/2}$. The shelving operation has no effect if the qubit state is $|1\rangle_{\text{Ba}}$, and a large number of photons will be produced by the subsequent 493 nm laser. In contrast, if the qubit state is $|0\rangle_{\text{Ba}}$, the population is shelved to $\text{D}_{5/2}$ and no photons are produced by the 493 nm laser. Hence, the number of scattered photons can be used to distinguish the qubit states.

In our multi-time measurements circuit, the ancilla ($^{138}\text{Ba}^+$ ion) is required to be detected and used repeatedly. However, as shown in Fig. 13(a), the detection of a bright state produces a large number of photons, thereby heating the ion chain and further degrading the performance of subsequent CNOT operations. To solve this problem, we adopt a post-selection approach for all ICDs, which uses only dark state data. For bright state data, we transfer bright states to dark states by a π pulse before the measurement.

All the error bars in the main text are obtained by the bootstrap method. We first re-sample the experimental raw data in Fig. 4(b), generating 1000 new datasets. Subsequently, we derive 1000 new results based on these datasets and obtain the standard deviations from the distribution of these 1000 results.

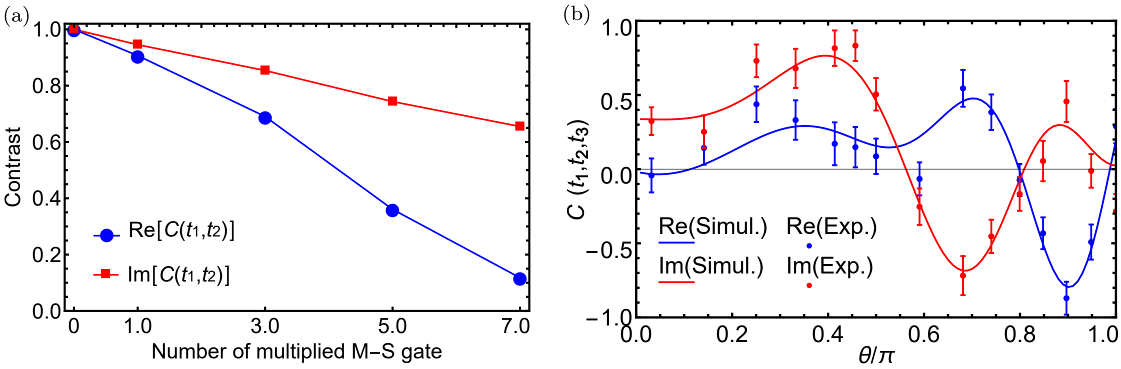

FIG. 12. The effect of imperfect M-S gates on the measurement scheme. (a) The blue circles and red squares represent the contrast of the real and imaginary parts of $C(t_1, t_2)$. The horizontal axis represents the number of imperfect M-S gates applied to the system, while 0 represents an ideal M-S gate. (b) Simulation results of three-time correlation functions based on the process matrix. Error bars are standard deviations. The blue and red lines represent the real and imaginary parts of $C(t_1, t_2, t_3)$. The blue and red dots represent the corresponding experimental results.

FIG. 13. Fluorescence detection of the ^{138}Ba$^+$ ion. The detection process consists of two steps: First, we use a 1762 nm laser to shelve the $|0\rangle_{\mathrm{Ba}}$ population to D$_{5/2}$, and then we use a 493 nm laser to drive the transition between S$_{1/2}$ and P$_{1/2}$. (a) Bright state detection. When the ancilla is in $|1\rangle_{\mathrm{Ba}}$, the shelving operation does not affect the qubit. The subsequent 493 nm laser produces a large number of photons. (b) Dark state detection. When the ancilla is in $|0\rangle_{\mathrm{Ba}}$, its population is shelved to D$_{5/2}$. Therefore, the 493 nm laser will not produce any photons.

Expectation values from theory

First, we consider two- and three-time correlation functions

$$\begin{aligned} &C(t_1,t_2)\\ &\quad = \mathrm{Tr}\left[\rho Z(t_1) Z(t_2)\right]\\ &\quad = \mathrm{Tr}\left[U_{t_1\to t_2}\rho_{t_1} Z U^\dagger_{t_1\to t_2} Z\right]\\ &C(t_1,t_2,t_3)\\ &\quad = \mathrm{Tr}\left[\rho Z(t_1) Z(t_2) Z(t_3)\right]\\ &\quad = \mathrm{Tr}\left[U_{t_2\to t_3} U_{t_1\to t_2}\rho_{t_1} Z U^\dagger_{t_1\to t_2} Z U^\dagger_{t_2\to t_3} Z\right], \end{aligned} \tag{21}$$

where $U_{t_i\to t_j}$ describes the unitary time evolution from time t_i to t_j, and ρ_{t_1} is the quantum state at time t_1. In this paper, we focus on the case where the initial state is prepared in $\rho_{t_1} = |1_x\rangle\langle 1_x|$ with $|1_x\rangle = (|0\rangle - |1\rangle)/\sqrt{2}$, and the evolution unitary operators are given as $U_{t_1\to t_2} = R_X(\theta) = e^{-i(\theta/2)X}$, and $U_{t_2\to t_3} = R_Y(\theta^2) = e^{-i(\theta^2/2)Y}$ with $\theta \in [0,\pi]$ and the Pauli matrices X, Y and Z. The theoretical expectation values of Eq. (21) are

$$\begin{aligned} &C(t_1,t_2)\\ &\quad = \mathrm{Tr}\left[U_{t_1\to t_2}|1_x\rangle\langle 1_x| Z U^\dagger_{t_1\to t_2} Z\right]\\ &\quad = \langle 1_x| Z U^\dagger_{t_1\to t_2} Z U_{t_1\to t_2}|1_x\rangle\\ &\quad = \langle 1_x| Z e^{i(\theta/2)X} Z e^{-i(\theta/2)X}|1_x\rangle\\ &\quad = \cos\theta + i\sin\theta\\ &C(t_1,t_3)\\ &\quad = \mathrm{Tr}\left[U_{t_2\to t_3}U_{t_1\to t_2}|1_x\rangle\langle 1_x| Z U^\dagger_{t_1\to t_2} U^\dagger_{t_2\to t_3} Z\right]\\ &\quad = \langle 1_x| Z U^\dagger_{t_1\to t_2} U^\dagger_{t_2\to t_3} Z U_{t_2\to t_3} U_{t_1\to t_2}|1_x\rangle\\ &\quad = \langle 1_x| Z e^{i(\theta/2)X} e^{i(\theta^2/2)Y} Z e^{-i(\theta^2/2)Y} e^{-i(\theta/2)X}|1_x\rangle\\ &\quad = \cos\theta^2(\cos\theta + i\sin\theta)\\ &C(t_2,t_3)\\ &\quad = \mathrm{Tr}\left[U_{t_2\to t_3}U_{t_1\to t_2}|1_x\rangle\langle 1_x| U^\dagger_{t_1\to t_2} Z U^\dagger_{t_2\to t_3} Z\right]\\ &\quad = \langle 1_x| U^\dagger_{t_1\to t_2} Z U^\dagger_{t_2\to t_3} Z U_{t_2\to t_3} U_{t_1\to t_2}|1_x\rangle\\ &\quad = \langle 1_x| e^{i(\theta/2)X} Z e^{i(\theta^2/2)Y} Z e^{-i(\theta^2/2)Y} e^{-i(\theta/2)X}|1_x\rangle\\ &\quad = \cos\theta^2, \end{aligned}$$

$$
\begin{aligned}
&C(t_1,t_2,t_3)\\
&\quad = \mathrm{Tr}\left[U_{t_2\to t_3}U_{t_1\to t_2}\left|1_x\right\rangle\left\langle 1_x\right|ZU^{\dagger}_{t_1\to t_2}ZU^{\dagger}_{t_2\to t_3}Z\right]\\
&\quad = \langle 1_x|ZU^{\dagger}_{t_1\to t_2}ZU^{\dagger}_{t_2\to t_3}ZU_{t_2\to t_3}U_{t_1\to t_2}\left|1_x\right\rangle\\
&\quad = \langle 1_x|Ze^{i(\theta/2)X}Ze^{i(\theta^2/2)Y}Ze^{-i(\theta^2/2)Y}e^{-i(\theta/2)X}\left|1_x\right\rangle\\
&\quad = \sin\theta^2(\cos\theta + i\sin\theta)\\
&C(t_2,t_3,t_1)\\
&\quad = \mathrm{Tr}\left[U_{t_2\to t_3}U_{t_1\to t_2}Z\left|1_x\right\rangle\left\langle 1_x\right|U^{\dagger}_{t_1\to t_2}ZU^{\dagger}_{t_2\to t_3}Z\right]\\
&\quad = \langle 1_x|U^{\dagger}_{t_1\to t_2}ZU^{\dagger}_{t_2\to t_3}ZU_{t_2\to t_3}U_{t_1\to t_2}Z\left|1_x\right\rangle\\
&\quad = \langle 1_x|e^{i(\theta/2)X}Ze^{i(\theta^2/2)Y}Ze^{-i(\theta^2/2)Y}e^{-i(\theta/2)X}Z\left|1_x\right\rangle\\
&\quad = \sin\theta^2(-\cos\theta + i\sin\theta)\\
&C(t_3,t_2,t_1)\\
&\quad = \mathrm{Tr}\left[U_{t_2\to t_3}ZU_{t_1\to t_2}Z\left|1_x\right\rangle\left\langle 1_x\right|U^{\dagger}_{t_1\to t_2}U^{\dagger}_{t_2\to t_3}Z\right]\\
&\quad = \langle 1_x|U^{\dagger}_{t_1\to t_2}U^{\dagger}_{t_2\to t_3}ZU_{t_2\to t_3}ZU_{t_1\to t_2}Z\left|1_x\right\rangle\\
&\quad = \langle 1_x|e^{i(\theta/2)X}e^{i(\theta^2/2)Y}Ze^{-i(\theta^2/2)Y}Ze^{-i(\theta/2)X}Z\left|1_x\right\rangle\\
&\quad = \sin\theta^2(\cos\theta - i\sin\theta).
\end{aligned}
\tag{22}
$$

Meanwhile, the two- and three-time QPDs are expressed as

$$
\begin{aligned}
&p(x_1,x_2)\\
&\quad = \mathrm{Tr}\left[U_{t_1\to t_2}\rho_{t_1}\Pi_{x_1}U^{\dagger}_{t_1\to t_2}\Pi_{x_2}\right]\\
&p(x_1,x_2,x_3)\\
&\quad = \mathrm{Tr}\left[U_{t_2\to t_3}U_{t_1\to t_2}\rho_{t_1}\Pi_{x_1}U^{\dagger}_{t_1\to t_2}\Pi_{x_2}U^{\dagger}_{t_2\to t_3}\Pi_{x_3}\right],
\end{aligned}
\tag{23}
$$

which can also be calculated similarly to the correlation functions. For the initial state $\rho_{t_1} = \left|1_x\right\rangle\left\langle 1_x\right|$ and the dynamics $U_{t_1\to t_2} = R_X(\theta) = e^{-i(\theta/2)X}$ and $U_{t_2\to t_3} = R_Y(\theta^2) = e^{-i(\theta^2/2)Y}$, we obtain

$$
\begin{aligned}
&p(x_1,x_2)\\
&\quad = \mathrm{Tr}\left[e^{-i(\theta/2)X}\left|1_x\right\rangle\left\langle 1_x\right|\Pi_{x_1}e^{i(\theta/2)X}\Pi_{x_2}\right]\\
&\quad = \langle 1_x|\Pi_{x_1}e^{i(\theta/2)X}\Pi_{x_2}e^{-i(\theta/2)X}\left|1_x\right\rangle\\
&\quad = \langle 1_x|x_1\rangle\langle x_1|e^{i(\theta/2)X}\left|x_2\right\rangle\left\langle x_2\right|e^{-i(\theta/2)X}\left|1_x\right\rangle\\
&p(x_1,x_2,x_3)\\
&\quad = \mathrm{Tr}\left[e^{-i(\theta^2/2)Y}e^{-i(\theta/2)X}\left|1_x\right\rangle\left\langle 1_x\right|\Pi_{x_1}e^{i(\theta/2)X}\Pi_{x_2}e^{i(\theta^2/2)Y}\Pi_{x_3}\right]\\
&\quad = \langle 1_x|\Pi_{x_1}e^{i(\theta/2)X}\Pi_{x_2}e^{i(\theta^2/2)Y}\Pi_{x_3}e^{-i(\theta^2/2)Y}e^{-i(\theta/2)X}\left|1_x\right\rangle\\
&\quad = \left\langle 1_x\right|\left.x_1\right\rangle\left\langle x_1\right|e^{i(\theta/2)X}\left|x_2\right\rangle\left\langle x_2\right|e^{i(\theta^2/2)Y}\left|x_3\right\rangle\left\langle x_3\right|\\
&\qquad e^{-i(\theta^2/2)Y}e^{-i(\theta/2)X}\left|1_x\right\rangle,
\end{aligned}
\tag{24}
$$

where each component can be straightforwardly obtained from the explicit form of the rotation matrices.

Tangling schedules eases hardware connectivity requirements for quantum error correction

Abstract. Error-corrected quantum computers have the potential to change the way we solve computational problems. Quantum error correction involves repeated rounds of carefully scheduled gates to measure the stabilisers of a code. A set of scheduling rules are typically imposed on the order of gates to ensure the circuit can be rearranged into an equivalent circuit that can be easily seen to measure the stabilisers. In this work, we ask what would happen if we break these rules and instead use circuit schedules that we describe as tangled. We find that tangling schedules generates long-range entanglement not accessible using nearest-neighbour two-qubit gates. Our tangled schedules method provides a new tool for building quantum error correction circuits and we explore applications to design new architectures for fault-tolerant quantum computers. Notably, we show that, for the widely used Pauli-based model of computation (achieved by lattice surgery), this access to longer-range entanglement can reduce the device connectivity requirements, without compromising on circuit depth.

1 Introduction

For certain types of quantum hardware, e.g. superconducting quantum computers, the quantum processing unit (QPU) typically has a fixed qubit layout and connectivity. Here, connectivity means which pairs of qubits can be acted on with native two-qubit gates. As connectivity increases, so too does crosstalk noise and related engineering challenges. Furthermore, a QPU with uniform connectivity structure is desirable so that different code sizes and algorithms can be executed. As such, uniform, low-degree QPUs are the natural choice.

Since qubits are unfortunately noisy, the need for quantum error correction (QEC) procedures arises. This may require the measurement of some irregular, non-local stabilisers, that cannot be measured in the standard way using one auxiliary qubit per stabiliser due to the QPU's low degree of connectivity. For instance, when performing a lattice surgery operation with the surface code that involves a Y Pauli term, the measurement of twist defects and elongated rectangles is needed, and it is not currently known how to do that on a square-grid connectivity QPU without increasing circuit depth substantially. Here, we present a general method of tangled syndrome extraction circuits, which enables measurement of observables involving distant qubits. We then apply this to the non-local stabilisers appearing during Pauli-based computation with the surface code, and construct low-depth circuits to measure them on a square-grid connectivity QPU. Therefore, tangling enables fault-tolerant logical quantum computation via Pauli-based computational model using the surface code on square-grid connectivity architectures.

2 Preliminaries

Consider a general stabiliser $g = P_1 P_2 \dots P_m$, where each of $P_1, P_2, \dots, P_m$ is a single-qubit Pauli operator, with no two of them acting on the same qubit. We can always measure g using the following circuit: prepare an auxiliary qubit in the $|+\rangle$ state; apply controlled-P_1; apply controlled-P_2; … apply controlled-P_m; and finally, measure out the auxiliary qubit in the X basis, see Figure 1. This measurement outcome corresponds to the measurement of g. In this circuit $\mathcal{C}$, all controlled gates use the auxiliary qubit as the control. Furthermore, we are free to shuffle the order of the controlled-P_j gates and we may also insert identity gates. We call this the *auxiliary syndrome extraction circuit of g*.

Next, consider a set of stabilisers $\{g_j\}_{j=1}^m$, and for each stabiliser g_j suppose an auxiliary syndrome extraction circuit $\mathcal{C}_j$. Assume the circuits have the same depth, i.e. number of layers including those with identity gates, and that we use different auxiliary qubits for different stabilisers. If we combine these circuits, so that they all occur simultaneously, the resulting circuit, which we denote by $\mathcal{C}$, then measures the set of stabilisers $\{g_j\}_{j=1}^m$ simultaneously and independently if and only if the following two conditions are satisfied:

(a) no qubit is involved in more than one gate at a time;

(b) for every pair of distinct circuits $j \neq k$, the simultaneous combination of $\mathcal{C}_j$ and $\mathcal{C}_k$ is equivalent to the serial execution $\mathcal{C}_j$ followed by $\mathcal{C}_k$.

The technical manuscript [5] contains a more formal equivalent statement of both (a) and (b) in its Section

*george.geher@riverlane.com
†ophelia.crawford@riverlane.com
‡earl.campbell@riverlane.com

2. An illustration of these two conditions can be found in [9, Figure 15].

3 Our main result

Our tangled syndrome extraction technique is based on the following violation of condition (b).

Definition 1 (Tangled circuits) *The auxiliary syndrome extraction circuits $\mathcal{C}_j$ and $\mathcal{C}_k$ are called tangled if condition (a) above is satisfied for them, but condition (b) is not.*

It turns out that by tangling the circuits $\{\mathcal{C}_j\}_{j=1}^m$, it is possible to measure the product $h = g_1 \cdots g_m$. Since, in this case, the operators g_j are no longer stabilisers themselves, we emphasise this by calling them *component operators* instead. We state our main result now.

Theorem 2 *Consider a set of pair-wise commuting Pauli product operators $\{g_j\}_{j=1}^m$ and an auxiliary syndrome extraction circuit for each: $\{\mathcal{C}_j\}_{j=1}^m$. Denote by $\mathcal{C}$ the combined circuit. Compose an (undirected) graph $G = (V, E)$ where $V = [1, \ldots, m]$ and $(j, k) \in E$ if and only if the circuits $\mathcal{C}_j$ and $\mathcal{C}_k$ are tangled. Suppose further that G is a forest whose connected components are $\mathcal{T}_1, \ldots, \mathcal{T}_\ell$. Then there exists a modification of $\mathcal{C}$ where*

- *we modify the single qubit Pauli measurements on the auxiliary qubits, and*
- *we apply a Clifford correction on the data qubits,*

such that the modified circuit $\tilde{\mathcal{C}}$ measures the products $h_r := \prod_{j \in \mathcal{T}_r} g_j$ for $r = 1, \ldots, \ell$ simultaneously and independently. Moreover, after two rounds of syndrome extraction $\tilde{\mathcal{C}}$, the accumulated Clifford corrections multiply into a Pauli correction that can be tracked in software.

The main feature of our tangling circuits technique is that it creates entanglement between the auxiliary qubits, unlike in the case when condition (b) is satisfied. This is illustrated in Figure 2 for the simplest case of our theorem, i.e. when G is a two-vertex tree graph. In this case we need to modify the basis of measurements on the auxiliary qubits from X to Y, and include a Clifford correction as shown in Figure 2. As can be seen, when we reorder the entangling gates of the circuit $\tilde{\mathcal{C}}$, so that the ones controlled on the first auxiliary qubit are in front of the ones controlled on the other auxiliary qubit, an additional CZ gate (red in bottom subfigure of fig. 2) appears between the two auxiliary qubits. In Section 2 of the technical manuscript [5], we prove a circuit pruning identity, depicted in Figure 5b there, which we then use to prove the above theorem. Namely, we iteratively identify leaves of G and remove them by using the pruning identity. We continue with this process until the remaining graph has no edges. The full details are in the technical manuscript [5].

Figure 2: (top) Graphical illustration of a pair of tangled syndrome extraction circuits that measures the stabiliser $h = g_1 g_2 = -XXYYZZ$ as a product of component operators $g_1 = XXXXII$ and $g_2 = IIZZZZ$. The X and Z Pauli terms of a component operator are coloured red and blue, respectively. (middle) Circuit for measuring h, as specified by the top subfigure, with the outcome given by $n_a \oplus n_b$. This circuit requires low connectivity and low depth to measure the product $g_1 g_2$ by violating the (b) condition. (bottom): An equivalent circuit that shows direct entanglement (red CZ gate) of auxiliary qubits. There is a Clifford correction to achieve the desired post-measurement state. However, after two rounds of the protocol, the Clifford correction becomes a Pauli correction.

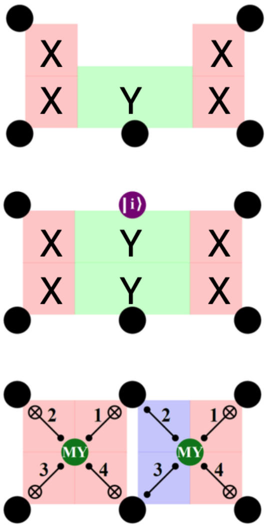

Figure 3: (top) A weight-5 twist-defect Pauli operator used for lattice surgery involving a Y Pauli term. The X, Y and Z Pauli terms are coloured red, green and blue, respectively. (middle) A sixth qubit (purple) initialised in the $|i\rangle$ state, and a weight-6 operator we can measure on these six qubits using our tangling schedules technique. (bottom) Graphical representation of the tangled circuit we can use to measure the weight-6 operator. Since the purple qubit was initialised in a Y-eigenstate, we effectively measure the weight-5 twist-defect $XXYXX$.

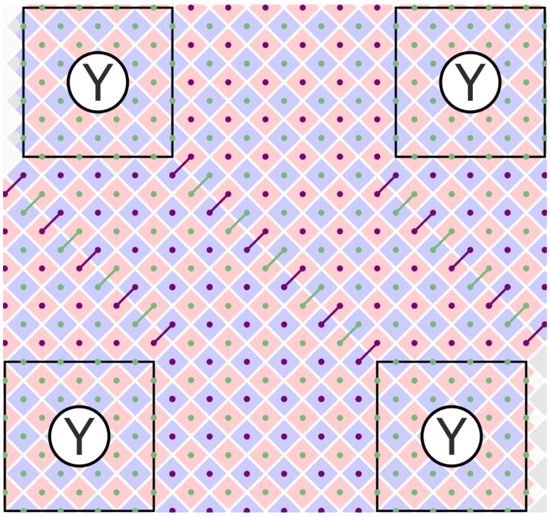

Figure 4: Example of a $YYYY$-lattice surgery patch whose stabilisers can be measured under square-grid connectivity using a low-depth circuit. The four logical qubits (enclosed in squares) are encoded into unrotated planar codes. Each red/blue plaquette is an X/Z-Pauli operator. Schedules between them are tangled if and only if their auxiliary qubits are connected with a line (essentially corresponding to the graph G from Theorem 2). The logical $YYYY$ measurement outcome corresponds to the joint parity of measurements made on the auxiliary qubits coloured in purple.

4 Fault-tolerant quantum computing on square-grid connectivity QPUs

In order to execute fault-tolerant quantum computation with the surface code, a popular way is to use the Pauli-based computational model [1, 2, 3, 8], where the major overhead is performing a series of multi logical qubit Pauli measurements. This can be achieved in a 2D planar architecture using *lattice surgery* [2, 3, 4, 7, 8, 9]. Some types of lattice surgery can be performed easily on a square-grid connectivity QPU by measuring only local stabilisers, meaning that one auxiliary qubit can be allocated for each stabiliser, connected to the qubits on which the stabiliser is supported. However, if the surface code patches are not positioned in a particular way, or if one of the logical Pauli terms is a Y, then the merge step of lattice surgery needs some irregularly-shaped, long-range stabilisers, typically so-called *elongated rectangles* or *twist defects*. A naive approach to measure these could be implemented using a high-depth circuit, swapping qubits as needed, but would be detrimental to logical fidelity and thresholds. More sophisticated, existing proposals to measure these irregular stabilisers mostly concentrate on changing the hardware either: globally by introducing additional connectivity (e.g. [2]); or locally by changing the connectivity of the QPU in certain regions (e.g. [3]).

With our tangled syndrome extraction, we show how to measure these elongated rectangles and twist defects under square-grid connectivity using a low-depth circuit. An example is shown in Figure 3 and the details can be found in Section 3 of the technical manuscript [5]. We also present two schemes to perform a general multi-qubit logical Pauli measurement, one with the unrotated planar code (see fig. 4) and another with the rotated planar code, thereby enabling fault-tolerant quantum computing under fourfold connectivity. We estimate their space-time cost based on numerical simulations that compare the quantum memory and stability experiment [6] performances of two types of rotated planar code patches: the default patches where each stabiliser is local, and their tangled versions where some stabilisers are replaced by elongated rectangles. The full details are in Section 4–5 and the Appendix of the technical manuscript [5].

5 Outlook

In our work, we have only considered applications of Theorem 2 where a stabiliser is a product of two component operators. It is, however, a very natural next step to explore schemes where we use more than two component operators to measure a stabiliser. Furthermore, whilst we have focused on planar codes in our work, we believe our tangled syndrome extraction method has applications for other stabiliser codes, and this would be another natural continuation of the present work.

Extended Abstract: Compression of quantum shallow-circuit states

Yuxiang Yang[1] *

[1]*QICI, The University of Hong Kong, Hong Kong SAR, China*

Keywords: Quantum compression, shallow circuits, NISQ, identical-form quantum states

See arXiv 2404.11177 for the full paper.

1 Background

Shallow quantum circuits are a focus of recent research, for they are arguably the most accessible resources with genuine quantum features and advantages. At the fundamental level, shallow quantum circuits with constant depth have been shown to be hard to simulate classically (unless BQP $\subseteq$ AM) [1], and they outperform their classical counterparts in certain computational tasks [2, 3]. In practice, variational shallow circuits [4, 5, 6, 7] will remain a core ingredient of quantum algorithms in the noisy and intermediate-scale quantum (NISQ) era [8]. Efficient methods of learning shallow and bounded-complexity quantum circuits have recently been proposed [9, 10, 11].

Here we ask a fundamental question: Given N copies of an *unknown* n-qubit state and the promise that it is generated by a shallow circuit, is there a faithful compression protocol that encodes the N-copy state into a memory of fewer (qu)bits and then decodes it up to an error vanishing at $N \to \infty$? Processing quantum states in the many-copy form is important for extracting, storing, and distributing quantum information. Tasks where many-copy states serve as a fundamental resource, to list a few, include quantum metrology [12, 13, 14], quantum state tomography [15, 16] and shadow tomography [17, 18], quantum cloning [19, 20, 21, 22], and quantum hypothesis testing [23, 24, 25, 26]. Quantum algorithms, such as quantum principle component analysis [27], may also require states in the many-copy form. As such, compression of quantum states in the many-copy form is a basic and crucial protocol required for their storage and transmission. In the literature, compression of many-copy states was first studied for the simple case of pure qubits by Plesch and Bužek [28], experimentally demonstrated in Ref. [29], and later generalized in a series of works to mixed qudits [30, 31, 32, 33]. However, regarding states generated by shallow quantum circuits, the existing results are not applicable, for they all assume the state to be in a fixed-dimension space. Here, instead, we consider states in a growing-dimension ($D = 2^n$) space with complexity constraints. Therefore, studying the compression of shallow-circuit states not only requires better understanding of this important family of states but also demands new techniques of asymptotic quantum information processing.

2 Overview of main results

Given a set S of quantum states, the task of faithful N-copy compression is to design a protocol that consists of an encoder $\mathcal{E}_N$ and a decoder $\mathcal{D}_N$ such that the compression error vanishes for large N:

$$\lim_{N\to\infty} \sup_{\rho\in\mathsf{S}} d_{\mathrm{Tr}} \left(\mathcal{D}_N \circ \mathcal{E}_N(\rho^{\otimes N}), \rho^{\otimes N}\right) = 0. \tag{1}$$

Here d_{Tr} denotes the trace distance between quantum states. The encoder $\mathcal{E}_N$ and the decoder $\mathcal{D}_N$ are dependent on N but are independent of the input state. The memory cost is characterized by the dimension of the Hilbert space spanned by $\{\mathcal{E}_N(\rho^{\otimes N})\}$. The goal of compression is to reduce the memory cost

$$M := \log_2 \left|\mathsf{Supp}\left\{\mathcal{E}_N(\rho^{\otimes N})\right\}_{\rho\in\mathsf{S}}\right|, \tag{2}$$

i.e., the number of (qu)bits required for storing $\mathcal{E}_N(\rho^{\otimes N})$, while respecting the faithfulness condition (1).

Here, we are interested in the set of shallow-circuit states S_{sc}, which contains all n-qubit pure states that can be generated from $|0\rangle^{\otimes n}$ by circuits of depth no more than a constant d. As a proof-of-principle example, we focus on the most representative case of brickwork shallow circuits and consider the set of *shallow-circuit states*

$$\mathsf{S}_{\mathrm{sc}} := \left\{|\psi\rangle \ : \ |\psi\rangle = U_{\mathrm{sc}}|0\rangle^{\otimes n}\, \exists\, U_{\mathrm{sc}}\right\}, \tag{3}$$

where U_{sc} is a brickwork circuit with bounded depth ($\leq d$).

Without compression, the memory cost of storing the input state equals $N \cdot n$ qubits. Our main contribution is to show that a faithful N-copy compression exists for S_{sc}, as long as N grows at least as a polynomial of n with a high enough degree. The memory cost of the compression is linear in n and logarithmic in N, i.e., $M = O(n \cdot \log_2 N)$, achieving an exponential memory reduction in terms of N. Moreover, the memory does not have to be fully quantum. Instead, one may use a classical-quantum hybrid memory, where the ratio between the number of qubits and the number of classical bits decreases as $O(\log_2 n/\log_2 N)$. That is to say, when N is large, the memory consists mainly of classical bits, while a fully classical memory doesn't work. More details can be found in the technical manuscript.

Following the main result, it is natural to ask if the memory cost can be further reduced. We prove that a memory of size $\Omega(n \cdot \log_2 N)$ is required for keeping the

*yuxiang@cs.hku.hk

compression faithful. In this sense, our compression protocol is optimal in the scaling of n and N.

To establish the compression protocol, we develop novel tools for quantum information processing in the asymptotic regime of many copies, including a method of parameterizing shallow-circuit states in a small neighborhood with only $\mathsf{poly}(n)$ parameters and a correspondence between copies of a low-complexity state and a multi-mode coherent state. These tools can be further applied to other information processing tasks involving complexity-constrained quantum states.

3 Discussions

We have shown that N copies of an n-qubit shallow-circuit state can be optimally compressed to $\Theta(n \cdot \log_2 N)$ qubits. Intriguingly, the two key parameters n (the number of qubits per copy) and N (the number of copies) take distinct positions in the compression rate. We may give an interpretation to this phenomenon: n is the parameter of informativeness, as it is proportional to the number of free parameters of a shallow-circuit state. On the other hand, N is the parameter of accuracy, since $1/\sqrt{N}$ is the error scaling of tomography, i.e., of how well can we learn the information in the state. Our result shows that the N-copy state can be exponentially compressed only in the parameter of accuracy.

Besides memory efficiency, one may also be curious about the computational efficiency of shallow-circuit state compression. Unfortunately, the compression protocol in this work, despite being memory-efficient, is not computational efficient. The main obstacle is that the protocol requires searching over a covering mesh of shallow-circuit states, whose cost is exponentially large (in n). It is noteworthy that this is also the key step of converting a part of the memory to classical bits. It is thus intriguing to conjecture that any protocol using a hybrid memory is computationally inefficient. On the other hand, there exist compression protocols using fully quantum memory [30, 31] that do not require searching, and there remains hope that these protocols could inspire a computationally efficient protocol for shallow-circuit states.

As we focused on the most fundamental case, there is plenty room for extension. For example, one may consider shallow-circuit states with a 2D structure, and the techniques developed here should apply. Moreover, the circuit depth d is treated as a constant throughout this work, but from the derivation of results it can be seen that the compression will still be faithful when d grows very slowly (e.g., $d \ll \log n$) with n. In particular, it would be interesting to cover pesudorandom quantum states [34], which are low-depth states processing approximate Haar-randomness and are thus of particular interest in quantum cryptography. At last, one may even take into account the effect of noise and consider the compression of noisy shallow-circuit states. While similar results are expected there, some techniques in this work do not immediately generalize to mixed states and require moderate adaptation.

This work serves as the first step of establishing a new direction of coherent quantum information processing where the complexity of resources determines the rate and performance of processing, which goes beyond the existing literature that focused on incoherent information processing [9, 10, 11]. For future perspectives, it is our goal to consider more tasks such as cloning [19, 20, 21, 22] and gate programming [35, 36, 37, 38, 39] and, ultimately, to re-examine the entire quantum Shannon theory established in the past decade from the new perspective of the NISQ era.

Abstract. In this work [arXiv:2401.13946], we present a polynomial-time quantum algorithm for solving the ground states of a class of classically hard Hamiltonians. The idea is to introduce a mapping $f: \rho \to |\rho\rangle$ to use density matrices to represent pure states. We show that this mapping makes sense by giving an efficient method to obtain the information of $|\rho\rangle$ from measurements on ρ. Under this mapping, the Lindblad master equation (LME) becomes a Schrödinger equation which contains natural imaginary time evolution. The steady state of the LME, therefore, corresponds to the ground state of $L^\dagger L$ with L the Liouvillian operator of the LME. We show the runtime of the LME has the $\mathcal{O}(log(\zeta^{-1}))$ scaling with ζ the overlap between the initial state and the ground state compared with the $\mathcal{O}(poly(\zeta^{-1}))$ scaling in other algorithms. We give concrete constructions on Hamiltonians that are quantumly easy by our algorithm and classically hard at the same time.

Keywords: Quantum algorithms, Open quantum systems, Quantum advantage

1 Introduction

Solving the ground states of general Hamiltonians is believed to be difficult for both classical and quantum computers. For quantum algorithms, a standard method is to use quantum phase estimation [1] (QPE) combined with amplitude amplification [2] (AA). Given a Hamiltonian whose spectral gap between the ground state and the first excited state is bounded by Δ, the required runtime to prepare its ground state to a fidelity $1-\varepsilon$ is of order $\mathcal{O}(poly(\Delta^{-1})poly(\varepsilon^{-1})poly(\zeta^{-1}))$ with ζ the overlap between the initial state and the ground state. More efficient algorithms based on linear combinations of unitaries and quantum signal processing [3, 4, 5] all adopt the idea of actively projecting out the ground state in some sense and can improve the runtime to an order $\mathcal{O}(poly(\Delta^{-1})log(\varepsilon^{-1})poly(\zeta^{-1}))$ with an exponential improvement over the precision ε.

However, from the $\mathcal{O}(poly(\zeta^{-1}))$ scaling of the runtime in the above algorithms, we can see why solving ground state can be even inefficient on quantum computers [6, 7]. As the number of qubits n of the system grows, with no prior knowledge, the overlap between an initial state and the ground state is exponentially small $\mathcal{O}(exp(n)^{-1})$, thus the runtime grows exponentially with the qubit number. However, in this work, we will present a quantum algorithm different from all the above types for solving ground states of a certain class of classically infeasible Hamiltonian with the runtime of order $\mathcal{O}(\Delta^{-1}log(\varepsilon^{-1/2}\zeta^{-1}))$ whose runtime is around $\Delta^{-1}(\frac{\ln(2)}{2}n+\ln(\varepsilon^{-\frac{1}{2}}))$.

2 Algorithm

We begin to introduce our algorithm. The first component comes from the dynamics of open quantum systems. Consider putting a system in an environment that is large enough such that the Markovian approximation is valid, then the dynamics of the system is governed by the Lindblad master equation (LME) [8, 9]:

$$\frac{d\rho}{dt} = \mathcal{L}[\rho] = -i[H,\rho] + \sum_i \lambda_i (F_i \rho F_i^\dagger - \frac{1}{2}\{\rho, F_i^\dagger F_i\}) \quad (1)$$

where $\rho = \sum_{ij}\rho_{ij}|i\rangle\langle j|$ is the density matrix of the system and F_i are quantum jump channels with strength λ_i. LME describes the dissipative nature of a system coupled with an environment. To see this more clearly, we can re-express the above LME as a vector form [10, 11]:

$$\frac{d\vec{\rho}}{dt} = L\vec{\rho} \quad (2)$$

where $\vec{\rho} = \sum_{ij}\rho_{ij}|i\rangle|j\rangle$ is the vector representation of the density matrix ρ and L is the Liouvillian generator for the LME semi-group which are not Hermitian in general has the following matrix form:

$$L = (-i(H\otimes I - I\otimes H^T) + \sum_i \lambda_i D[F_i]) \quad (3)$$

$$\text{where} \quad D[F_i] = F_i \otimes F_i^* - \frac{1}{2}F_i^\dagger F_i \otimes I - I \otimes \frac{1}{2}F_i^T F_i^*$$

Eq. 2 is attractive as it can be understood as a Schrödinger equation with non-Hermitian Hamiltonian iL which thus contains a natural imaginary time evolution. If the LME has a steady density matrix ρ_{ss} i.e. $\mathcal{L}[\rho_{ss}] = 0$, then the corresponding $\vec{\rho_{ss}}$ is the unnormalized ground state of Hermitian Hamiltonian $L^\dagger L$ with

Table 1: The 16 2-qubit Pauli operators (A) and their corresponding 2-qubit Pauli substitute operators (B). Each B is unitary whose eigenvalues are presented.

zero ground energy. Thus, the information of the ground state of $L^\dagger L$ is contained in ρ_{ss}. The question is how to retrieve the information, which leads to the second component of our algorithm. We introduce the following mapping:

$$f: \quad \rho \to |\rho\rangle \tag{4}$$

where $|\rho\rangle$ is defined as $\frac{1}{C_\rho}\sum_{ij}\rho_{ij}|i\rangle|j\rangle$ with the normalization factor $C_\rho = ||\rho||_F = \sqrt{\sum_{ij}|\rho_{ij}|^2}$. The key is how to understand this mapping. In this work, this mapping means that we are treating density matrices as pure states. For example, a single-qubit maximum mixed density matrix $(|0\rangle\langle 0| + |1\rangle\langle 1|)/2$ is treated as a two-qubit Bell state $(|0\rangle|0\rangle + |1\rangle|1\rangle)/\sqrt{2}$. We will call the subsystem labeled by index i the row subsystem and the subsystem labeled by index j the column subsystem. This mapping makes sense due to the following relation:

$$\langle\rho|A|\rho\rangle = \frac{Tr(B\rho\otimes\rho)}{Tr(\rho^2)} \tag{5}$$

where each matrix element of B $B_{il,jk} = \langle i|\langle l|B|j\rangle|k\rangle$ has the following relation with A:

$$B_{il,jk} = A_{ij,kl} \tag{6}$$

Eq. 5 means the information of $|\rho\rangle$ i.e. the value of $\langle\rho|A|\rho\rangle$ with A a Hermitian operator can be obtained from ρ by the value of the ratio of an operator B's expectation value under $\rho\otimes\rho$ to the purity of ρ. We name B as the substitute operator of A.

Having the formula Eq. 5, the following questions are how to measure its right-hand side and how efficient the measurement can be. Before introducing the measurement procedure, a prior thing to show is that the tensor product properties of A are not lost in B. More clearly, if each index of A in Eq. 6 actually contains indexes of n qubits e.g. $i \to i_1 i_2 ... i_n$, then the following relation is satisfied:

$$\begin{aligned}
&\text{if:} \quad A_{i_1 i_2 ... i_n j_1 j_2 ... j_n, k_1 k_2 ... k_n l_1 l_2 ... l_n} = \\
&\quad A^1_{i_1 j_1, k_1 l_1} A^2_{i_2 j_2, k_2 l_2} ... A^n_{i_n j_n, k_n l_n}, \\
&\text{then:} \quad B_{i_1 i_2 ... i_n l_1 l_2 ... l_n, j_1 j_2 ... j_n k_1 k_2 ... k_n} = \\
&\quad B^1_{i_1 l_1, j_1 k_1} B^2_{i_2 l_2, j_2 k_2} ... B^n_{i_n l_n, j_n k_n}
\end{aligned} \tag{7}$$

where relations between $A^1, A^2, ... A^n$ and $B^1, B^2, ... B^n$ satisfy the rules in Eq. 6. Due to the relation in Eq. 6, $n > 1$ situations can be generalized from the basic $n = 1$ case where A is a 2-qubit operator. For this case, the Hermitian A can be expressed as a real linear combination of 16 2-qubit Pauli operators. Each operator has a corresponding B operator which we will call the 2-qubit Pauli substitute operator. Interestingly, although the Hermiticity of 2-qubit Pauli operators is lost in the 2-qubit Pauli substitute operators, the unitarity is not, i.e. each 2-qubit Pauli substitute operator is unitary. All 16 2-qubit Pauli substitute operators are summarized in Table. 1. The unitarity of 2-qubit Pauli substitute operators makes sure that we can measure the expectation $Tr(B\rho\otimes\rho)$ by Hadamard tests [12]. Concretely, consider a to be measured $2n$-qubit Hermitian operator expressed as a combination of m terms:

$$A = \sum_{i=1}^{m} g_i P_i \tag{8}$$

where P_i are $2n$-qubit Pauli operators and g_i are the strengths which are real numbers. The substitute operator of A in Eq. 8 can be expressed as a similar form:

$$B = \sum_{i=1}^{m} g_i Q_i \tag{9}$$

where due to the transformation rule Eq. 6, the tensor product relation and the unitarity of the 2-qubit Pauli substitute operators, each $2n$-qubit Pauli substitute operator Q_i is unitary. Thus, the Hadamard test of $\mathcal{O}(1)$ depth can be used to evaluate each $Re(Tr(Q_i\rho\otimes\rho))$. The σ_z expectation value of the ancillary qubit gives the value of $Re(Tr(Q_i\rho\otimes\rho))$. By multiplying each estimated value of $Re(Tr(Q_i\rho\otimes\rho))$ by its weight g_i and summing up the results, we can obtain an estimation of the numerator $Tr(B\rho\otimes\rho)$ in Eq. 5. There is no need to measure the imaginary value of each Q_i since they will cancel out eventually guaranteed by the Hermiticity of A. For the purity $Tr(\rho^2)$ in the denominator, Swap tests [13] of $\mathcal{O}(1)$ depth are used to obtain the purity $Tr(\rho^2)$ in the denominator of Eq. 5 as $2p_s - 1$ where p_s is the probability of measuring the ancillary qubit in the $|0\rangle$ state. Thus, by using Hadamard tests and Swap tests, we can measure the value of $\langle\rho|A|\rho\rangle$.

Currently, the Hamiltonian $L^\dagger L$ we solved is calculated from the given L, which is easy as long as there are only polynomial terms in L. However, given a Hamiltonian H with given ground energy E_0 first, the reverse procedure of getting L that makes $H - E_0 = L^\dagger L$ is non-trivial. Fortunately, if we add some restrictions on L and $L^\dagger L$ such as locality or connectivity constraints which are very practical on real quantum computers, we can get the corresponding L in only polynomial-time by a classical algorithm called the XL algorithm [14, 15], which is the final component of our algorithm.

Having introduced the three components of our algorithm, we can now formally describe our algorithm. Given a Hamiltonian H with known ground energy E_0, we first judge and solve whether there exists L makes $H - E_0 = L^\dagger L$. If the XL algorithm gives a solution L, then we can generate a quantum system whose LME dynamics are governed by the $L \otimes L$. Then, let the system evolve freely to the steady state $\rho_{ss} \otimes \rho_{ss}$ of the LME. Next, we can do the measurement procedure introduced above and use Eq. 5 to obtain ground state information such as $\langle \rho_{ss} | A | \rho_{ss} \rangle$ with A an observable.

The total runtime of this algorithm depends on the time of the XL algorithm, the time of LME evolution, and the time of measurement. The evolution part depends on the overlap ζ between the initial state ρ_0 and the steady state ρ_{ss} defined as $\zeta = |\langle \rho_0 | \rho_{ss} \rangle|$, the smallest real part of the gaps between the steady state and other eigenvectors of L (assuming L is diagonalizable [11]) denoted as Δ and the required final overlap $1 - \varepsilon$ to be achieved. We prove the runtime of this part is of order $\mathcal{O}(\Delta^{-1} log(\varepsilon^{-1/2}) log(\zeta^{-1}))$ which is bounded by $\Delta^{-1}(\frac{\ln(2)}{2} n + \ln(\varepsilon^{-\frac{1}{2}}))$. The measurement part depends on the purity of ρ_{ss} and the number of terms in A. Assuming $Tr(\rho_{ss}^2) \geq \gamma$ and A contains m terms, then to achieve the MSE below an accuracy ϵ^2, the number of measurement is of order $\mathcal{O}(m\gamma^{-2}\epsilon^{-2})$.

3 Quantumly easy and classically hard examples

A direct example of quantumly easy and classically hard Hamiltonians under our algorithm can be found in Ref. [16] where LME is designed to encode quantum circuits. Suppose we want to simulate a quantum circuit: $|\psi_T\rangle = U_T U_{T-1} ... U_1 |0\rangle^{\otimes n}$ with all layers local, we can then define an LME with no internal Hamiltonian and with two types of jump operators:

$$F_i = |0\rangle_i \langle 1|_i \otimes |0\rangle_a \langle 0|_a \tag{10}$$

$$F_t = U_t \otimes |t+1\rangle_a \langle t|_a + U_t^\dagger \otimes |t\rangle_a \langle t+1|_a \tag{11}$$

with $i = 1, ..., n$ and $t = 0, ..., T$. This LME has a unique state state:

$$\rho_{ss} = \frac{1}{T+1} \sum_{t=0}^{T} |\psi_t\rangle \langle \psi_t| \otimes |t\rangle \langle t| \tag{12}$$

Thus, assuming P $\neq$ BQP, this LME is classically hard and satisfies all the conditions (spectral gap of L, purity of the steady state, and the locality of L.) for our algorithm to be in a polynomial time. Thus, its corresponding $L^\dagger L$ is exactly such an example.

Faster Quantum Algorithms with “Fractional”-Truncated Series

Yue Wang[1] * Qi Zhao[1] †

[1] *Department of Computer Science, University of Hong Kong, Pokfulam Road, Hong Kong*

Abstract. Quantum algorithms frequently rely on truncated series approximations, where the truncation order determines the circuit complexity. Achieving even moderate accuracy necessitates intensive circuit complexity. In response, we propose a general framework, the Randomized Truncated Series (RTS), which offers a quadratic improvement on the truncation error and enables a continuously adjustable effective truncation order. The core idea is that randomly mixing two series of specific forms substantially reduces the truncation error. We present an error analysis for RTS with a new mixing lemma accounting for near-unitary operators. We provide four illustrative examples to demonstrate the effectiveness and versatility of RTS. RTS shed light on the path towards practical quantum advantage.

1 Introduction

Quantum computing holds the promise to redefine the limits of information processing. Quantum algorithms, such as those for Hamiltonian simulation (HS) [1, 2, 3, 4, 5, 6, 7], solving differential equation [8, 9], and singular value transformation [10, 11], achieve at most exponential asymptotic speedup compared to their classical counterparts [12]. These algorithms provide the computational power necessary for exploring complex systems, holding the potential to empower researches like chemistry [13, 14, 15, 16, 17, 18], condensed matter physics [19, 20, 21], cryptography [22], engineering problems [23, 24, 25] and finance [26].

Realizing a transformation on an operator, $f(H)$, frequently appears in quantum algorithms such as Hamiltonian simulation, amplitude amplification, matrix inversion, and factoring [4, 3, 12]. We often approximate these functions by truncated series (TS) at an integer order K, i.e. $f(H) \approx \sum_{k=0}^{K} \alpha_k H^k$ for some real coefficients α_k, and treat the rest as truncation error δ. An increased K indicates higher precision but requires more qubits and gates, and a complicated circuit leads to vanishing quantum advantage [27, 28]. Yet, harnessing practical advantages from any quantum algorithm remains challenging.

Simplifying circuits without compromising precision can be achieved by reducing K. Inspired by Ref. [5], we utilize random mixing of TS such that multiple δ cancel out each other. Also, random mixing effectively produces fractional K, releasing the necessity of ceiling rounding K. In this work, we introduce Randomized Truncated Series (RTS), a simple and general framework featuring random mixing, applicable for general TS-based quantum algorithms. RTS results in a quadratically improved and continuously adjustable truncation error. On the high level, we mix $f_1(H) := \sum_{k=0}^{K_1} \alpha_k H^k$ and a modified TS of order $K_2 > K_1$, $f_2(H) := \sum_{k=0}^{K_1} \alpha_k H^k + 1/(1-p) \sum_{i=K_1+1}^{K_2} \alpha_k H^k$, where $p \in [0,1)$ is the mixing probability. By simple observation, the mixture, $f_{\text{mix}}(H) := pf_1(H) + (1-p)f_2(H) = \sum_{k=0}^{K_2} \alpha_k H^k$, better approximates $f(H)$. In real cases, we may not be able to implement $f_1(H)$ and $f_2(H)$ exactly with high probability. We thus denote V_1 and V_2 as corresponding actual operators. Moreover, $V_{1(2)}$ is generally non-unitary, and can only be probabilistically implemented by a quantum circuit $\mathfrak{V}_{1(2)}$. We thus renew the proof for the mixing lemma proposed in Ref. [29, 30] accounting for near-unitary dynamics.

To employ RTS, we first consider a general procedure: 1. prepare a quantum state with some ancilla $|\psi\rangle \otimes |ancilla\rangle$; 2. apply $\mathfrak{V}_{1(2)}$ on both system; 3. and heralding on correct measurement outcome on the ancilla system obtain the desired output state $V_{1(2)}|\psi\rangle$. We can then measure observable, perform tomography, or feed the resultant state into another quantum system. To employ RTS, we apply $\mathfrak{V}_{1(2)}$ with probability $p(1-p)$ in step 2 and collectively sample from the measurement result. In this manner, we can only reconstruct the classical information about the final state. However, we also find that we can obtain the final state coherently if $\mathfrak{V}_{1(2)}$ is a concatenation of identical segments. We call this kind of algorithm segmented algorithms. For example, in Hamiltonian simulation, we often split the entire evolution into pieces, where each segment corresponds to the evolution of a small time step. We, therefore, can perform randomization on these segments to enable coherent error cancellation.

RTS is a versatile protocol that optimizes various algorithms, and we demonstrate a few in detail. We anticipate further generalizations to analog quantum computing and time-dependent evolution. RTS is compatible with other circuit optimization tools, and we anticipate that RTS helps quantum devices handle more complicated tasks.

2 Main results

We obtain the following renewed mixing lemma.

Lemma 1 *Let V_1 and V_2 approximate an ideal operator U, and let the corresponding quantum channel on a den-*

*yuewang23@connect.hku.hk

†zhaoqi@cs.hku.hk

sity matrix $\rho = |\psi\rangle\langle\psi|$ be $\mathcal{V}_1 = V_1\rho V_1^\dagger$, $\mathcal{V}_2 = V_2\rho V_2^\dagger$ and $\mathcal{U} = U\rho U^\dagger$. Denote the operator $V_m := pV_1 + (1-p)V_2$. Assume the operator norm $\|V_1 - U\| \le \delta_1$, $\|V_2 - U\| \le \delta_2$, and $\|V_m - U\| \le \delta_m$, then the mixed channel $\mathcal{V}_{mix} := p\mathcal{V}_1 + (1-p)\mathcal{V}_2$ satisfies

$$R(\mathcal{V}_{mix}, \mathcal{U}) \le 2\varepsilon, \tag{1}$$

where $R(\mathcal{A}, \mathcal{B}) := \|\mathcal{A} - \mathcal{B}\|_1$ and $\varepsilon = 2\delta_m + p\delta_1^2 + (1-p)\delta_2^2$.

The protocol to conduct RTS is summarized below:

RTS Protocol

1. Random generate 1 and 2 with the probability p and $(1-p)$ respectively
2. Construct a quantum circuit $\mathfrak{V}_{1(2)}$ when the outcome in Step 1 is 1(2);
3. Post-select the measurement result on the ancilla system;
4. Post-process the output state.

The treatment of segmented algorithms differs in step 2, we instead concatenate proper amounts of $\mathfrak{V}_{1(2)}$ according to specification. The algorithmic error after applying RTS is quantified by the main theorem.

Theorem 2 *Let $U = \sum_{i=0}^{\infty} \alpha_k H^k$ be an operator in series expansion form and $\mathcal{U}(\rho) = U\rho U^\dagger$ be the corresponding quantum channel. Assume a quantum circuit $\mathfrak{V}_1$ encodes the truncated operator V_1 such that $\|U - V_1\| \le \delta_1$, there exist another quantum circuit $\mathfrak{V}_2$ that encodes V_2, where $\|U - V_2\| \le \delta_2$ and $\delta_2 = \mathcal{O}(\delta_1)$. Employing RTS on V_1 and V_2 yields an mixing channel $\mathcal{V}_{mix}$ such that*

$$R(\mathcal{V}_{mix}, \mathcal{U}) = \mathcal{O}\big(\delta_1^2\big) \tag{2}$$

In Theorem 2, we neglect δ_{m} in the asymptotic regime as it will be exponentially smaller than δ_1 in the case of large K_2.

When employing RTS, we choose a large p such that we only substitute a small portion of $\mathfrak{V}_1$ by $\mathfrak{V}_2$, introducing few extra costs. However, Theorem 2 indicates that a quadratic reduction in the algorithmic error will be generated. We demonstrate how to utilize RTS and the performances with several examples, and the results are shown below. Beginning with the simplest case, Hamiltonian Simulation (HS), as HS itself is implementing a function of a Hamiltonian, $f_{\mathrm{HS}} = e^{-iHt}$. In the BCCKS algorithm, we approximate f_{HS} in the Taylor series and truncated it at order K, i.e. $\tilde{f}_{\mathrm{HS}} = \sum_{k=0}^{K} \frac{(-iHt)^k}{k!}$. We can construct two series with maximum orders of K_1 and K_2. The BCCKS algorithm implements these two series with two operators, denoted as $V_{1,\mathrm{HS}}$ and $V_{2,\mathrm{HS}}$ respectively, such that $\|V_{1,\mathrm{HS}} - f_{\mathrm{HS}}\| \le \delta_{1,\mathrm{BCCKS}}$ and $\|(pV_{1,\mathrm{HS}} + (1-p)V_{2,\mathrm{HS}}) - f_{\mathrm{HS}}\| \le \delta_{\mathrm{m,BCCKS}}$.

Corollary 3 *For the BCCKS algorithm approximating the Hamiltonian dynamic $\mathcal{U}_{HS} = e^{-iHt}\rho e^{iHt}$ [4], RTS achieves an upper bound on algorithmic error*

$$R(\mathcal{V}_{mix,BCCKS}, \mathcal{U}_{HS}) \le \max\left\{\frac{40}{1-p}\delta_{1,\mathrm{BCCKS}}^2, 8\delta_{m,\mathrm{BCCKS}}\right\}, \tag{3}$$

where $\delta_{1,\mathrm{BCCKS}} = 2\frac{(\ln 2)^{K_1+1}}{(K_1+1)!}$ and $\delta_{m,\mathrm{BCCKS}} = 2\frac{(\ln 2)^{K_2+1}}{(K_2+1)!}$.

Quantum signal processing (QSP) implements Chebyshev's polynomials with quantum walk. Thus we instead approximate f_{HS} using Jacobi-Anger expansion and define the series expansion operator $V_{1(2),\mathrm{HS\_QSP}}$ and the corresponding error $\delta_{1(2),\mathrm{HS\_QSP}}$ similar to the BCCKS case. See the technical version for detailed constructions of operators.

Corollary 4 *In QSP implementation of $\mathcal{U}_{HS}$, the algorithmic error is upper bounded by*

$$R(\mathcal{V}_{mix,HS\_QSP}, \mathcal{U}_{HS}) \le \max\left\{28\delta_{1,\mathrm{HS\_QSP}}, 8\sqrt{\delta_{m,\mathrm{HS\_QSP}}}\right\}, \tag{4}$$

where $\delta_{1,\mathrm{HS\_QSP}} = \frac{4t^{K_1}}{2^{K_1}K_1!}$ and $\delta_{m,\mathrm{HS\_QSP}} = \frac{4t^{K_2}}{2^{K_2}K_2!}$.

QSP can also implement other function transformations on the Hamiltonian to realize all kinds of algorithms. In specific, we further elaborate on the truncated linear function (TLF), $f_{\Gamma,\mathrm{TLF}}(\lambda) = \frac{\lambda}{2\Gamma}, \forall|\lambda| \in [0, \Gamma]$, corresponding to the uniform spectral amplification algorithm. TLF can be implemented by a linear combination of two error functions, approximated by Jacobi-Anger expansion variants. We thus construct K_1 and K_2 truncated series expansions to approximate the error function and combine them to implement TLF.

Corollary 5 *In QSP implementation of $\mathcal{U}_{\Gamma,\mathrm{TLF}}$ to perform USA, the algorithmic error is upper bounded by*

$$R(\mathcal{V}_{mix,USA}, \mathcal{U}_{\Gamma,\mathrm{TLF}}) \le \max\left\{8\delta_{m,\mathrm{USA\_QSP}}, \frac{4}{1-p}\delta_{1,\mathrm{USA\_QSP}}^2\right\}, \tag{5}$$

where $\delta_{1,\mathrm{USA\_QSP}} = \frac{8\Gamma e^{-8\Gamma^2}}{\sqrt{\pi}}\frac{4(8\Gamma^2)^{K_1/2}}{2^{K_1/2}(K_1/2)!}$ and $\delta_{m,\mathrm{USA\_QSP}} = \frac{8\Gamma e^{-8\Gamma^2}}{\sqrt{\pi}}\frac{4(8\Gamma^2)^{K_2/2}}{2^{K_2/2}(K_2/2)!}$.

Lastly, we consider the application of RTS to solving ordinary differential equations in the form $d\vec{x}/dt = A\vec{x} + \vec{b}$. The solution is given by $\vec{x}(t) = e^{At}\vec{x}(0) + \big(e^{At} - \mathbb{1}\big)A^{-1}\vec{b}$, where e^{At} and $\big(e^{At} - \mathbb{1}\big)A^{-1}$ can be approximated by truncated Taylor series. We can achieve a much lower error by RTS.

Corollary 6 *Suppose $|x_{mix}^j\rangle$ is an approximated solution to the differential equation at time $t = jh$ using RTS and*

Table 1: Algorithmic error and corresponding cost for the BCCKS algorithm with and without RTS. $\tilde{G} = (7.5 \times 2^w + 6w - 26)r$ is the CNOT gate cost, where $w = \log_2 L$.

Cost Error	$7\tilde{G}$	$8\tilde{G}$	$9\tilde{G}$	$10\tilde{G}$
BCCKS	1.53×10^{-1}	1.17×10^{-2}	8.14×10^{-4}	5.13×10^{-5}
with RTS	3.59×10^{-3}	3.25×10^{-5}	2.14×10^{-7}	1.15×10^{-9}
Improvement	42.5×	361×	3810×	44500×

$|x(jh)\rangle$ is the exact solution. We can upper bound the estimation error by

$$\left\| |x^j_{mix}\rangle - |x(jh)\rangle \right\| \le \max\left\{ \frac{4}{1-p}\delta^2_{1,\mathrm{ODE}}, 8\delta_{m,\mathrm{ODE}} \right\}, \tag{6}$$

where $\delta_{1,\mathrm{ODE}} \le \frac{\mathcal{C}_j}{(K_1+1)!}$, and $8\delta_{m,\mathrm{ODE}} \le \frac{\mathcal{C}_j}{(K_2+1)!}$, and $\mathcal{C}_j$ is a problem specific constant.

For comparison, the original error upper bounds are, keeping the leading term, $2\delta_{1,\mathrm{BCCKS}}$, $\sqrt{\delta_{1,\mathrm{HS\_QSP}}}$, $\delta_{1,\mathrm{USA\_QSP}}$ and $\delta_{1,\mathrm{ODE}}$ for Corollaries 3, 4, 5, and 6 respectively. It can be easily seen that RTS achieves a quadratic speed-up.

Although any set of parameters $\{p, K_1, K_2\}$ provides a quadratic speed-up, the choice does influence the actual error, and a wise choice of parameters ensures better performance. However, it is hard to develop a procedure that provides the optimal parameters as $f(H)$ is arbitrary. We instead perform a brute force search over the error upper bound. Since K_1 and K_2 are discrete with typical values being less than 100 and the error upper bound function is smooth with respect to p, the classical computation for the brute force search is efficient. For algorithms with tight upper bounds, we generate a good suggestion on the actual error.

3 Numerical Result

We analyze the error upper bounds and costs implement RTS on the BCCKS algorithm [4] simulating the Ising model for $t = 100$ with

$$H = \sum_{i=1}^{n} \sigma_i^x \sigma_{i+1}^x + \sum_{i=1}^{n} \sigma_i^z, \tag{7}$$

where σ_i are Pauli operators acting on the i^{th} qubit and $n = 100$. The simulation consists of $r = 28854$ segments. To make a focused illustration of RTS, we only consider the gate cost of the **SELECT** oracle since it is the dominant contribution.

Each segment performing $\mathfrak{V}_{1(2)}$ need 3(4) **SELECT** oracles, and each costs $K(7.5\times2^w+6w-26)$ CNOT gates [31], where K is the truncation order and $w = \log_2(L)$. For a fixed cost budget, we traverse all feasible sets $\{K_1, K_2, p\}$ that use up the budget and find the minimum $r\epsilon$, which is the final algorithmic error with RTS. The result is shown in Fig. 1, with crosses representing the performance under discrete truncation, and the blue line indicating the optimal error achieved at a specific cost using RTS. We can see in Fig. 1 that the blue line declines faster than the orange dotted line, which is the line fitting the 4 cross marks, meaning we greatly improved the accuracy. Therefore we can use much fewer gates for simulation, i.e. targeting $\epsilon = 10^{-8}$, we save about 30% of CNOT gates.

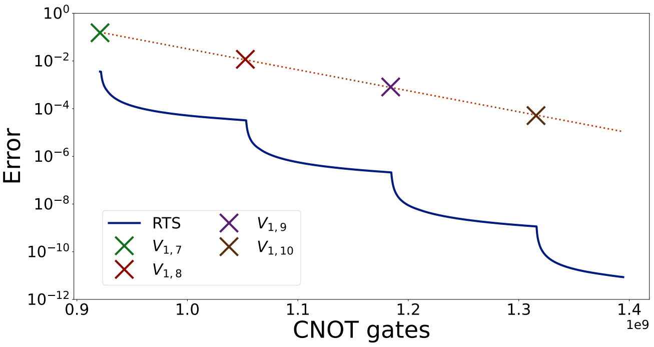

Figure 1: Algorithmic error and corresponding CNOT gate cost. Cross markers with different colors correspond to the original BCCKS algorithm with discrete truncation, where we denote V_{1,K_1} for a K_1-truncated V_1 operator. The solid blue line indicates the performance when employing RTS. Any point on the line corresponds to the error obtained by the optimal set of parameters $\{K_1, K_2, p\}$ using up all CNOT gates.

We also evaluate how much RTS improves the BCCKS algorithm in table 1. Note that we are restricted by only four costs with the original algorithm within the error range $\epsilon = [10^{-1}, 10^{-5}]$, whereas RTS enables a much finer adjustment on circuit cost.

4 Conclusion and open problems.

We presented a simple framework RTS that applies to arbitrary quantum algorithms relying on truncated series approximation. RTS enables a “fractional” truncation order and provides a quadratic improvement on algorithmic error. Essentially, we leverage random mixing to cancel out truncation error in two input quantum circuits $\mathfrak{V}_1$ and $\mathfrak{V}_2$. We specifically exhibit the implementation of RTS in various contexts to illustrate the flexibility of RTS. Although not evaluated in this work, RTS can also apply to non-unitary dynamics Ref. [32, 33, 34] and truncated-integral algorithms. We anticipate the generalization of the framework into dynamics determined by time-dependent operators, i.e. Dyson series, and analog quantum computing model.

Abstract. In covert target detection, Alice sends probe light to decide if a target is present within a region containing thermal background radiation while remaining undetected by an adversary, Willie, who is co-located with the target and collects all non-returning light. We rigorously formulate this problem and derive quantum limits on Alice's error probability in entanglement-assisted target detection given any level of her detectability by Willie. We demonstrate how Alice approaches this limit using two-mode squeezed vacuum probes for small to moderate background brightness while outperforming a scheme using Gaussian-distributed coherent states.

Keywords: Quantum illumination, Covert sensing, Target detection

Alice wishes to interrogate a distant region embedded in a thermal background for the presence or absence of a target adversary by probing it with a microwave or optical beam and monitoring the resulting reflections. Meanwhile, the adversary, Willie, monitors his thermal background for statistical deviations from thermal noise, aiming to detect if Alice is actively probing him. In this cat-and-mouse game, *how can Alice maximize her probability of correctly detecting Willie while minimizing Willie's chances of knowing he is being probed*? This question falls under the domain of *covert sensing* and naturally arises in the adversarial arms race between radar and radar detectors [1].

Sending a probe with greater energy can better sense Willie but also risks being detected. Alice thus faces a trade-off between performance and covertness. We seek the ultimate limit of Alice's performance, and ask whether moving towards this limit be facilitated by employing nonclassical light, as is well-known for quantum illumination (henceforth abbreviated as QI) in non-adversarial settings [2, 3, 4, 5, 6, 7, 8]? Indeed, several other covert protocols have been introduced in the continuous-variable setting [9, 10, 11, 12, 13, 14]. We suppose that Alice wishes to remain ϵ-covert, i.e., that the probability of Willie detecting her is at most $1/2+\epsilon$, and then obtain a closed-form lower bound on her error probability as a function of ϵ, the number of available optical modes M, and levels of loss and noise in the system. We show that two-mode squeezed vacuum (TMSV) probes can approach this limit in certain regimes. Comparing TMSV performance with that of Gaussian-distributed coherent state probes, we show that TMSV probes enable a reduction in error probability by a factor scaling exponentially with M.

1 Problem Setup

Entanglement-assisted target detection is illustrated in Fig. 1. Alice (A) wishes to detect the absence ($h=0$) or presence ($h=1$) of a weakly reflecting target (the two cases are assumed equally likely for simplicity) with round-trip reflectivity. The target is immersed in a thermal background such that each background mode is in a thermal state $\rho_{\mathsf{th}}(N_B) = \sum_{n=0}^{\infty} N_B^n/(N_B+1)^{n+1} |n\rangle\langle n|$ with average photon number N_B. Alice controls both the transmitter and receiver, and can prepare at most M signal modes. Thus, any covert sensing protocol involves preparing some incident probe state

$$|\psi\rangle_{IS} = \sum_{\mathbf{n}} \sqrt{p_{\mathbf{n}}}\, |\chi_{\mathbf{n}}\rangle_I\, |\mathbf{n}\rangle_S\,, \tag{1}$$

where $|\mathbf{n}\rangle_S = |n_1\rangle_1 |n_2\rangle_2 \cdots |n_M\rangle_M$ is an M-mode number state of the *signal* (S) system, $\{|\chi_{\mathbf{n}}\rangle_I\}$ are normalized (not necessarily orthogonal) states of an *idler* (I) system, and $p_{\mathbf{n}}$ is the probability mass function (pmf) of $\mathbf{n}$. The signal modes are sent to probe the target region while the idler is held losslessly. In the return (R) modes, Alice obtains an h-dependent return-idler state $\rho_{IR}^{(h)}$ that she measures to make a guess h_{est} for the value of h. Alice's performance is given by the *error probability* $P_{\mathfrak{e}}^{A}$, i.e., the probability that $h_{\text{est}} \neq h$.

The adversary, Willie (W), is situated at the target's location. We model the target by a beam splitter with reflectance $\eta \ll 1$. Let $\hat{a}_S^{(m)}$ and $\hat{a}_B^{(m)}$ be annihilation operators of the corresponding signal and background modes (see Fig. 1). Then

$$\hat{a}_R^{(m)} = \sqrt{\eta^{(h)}}\, \hat{a}_S^{(m)} + \sqrt{1-\eta^{(h)}}\, \hat{a}_B^{(m)}, \tag{2}$$

represents the annihilation operator of the mth mode returning to Alice, where $\eta^{(0)} = 0$ and $\eta^{(1)} = \eta$. When Willie is present ($h=1$), he receives the modes $\hat{a}_W^{(m)}$ for each $m = 1, \ldots, M$ from the other output of the beam splitter so that

$$\hat{a}_W^{(m)} = \sqrt{1-\eta}\, \hat{a}_S^{(m)} - \sqrt{\eta}\, \hat{a}_B^{(m)}. \tag{3}$$

Thus Alice faces the hypothesis test

$$\begin{aligned} &\mathrm{H}_0: \ \rho_0 = (\mathrm{Tr}_S\, \Psi) \otimes \rho_{\mathsf{th}}(N_B)^{\otimes M}, \\ &\mathrm{H}_1: \ \rho_1 = \left(\mathrm{id}_I \otimes \mathcal{L}_{\eta,N_B}^{\otimes M}\right) \Psi, \end{aligned} \tag{4}$$

*tham0157@e.ntu.edu.sg

†ranjith.nair@ntu.edu.sg

‡gumile@ntu.edu.sg

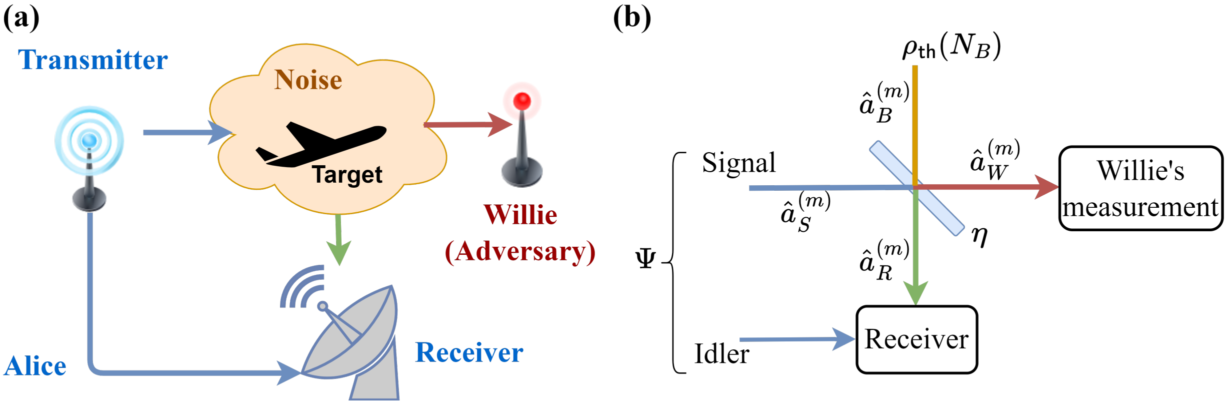

Figure 1: (a) In covert target detection, Alice (A) attempts to detect the presence of the adversary Willie (W) using an ancilla-entangled probe while remaining undetected herself. In the beam-splitter model (b), Alice prepares a joint state Ψ with M signal (S) and idler modes (I). Each signal mode $\hat{a}_S^{(m)}$ is either replaced by a background mode $\hat{a}_B^{(m)}$ when Willie is absent, or mixed with the background at a beam splitter with reflectance $\eta \ll 1$ representing the target. Alice makes an optimal measurement on the return modes $\hat{a}_R^{(m)}$, $m = 1, \dots M$ along with the idler system. Willie, when present, makes an optimal measurement on all his modes $\hat{a}_W^{(m)}$.

where $\mathcal{L}_{\kappa,N}$ denotes a thermal loss (or noisy attenuator) channel of transmittance κ and excess noise N [15]. Meanwhile, Willie is constrained only by the laws of physics and can have prior knowledge of which probe $\Psi = |\psi\rangle\langle\psi|_{IS}$ Alice plans to use. He thus faces the hypothesis test

$$\begin{aligned} \mathrm{H}_0' &: \ \sigma_0 = \rho_{\mathsf{th}}(N_B)^{\otimes M}, \\ \mathrm{H}_1' &: \ \sigma_1 = \mathcal{L}_{1-\eta,N_B}^{\otimes M}(\mathrm{Tr}_I\,\Psi). \end{aligned} \tag{5}$$

to decide whether Alice has sent a probe (H_1') or not (H_0').

Assuming that both parties make optimal quantum measurements and that their hypotheses are equally likely, their resulting average error probabilities are given by the Helstrom formula [16]:

$$P_{\mathfrak{e}}^A = 1/2 - \|\rho_0 - \rho_1\|_1/4 \le \inf_{0\le s\le 1} \mathrm{Tr}\,\rho_0^s\rho_1^{1-s}/2, \tag{6}$$

$$P_{\mathfrak{e}}^W = 1/2 - \|\sigma_0 - \sigma_1\|_1/4 \le \inf_{0\le s\le 1} \mathrm{Tr}\,\sigma_0^s\sigma_1^{1-s}/2, \tag{7}$$

where $\|X\|_1 := \mathrm{Tr}\,\sqrt{X^\dagger X}$ is the trace norm. We have also indicated the *quantum Chernoff bound* [17] (QCB) that is an exponentially tight upper bound on the average error probability. Alice's probe state is said to be ϵ-covert if

$$P_{\mathfrak{e}}^W \ge 1/2 - \epsilon. \tag{8}$$

We then ask: What is Alice's minimal error probability $P_{\mathfrak{e}}^A$ (as a function of M) when optimized over ϵ-covert probes?

The above framework deviates in several ways from previous studies of covert target detection. Firstly, our notion of ϵ-covertness defined by way of Willie's error probability has clear operational significance unlike previous formulations that use the relative entropy [18]. Secondly, the background brightness is fixed at N_B regardless of whether a target is present or absent. In contrast, most prior work on QI makes – for mathematical expediency – the so-called *No Passive Signature* (NPS) assumption which fine-tunes background brightness from its nominal value of N_B to $N_B/(1-\eta)$ when the target is present. While the NPS approximation is accurate when M is not very large, even standard QI has a quantum advantage only when $M \gg 1$, so that the physical basis of the assumption is questionable for standard QI and for covert detection (see [19] for a detailed discussion). As we show below, dropping the NPS assumption induces new qualitative behaviour in both non-adversarial and covert QI. Alice's performance then explicitly depends on the number M of signal modes, e.g. the available time-bandwidth product for temporal modes . This is the case for many other other quantum sensing and discrimination problems [20, 21, 22, 23] – since Alice gains some information even for a vacuum probe, this phenomenon is referred to as a *passive signature* (PS).

2 Technical Tools

2.1 QI with Passive Signature

We first derive analytical bounds on Alice's performance in the *non-adversarial* setting, i.e., for standard QI but without the NPS approximation. In ref. [19], we derive a general lower bound for Alice's error probability:

$$\begin{aligned} P_{\mathfrak{e}}^A &\ge \frac{1}{2}\left[1 - \sqrt{1 - \nu^{2M}\left[\sum_{n=0}^{\infty} p_n\left(1-\gamma_{\eta,N_B}\right)^{\frac{n}{2}}\right]^2}\,\right] \\ &\ge \frac{1}{2}\left[1 - \sqrt{1 - \nu^{2M}\left(1-\gamma_{\eta,N_B}\right)^{\mathcal{N}_S}}\,\right], \end{aligned} \tag{9}$$

where $\gamma_{\eta,N_B} = \frac{\eta}{(1-\eta)N_B+1}$, $\mathcal{N}_S := \sum_{n=0}^{\infty} np_n$ is the total signal energy, and we have used Jensen's inequality in the last step. The above result gives the ultimate limit of Alice's performance in QI with the PS assumption. It contrasts with the ultimate quantum limits of NPS QI derived in ref. [24] (see Eqs. (12)-(13) therein), which do not include the M-dependent factor ν^{2M} characteristic of the passive signature.

2.2 Necessary condition for ϵ-covertness

To incorporate the covertness constraint, we formulate a necessary condition for ϵ-covertness. Suppose that Alice transmits the probe Ψ of Eq. (1) with signal energy $\mathcal{N}_S$. The Fuchs-van de Graaf inequality $P_{\mathfrak{e}}^W \leq F(\sigma_0, \sigma_1)/2$ that relates the trace distance to the fidelity [25] between Willie's hypothesis states (5) implies that $F(\sigma_0, \sigma_1) \geq 1 - 2\epsilon$ is a necessary condition for ϵ−covertness. We use this to show that

$$\sum_{n=0}^{\infty} \sqrt{q_n} \sqrt{\binom{n+M-1}{n} \frac{N_B^n}{(N_B+1)^{n+M}}} \geq 1 - 2\epsilon \qquad (10)$$

is a necessary condition for ϵ−covertness, where $q_{\mathbf{n}} = \langle \mathbf{n} | \sigma_1 | \mathbf{n} \rangle_W$ and $\left\{ q_n = \sum_{\mathbf{n}: n_1 + \cdots + n_M} q_{\mathbf{n}} \right\}_{n=0}^{\infty}$ is the pmf of the total photon number seen by Willie under H_1' [19]. The condition of Eq. (10) implies that as ϵ is decreased, Alice's per-mode probe must look progressively more similar to the thermal background as we increase M (see [19] for details). In a significant departure from standard QI, it therefore does not make operational sense to consider the scaling of Alice's performance with signal energy $\mathcal{N}_S$. Instead, the key resource is the number of available optical modes M.

3 Fundamental limit of $P_{\mathfrak{e}}^A$ under ϵ-covertness

The thermal loss channel $\mathcal{L}_{1-\eta, N_B}$ connecting the modes in S to those in W (cf. Eq. (5)) admits the decomposition

$$\mathcal{L}_{1-\eta, N_B} = \mathcal{A}_G \circ \mathcal{L}_{(1-\eta)/G} \qquad (11)$$

into a quantum-limited amplifier $\mathcal{A}_G$ of gain $G = \eta N_B + 1$ and a pure-loss channel $\mathcal{L}_{(1-\eta)/G}$ of transmittance $(1 - \eta)/G$ [26]. The right-hand side of the bound of Eq. (9) is expressed in terms of the *probability generating function* (pgf) $\mathcal{P}_S(\xi)$ of the total photon number in S, defined as $\mathcal{P}_S(\xi) := \sum_{n=0}^{\infty} p_n \xi^n$ evaluated at $\xi = \sqrt{1 - \gamma_{\eta, N_B}}$. Using Eq. (11), we can extend Haus's pioneering work on connecting the input and output photon number pgfs of these single-mode quantum-limited channels [27] to multimode thermal loss channels and find the one-to-one mapping between the photon number pgf of the probe and the pgf $\mathcal{P}_W(\xi) := \sum_{n=0}^{\infty} q_n \xi^n$ of the total photon number in Willie's modes under H_1'. By connecting $\mathcal{P}_W(\xi)$ to the covertness condition of Eq. (10), we can show that [19]

$$P_{\mathfrak{e}}^A \geq \frac{1 - \sqrt{1 - (1-2\epsilon)^4 f_{\eta, N_B}^{2M}}}{2}, \qquad (12)$$

where $f_{\eta, N_B} = \nu(N_B + 1 - \frac{N_B}{x})[\eta N_B(1 - x) + 1]$, $x = 1 - \frac{\Theta}{\eta[1 + N_B(1-\Theta)]}$ and $\Theta = \frac{\sqrt{(1-\eta)(N_B+1)}}{\sqrt{1+(1-\eta)N_B}}$. This provides a universal, analytical and probe-independent lower bound for Alice's error probability for any desired covertness level ϵ.

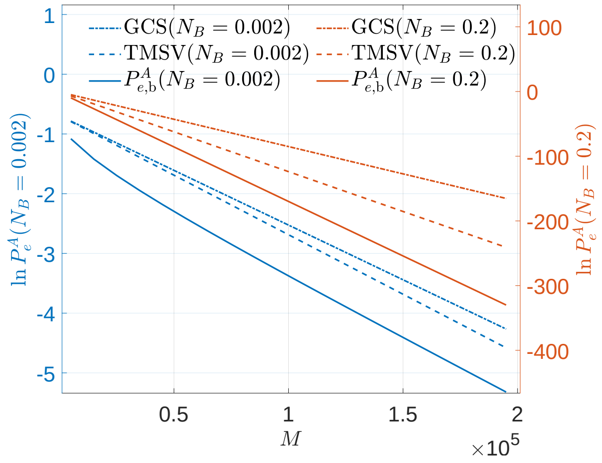

Figure 2: The lower bound Eq. (12) (solid) on Alice's error probability is compared to that of ϵ-covert TMSV (dashed) and GCS probes (dash-dotted line) for $N_B = 0.2$ (blue) and $N_B = 0.002$ (red). $\epsilon = 10^{-3}$ for both. For large M, the ratio of the error exponents predicted by the bound (12) and of TMSV probes are 1.37 (for $N_B = 0.2$) and 1.16 (for $N_B = 0.002$) respectively.

When limited to classical probes, Alice can generate Gaussian-distributed coherent state (GCS) probes − coherent states in each signal mode with amplitude $\alpha \in \mathbb{C}$ chosen according to a product circular Gaussian distribution $P(\alpha) = \frac{1}{(\pi N_S)} e^{-|\alpha|^2/N_S}$ with identical per-mode energy as for the TMSV probe (Alice's measurement can be conditioned on her knowledge of the amplitude transmitted in each of the M shots). Note that taking $N_S = N_B$ ensures perfect covertness. Figure 2 compares the lower bound of Eq. (12) to quantum TSMV and classical GCS probes. For each M, we consider the M-mode independently and identically distributed (iid) TMSV state with per-mode signal energy N_S chosen to be the maximum allowable by the covertness constraint. For $N_B = 0.2$, the large-M error exponent achieved by TMSV probes was about a factor of 1.37 lower than that of the bound, with the discrepancy becoming smaller for smaller N_B, along with the gap between the GCS and TMSV exponents.

4 Discussion & Outlook

We introduced an operational framework for ϵ-covert quantum target detection and obtained a fundamental lower bound (12) on Alice's error probability. As Fig. 2 indicates, the TMSV error exponent is close to that of our lower bound in the optical regime of $N_B \ll 1$, with the maximum advantage over the Gaussian-distributed coherent states being obtained for $N_B \simeq 0.2$. Equation (9) also constitutes the first universal performance limit for standard non-covert QI without the unphysical NPS assumption. For many further research avenues opened up by our work, as well as detailed proofs of our results, see ref. [19].

Abstract. Recent proposals for global-scale quantum networking leverage strings of space-borne quantum repeaters with on-board quantum memories. Here, we propose an alternative to such repeater constellations using only a single satellite with two memories that effectively acts as a time-delayed version of a single quantum repeater node. We estimate the secure finite keys and demonstrate an improvement of at least three orders of magnitude over prior single-satellite methods that rely on a single memory, while simultaneously reducing the necessary memory capacity by the same amount. We propose an experimental platform to realise this scheme based on rare-Earth ion doped crystals.

Keywords: Quantum networking, quantum key distribution, entanglement distribution.

Long-distance ($> 10^3$ km) quantum entanglement distribution will be crucial for the development of global networked quantum computers, sensors, positioning, navigation and timing, as well as for fundamental tests of physics. The main scientific and technical challenge is the high loss suffered by directly transmitted quantum signals that constrains the range and rate of entanglement distribution. Currently, fibre-based long-distance quantum communication experiments are limited to around a few hundred to a thousand kilometres [1], made possible by new techniques such as twin-field (TF) quantum key distribution (QKD) [2] and developments in low-loss fibre and low-noise single photon detectors. However, going beyond $\sim 10^3$ km requires alternate approaches, such as quantum repeaters (QRs) or free-space channels via space-based platforms.

The use of free-space channels can extend the direct-transmission limit, with fibre exponential loss scaling replaced by the (mainly) inverse square loss scaling of free-space propagation. Recently, the Micius satellite [3] demonstrated milestones such as ground-space teleportation [4], QKD with entangled photons across 1120 km [5], intercontinental QKD operated in trusted node [6] and the integration of satellite links into long-distance, trusted node ground networks [7]. These groundbreaking achievements are however limited by line-of-sight, the connection distance d between two ground stations is limited by the requirement to be in simultaneous view of the satellite ($d \leq 2000$ km for altitude $h = 500$ km) unless the satellite operates as a trusted node [8].

Fully global ($d > 10^4$ km) coverage with satellites has been proposed by several groups. An initial proposal was a hybrid, space-ground QR system [9] where quantum memories (QMs) were located in ground stations. This scheme was recently extended towards fully satellite-based QRs [10, 11] where the QMs are located onboard satellites, eliminating intermediate trans-atmospheric quantum links. These works demonstrated that entanglement distribution across the whole globe would be possible with a network of satellites equipped with QMs and entangled photon pair sources. It was shown that a storage time of around <1 s would be sufficient to reach global distances [10, 11] whereas intercontinental distances of > 8000 km would be possible with memory times of around 100 ms [11, 12].

An alternative to multiple QR nodes is to physically transport [13] entangled qubits, given sufficiently long qubit coherence times. This could be achieved via active quantum error correction [14] or by with ultra-long lifetime QMs [15, 16]. Here, we propose a time-delayed version of a single-node quantum repeater that can be implemented with a single orbiting satellite carrying an ultra-long-lived QM, which we refer to as QM1, in combination with a shorter lived (∼ms) QM (QM2). The addition of the lower requirement QM2 provides a feasible route towards dramatic improvements in secure key generation over QM1 alone. Using QKD as a benchmark for quantum communication, our scheme extends the performance and reduces the hardware requirements of a previous related proposal [15] by several orders of magnitude, especially when taking into account fine-block size effects.

To start, we first provide an overview of our time-delayed quantum repeater protocol. First, global quantum communications using a low-Earth orbit (LEO) satellite equipped with a QM with a lifetime in the order of the associated orbital period (90 minutes for LEO) and an entangled photon pair source has been previously proposed [15]. The source first sends one of the photons in each entangled pair to ground station A and the other half is stored in the on-board QM. The satellite then continues in its orbit and stored photons in the QM are retrieved and sent to ground station B as it flies over. Our scheme instead supplements a long-lived QM together with a second shorter-lived QM. QM1 needs to have $\tau_{QM1} > 1$ hour with a high multimode capacity

*guendomu@physik.hu-berlin.de
†jsmdrsidhu@gmail.com

whereas QM2 only needs $\tau_{QM2} \sim 2L/c$, where L is the range between the satellite and the ground station. Using a single QM limits the key length scaling to η_{ch}^2 whereas a second QM enhances the scaling to $\sim \eta_{ch}$, where η_{ch} is the average single channel loss, all else being equal. Our scheme can be regarded as the time delayed version of a single quantum repeater node [17, 18, 19] that enhances the achievable key rates and tolerable losses and eliminates the requirement for the two ground stations to be in simultaneous view.

The protocol begins with the start of the satellite pass over ground station A and operating its entangled photon-pair source (EPS, rate s). One photon in each pair is stored in QM1, the other photon is sent to ground station A through the space-ground channel. If this transmitted photon is lost, then the corresponding stored photon in the QM1 is erased, else the stored photon is kept if ground station A indicates successful reception. For QKD, the received photon is measured (as in BBM92 [20]) or, more generally, the ground stations could store the received photons in a QM if entanglement was required instead.

After the first overpass, the satellite continues in its orbit and the source again starts emitting entangled photon pairs when passing over ground station B. One photon of each pair is sent to ground station B whereas the other photon is stored in QM2. If ground station B successfully receives the transmitted photon, then the corresponding photon from QM2 is immediately retrieved together with a photon stored in QM1 and entanglement swapping performed by a Bell state measurement (BSM). The result of the BSM is then broadcast for local unitary corrective operations [17, 18]. Although we consider a QM paired with an entangled photon pair source, the same protocol can be realised with a DLCZ-type memory, where the QM can emit a single photon entangled with its internal atomic states [21].

Having now conceptually introduced our time-delayed quantum repeater protocol, we can quantify the relative performance against the previous single-memory scenario. Using QKD as a benchmark, we follow the approach of Ref. [5] to write the BBM92 finite-key length with symmetric basis choice. Specifically, considering the successfully entanglement-swapped pairs shared by ground stations A and B, the finite key length in the Z basis is then given by,

$$\begin{aligned} L_Z =& n_Z - n_Z h\left[\frac{e_X + \sqrt{\frac{(n_Z+1)\log\left(\frac{1}{\epsilon_{\rm sec}}\right)}{2n_X(n_X+n_Z)}}}{1-\Delta}\right] \\ &- f_{\rm e} n_Z h\left(e_Z\right) - n_Z\Delta - \log\frac{2}{\epsilon_{\rm corr}\epsilon_{\rm sec}^2}, \end{aligned} \tag{1}$$

where $\epsilon_{\rm sec}$ and $\epsilon_{\rm corr}$ are secrecy and correctness levels so that the protocol is ϵ-secure if $\epsilon \geq \epsilon_{\rm sec} + \epsilon_{\rm corr}$ [5], Δ is a factor to account for the mismatch of different detector efficiencies, $n_{Z/X}$ are the number of matching and coincident Z and X basis detection events respectively, and $e_{Z/X}$ are the quantum bit error rates (QBER) for each basis. The key length calculation for the X basis is similar to Eq. 1 thus the total key length becomes $L = L_X + L_Z$. Note that a more refined model of the key length is possible, but we choose this approach due to its relative simplicity for comparative purposes.

The QBERs with a single QR node (2 QMs) as in our protocol are given by [17],

$$\begin{aligned} e_X =& \lambda_{\rm BSM}\alpha_A\alpha_B\left[\epsilon_m\left(1-\epsilon_{\rm dp}\right) + \left(1-\epsilon_m\right)\epsilon_{\rm dp}\right] \\ &+ \frac{1}{2}\left[1-\lambda_{\rm BSM}\alpha_A\alpha_B\right], \end{aligned} \tag{2}$$

and

$$e_Z = \lambda_{\rm BSM}\alpha_A\alpha_B\epsilon_m + \frac{1}{2}\left[1-\lambda_{\rm BSM}\alpha_A\alpha_B\right]. \tag{3}$$

Here $\lambda_{\rm BSM}$ is a parameter that quantifies the ideality of the BSM and it is related to the BSM fidelity $F_{\rm BSM} = \sqrt{3(\lambda_{\rm BSM+1})/4}$; α_k is the probability of a real detection event in ground station k; ϵ_m is the misalignment error that also includes the source infidelity due to possible multi-photon excitations and ϵ_{dp} is total dephasing during the storage in memories which depends on the individual memory errors e_m. Ensemble based memories that we consider in this work have been shown to preserve the phase, independent of the storage time [22, 23, 24].

This is since re-emission of the stored information relies on rephasing of these excitations [25], any dephasing will result in lower operation efficiency while maintaining high fidelity. We assume a memory efficiency of $\sim 60\%$ at 90 minutes following the observed $T_2 = 6$ hours in a Europium doped crystal [16, 26] and $\lambda_{\rm BSM} = 0.98$ [17, 18] corresponding to $F_{\rm BSM} = 0.9925$. We further assume two identical passes over ground stations A and B each of 240 s duration and without memory constraints. Consequently, we will determine the required memory capacity as a result. We also do not assume a particular orbit, apart from being consistent with the overpass times and channel losses considered and achievable with realistic transmitter and receiver apertures. In the following, we finally assume an entangled photon pair source rate $s = 5$ MHz, a source infidelity $\epsilon_m = 2\%$, and a tight $\epsilon_{corr} = \epsilon_{sec} = 5\times10^{-12}$.

Compared with the 1-QM scheme [15], the second QM provides a marked advantage in the finite key setting (Fig. 1). With a single QM, finite size effects becomes significant after $\eta_{ch} \sim 26$ dB and the maximum tolerable average loss is 28 dB, beyond which secure key generation is not possible in a single set of overpasses. This also means that the 1-QM scheme would not produce any finite key with channel losses such as those reported in Ref. [5]. Fig. 1a shows the key rate per *received* pair, R, for the single and double memory scheme as a function of average single channel loss (η_{ch}). Notice that a crossover between finite key rates is observed at an average channel loss of $\eta_{ch} = 25.9$ dB. Fig. 1b explicitly demonstrates the advantage of the two-memory scheme, with higher loss tolerance and with up to three orders of magnitude (at around ~ 26.5 dB loss, beyond which 1-QM scheme is unable to generate secret keys) higher secure key lengths, L, due to the repeater effect on the

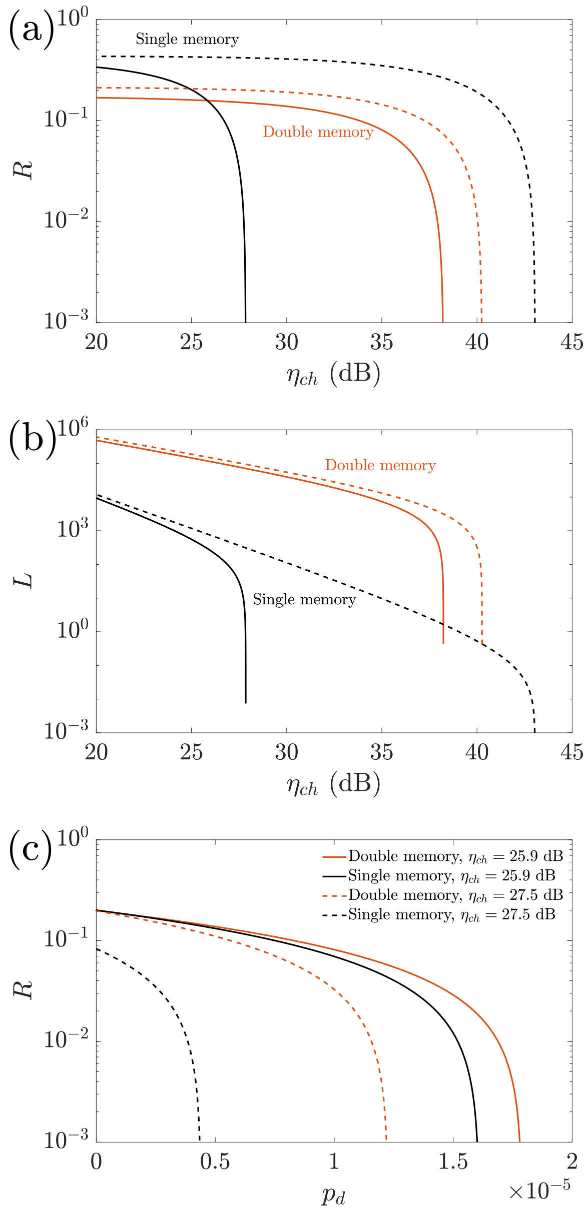

Figure 1: Comparison of 1-QM and 2-QM Key Generation. a) Finite key rate per received pair (R) for $e_m = 5\%$ (solid/dashed curves finite/asymptotic key rate); b) total finite key length (L) as a function of average single channel loss (η_{ch}) for $e_m = 5\%$ (solid/dashed curves finite/asymptotic key length). (c) Finite key rate per received pair versus total incoherent noise for fixed channel losses.

second downlink indicated by the lower slope of the curve for the 2-QM case.

The 2-QM protocol can achieve a finite key rate that approaches its asymptotic limit even for high channel loss and contact times of only a few minutes. In contrast, the 1-QM scheme shows a 15 dB gap between the maximum tolerable loss and finite key limit due to the greatly reduced number of received pairs, without the repeater effect of the second QM, imposing a severe finite block size penalty. In the asymptotic limit, however, the single-memory scheme could in principle tolerate higher losses than the two-memory case due to a reduction of errors from the absence of a non-perfect BSM ($\lambda_{\text{BSM}} = 1$ in the 1-QM case effectively) and the additional dephasing in QM2. We also note that in the 2-QM case, the BSM maximum success rate of 50% (assuming passive ancilla-less static linear optics) halves the number of received pairs, hence the implementation of deterministic entanglement swapping BSMs could provide a tangible improvement in finite key generation and increasing loss tolerance due to longer blocks and better finite statistics.

Fig. 1c shows the effect of incoherent detector clicks, p_d, on the key rate for $\eta_{ch} = 25.9$ dB, the crossover point in Fig. 1a between the two schemes in the finite key setting. The two-memory scheme is more resilient to noise, despite the additional errors introduced by the BSM/entanglement swapping and second memory required. This is due to the much larger block size achievable with 2-QMs leading to lower statistical uncertainties, hence tighter bounds in Eq. 1. The sensitivity on the single channel loss is also illustrated: the dashed curves for $\eta_{ch} = 27.5$ dB show that the double memory scheme has more than three times better noise tolerance than its single memory counterpart.

In conclusion, we conceptually propose a new quantum communication protocol that physically transports stored qubits in an ultra-long-lived QM (lifetime in the order of the orbital period) on an orbiting satellite, and uses a second shorter-lived QM (lifetime in the order of a round-trip classical communication signal) to substantially enhance entanglement distribution over long distances. We quantify the performance of our protocol, and find it dramatically reduces system complexity of global quantum networks by taking advantage of two different paradigms, i.e. quantum repeater behaviour and physically moving qubits, eliminating the need to coordinate orbiting strings of QR satellites and multiple optical links simultaneously. Using two QMs instead of one significantly increases the maximum tolerable channel loss while reducing the required multimode capacity from $\sim 10^8$ [15] to $\sim 10^6$ despite additional errors from the second QM, a non-ideal BSM, and 50% BSM outcome inefficiency in the 2-QM case. Recent progress in QMs indicates that the necessary storage time and multimode capacity should be achievable in the near future.

These results could be improved by utilising more recent finite key calculations that specifically address space-based QKD scenarios. The secure key lengths may be increased by approximately $\sim 10\%$ or else smaller block sizes could be used [27]. Wavelength division multiplexing may allow increased rates at which entangled pairs can be sent through the space-Earth quantum optical channel despite QM linewidth limitations. Finally, ultra-long-lived QMs in orbit may also serve as useful probes to investigate the intersection of quantum physics and general relativity and enable Bell tests across Earth-Moon distances.

Anonymous communication in quantum networks

Gláucia Murta[1 2 *]

[1] *Atominstitut, Technische Universität Wien, Stadionallee 2, 1020 Vienna, Austria*

[2] *Institute for Theoretical Physics III, Heinrich Heine University Düsseldorf, D-40225 Düsseldorf, Germany*

Abstract. A fundamental cryptographic task is secure communication, in which two or more parties exchange confidential messages in the presence of an eavesdropper. In some scenarios, however, the identity of the communicating parties may also be sensitive information. In these situations, it is essential to ensure that the identities remain concealed throughout the protocol. In this talk, I will explore how quantum systems bring advantages to anonymous communication. I will then focus on the task of anonymously establishing a secret key among several users in a quantum network, introducing a security framework that encompasses both secrecy of the key and user anonymity. I will present efficient and noise-tolerant protocols that leverage the correlations of multipartite Greenberger–Horne–Zeilinger (GHZ) states, demonstrating their superiority over protocols based on bipartite entanglement. Finally, I will discuss a recent experiment showcasing that the advantages of multipartite entanglement can already be witnessed with current technology.

Toward large-scale quantum computing –from the viewpoint of computer system architecture–

Teruo Tanimoto[1] *

[1] *Kyushu University*

Abstract. Quantum computers are recognized as an important computing platform in the post-Moore era. We need to scale quantum computers much more to achieve a quantum advantage with a practical problem. The talk will cover our recent activity on noisy-intermediate scale (NISQ) computers and fault-tolerant quantum computers (FTQCs) using superconducting qubits. Superconducting qubits require a cryogenic environment because they are sensitive to thermal noise. We have proposed system-level thermal modeling and power-efficient system architectures to scale cryogenic quantum computers. The bottleneck to scalability is the heat inflow through the wires transmitting and receiving microwaves in/out of the cryostat and the heat generation from the components installed in the cryostat.

For NISQ computers, target algorithm-specific system architecture has been explored. NISQ algorithms, such as the quantum approximate optimization algorithm and the variational quantum eigensolver, collect numerous samples by executing the same quantum circuit repeatedly. Based on the analysis of communication in/out of the cryostat, we have proposed a simple cryogenic digital information processing circuit in the 4 K stage.

FTQCs require various classical digital processing components for quantum error-corrected computation. The primary challenge was to establish a scalability analysis tool (XQsim) to identify the scalability bottleneck of FTQCs using superconducting qubits. By constructing a reference FTQC microarchitecture, we identified the major scalability factors as the power dissipation in the 4 K stage, the latency of quantum error decoding, and the required bandwidth in/out of the cryostat. On the basis of the scalability analysis, design improvements for further scalability from the viewpoint of computer architecture have been proposed.

Abstract. We show that any noise 'truncates' most quantum circuits to effectively logarithmic depth, in the task of estimating Pauli expectation values. We then prove that non-unital noise induces lack of barren plateaus for local cost functions, but we also design a classical algorithm to estimate Pauli expectation values within inverse-polynomial additive error with high probability over the ensemble. Its runtime is polynomial for 1D and quasi-polynomial for higher dimensional architectures. Taken together, our results showcase that, unless we carefully engineer the circuits to take advantage of the noise, it is unlikely that noisy circuits are preferable over shallow ones.

Keywords: Noise, Classical simulation, Random quantum circuits, Barren plateaus

1 Introduction

Note: This submission is based on this work recently posted on ArXiv [1].

In the era of pre-fault-tolerant quantum processors, two popular candidate tasks to demonstrate quantum advantage are random circuit sampling and solving optimization problems via variational algorithms. It is crucial to understand whether quantum advantage in these settings, proven or conjectured to hold with ideal noiseless circuits, persists when the circuits running these computations are affected by realistic hardware noise.

Previous works paint a pessimistic picture: in random circuit sampling, noise makes it possible to simulate the systems efficiently classically [2]. Similarly, in variational quantum algorithms, noise quickly drives the system to computationally trivial states, causing a phenomenon known as "barren plateaus"—the cost function landscape becomes effectively flat, making optimization difficult [3, 4]. However, the overwhelming majority of these results require strong structural assumptions on the noise—that the noise is *local, unital, primitive*, and often, even more specifically, depolarizing noise. In this work, we significantly generalize these results, focusing on random quantum circuits with possibly *non-unital noise.* Up to our knowledge, we prove the strongest result to date about how much such noisy circuits contract two input states, with the implication that unless these circuits are carefully engineered to take advantage of noise [7], quantum advantage will likely not materialize in its presence.

Why non-unital noise? Non-unital noise is physically relevant: for a number of current physical platforms (e.g. superconducting qubits and optical networks), it is more natural and realistic to take the noise to be *non-unital* [5, 6]. Mathematically, non-unital noise is a generalization of unital noise, with qualitatively different results on computation. Strikingly, Ref. [7] has shown a threshold theorem to perform exponentially long quantum computations under non-unital noise, with specially constructed circuits. This can never be the case with depolarizing noise, which converges to the maximally-mixed state in logarithmic time. Additionally, Ref. [8] shows how existing easiness and hardness proofs of random circuit sampling break down under non-unital noise. The intuition is that while unital noise always increases the entropy of its input, non-unital noise may not do so. Non-unital noise is not "depolarizing noise, but worse" – it is mathematically compelling in its own right.

2 Our contributions.

We study the impact of possibly non-unital noise on algorithms estimating expectation values. We consider families of random quantum circuits with local gates picked from a 2-design and show three main results:

- **Effective depth:** We show that arbitrary deep random quantum circuits, under *any* uncorrected any (possibly non-unital) noise, effectively get "truncated", in the following sense: the influence

[**] yquek@mit.edu

of gates on local expectation values decreases exponentially in their distance from the last layer, i.e., only the last $\log(n)$ layers contribute significantly to any expectation value.

Formally, we show the following:

Theorem 1 (Effective depth) *Let P be a Pauli, ρ_{in} and σ_{in} be any quantum states and Φ be a noisy random quantum circuit. Then*

$$\mathbb{E}_\Phi \left[\mathrm{Tr}(P\Phi(\rho_{in} - \sigma_{in}))^2\right] \leq \mathcal{O}(C^{depth(\Phi)}) \qquad (1)$$

where the expectation is taken over the choice of random gates and $C < 1$ is a parameter related to the noise (which we assume non-reversible, i.e., not associated to a unitary channel).

- **Lack of barren plateaus:** In the variational quantum algorithms (VQAs) setting, non-unital noise induces absence of barren plateaus for cost functions made out of local observables—the cost landscape is never flat, and the gradient of the cost function never vanishes, at any depth. This can be intuitively understood as originating from the shallowness of the effective circuit under noise. This phenomenon, however, is not good news for VQAs, as the resultant shallow circuits also have more limited computational power. This contrasts with the finding [4] that depolarizing noise in fact causes barren plateaus at $\log(n)$ depth.
- **Classical simulation:** We also give an algorithm to classically estimate Pauli expectation values up to ε additive inverse-polynomial precision and high success probability (over the ensemble), with runtime of $\sim \exp\left(\log^D\left(\varepsilon^{-2}\right)\right)$, where D is the spatial dimension of the system. The algorithm's runtime is independent of circuit depth. So, for constant precision, our algorithm is efficient for *any* spatial dimension; for inverse-polynomial precision, our algorithm is efficient for 1D architectures. Our algorithm is faster than the classical simulation algorithm of Ref. [9], which (for constant precision and in 2D) has a depth-dependent runtime that scales as $n2^{\mathcal{O}(L^2)}$ where L is depth.

Taken together, our results substantially advance our understanding of the effect of non-unital noise on near-term quantum computation. They showcase that even though we provably always avoid barren plateaus, unless we carefully engineer special circuits to take advantage of the noise, it is unlikely that noisy quantum computers provide any advantage in quantum processing tasks that output expectation values.

Preliminaries. We consider n-qubit, depth-L quantum circuits Φ consisting of layers of two-qubit gates interleaved by local (single-qubit) noise. No assumptions about geometrical locality are needed, except where explicitly mentioned. Let $\Phi^*_{[L,k]}$ denote the circuit in the Heisenberg picture from layer L to k, where $k \leq L$. Let $\Phi_{[1,k]}$ denote the circuit in the Schrödinger picture, i.e., the first $k-1$ layers.

Effective shallow circuits. To explain the significance of Theorem 1, let us restate it, via one application of Jensen's inequality, as

$$\mathbb{E}_\Phi[|\,\mathrm{Tr}(P\Phi(\rho)) - \mathrm{Tr}(P\Phi(\sigma))|] \leq \mathcal{O}(C^{\mathrm{depth}(\Phi)}), \qquad (2)$$

Proof. [Proof Sketch of Theorem 1] Observing that the quantity we need to bound is a second-moment quantity in the distribution over gates reduces the task to proving contraction over ensembles of random Clifford circuits. We also choose to work with a sparse parametrization of non-unital noise (the 'normal form' [10]). The proof is conducted by working in the "Heisenberg picture", peeling off a layer of noise and a layer of 2-qubit gates, and then applying the adjoint of these layers to the Pauli operator in the beginning. This incurs a multiplicative factor to the same quantity but with one less circuit layer. The process is then iterated for all remaining circuit layers, resulting in the claimed exponential-in-depth decrease. The above-described technique strengthens previous second moment bounds on non-unital noisy circuits found in Ref. [8]. □

To parse the previous result, take a noisy circuit of interest $\mathcal{C}$ and let $\Phi = \mathcal{C}_{[L-k,L]}$, $\rho = \mathcal{C}_{[1,L-k]}(\rho_0)$ and $\sigma = \rho_0 = |0^n\rangle\langle 0^n|$. From this, the connection to shallow circuits becomes clear, since we have

$$\mathbb{E}_\Phi[|\,\mathrm{Tr}(P\mathcal{C}(\rho_0)) - \mathrm{Tr}(P\mathcal{C}_{[1,L-k]}(\rho_0))|] \leq \mathcal{O}(C^{\mathrm{depth}(\Phi)})$$

Why taking averages over circuits is crucial. Eq.(1) talks about how much a noisy circuit *contracts* the distance between two different input states *on average over circuits* of a fixed architecture. This is known as a 'contraction result' in the literature and was previously proven for depolarizing and more general types of unital noise. The crux is that any quantum circuit affected by depolarizing noise *converges* to the maximally-mixed state exponentially fast in depth [12, 11] as

$$\left\|\Phi(\rho_{\mathrm{in}}) - \frac{\mathbb{I}}{2^n}\right\|_1 \leq \mathcal{O}(\sqrt{n}c^{\mathrm{depth}(\Phi)}), \qquad (3)$$

for some constant $c < 1$ depending on the noise strength. What is notable about this expression is that a *single* state – the maximally-mixed state – is the 'limit' to which all circuits affected by depolarizing noise converge, independent of what gates are actually in the circuit, or its input state. Because of this, no averages over circuits are necessary in Eq.3.

In contrast, for circuits affected by non-unital noise, the convergence point is some point in the Bloch sphere that is not necessarily the maximally mixed state—in fact, for many cases, a unique, circuit-independent convergence point need not exist! There is yet another subtlety to overcome for proving contraction: in [7] the authors show that if non-unital noise is small enough, it is possible to implement exponentially deep quantum circuits in our model. Thus, our families of random circuits *potentially contain circuits for which no contraction is observed for subexponential depths.* Thus, a worst-case bound is not possible in the depth regimes we study; only *on average over circuits* do we escape these 'pathologies'.

Proposition 2 (1-norm bound) *For any quantum states ρ, σ:*

$$\mathbb{E}_\Phi[\|\Phi(\rho)-\Phi(\sigma)\|_1] \leq 2^{n+1}c^{\frac{L-1}{2}}. \quad (4)$$

Notice that at linear depth $L=\Omega(n)$, the right-hand side of the above expression becomes $\exp(-\Theta(n))$. This is a *stronger* result than (1), for linear depth and beyond, as it talks about indistinguishability of the states themselves, and not just Pauli expectation values. Additionally, for high noise rates, we show that the statement in (4) can be strengthened to worst case circuits, even for non-unital noise. Specifically, we obtain

$$\|\Phi(\rho)-\Phi(\sigma)\|_1 \leq \mathcal{O}(nb^L), \quad (5)$$

where the parameter b is strictly smaller than one only if the noise rate exceeds a certain threshold.

Lack of barren plateaus. The *barren plateaus phenomenon* [3, 4] stands as a central obstacle for *variational quantum algorithms.* These algorithms involve encoding the solution to a problem in the minimization of a cost function, typically defined in terms of the expectation value of an observable, with the free parameters for optimization being the gate parameters. Barren plateaus, are characterized by the phenomenon where the gradient norm of the cost function exhibits, on average, an exponential decay $O(\exp(-n))$ in the number of qubits n. We prove that cost landscapes, with non-unital noise, are not flat, and as a result, we do not get barren plateaus. In more mathematical terms, we show that:

Theorem 3 (Lack of barren plateaus) *Let H be any local Hamiltonian and $C(\theta)=\mathrm{Tr}(H\Phi(\rho))$ the cost function. When the noise is non-unital, then at any depth, we have*

$$\mathrm{Var}[\mathrm{Tr}(H\Phi(\rho))]=\Omega(1), \quad \mathrm{Var}[\|\nabla C\|_2^2]=\Omega(1). \quad (6)$$

The main idea behind both proofs is similar to the proof of (1). We start from the end of the circuit, use the Heisenberg picture, and properties of the random circuit to simplify the expression. We also do a much finer grained analysis of partial derivatives to show that only the last few layers of the circuit have non-trivial partial derivatives. That is,

Proposition 4 (Trainability) *Let μ be any parameter (in the light cone) of the k-th layer of a L-depth circuit, evaluating a cost function $C=\mathrm{Tr}(H\Phi(\rho))$, for a local Hamiltonian H and an ensemble of non-unital noisy random circuits Φ. Then, we have*

$$\mathrm{Var}[\partial_\mu C]=\exp(-\Theta(L-k)). \quad (7)$$

Qualitatively, one way to think about the lack of barren plateaus for our setup is to argue that the circuits are "effectively" shallow, and shallow random circuits do not exhibit barren plateaus for local cost functions [13]. Along with a rigorous mathematical proof, we provide numerical simulations that strongly bear out this claim in our technical manuscript. The technical tools developed in this work also allow, in the unital-noise scenario, to improve upon the Barren Plateaus upper bounds presented in Ref. [4], as discussed in our main draft.

As an auxiliary result, we also give strong evidence that certain types of quantum kernels – a popular 'quantum' method for machine learning – also offer no advantage in optimization tasks, for similar mathematical reasons.

Classical simulation of noisy circuits at any depth. The effective shallowness of noisy circuits implies that they can be classically simulated. More formally, we prove that:

Proposition 5 (Classical simulation) *Let $\varepsilon,\delta>0$. Let P be a Pauli. Let $\rho_0 := |0^n\rangle\langle 0^n|$. Let Φ be a noisy geometrically local with spatial dimension D quantum circuit of depth L sampled according to the described circuit distribution. There is a classical algorithm that outputs a value $\hat{C}$ that satisfies:*

$$|\hat{C}-\mathrm{Tr}(P\Phi(\rho_0))| \leq \varepsilon \quad (8)$$

with at least $1-\delta$ probability of success and runtime $\mathcal{O}(\exp(\log^D(\varepsilon^{-2}\delta^{-1})))$. The runtime in the precision is polynomial for 1-D local architectures, and quasipolynomial for 2-D local architectures.

To prove this theorem, we work in the Heisenberg picture and 'propagate' the observable P only a few layers backwards—the number of layers we propagate it through is inversely proportional to the precision we want. Furthermore, we provide an alternative *early-break condition* that, if met at some step t, guarantees an ε approximation.

Discussion. In this work, we have shown how non-unital noise, when starting with a random ansatz, "truncates" the circuit. This truncated circuit escapes barren plateaus but the cost functional values, obtained from such a circuit, can be simulated classically. Thus, quantum advantage with uncorrected non–unital noise in quantum machine learning is implausible and elusive. Although, in the same vein as Ref. [8], the complexity of sampling from such circuits still remains open, we expect the effective depth picture and our techniques to help in resolving this question.

Abstract. Quantum theory is consistent with a model of computation that allows black-box operations to be applied in an indefinite causal order, going beyond the standard circuit model of computation. The simplest and most widely studied example of indefinite causal order is the quantum switch, which takes as input one call to each of two n-qubit black-box quantum channels, and has been shown to provide information-processing advantages in a wide variety of tasks. Yet, no exponential separation in query complexity has been shown between processes with an indefinite causal order and standard quantum circuits. In this work, we show that no quantum circuit with fixed causal order (or classical control of the causal order) using multiple calls to one of the two n-qubit channels can reproduce the output of the quantum switch if the number of calls is less than 2^n. This shows that quantum processes with indefinite causal order can exhibit an exponential enhancement in query complexity, as a function of the number of qubits, over all quantum circuits with fixed, or classically controlled, causal order.

Keywords: Quantum supermaps, Indefinite causal order, Higher-order quantum computation

1 Introduction

The possibility of performing classical or quantum operations in an indefinite causal order has attracted significant attention in the last two decades [1–10]. From a foundational perspective, this possibility has far-reaching consequences for our understanding of causality, with important implications for the quantum nature of spacetime [1, 2, 11, 12]. From an information-theoretic standpoint, this possibility is equally significant, challenging the standard conception of computation in which gates are performed in a well-defined causal order [3, 4, 6, 7, 13]. The simplest example of a quantum process with indefinite causal order is the quantum switch [4]: a transformation that maps two quantum channels $\mathcal{A}$ and $\mathcal{B}$ to a controlled operation between their two possible orderings $\mathcal{B} \circ \mathcal{A}$ and $\mathcal{A} \circ \mathcal{B}$ [4]. So far, the power of the quantum switch has been demonstrated in various tasks such as reducing the number of queries needed for quantum channel discrimination problems [14] and computational promise problems [15–18], reducing the number of communication rounds required for distributed computation tasks [19], increasing the winning probability in multiparty games [5–7], increasing the capacity of noisy communication channels [20–31], and providing enhancements in quantum metrology [32–35] and quantum thermodynamics [36, 37].

Yet, in the context of quantum computation, no exponential separation in query complexity has been shown between processes with indefinite causal order and those in which operations are performed in a definite order. Indeed, for the case of unitary channels it is known that the quantum switch can be simulated by a quantum circuit querying the unitary channels in a fixed order, with just one extra query to one of the channels [4]. This result holds for any size of the target system. A crucial open question is whether the same holds for general quantum channels.

In this work, we answer this question in the negative. We prove a no-go theorem which states that the quantum switch of two n-qubit channels cannot be simulated using a quantum circuit with fixed causal order, with a single call to one of the channels and M calls to the other channel, if $M \leq \max(2, 2^n - 1)$. Additionally, we conjecture that the same bound holds when M calls to both channels are allowed. Our theorem demonstrates the first known exponential separation in query complexity between quantum processes with indefinite causal order and standard quantum circuits, as a function of the number of qubits.

If our conjecture is proven to be correct, this would demonstrate that not all processes with indefinite causal order can be efficiently simulated using standard quantum circuits. The separation we prove is formulated with respect to a computational task where the inputs and outputs of the computation are both given by black-box quantum channels [4, 22, 38, 39]. This is in contrast to previous works on the query complexity of the quantum switch, where the output of the computation is a bit representing the evaluation of a classical function, in which case no exponential separation has been found [14–18].

In the remainder of this work, we will formalise the notion of indefinite causal order and the problem of simulat-

*These three authors contributed equally.

ing the quantum switch, then present our main theorem and sketch of the proof for the case of $M = 2$.

2 Framework

Processes with indefinite causal order arise as a special case of higher-order quantum transformations [4, 22, 38, 40] (also known as quantum supermaps [39] or process matrices [5]). These are defined according to the following hierarchy. We denote as $\mathbb{L}(A)$ the set of all bounded linear operators on a Hilbert space $\mathcal{H}^A$ corresponding to a physical system A. A *quantum state* is any linear operator $\rho \in \mathbb{L}(A)$ that is both positive semidefinite $\rho \geq 0$ and of unit trace $\operatorname{Tr} \rho = 1$. A *quantum channel* is any linear map $\mathcal{C} : [\mathbb{L}(I) \to \mathbb{L}(O)]$ from quantum states to quantum states that is both completely positive (**CP**) and trace preserving (**TP**). A *quantum supermap* $\mathcal{S}$ is any multilinear map $\mathcal{S} : \bigotimes_{i=1}^{M} [\mathbb{L}(I_i) \to \mathbb{L}(O_i)] \to [\mathbb{L}(P) \to \mathbb{L}(F)]$ from the space of M-tuples of quantum channels to the space of quantum channels that is both completely CP-preserving and TP-preserving [41, 42].

Throughout, we will find it useful to use the Choi representation [43, 44] of linear maps, which encompasses both channels and supermaps. For any linear operator $V : \mathcal{H}^A \to \mathcal{H}^B$, its Choi vector is defined as

$$|V\rangle\!\rangle := \sum_i |i\rangle^A \otimes V |i\rangle^A \in \mathcal{H}^A \otimes \mathcal{H}^B , \tag{1}$$

and for any linear map $\mathcal{Q} : [\mathbb{L}(A) \to \mathbb{L}(B)]$ its Choi matrix is defined by

$$Q := \sum_{ij} |i\rangle\!\langle j|^A \otimes \mathcal{Q}(|i\rangle\!\langle j|^A) \in \mathbb{L}(A \otimes B) , \tag{2}$$

where $\{|i\rangle\}_i$ is the computational basis.

The CPTP conditions imply that any quantum channel $\mathcal{C} : [\mathbb{L}(I) \to \mathbb{L}(O)]$ has a positive semidefinite Choi matrix $C \in \mathbb{L}(I \otimes O)$ normalised such that $\operatorname{Tr}_O C = \mathbb{1}^I$, where $\mathbb{1}^I$ is the identity matrix on $\mathcal{H}^I$. Similarly, any quantum supermap $\mathcal{S} : \bigotimes_{i=1}^{M} [\mathbb{L}(I_i) \to \mathbb{L}(O_i)] \to [\mathbb{L}(P) \to \mathbb{L}(F)]$ can be written in the Choi representation as a positive semidefinite matrix $W \in \mathbb{L}[P \otimes \bigotimes_{i=1}^{M} (I_i \otimes O_i) \otimes F]$, called the *process matrix*, satisfying the condition of being in a specific subspace corresponding to the TP preserving conditions, and normalised such that $\operatorname{Tr} W = d^P \Pi_{i=1}^{M} d^{I_i}$, where $d^A := \dim(\mathcal{H}^A)$ [45]. The composition of quantum states, quantum channels, and quantum supermaps can be represented by the *link product* $*$ on their Choi matrices [46]. In particular, the action of a quantum supermap on a set of quantum channels is represented as follows [46]: $\mathcal{S}(\mathcal{C}_1, \ldots, \mathcal{C}_M) \cong W * (C_1 \otimes \cdots \otimes C_M)$, where the link product on any two matrices $Q \in \mathbb{L}(A \otimes B), R \in \mathbb{L}(B \otimes C)$ is defined as $Q * R := \operatorname{Tr}_B[(Q^{AB} \otimes \mathbb{1}^C)^{\mathrm{T}_B} (\mathbb{1}^A \otimes R^{BC})]$, with $\mathrm{T_B}$ being the partial transpose with respect to system B.

Ordinary quantum circuits correspond to the special class of quantum supermaps known as *quantum circuits with fixed causal order* (QC-FOs) [10] or *quantum combs* [38]. An M-slot quantum circuit with fixed causal order is a quantum supermap which can be decomposed as a quantum circuit with $M + 1$ fixed quantum channels $\mathcal{V}_0 \in [\mathbb{L}(P) \to \mathbb{L}(I_1 \otimes E_1)], \mathcal{V}_1 \in [\mathbb{L}(O_1 \otimes E_1) \to \mathbb{L}(I_2 \otimes E_2)], \ldots, \mathcal{V}_M \in [\mathbb{L}(O_M \otimes E_M) \to \mathbb{L}(F)]$, connected sequentially with auxiliary systems $\{E_i\}_{i=1}^{M}$. The action of such a supermap on M input quantum channels $[\mathbb{L}(I_i) \to \mathbb{L}(O_i)]$ 'inserted' into the slots between each of the $\mathcal{V}_i$ is given by $W * (C_1 \otimes \cdots \otimes C_M) = V_M * C_M * \cdots * V_1 * C_1 * V_0$.

However, QC-FOs are not the most general quantum supermaps compatible with an underlying definite causal structure. Convex combinations of QC-FOs and supermaps where the order of operations is determined dynamically are also both possible. A more general class which includes such possibilities is *quantum circuits with classical control of causal order* (QC-CCs) [10, 47]. Quantum supermaps which are not compatible with an underlying definite causal structure are called *causally non-separable processes* [5, 45, 48] and are said to have indefinite causal order. Although it is currently an open question whether there exist processes compatible with a definite causal structure but are not QC-CCs [10], no such processes have been found to date, and therefore, any computational advantage of processes with indefinite causal order is most reasonably determined by comparing with QC-CCs.

3 Quantum switch and its simulations

The simplest and most widely studied example of a process with indefinite causal order is the quantum switch [4], which combines two quantum channels $\mathcal{A} \in [\mathbb{L}(I) \to \mathbb{L}(O)]$ and $\mathcal{B} \in [\mathbb{L}(I') \to \mathbb{L}(O')]$ in their two possible sequential orderings, depending on the state of a quantum control qubit P_C. The process matrix of the n-qubit quantum switch $\mathcal{S}_{\texttt{SWITCH}} : [[\mathbb{L}(I) \to \mathbb{L}(O)] \otimes [\mathbb{L}(I') \to \mathbb{L}(O')]] \to [\mathbb{L}(P_C \otimes P_T) \to \mathbb{L}(F_C \otimes F_T)]$, where I, O, I', O', P_T, F_T, correspond to n-qubit Hilbert spaces and P_C, F_C correspond to qubit Hilbert spaces, is given by $S_{\texttt{SWITCH}} = |S_{\texttt{SWITCH}}\rangle\!\rangle\langle\!\langle S_{\texttt{SWITCH}}|$, with

$$\begin{aligned} |S_{\texttt{SWITCH}}\rangle\!\rangle^{PFIOI'O'} &:= |0\rangle^{P_C} |0\rangle^{F_C} |\mathbb{1}\rangle\!\rangle^{P_T I} |\mathbb{1}\rangle\!\rangle^{OI'} |\mathbb{1}\rangle\!\rangle^{O'F_T} \\ &+ |1\rangle^{P_C} |1\rangle^{F_C} |\mathbb{1}\rangle\!\rangle^{P_T I'} |\mathbb{1}\rangle\!\rangle^{O'I} |\mathbb{1}\rangle\!\rangle^{OF_T} . \end{aligned} \tag{3}$$

For the case where the input channels are unitary, i.e. $\mathcal{U}(\cdot) = U(\cdot)U^\dagger$ and $\mathcal{V}(\cdot) = V(\cdot)V^\dagger$, the action of the quantum switch takes the particularly simple form:

$$\mathcal{S}_{\texttt{SWITCH}} : (U, V) \mapsto VU \otimes |0\rangle\!\langle 0| + UV \otimes |1\rangle\!\langle 1| . \tag{4}$$

To understand the computational power of the quantum switch, it is essential to understand whether its action can be efficiently simulated with causally ordered quantum supermaps by using more queries to one or both of the channels. It is known that the action of the quantum switch on unitary channels can be simulated deterministically and exactly with a quantum circuit with fixed causal order C_{sim}, using just one extra call to either of the two channels [4]:

$$\mathcal{C}_{\text{sim}}(\mathcal{U}, \mathcal{V}, \mathcal{U}) = \mathcal{S}_{\texttt{SWITCH}}(\mathcal{U}, \mathcal{V}) \quad \forall \mathcal{U}, \mathcal{V} . \tag{5}$$

The circuit for C_{sim} is depicted in Figure 1.

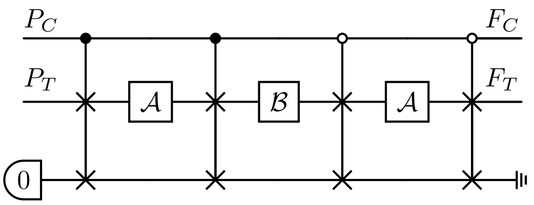

Figure 1: A quantum circuit with fixed causal order taking two calls to a quantum channel $\mathcal{A}$ and a single call to a quantum channel $\mathcal{B}$. When $\mathcal{A}$ is a unitary channel, this circuit simulates the action of the quantum switch of $\mathcal{A}$ and $\mathcal{B}$.

4 Main results

Interestingly, we observe that the same quantum circuit C_{sim} can simulate the action of the quantum switch on one unitary channel and one general quantum channel, with one extra call to the unitary channel. That is, for any unitary channel $\mathcal{U}$, and any quantum channel $\mathcal{B}$,

$$\mathcal{C}_{\text{sim}}(\mathcal{U},\mathcal{B},\mathcal{U}) = \mathcal{S}_{\texttt{SWITCH}}(\mathcal{U},\mathcal{B})\,. \tag{6}$$

However, when C_{sim} is applied to two general quantum channels $\mathcal{A},\mathcal{B}$, with 2 copies of $\mathcal{A}$, it does not in general reproduce the action of the quantum switch. This can be explained by the fact that the quantum switch correlates the randomness associated with a non-unitary channel between its $|0\rangle$ and $|1\rangle$ branches.

As such, one might wonder whether there exists some other causally ordered supermap, either a QC-FO or QC-CC, which can reproduce the action of the quantum switch, given $M \geq 2$ copies of one of the two channels. Here, we answer this in the negative for $M \leq \max(2, 2^n - 1)$:

Theorem 1. *There is no $(M+1)$-slot supermap $\mathcal{C} : \bigotimes_{i=1}^{M}[\mathbb{L}(I_i) \to \mathbb{L}(O_i)] \otimes [\mathbb{L}(I'_1) \to \mathbb{L}(O'_1)] \to [\mathbb{L}(P_C \otimes P_T) \to \mathbb{L}(F_C \otimes F_T)]$, where $\{I_i\}_i, \{O_i\}_i, I'_1, O'_j$ correspond to n-qubit Hilbert spaces, with fixed causal order or classical control of the causal order satisfying*

$$\mathcal{C}(\underbrace{\mathcal{A},\dots,\mathcal{A}}_{M},\mathcal{B}) = \mathcal{S}_{\texttt{SWITCH}}(\mathcal{A},\mathcal{B}) \tag{7}$$

for all quantum channels $\mathcal{A}$ and $\mathcal{B}$, if $M \leq \max(2, 2^n-1)$.

The full proof is given in the Technical Manuscript [47]. In the following, we give a sketch of the proof for the case of $M = 2$. We begin by assuming that a 3-slot QC-CC quantum supermap $\mathcal{C}$ simulates the quantum switch for all unitary channels and all convex combinations of unitary channels, i.e.,

$$\mathcal{C}\left(\frac{\mathcal{U}_1+\mathcal{U}_2}{2},\frac{\mathcal{U}_1+\mathcal{U}_2}{2},\mathcal{V}\right) = \mathcal{S}_{\texttt{SWITCH}}\left(\frac{\mathcal{U}_1+\mathcal{U}_2}{2},\mathcal{V}\right), \tag{8}$$

$$\forall l \in \{1,2\}: \quad \mathcal{C}(\mathcal{U}_l,\mathcal{U}_l,\mathcal{V}) = \mathcal{S}_{\texttt{SWITCH}}(\mathcal{U}_l,\mathcal{V})\,, \tag{9}$$

for all unitary operations $\mathcal{U}_1,\mathcal{U}_2,\mathcal{V}$. By linearity of supermaps, we obtain

$$\mathcal{C}(\mathcal{U}_1,\mathcal{U}_2,\mathcal{V}) + \mathcal{C}(\mathcal{U}_2,\mathcal{U}_1,\mathcal{V}) = \mathcal{S}_{\texttt{SWITCH}}(\mathcal{U}_1+\mathcal{U}_2,\mathcal{V}). \tag{10}$$

Since $\mathcal{C}(\mathcal{U}_2,\mathcal{U}_1,\mathcal{V})$ is a CP map, $\mathcal{S}_{\texttt{SWITCH}}(\mathcal{U}_1+\mathcal{U}_2,\mathcal{V}) - \mathcal{C}(\mathcal{U}_1,\mathcal{U}_2,\mathcal{V})$ is CP. In terms of the Choi matrix, this relation can be written as

$$\begin{aligned}&C \star (|U_1\rangle\rangle\langle\langle U_1| \otimes |U_2\rangle\rangle\langle\langle U_2| \otimes |V\rangle\rangle\langle\langle V|)\\ &\leq |S_{\texttt{SWITCH}}\rangle\rangle\langle\langle S_{\texttt{SWITCH}}| * [(|U_1\rangle\rangle\langle\langle U_1| + |U_2\rangle\rangle\langle\langle U_2|) \otimes |V\rangle\rangle\langle\langle V|].\end{aligned} \tag{11}$$

Since $\mathcal{C}$ can be implemented by a QC-CC, the Choi matrix C can be decomposed as $C = \sum_{(i,j,k)\in\text{Perm}(1,2,3)} C_{ijk}$ such that C_{ijk} satisfies $C_{ijk} \geq 0$ and several affine conditions (which we refer to the QC-CC conditions) [10, 47]. Using an eigendecomposition of C_{ijk} given by $C_{ijk} = \sum_a |C^{(a)}_{ijk}\rangle\rangle\langle\langle C^{(a)}_{ijk}|$, we obtain

$$\begin{aligned}&|C^{(a)}_{ijk}\rangle\rangle\langle\langle C^{(a)}_{ijk}| \star (|U_1\rangle\rangle\langle\langle U_1| \otimes |U_2\rangle\rangle\langle\langle U_2| \otimes |V\rangle\rangle\langle\langle V|)\\ &\leq |S_{\texttt{SWITCH}}\rangle\rangle\langle\langle S_{\texttt{SWITCH}}| * [(|U_1\rangle\rangle\langle\langle U_1| + |U_2\rangle\rangle\langle\langle U_2|) \otimes |V\rangle\rangle\langle\langle V|].\end{aligned} \tag{12}$$

Therefore, the left-hand side of Eq. (12) can be written as

$$\begin{aligned}&|C^{(a)}_{ijk}\rangle\rangle * (|U_1\rangle\rangle \otimes |U_2\rangle\rangle \otimes |V\rangle\rangle)\\ &= \sum_{l=1}^{2} p^{(a,l)}_{ijk}(U_1,U_2,V)|S_{\texttt{SWITCH}}\rangle\rangle * (|U_l\rangle\rangle \otimes |V\rangle\rangle),\end{aligned} \tag{13}$$

using $p^{(a,l)}_{ijk}(U_1,U_2,V) \in \mathbb{C}$. If $|C^{(a)}_{ijk}\rangle\rangle$ is given by

$$|C^{(a)}_{ijk}\rangle\rangle = \sum_{l=1}^{2} |S_{\texttt{SWITCH}}\rangle\rangle^{PI_lO_lI_3O_3F} \otimes |p^{(a,l)}_{ijk}\rangle\rangle \tag{14}$$

for $|p^{(a,1)}_{ijk}\rangle\rangle \in \mathbb{L}(I_2 \otimes O_2)$ and $|p^{(a,2)}_{ijk}\rangle\rangle \in \mathbb{L}(I_1 \otimes O_1)$, the corresponding quantum supermap $\mathcal{C}$ satisfies Eq. (13). We show that the converse holds, i.e., if Eq. (13) holds for all unitary operators U_1,U_2,V, $|C^{(a)}\rangle\rangle$ can be written as Eq. (14). The rough idea for this proof is based on differentiation with respect to a parametrisation of the input unitary operators, a technique introduced concurrently in Ref. [49] by some of the present authors. By considering the differentiation of $p^{(a,1)}_{ijk}(U_1,U_2,V)$ with respect to U_1 and U_2, we show that $p^{(a,1)}_{ijk}(U_1,U_2,V)$ can be given as a linear function of U_2 that does not depend on U_1 and V [47]. Then, $p^{(a,1)}_{ijk}(U_1,U_2,V)$ can be written as $p^{(a,1)}_{ijk}(U_1,U_2,V) = |p^{(a,1)}_{ijk}\rangle\rangle * |U_2\rangle\rangle$ using $|p^{(a,1)}\rangle\rangle \in \mathbb{L}(I_2 \otimes O_2)$. Similarly we show that $p^{(a,2)}_{ijk}(U_1,U_2,V)$ can be written as $p^{(a,2)}_{ijk}(U_1,U_2,V) = |p^{(a,2)}_{ijk}\rangle\rangle * |U_1\rangle\rangle$ using $|p^{(a,2)}\rangle\rangle \in \mathbb{L}(I_1 \otimes O_1)$. Then, we obtain

$$\begin{aligned}&|C^{(a)}_{ijk}\rangle\rangle * (|U_1\rangle\rangle \otimes |U_2\rangle\rangle \otimes |V\rangle\rangle)\\ &= \sum_{l=1}^{2} |S_{\texttt{SWITCH}}\rangle\rangle^{PI_lO_lI_3O_3F} \otimes |p^{(a,l)}_{ijk}\rangle\rangle * (|U_1\rangle\rangle \otimes |U_2\rangle\rangle \otimes |V\rangle\rangle).\end{aligned} \tag{15}$$

Since this holds for all unitary operators U_1,U_2,V, we obtain Eq. (14). Finally, we show that any quantum supermap given in the form of Eq. (14) does not satisfy the QC-CC conditions, thereby completing the proof [47].

Complexity-theoretic foundations of BosonSampling with a linear number of modes

A. Bouland, D. J. Brod, I. Datta, B. Fefferman, D. Grier, F. Hernández, M. Oszmaniec

Abstract BosonSampling is the leading candidate for demonstrating quantum computational advantage in photonic systems. While we have recently seen many impressive experimental demonstrations, there is still a formidable distance between the complexity-theoretic hardness arguments and current experiments. One of the largest gaps involves the ratio of photons to modes–all current hardness evidence assumes a "high-mode" regime in which the number of linear optical modes scales at least quadratically in the number of photons. By contrast, current experiments operate in a "low-mode" regime with a linear number of modes. In this paper we bridge this gap, bringing the hardness evidence for the low-mode experiments to the same level as had been previously established for the high-mode regime. This involves proving a new worst-to-average-case reduction for computing the Permanent which is robust to both large numbers of row repetitions and also to distributions over matrices with correlated entries.

Introduction In the decade since it was proposed by Aaronson and Arkhipov [AA13], BosonSampling has become one of the most promising candidates for achieving quantum computational advantage the experimental demonstration of a quantum computation which exponentially surpasses classical computers. This requires a task which is both experimentally feasible and has strong complexity-theoretic evidence for hardness. We have now seen several experimental demonstrations of BosonSampling [WQD+19] and its Gaussian variant at scale [ZPL+19, ZDQ+21, MLA+22], as well as substantial work building the theory of these experiments and bringing them closer to feasibility (see e.g. [HKS+17, CC17, DMV+22, GBA+22]).

Despite this progress, there is still a formidable distance between experiment and theory. One of the most notable gaps involves the ratio between the number of modes and number of photons. The original BosonSampling proposal calls for a "high-mode regime" in which n photons are passed through an $m = \Omega(n^2)$-mode Haar-random interferometer followed by the measurement of each mode in the photon number basis.[1] By contrast, all experiments to date operate in a "low-mode regime" in which the number of modes scales linearly in the number of modes, $m = \Theta(n)$. Understanding this low-mode regime has long been cited as a major open problem going back to the original paper [AA13] which asked explicitly:

> *"Can we reduce the number of modes needed for our linear-optics experiment, perhaps from $O(n^2)$ to $O(n)$?"*

It is reasonable to conjecture that the need for such a high number of modes is an artifact of current proof techniques, rather than intrinsic to the hardness of the sampling problem. For one, state-of-the-art classical simulation algorithms are not able to take advantage of the low-mode regime to achieve dramatically faster runtimes[2] [CC18], albeit some improvements are possible [CC20, MRK+23]. Furthermore, the low-mode regime is sufficient to perform universal quantum computation [KLM01]. However, analyzing the hardness of BosonSampling in the low-mode regime is quite challenging for two reasons. First, current proof techniques rely heavily on a property of the high-mode regime known as the "Bosonic Birthday Paradox" [AK11] which ensures that most measurement outcomes are collision-free—i.e., have a single photon in each occupied output mode. By contrast, low-mode BosonSampling

[1] We note that the original paper used $m = \omega(n^5)$ modes, but they showed that an $O(n^2)$ experiment would suffice under a plausible random matrix theory conjecture, and subsequent work proved variants of BosonSampling like Bipartite BosonSampling [GBA+22] can be analyzed with as few as $O(n^2)$ modes.

[2] To be precise, these algorithms run in time which is exponential in the number of photons, but merely polynomial in the number of modes. In other words, high-mode experiments with few photons provably cannot lead to exponential quantum advantage.

has a large number of collisions. Second, in the high-mode regime the probability of each outcome is the squared permanent of a submatrix of the Haar random unitary that encodes the interferometer. These submatrices have i.i.d. Gaussian entries, which are convenient to analyze. In the low-mode regime, the relevant submatrices do not have i.i.d. entries and this is the case even in the absence of collisions.

In this work (see [BBD$^+$23] for the technical version of the manuscrip) we overcome these obstacles and build the complexity-theoretic foundations for BosonSampling in the low-mode regime, answering Aaronson and Arkhipov's question in the affirmative. The starting point, following Aaronson and Arkhipov, is to prove that hardness of classical approximate sampling from low-mode BosonSampling experiments follows from the hardness of an appropriate average-case hardness conjecture:

Theorem 1 (Informal)**.** *Assuming average-case hardness of computing output probabilities of low-mode BosonSampling experiments, there is no efficient randomized classical algorithm to sample from the output distribution of such an experiment to inverse polynomial additive error.*

Our main results give strong evidence in favor of this average-case hardness conjecture. In particular we show it is #P-hard to compute the output probabilities of random low-mode experiments, and also provide numerical evidence for anticoncentration in this regime. This brings low-mode BosonSampling to essentially the same level of theoretical support as high-mode experiments.

Proof sketch The first obstacle present in the low-mode regime—the presence of photon collisions in typical outcomes—breaks a property of the experiment known as *hiding*. Hiding[3] is the property that all outputs of the experiment are symmetrical over the choice of random experiment. This simple property plays a surprisingly key role in current quantum advantage arguments. The basic reason is that these arguments try to show no approximate classical sampler exists to small total variation distance error. If all outputs are on equal footing then this error can be spread over all outputs by Markov's inequality. However if only a few outputs matter for the hardness arguments, one might worry the approximate sampler could corrupt these outputs only, and the arguments become implausible. This symmetry property trivially holds for Random Circuit Sampling, IQP, Fermion Sampling, and many other advantage schemes, and also trivially carries over to BosonSampling experiments in the high-mode regime. However in the low-mode regime this symmetry fails spectacularly—the output space shatters into an exponential number of incomparable output types each with probability mass that is relatively well spread.[4]

We instead proceed by formulating a modified version of the Stockmeyer counting reduction which does not require the hiding symmetry. We choose a uniformly random outcome of the experiment and use Stockmeyer counting to estimate the probability of this outcome. By Markov's inequality we can ensure that most output probabilities of the approximate sampler are mostly correct. However, this modified reduction comes at a cost—to show hardness of sampling, it no longer suffices to show hardness of computing a single type of output, but instead we must now show an *entire suite* of hardness results for *most* outputs of the experiments. More formally, for low-mode BosonSampling the output space consists of an exponential number of incomparable collision patterns—i.e., unordered lists of occupation numbers of modes. We need to argue it is hard to estimate the output probabilities of most collision patterns under a suitable measure.

Our next step is to show such a suite of average-case hardness results of computing most outputs of low-mode experiments:

Theorem 2 (Informal)**.** *It is* #P*-hard to compute most output probabilities of most BosonSampling experiments in the low-mode regime to within additive error $e^{-O(n \log n)}$.*[5]

This is nearly what we need to show hardness of sampling via the modified Stockmeyer reduction ($e^{-O(n)}$ robustness). Here we need to overcome both of the major differences that distinguish the low and

[3] "Hiding" also refers to an input type conversion problem in the original paper [AA13], but in subsequent papers was used only to describe this symmetry property.

[4] That is, it is unclear if any particular output type occurs with a probability that scales as an inverse polynomial.

[5] We note that this additive error is dependent on the output type of the outcome, though this dependence is subleading in the exponent.

high-mode regimes. First, one must deal with the presence of collisions—to do this we identify a collection of output types which cover a large fraction of the output probability distribution of typical experiments. This requires a careful combinatorial accounting of typical collision patterns in typical outputs of low-mode experiments. Once a suitable collision pattern is identified, we need to show average-case hardness for computing outputs of that collision type over the random choice of interferometer. This is equivalent to showing hardness of computing the permanent of a large submatrix of a random unitary, with a particular pattern of repeated rows.

In the high-mode regime this average-case hardness argument proceeds using a variant of Lipton's argument. The basic idea is that since a Gaussian is perturbed only slightly by shifting and rescaling, one can in some sense "sneak" a tiny amount of a worst-case matrix into an average-case matrix. This uses an entry-by-entry analysis of the matrix. This proof strategy breaks in the low-mode case since the relevant submatrices are far from i.i.d. Gaussian [Jia06]—instead, the entries come from a highly correlated measure. We show that surprisingly, this highly correlated distribution is nonetheless approximately shift-and-scale invariant so that we recover Lipton's proof. To do this, we directly study the probability density of the singular values of a submatrix of a Haar-random unitary [Col03, Réf05]. We reduce the desired invariance property to estimating the gradient of this probability density, which we show is equivalent to proving sharp tail bounds on the maximum singular value. Our desired bounds require that we go beyond generic concentration inequalities such as Levy's lemma or log-Sobolev inequalities, and instead we derive them from high-dimensional geometry. Considering the ubiquity of the Haar measure over unitaries, we expect that this bound may be of independent interest.

Finally we address the issue of anticoncentration of low-mode experiments. Anticoncentration is a necessary ingredient for converting additive estimates of output probabilities to multiplicative estimates—which we conjecture to be hard. It remains open to prove anticoncentration for all variants of BosonSampling, but there has been partial progress in this direction [Nez21], as well as numerical evidence for anticoncentration in the high-mode regime [AA13]. However, as one reduces the number of modes, one might worry that anticoncentration might begin to fail, both due to the row repetitions in the submatrices, and the correlations between submatrix entries. This could be an issue as many of the known attacks on quantum advantage schemes hold in the non-anticoncentration regime, e.g. constant-depth random circuits [NLPD$^+$22]. To alleviate this concern and to support our anticoncentration conjecture, we provide numerical evidence that anticoncentration holds in the low-mode regime, and indeed has very similar behavior to the i.i.d. Gaussian case.

Discussion Our work better connects the theory of BosonSampling to its empirical implementation. Aaronson and Arkhipov's foundational work led to a number of important extensions which improved our understanding of the complexity of BosonSampling—from generalizations to Gaussian BosonSampling, to improving the robustness of average-case hardness arguments, to efficiently spoofing or verifying of experiments, to characterizing the effects of noise. While many of the more empirical works have focused on the low-mode regime due to its connection with experiment, most of the theoretical arguments have focused on high-mode regime and may need to be re-investigated in this new context. Many interesting questions remain. For example, can we improve the robustness of average-case hardness of these experiments to $e^{-O(n)}$, i.e. to be only off by a constant in the exponent as with high-mode BosonSampling [BFLL21]? Do spoofing algorithms for BosonSampling become easier or harder in the low-mode case? How few modes are needed for intractability, for example, for which α do $m = \alpha n$ experiments have the best evidence for hardness,[6] and are there any fundamental limits on this constant?

Abstract. Unpredictable functions (UPFs) play essential roles in classical cryptography. In this paper, we introduce a quantum analog of UPFs, which we call unpredictable state generators (UPSGs). UPSGs are implied by pseudorandom function-like states generators (PRFSs), which are a quantum analog of pseudorandom functions (PRFs), and therefore UPSGs could exist even if one-way functions do not exist. Although UPFs are equivalent to PRFs, UPSGs could be weaker than PRFSs. Despite this, we demonstrate that all known applications of PRFSs are also achievable with UPSGs. Our findings suggest that, for many applications, quantum unpredictability, rather than quantum pseudorandomness, is sufficient.

Keywords: Quantum cryptography, unpredictability, secret-key encryption, message authentication codes with unclonable tags

1 Background

Pseudorandom functions (PRFs) [GGM86] are one of the most fundamental primitives in classical cryptography. A PRF is an efficiently computable keyed function that is computationally indistinguishable from a random function for any polynomial-time adversary that can query the function. PRFs have many important applications in cryptography, and in particular, they are essential building blocks of EUF-CMA-secure message authentication codes (MACs) and IND-CPA-secure secret-key encryption schemes (SKE).

Naor and Reingold [NR98] introduced a related primitive so-called unpredictable functions (UPFs). Like PRFs, a UPF is an efficiently computable keyed function $f_k(\cdot)$, but the crucial difference is that the goal of the adversary is not to distinguish it from the random function but to predict the output $f_k(x^*)$ without querying x^*. Naor and Reingold showed that the existence of PRFs is equivalent to that of UPFs.

What happens if we consider quantum versions of PRFs and UPFs? Recently, quantum analogs of elementary primitives have been extensively studied [JLS18, MY22b, AQY22, BCQ23, AGQY22, Yan22, MY22a, BBSS23, ALY23]. For example, pseudorandom states generators [JLS18], One-way states generators (OWSGs) [MY22b] and EFIs [BCQ23]. There are mainly two reasons why studying such new quantum elementary primitives are important. First, they could exist without (quantumly-secure) one-way functions (OWFs) [Kre21, KQST23], which are the most fundamental assumptions in classical cryptography. Second, despite that, they have many useful applications. These facts suggest that these primitives will play the role of the most fundamental assumptions in quantum cryptography, similar to OWFs in classical cryptography.

Quantum versions of PRFs have been already studied. Pseudorandom function-like states (generators) (PRFSs) [AQY22, AGQY22] are one of the quantum analogs of PRFs. A PRFS is a quantum polynomial-time (QPT) algorithm that, on input a secret key k and a classical bit string x, outputs a quantum state $|\phi_k(x)\rangle$. The security roughly means that no QPT adversary can tell whether it is querying the PRFS oracle or the oracle that returns Haar random states. PRFSs could also exist without OWFs, and imply EUF-CMA-secure MACs (with quantum tags) and IND-CPA-secure SKE (with quantum ciphertexts) [AQY22].

On the other hand, no quantum analog of UPFs was explored before. Is it equivalent to a quantum analog of PRFs, such as PRFSs? Does it imply EUF-CMA-secure MACs and IND-CPA-secure SKE like PRFSs? Can we gain any meaningful insight for quantum cryptography by studying it?

2 Our Results

The present paper aims to initiate the study of a quantum version of UPFs which we call unpredictable states generators (UPSGs). We define UPSGs and construct several cryptographic applications from UPSGs.

Defining UPSGs. Our first contribution is to define UPSGs. A UPSG is a QPT algorithm Eval that, on input a secret key k and a classical bit string x, outputs a quantum state $|\phi_k(x)\rangle$. Intuitively, the security (unpredictability) is as follows: no QPT adversary, which can quantumly query the oracle $\mathsf{Eval}(k,\cdot)$, can output (x^*,ρ) such that x^* was not queried and ρ is close to $|\phi_k(x^*)\rangle$.

In the classical case, PRFs and UPFs are equivalent [NR98]. What happens in the quantum case? In fact, we can show that PRFSs imply UPSGs. However, the other direction is not clear. In the classical case, the construction of PRFs from UPFs is done by using the Goldreich-Levin [NR98, GL89]: if $f_k(\cdot)$ is a UPF, $g_{k,r}(x) := f_k(x)\cdot r$ is a PRF with the key (k,r), where $x \cdot y$ is the inner product between bit strings x and y. However, we cannot directly apply that idea to UPSGs: In particular, what is $|\phi_k(x)\rangle \cdot r$?

[*] tomoyuki.morimae@yukawa.kyoto-u.ac.jp
[†] shogo.yamada@yukawa.kyoto-u.ac.jp
[‡] takashi.yamakawa@ntt.com

In summary, a quantum analog of UPFs, UPSGs, are implied by PRFSs, which especially means that UPSGs could also exist without OWFs. However, the equivalence is not clear, and UPSGs could be weaker than PRFSs. Then, a natural question is the following: Do UPSGs have useful applications like PRFSs?

IND-CPA-secure SKE. Our second contribution is to construct IND-CPA-secure SKE (with quantum ciphertexts) from UPSGs. In the classical case, unpredictability implies pseudorandomness [NR98], which implies encryption. However, as we have explained before, we do not know how to convert unpredictability to pseudorandomness in the quantum case. Therefore we cannot use the same technique in the quantum case.

Before the construction of IND-CPA-secure SKE from UPSGs, let us first recall the definition of IND-CPA-secure SKE. SKE consists of an encryption algorithm Enc and a decryption algorithm Dec. On input a secret key and a bit b, Enc outputs a (possibly quantum) ciphertext ct_b, and Dec, on input the secret key and ciphertext ct_b, outputs b. As the IND-CPA security, we require that no QPT adversary can distinguish ct_0 from ct_1.

Our idea to construct IND-CPA-secure SKE is based on the duality between the swapping and the distinction [AAS20, HMY23]. The duality intuitively means that distinguishing two orthogonal states $|\psi\rangle$ and $|\phi\rangle$ is as hard as swapping $|\psi\rangle + |\phi\rangle$ and $|\psi\rangle - |\phi\rangle$ with each other. Our ciphertext for a single-bit message $b \in \{0,1\}$ is, then, $\mathsf{ct}_b := (x, y, |\mathsf{ct}^b_{x,y}\rangle)$, where

$$|\mathsf{ct}^b_{x,y}\rangle := |0\rangle\,|x\rangle\,|\phi_k(x)\rangle + (-1)^b\,|1\rangle\,|y\rangle\,|\phi_k(y)\rangle\,,$$

and x and y are random bit strings. The secret key of our SKE scheme is the key k of the UPSGs. From the unpredictability of UPSGs, any QPT adversary cannot convert $|\phi_k(x)\rangle$ to $|\phi_k(y)\rangle$, which means that any QPT adversary cannot distinguish ct_0 and ct_1 due to the duality.

This argument seems to work. There is, however, one subtle issue here. The adversary of the IND-CPA security can query the encryption oracle. However, in general, we do not know whether the duality works if the distinguisher queries an oracle because the swapping unitary is constructed from the distinguishing unitary and its inverse.

We can solve the issue by observing that the oracle query by the adversary can actually be removed. Because the oracle is an encryption algorithm for single-bit messages and the adversary queries the oracle only polynomially many times, we can remove the oracle by giving sufficiently many outputs of the oracle to the adversary in advance as an auxiliary input. The duality in [HMY23] takes into account the auxiliary inputs to the adversary, and therefore now we can use the duality.

Moreover, since it is known that IND-CPA-secure SKE imply IND-CPA-secure SKE for quantum messages [BJ15], we get the following result.

Theorem 1 *If UPSGs exist, then IND-CPA-secure SKE (for quantum messages) exist.*

MACs with unclonable tags. Our third contribution is to define MACs with unclonable tags and to construct it from UPSGs. The unclonability of tags roughly means that no QPT adversary can, given t-copies of a quantum tag, output a large (possibly entangled) quantum state that contains at least $t+1$ valid tag states. MACs with unclonable tags are useful in practical applications. For example, consider the following attack (which is known as the *replay attack* in the classical cryptography): Alice sends the message "transfer \$100 to Bob" with a MAC tag to a bank. Malicious Bob can steal the pair of the message and the tag, and sends it ten times to the bank so that he can get \$1000. In classical cryptography, the standard EUF-CMA security of MACs cannot avoid such an attack, and some higher-level treatments are necessary.

If tags are unclonable, we can avoid such a replay attack. It is easy to see that UPSGs imply EUF-CMA-secure MACs with quantum tags. (We have only to take $|\phi_k(m)\rangle$ as the tag of the message m.) However, it is not self-evident whether the quantum unpredictability implies unclonability. For instance, if $f_k(\cdot)$ is a PRF, $|\phi_k(x)\rangle := |f_k(x)\rangle$ is a UPSG but $|\phi_k(x)\rangle$ is not unclonable.

Our idea to construct unclonable tags is to use the unclonability of random BB84 states. (In other words, to use Wiesner money [Wie83].) For two bit string x and θ, we define $|x\rangle_\theta := \bigotimes_i H^{\theta^i}|x^i\rangle$, where H is the Hadamard gate, and x^i and θ^i are ith bit of x and θ, respectively. If we set $\tau_m := |\phi_k(m)\rangle \otimes |x\rangle_\theta$, where x and θ are chosen at random, as a tag for classical message m, it seems unclonable.

Here, $\tau_m = |\phi_k(m)\rangle \otimes |x\rangle_\theta$ does not contain any information about x and θ except for $|x\rangle_\theta$. From this, two crucial issues arise. First, τ_m is not unclonable in general. To understand this issue, assume that $|\phi_k(m)\rangle$ is not unclonable. (As mentioned above, we cannot ensure that $|\phi_k(m)\rangle$ is unclonable.) Then, the following adversary $\mathcal{A}$ breaks unclonability: $\mathcal{A}$, given $\tau_m = |\phi_k(m) \otimes |x\rangle_\theta\rangle$, clones $|\phi_k(m)\rangle$ and generates $|x'\rangle_{\theta'}$ by choosing x' and θ' at random. It is clear that $\mathcal{A}$ can generate two valid tags $|\phi_k(m)\rangle \otimes |x\rangle_\theta$ and $|\phi_k(m)\rangle \otimes |x'\rangle_{\theta'}$ from a single copy of $\tau_m = |\phi_k(m)\rangle \otimes |x\rangle_\theta$.

How can we avoid this issue? It seems that we can avoid the first issue just by replacing the tag $\tau_m = |\phi_k(m)\rangle \otimes |x\rangle_\theta$ with $\tau'_m := |\phi_k(m,x,\theta)\rangle \otimes |x\rangle_\theta$, where $|\phi_k(m,x,\theta)\rangle$ is the output of UPSGs on input (m,x,θ). This is because, if no adversary can know x and θ from $|\phi_k(m,x,\theta)\rangle$, no adversary can clone $\tau'_m = |\phi_k(m,x,\theta)\rangle \otimes |x\rangle_\theta$ from the unclonability of random BB84 states. However, it is not clear whether UPSGs satisfy its property in general.

The second issue is that the verifier of MAC cannot verify whether $\tau_m = |\phi_k(m)\rangle \otimes |x\rangle_\theta$ (or $\tau'_m = |\phi_k(m,x,\theta)\rangle \otimes |x\rangle_\theta$) is a valid tag or not. This is because, in general, the verifier cannot know x and θ from the tag to verify the BB84 state $|x\rangle_\theta$. To solve this issue, we have to encode x and θ into a tag for the sake of verification. However, if we do so directly, e.g., we set $\tau''_m := (x, \theta, |\phi_k(m, x, \theta)\rangle \otimes |x\rangle_\theta)$, the new tag is not unclonable because x and θ are open.

From the above observation, if we can encrypt x, θ and $|\phi_k(m, x, \theta)\rangle$, we can construct a tag that is unclonable and verifiable. We can do it by using IND-CPA-secure SKE for quantum messages, which exist from Theorem 1 since we assume the existence of UPSGs. Therefore, by setting $\tau'''_m := \mathsf{Enc}(\mathsf{sk}, |(x,\theta)\rangle \otimes |\phi_k(m, x, \theta)\rangle) \otimes |x\rangle_\theta$, where Enc is the encryption algorithm of IND-CPA-secure SKE for quantum messages, we can construct MACs with unclonable tags from UPSGs. Therefore we have the following result.

Theorem 2 *If UPSGs exist, then MACs with unclonable tags exist.*

OWSGs with pure output and a necessary condition for UPSGs As our fourth contribution, we construct OWSGs with pure outputs from UPSGs, which means that $\mathbf{PP} \neq \mathbf{BQP}$ is necessary for the existence of UPSGs [CGG$^+$23]. At first glance, the former looks trivial since UPSGs imply IND-CPA-secure SKE from Theorem 1 and IND-CPA-secure SKE imply OWSGs [MY22a]. However, in general, the outputs of OWSGs constructed from IND-CPA-secure SKE are not pure states. Therefore, Theorem 1 does not mean that UPSGs imply OWSGs with pure outputs.

Before explaining how to construct OWSGs with pure outputs, let us recall the definition of OWSGs with pure outputs. An OWSG with pure outputs is the QPT algorithm that, on input secret key k, then outputs a pure state $|\psi_k\rangle$. The security is the following: no QPT adversary, given many copies of $|\psi_k\rangle$, can output the correct secret key k.

Our idea to construct OWSGs with pure outputs is based on the following observation: from the unpredictability of UPSGs, no QPT adversary $\mathcal{A}$ cannot correctly guess the secret key k of UPSGs using $|\phi_k(x)\rangle$ for polynomially many bit strings x. This is because, if $\mathcal{A}$ can do that, $\mathcal{A}$ breaks the unpredictability of UPSGs as follows: $\mathcal{A}$ query polynomially many bit strings x to $\mathsf{Eval}(k, \cdot)$ to guess the secret key k and output $|\phi_k(x')\rangle$ by running $\mathsf{Eval}(k, x')$, where x' is not queries before.

From the above observation, we construct OWSGs as follows. We set secret key $k' := (k, x_1, ..., x_t)$ of our OWSG. Here, k is a secret key of UPSGs, and $x_1, ..., x_t$ are bit strings chosen uniformly at random, where t is a polynomial of the length of k. Our OWSG runs $|\phi_k(x_i)\rangle \leftarrow \mathsf{Eval}(k, x_i)$ for all i and outputs

$$|\psi_{k'}\rangle := \bigotimes_{i=1}^{t} |x_i\rangle |\phi_k(x_i)\rangle .$$

As explained before, no QPT adversary can correctly guess k (and also $k' = (k, x_1, ..., x_t)$) even if the adversary gets many copies of $|\psi_{k'}\rangle$, which means our OWSG with pure outputs satisfies the security. Therefore, we have the following result.

Theorem 3 *If UPSGs exist, then OWSGs with pure outputs exist.*

Because pure OWSGs are broken if $\mathbf{PP} = \mathbf{BQP}$ [CGG$^+$23], we also have the following corollary, which means $\mathbf{PP} \neq \mathbf{BQP}$ is a necessary condition for the existence of UPSGs:

Corollary 4 *If UPSGs exist, then* $\mathbf{PP} \neq \mathbf{BQP}$.

Implication of our result. IND-CPA-secure SKE implies EFIs [MY22a]. Moreover, MACs with unclonable tags straightforwardly imply private-key quantum money schemes in the sense of [AC12, JLS18]. We therefore have the following as a corollary of Theorem 1 and Theorem 2.

Corollary 5 *If UPSGs exist, then EFIs and private-key money schemes exist.*

IND-CPA-secure SKE, MACs with unclonable tags, OWSGs, EFIs, and private-key money schemes are also implied by PRFSs, and these primitives are all known applications of PRFSs. This suggests the following: *For many applications, quantum unpredictability, rather than quantum pseudorandomness, is sufficient.*

Abstract. Reliable randomness is a core ingredient for cryptographic applications. The outcomes of measurements on entangled states can violate Bell inequalities, thus guaranteeing their intrinsic randomness, which constitutes the basis for certified randomness generation. However, this certification requires space- like separated devices, making it unfit for practical applications. Here we provide a general method to certify randomness on a small-scale apparatus and implement the corresponding protocol on a device that combines a solid-state emitter and a glass chip. In contrast to most existing randomness certification techniques, our protocol accounts for information leakage and is thus compatible with emerging compact devices.

Keywords: Quantum correlations, randomness certification, quantum cryptography, quantum photonics

This submission is based on the following pre-print: `https://arxiv.org/pdf/2301.03536v2` (new version published on 15 May 2024).

Reliable randomness is a core ingredient in algorithms and applications ranging from numerical simulations to statistical sampling and cryptography. The strictest requirements on randomness sources are typically destined to cryptographic applications. There, randomness should ideally be both unpredictable and private, so that no information about the generated sequence can be gained by an eavesdropper either prior to or immediately after its generation. Quantum sources admit certification of these properties, by exploiting links between the unpredictability of a quantum behaviour and the violation of Bell inequalities. A guarantee that numbers have been sampled from empirical data exhibiting Bell nonlocality or, more generally, contextuality can suffice to certify unpredictability and privacy.

Randomness certification and other Bell-inequality-based protocols offer attainable cryptographic advantages for quantum information processing but they are susceptible to loopholes. One way to close the locality, or more generally, the compatibility loophole, is to ensure space-like separation between the players of the non-local game [1, 2, 3, 4]. However, that is not an option for a practical compact device. Merely asserting that the relevant parts of the device are shielded [5] is unsatisfactory for users who would like to prevent themselves against a device deteriorating with time. For such a device, the compatibility loophole must be carefully addressed, because crosstalk can lead to detrimental information flow between components. This compromises theoretical analyses and security proofs even outside of adversarial scenarios. More broadly, all future on-chip quantum information processing will be susceptible to such effects, for which reason it is essential that they be taken into account in protocols and algorithms at the information processing level.

In this work, we introduce novel theoretical tools to take into account crosstalk and address the locality loophole. We demonstrate these tools in a randomness certification protocol performed on a compact photonic chip. Idealised analyses typically lead to relations between the relevant figure of merit (fidelity, rate, guessing probability...) on the one hand, and Bell violations or more general contextuality measures [6] on the other hand. Here, we provide relations suited to realistic devices, which allow the evaluation of the relevant figures of merit in terms of both beneficial contextuality and detrimental crosstalk. Moreover, we introduce a method to upper bound the amount of crosstalk by computing how far the device's observed behaviour is from the set of quantum correlations approximated by the Navascués–Pironio–Acín (NPA) hierarchy [7]. This enables detection of adversarial manipulation of the device which may seek to exploit the locality loophole to spoof certification.

We incorporate our method in a randomness certification protocol that is secure against quantum side information, meeting the highest security standards. Such protocols require acquiring large statistics while maintaining high photon purity and indistinguishability [8, 9], which puts knock-on constraints on hardware efficiency and stability. Our theoretical contribution bridging the gap between ideal situations and realistic implementations, combined with finely controlled and robust hardware, allow us to implement the first on-chip certified quantum random number generation protocol with a full security proof against quantum side information.

1 Theoretical contribution

Our work uses the semi-device-independent framework: we aim to derive a lower bound on the randomness generated during the experiment, based on the input-output correlations that characterise this experiment and a physical assumption that restricts the correlations that can be accessed. The experiments we consider can be formulated as n-player games, where each (virtual) player can choose an input (that correspond to a measurement choice) and obtains an output (that corresponds to a measurement result). The set of probabilities of obtaining an output tuple given an input tuple is called a behaviour. If no information can flow between the players, the behaviour satisfies the property of no-signalling. If the input-output correlations stem from a quantum experiment (i.e., performing quantum measurements on potentially entangled particles), the behaviour is said to be quantum. If the probability distributions for each input tuples can't be obtained as the marginals of a single probability distribution of global assignments of outcomes to all measurements, the behaviour is said to be contextual. Thanks to Bell's theorem, we know there exist contextual quantum behaviours, and such behaviours are useful from a cryptographic perspective as the randomness with which the outputs are obtained can't be apparent: the outputs obtained during the experiment are inherently random [10, 11]. A behaviour is necessarily contextual when it violates a Bell inequality, or equivalently when it reaches a value above a certain score, called non-contextual or classical score, in a contextual game. The score corresponds to the sum of the probabilities weighted by a scalar for each input and output tuple and the input probabilities. The set of such scalars is called the scoring function and defines the game.

Our theoretical contribution is threefold.

- We define the signalling fraction SF (simultaneously introduced in a companion paper [12]), a measure of the information flow that can take place between the components of the experiment, which correspond to the players mentioned above. This measure is defined in a similar way as the contextual fraction [6] and the local fraction [13], but relative to the set of no-signalling behaviours: it is equal to 0 for a no-signalling behaviour and to 1 for a maximally signalling behaviour. We generalise the signalling fraction by defining the approximate quantum fractions SF_ℓ, that are relative to the set of quantum correlations approximated at the ℓ^{th} level of the NPA hierarchy [7, 14].

- We then define, for a given scoring function, two scores: the maximal score that can be reached by behaviour with maximal contextual fraction ξ, and the maximal score that be reached by behaviours with signalling fraction at most σ and the further requirement that the behaviour be deterministic on a specific input tuple. The first score is related to a characteristics of the game called consistency and can be easily computed, while the second one is the quantity of interest for the protocol we want to implement (see next point). We prove that the latter is upper-bounded by the former for any n-partite games with binary inputs.

- Finally, we introduce a protocol for private randomness generation and randomness expansion[1] in the presence of crosstalk. We use the approximate quantum fraction to quantify the crosstalk, and not the signalling fraction, because we assume that our experiment is governed by the laws of quantum mechanics, and thus want to discard supra-quantum behaviours. Our protocol is derived from Miller and Shi's spot-checking protocol [16] and provides a lower bound on the amount of randomness that it generates, valid even in the presence of quantum side information.

This protocol allows us to certify randomness generation with a compact apparatus, provided that the following assumption is satisfied: the measure of crosstalk by the approximate quantum fraction is a fair estimate of the information flow at the hidden variable level. This assumption is well-founded if the devices were fabricated by an honest provider, i.e. were not programmed to act maliciously in order to function with a high level of crosstalk while keeping the empirically observable signalling low. In that case, an eavesdropper can only take advantage of flaws in the implementation and deterioration of the devices with time to try and predict the outputs.

Compared to Ref. [17], which also uses the spot-checking security proof of Miller and Shi [16] and takes into account imperfect compatibility between the measurements, our analysis is more general, as it applies to any n-partite nonlocal game with binary inputs. Another approach to derive a lower bound on the physical crosstalk from the observed behaviour was proposed in [18], which puts a constraint at the level of the measurements rather than on the behaviours. Both metrics provide valid lower bounds on the crosstalk; the advantage of ours is that it integrates well with convex optimisation techniques used to compute maximal scores, Bell inequality violations and guessing probabilities.

2 Experimental contribution

We then implement our protocol on a photonic setup, which is depicted in Fig 1. The contextual game we implement is the Clauser-Horne-Shimony-Holt (CHSH) game [19]. It's a two-party game and we call the (virtual) players Alice and Bob. In the setup, an electrically controlled semiconductor quantum dot in a 2-µm-diameter micropilar cavity generates single photons that are sent to a reconfigurable glass chip, implementing the CHSH game by varying the measurement choices via optical phases and measuring output coincidences.

By a periodical calibration during the experiment, we maintain a high precision over the implemented measurement bases to limit crosstalk between the two par-

[1] Concerning the difference between the two notions, see [15].

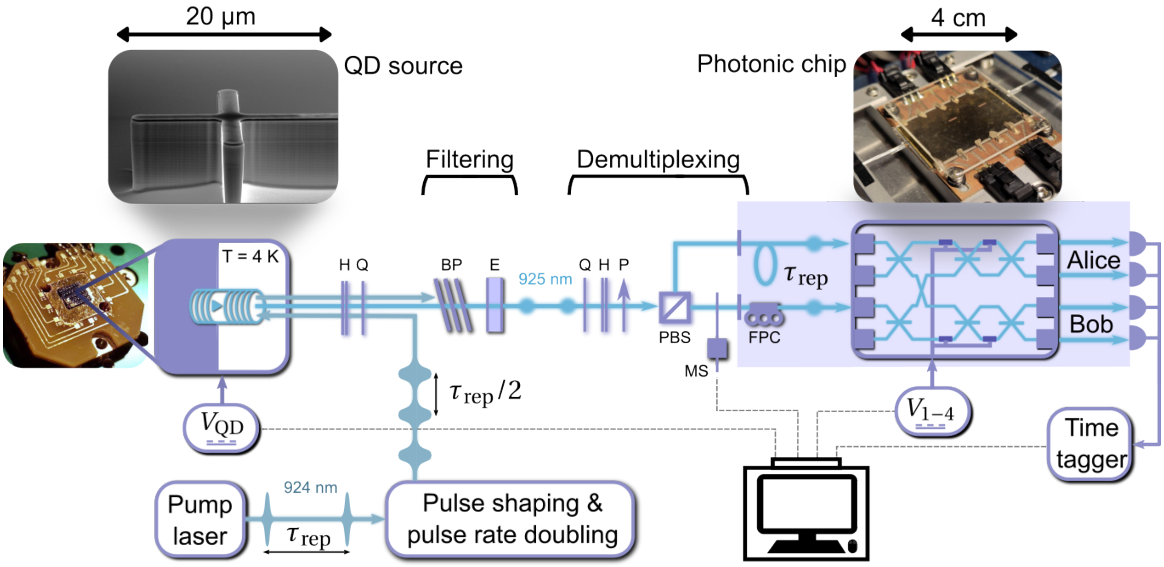

Figure 1: **Compact implementation of a certified quantum random number generator.** The quantum dot (QD) photon emitter generates photons at 925 nm via a phonon-assisted excitation scheme (see Methods). H, Q: half and quarter-wave plates. BP: bandpass filters. E: etalon. P: polarizer. After a demultiplexing stage (see Methods), the outputs of a polarizing beamsplitter (PBS) are collected with collimators. The setup is entirely fibered or waveguided in the blue area. A fibered delay τ_{rep}, allows to synchronize pairs of photons sent into the photonic chip. A motorized shutter (MS) enables chip voltage calibration. The fibered polarisation controller (FPC), ensures both photons enter the photonic chip with the same polarisation. Dashed grey lines indicate that elements of the setup are automated to implement the randomness generation protocol, by adapting the voltage on the photon source for optimal brightness and periodic calibrations of the thermo-optic phase-shifter voltages. V_{1-4} control the phases on chip and hence measurement bases of Alice and Bob. V_{QD} feedback loop ensures the QD emission remains bright and the emitted photons indistinguishable.

ties. We use a bright and stable Quandela semiconductor quantum dot (QD) based single photon source [20] that delivers indistinguishable single photons, allowing us to obtain high Bell inequality violations. The polarised fibered-device brightness of our QD-based single-photon source is 8.3(8) % (all error bars represent one standard deviation). The purity of the single photons, quantified by the second-order normalised correlation function, is $g^{(2)}(0) \approx 2.31(3)\,\%$ and their indistinguishability, quantified with the Hong-Ou-Mandel (HOM) visibility, is $V_{\text{HOM}} = 93.09(4)\,\%$ [21]. The train of emitted photons is converted with a passive demultiplexing stage into pairs of photons entering simultaneously the photonic chip. On exiting the chip, the photons are detected by high-efficiency single photon detectors and time tagged. The overall transmission of the setup is 2.7 %.

Certifiying randomness requires witnessing correlations that win the CHSH game, or equivalently that violate the CHSH inequality. This places requirements on the purity and indistinguishability of the photons emitted by the single-photon source. For the ideal case of a source emitting only pure photons in a lossless optical circuit, denoting I_{CHSH} the value obtained for the CHSH expression, we derive the following relation:

$$I_{\text{CHSH}} = \sqrt{2}(V_{\text{HOM}} + 1). \tag{1}$$

The choice of inputs for Alice and Bob corresponds to applying different phases on their side of the chip, that are controlled by thermo-optic phase shifters. We use a spatial encoding, which means that the outputs recorded by Alice and Bob are determined by the modes in which each of their photons exit the chip. The protocol alternates between generation rounds, for which Alice's and Bob's phases are fixed, and test rounds, for which they each choose at random one of their two possible measurement choices. We assume that the detected photons are representative of the whole optical setup behaviour, i.e. that the sampling is fair. The measured coincidence rate is about $14\,200(600)\,\text{s}^{-1}$. Before data acquisition we measured a violation of the CHSH inequality $I_{\text{CHSH}} = 2.68$, which we used to fix the optimal parameters for the protocol. We ran our protocol for a total number of rounds $N = 2.4 \times 10^9$, and we obtained a CHSH violation of $I_{\text{CHSH}} = 2.685$ and an approximate quantum fraction of 0.005 (at level 3 of the NPA hierarchy). Our protocol then certifies that this generates 7.21×10^6 private random bits, quantified by the min-entropy of the outputs. This amount of randomness is compatible with randomness expansion, in the sense that if we were to use the interval algorithm to generate our strongly biased input bits from a small number of uniform bits [22, 23], the input randomness required for our implementation would be 5.24×10^6, which is smaller than the amount of randomness we generate at the output.

Abstract. In recent years, achieving verifiable quantum advantage on a NISQ device has emerged as an important open problem in quantum information. The sampling-based quantum advantages are not known to have efficient verification methods. This paper investigates the verification of quantum advantage from a cryptographic perspective. We establish a strong connection between the verifiability of quantum advantage and cryptographic and complexity primitives, including efficiently samplable, statistically far but computationally indistinguishable pairs of (mixed) quantum states (EFI), pseudorandom states (PRS), and variants of minimum circuit size problems (MCSP). Specifically, we prove that a) a sampling-based quantum advantage is either verifiable or can be used to build EFI and even PRS and b) polynomial-time algorithms for a variant of MCSP would imply efficient verification of quantum advantages. Full version: https://arxiv.org/pdf/2310.14464.

Keywords: Verifiable quantum advantage, EFI, Pseudorandom States, Minimal circuit size problem

1 Introduction

Quantum advantage experiments aim to demonstrate that quantum computers can perform some tasks faster than classical computers with a more favorable amount of computational resources. In the NISQ (Noisy Intermediate Scale Quantum) era, sampling tasks such as random circuit sampling (RCS) [2] and Boson sampling [1] emerge as promising candidates for quantum advantage experiments since they can be implemented on a NISQ device and are provably hard for classical computers. Besides classical hardness and implementation on a NISQ device, an equally important aspect is how to allow an efficient classical computer to verify the samples from such experiments. Consequently, the challenge remains open to designing a quantum advantage experiment that satisfies all three criteria.

In terms of the verifiability of RCS, the linear cross-entropy benchmarking (XEB) is first proposed as a verification method [2]. However, XEB is sample-efficient, but not computationally efficient. Moreover, XEB can be spoofed [9, 16]. Perhaps there is a better verification method for RCS? Hangleiter and his colleagues showed that the answer is no [10]. They show that if the target distribution anticoncentrates, certifying closeness to the target distribution requires exponentially many samples, which covers RCS, Boson sampling, and IQP sampling.

What about general quantum sampling experiments? How do we determine if such an experiment has an efficient verification method? In [8], the verification task is modeled as a game between a quantum party, a classical challenger, and a classical referee, which we will discuss later. However, they can only show the limitations of the verification method that calculates the empirical average of some scoring function of individual samples in this model.

2 Our results

In this paper, we investigate the verifiability of sampling-based quantum advantage experiments via a *cryptographic* perspective. To this end, we first put forth formal definitions of verifiability. Subsequently, we study the implication of the hardness of a variant of the minimal circuit size problem (MCSP) on verifiability. Furthermore, we establish the connection between verifiability and fundamental quantum cryptographic primitives: EFI (efficiently generated, statistically far, and computationally indistinguishable states) and PRS (pseudorandom states). Lastly, we generalize verifiable quantum advantage to capture the verifiability of interactive proof of quantumness. We hope that our work will advance the understanding of the verifiability of quantum advantage experiments and provide insights into the development of future quantum advantage experiments.

To address the verifiability of quantum advantage experiments, we model the verification process as an interaction between three parties: Alice (a quantum advocate and experiment designer), Bob (a quantum skeptic), and a verifier [1]. Alice runs the quantum experiment and sends transcripts of her experiment, including the setup of the experiment apparatus and outcomes, to the verifier. She also tells Bob about her experiment apparatus but not the outcomes. Bob proposes a classically samplable distribution that depends on Alice's experiment and is indistinguishable from Alice's distribution, and sends the description of his sampling algorithm along with samples of his distribution to the verifier. The verifier's goal is to distinguish Alice and Bob's samples, so we also call him the distinguisher. The distinguisher takes all the information from Alice and Bob as input. In the case of RCS, Alice publishes her random circuit C, and sends her measurement outcome on $C|0^n\rangle$ to the distinguisher. Bob proposes a C-dependent spoofing algorithm, and sends the description of the algorithm along with his samples to the distinguisher.

Definition 1 (Verifiable quantum advantage) *Let $\mathfrak{C}$ be a set of polynomial-sized quantum circuits on n qubits. We say the experiment that samples a $C \in \mathfrak{C}$ and repeatedly measures the output state in the computational basis achieves* verifiable quantum advantage *if for all $\mathfrak{D} = \{D_C, \mathcal{S}_C\}_{C\in\mathfrak{C}}$ where $\mathcal{S}_C$ is a time-s classical sampler for D_C, there exists a classical polynomial time distinguisher $\mathcal{A}$ such that*

$$\mathop{\mathbb{E}}_{C\leftarrow\mathfrak{C}} |\Pr[\mathcal{A}(C, \mathcal{S}_C, \boldsymbol{z}_C) = 1] - \Pr[\mathcal{A}_D(C, \mathcal{S}_C, \boldsymbol{z}_{\mathcal{D}_C}) = 1]| \geq 1/\,\mathsf{poly}(n),$$

where $\boldsymbol{z}_C$ is a polynomial-sized set of samples generated from measuring $C|0^n\rangle$ in the computational basis, and $\boldsymbol{z}_{\mathcal{D}_C}$ is a set of samples drawn from $\mathcal{D}_C$.

We give several VQA examples to demonstrate the expressiveness of our verifiability definition, such as Fourier sampling (e.g., based on Shor's algorithm and Simon's problem). Note that our distinguisher is more general than the ones used in the experiments [2] and studied in [8]. Their distinguishers are agnostic about how the classical samples are sampled, and they score each sample individually, and make their decisions based on the average of the scores. As pointed out in [8], if the distinguisher knows the spoofing algorithm of XEB proposed in [16], the distinguisher can distinguish the spoofing samples from the quantum samples. Hence, we define VQA with respect to a more general distinguisher.

Minimum circuit size problem (MCSP) vs. VQA. We aim to identify the computational hardness of verifying quantum advantages. One potential approach is finding a problem for which the existence of efficient algorithms would lead to efficient verification. This is similar to the connections between Meta-complexity problems and cryptography.

Classical meta-complexity problems, which ask to identify specific complexity measures (e.g., circuit complexity) of given Boolean functions, is a fundamental topic in complexity theory. It is worth noting that efficient classical algorithms for these problems imply that one-way functions do not exist [12, 17]. Inspired by the connections between meta-complexity problems and cryptography, we introduce a variant of meta-complexity problems called the *minimum circuit size problems for samples* (SampMCSP), which asks the minimal size of classical samplers that can generate samples indistinguishable from the given samples. This problem is analogous to the state minimum circuit size problem introduced in [7], which asks to identify the quantum circuit complexity of given quantum states. We demonstrate that if SampMCSP can be solved in polynomial time, then quantum advantage experiments that only generate polynomially many samples can be verified efficiently.

EFI vs. VQA. Next, we study the relationships between verifiability and the quantum cryptographic primitive EFI. EFI is a fundamental quantum cryptographic primitive, which is equivalent to quantum commitment schemes, quantum oblivious transfer, quantum multi-party computation and others [3]. We show a *duality* between EFI and verifiable quantum advantage, when we consider classically-secure EFI pairs, i.e., whose computational indistinguishability holds only against classical algorithms.

Theorem 2 (Informal) *Suppose that a quantum experiment admits quantum advantage. Then, the experiment is verifiable if and only if there exists a sufficiently large faction of the circuits' output states that do not form an EFI pair with any quantum state that encodes a classical samplable distribution.*

If we allow verifying quantum advantage by a quantum computer, we obtain a similar duality between quantum-secure EFIs and quantum verifiability. These results provide necessary and sufficient conditions for verifiability based on whether the quantum circuit family can form EFI pairs with classical polynomial-time samplable distributions. To the best of our knowledge, all existing EFI pairs satisfy such a property, i.e., one of the EFI generators can be simulated by classical polynomial-time

[1] We came up with this model unaware of the two-party game proposed in [8], although the two models share some similarities

sampling algorithms.

Pseudorandom states (PRS) vs. VQA A set of states is a PRS if a random state in this set is computationally indistinguishable from a Haar random state [11]. PRS is an essential quantum cryptographic primitive that can be used to build other primitives, including one-time digital signature and EFI. Moreover, the existence of PRS implies the existence of EFI, and thus the aforementioned applications that are equivalent to EFI can also be constructed from PRS. There is also evidence showing that the existence of PRS is a weaker assumption than the existence of one-way functions [14].

Intuitively, if the output states of a quantum advantage experiment are pseudorandom, the measurement output distribution should be indistinguishable from the measurement output distribution of Haar random states. In addition, the measurement output distribution of Haar random states can be approximated by a classical distribution, so this quantum advantage experiment doesn't achieve verifiability. However, in the definition of PRS, the distinguisher is unaware of the preparation circuit of the given state, but the distinguisher in a quantum advantage experiment is. Hence, we can only prove this result for a subclass of PRS, called classically unidentifiable PRS, which intuitively says that when distinguishing samples from measuring different states, knowing the circuit doesn't help. Many existing PRS constructions, such as the random phase states and binary phase states [11, 6], are classically unidentifiable.

Theorem 3 (Informal) *If the quantum advantage of a quantum sampling algorithm is verifiable, then the output states are not classically unidentifiable PRS.*

The motivation behind Theorem 3 is that RCS is proposed as a candidate construction of PRS [15]. If the output states of random circuits are classically unidentifiable, Theorem 3 gives us a proof that RCS experiments are unverifiable. Note that [10] shows the distribution induced by measuring a random circuit is indistinguishable from some classical distribution, which doesn't imply RCS is not VQA according to Theorem 1. Conversely, Theorem 3 also tells us that if some construction of PRS fails, it is possible to use this construction for verifiable quantum advantage. This is a win-win situation.

What about interactive quantum advantage experiments? So far, we have focused on sampling-based quantum advantage experiments. There are interactive verifiable quantum advantage proposals called proof of quantumness (PoQ) [4, 5, 13]. These PoQs achieve verifiability, but one obstacle in implementing these protocols is maintaining coherence during the interactions.

Hence, we generalize Theorem 1 to capture the strength of both Theorem 1 and the verifiability of PoQ. In the generalized definition, the trusted party is the *designated verifier*, who generates public parameters and a private verification key. After getting all the samples, the designated verifier uses the verification key to distinguish Alice's quantum samples from Bob's samples. We call this *Designated verifiable quantum advantage* or DVQA.

Under this definition, the trusted verifier is offline, so Alice doesn't need to interact with the trusted verifier and can generate the samples on her own as in Theorem 1. Moreover, it is possible to compile existing PoQ to satisfy the new definition. For example: Assuming a random oracle, the interactive protocol of [4] fits this definition. The function keys and trapdoors of their protocol are the public parameters and private verification keys here. Then, the classical or quantum prover can run the operations of the verifier in the original protocol locally by querying the random oracle for the challenges. In the end, the prover sends all the generated transcripts to the distinguisher $\mathcal{A}$, who uses the verification key to distinguish the transcripts. In the compiled protocol, the verifier is offline as in Theorem 1, and the verifiability of the original PoQ is preserved.

3 Conclusion and discussions

In summary, our results show connections between the verifiability of quantum advantages and the quantum cryptographic primitives. It is worth noting that computational tasks demonstrating quantum advantages on near-term quantum devices might not directly result in useful applications; however, our results show that the quest for quantum advantages and their verifiability can provide new insights and methods to build fundamental quantum cryptographic primitives. For a quantum experiment designer: The study of quantum cryptography can provide new insights into designing a verifiable quantum advantage experiment. For a quantum cryptographer: The quest for verifiability of quantum advantages might lead to quantum cryptographic applications. Theorem 2 implies that if an experiment is not verifiable, then it will form a classical-secure EFI with a classical polynomial-time samplable distribution.

1 Extended abstract

Quantum theory is in principle compatible with processes that violate causal inequalities, an analogue of Bell inequalities that constrain the correlations observed by parties operating in a definite order [1–3]. To date, many examples of causal inequalities that are potentially violated by processes with indefinite causal order have been found [2, 4–11]. However, in general, the maximum quantum violations of these inequalities are still unknown even in the simplest cases, unlike in the case of Bell inequalities such as Clauser-Horne-Shimony-Holt (CHSH) inequality [12], for which Tsirelson bound provides the ultimate violation achievable in quantum theory. The lack of exact bounds on the quantum violation of causal inequalities limits our understanding of indefinite causal order in quantum mechanics. In addition, new questions have recently arisen from the introduction of a new class of scenarios where not only the causal order of the experiments, but also the temporal direction of the information flow within the local laboratories can be indefinite [13]. Can these scenarios lead to even larger violations? And in the affirmative case, where does the boundary lie between the correlations achievable with indefinite causal order alone and those achievable when indefinite causal order is combined with indefinite temporal direction?

Here we answer all the above questions. First, we develop a general method for bounding the violation of causal inequalities by quantum processes with indefinite causal order. We start by showing that the maximal violation of a special class of causal inequalities, termed *single-trigger causal inequalities*, can be determined explicitly. The maximal violation of single-trigger causal inequalities provides upper bounds on the violations of arbitrary causal inequalities. Mathematically, these upper bounds can be seen as an semidefinite programming (SDP) relaxation of the original problem of computing the maximal quantum violation of causal inequalities.

Using this method, we establish the analogue of Tsirelson bound for paradigmatic examples of causal inequalities. We show the maximal violation of the Oreshkov-Costa-Brukner (OCB) inequality [2] and the inequality associated with Lazy Guess Your Neighbor's Input game [5]. In addition, we provide a non-trivial upper bound of the success probability of Guess Your Neighbor's Input game [5]. Our results allow for a geometric representation of the quantum correlations arising from indefinite causal order. Intriguingly, we find that the geometric representation of the OCB correlations coincides with the representation of the CHSH correlations in the Bell inequality setting [14].

Then, we show that classical processes with indefinite causal order and time direction can violate all causal inequalities to their algebraic maximum. These processes are the classical version of the quantum processes with indefinite time direction introduced in Ref. [13]. They are in principle compatible with the validity of classical physics in the laboratories of the different parties, but do not assume a privileged direction of time outside each laboratory. In particular, we construct a classical process which allows two parties to perfectly signal to each other.

Our results offer new insights into the structure of the set of quantum correlations generated by quantum indefinite-causal-order processes, and can be used as a tool to better understand the operational implication of indefinite causal order in quantum

[*] `zixuanliu@connect.hku.hk`

[†] `giulio@cs.hku.hk`

theory. An open question is whether our general bound could be tight for all the other causal inequalities. The analogy with Bell inequalities, however, suggests a negative answer. In Bell scenarios, a converging sequence of upper bounds on the value of maximal quantum violations is provided by the Navascués-Pironio-Acín SDP hierarchy [15, 16]. The analogy with this situation suggests that our SDP relaxation may be just the first level of a a similar hierarchy of SDPs. Determining whether this analogy is correct, and, in the affirmative case, identifying the other levels of the hierarchy are among the most important research directions opened by our work. Another interesting direction is to extend our method for the calculation of the ICO bound to other type of inequalities with non-trivial causal structure, such as the inequalities recently studied in Refs. [17, 18]. Another interesting direction of future research is to establish self-testing results for causal inequalities, in analogy to the self-testing results in Bell scenarios [19, 20]. Such a self-testing result may have cryptographic implications, in a similar way as it was observed in the setting of Bell correlations. While the physical realization of the OCB process is still an open problem, these implications would provide important foundational insights into the operational understanding of indefinite causal order in quantum theory. Finally, our results open up a search for physical principles capable of explaining why the violation of causal inequalities by ICO quantum processes is not equal, in general, to the algebraic maximum, and, of determining the exact value of the quantum violation. In the context of Bell inequalities, the analogue question was originally raised by Popescu and Rohrlich [21], and led to the discovery of new information theoretic principles, such as non-trivial communication complexity [22–24], non-trivial nonlocal computation [25], information causality [26], macroscopic locality [27], and local orthogonality [28].

Abstract. We show that quantum entanglement provides an exponential advantage in learning properties of a bosonic continuous-variable (CV) system. Considering learning n bosonic mode random displacement channel, we prove that without an ancillary quantum memory, an exponential number of copies of the channel in n is required to estimate its characteristic function to reasonable precision. In contrast, we present an entanglement-assisted scheme that only requires the number of samples independent of n, given a sufficient amount of squeezing. This establishes an exponential separation in sample complexity. We then show that the entanglement-assisted scheme is sufficiently robust against photon loss.

Keywords: Quantum learning, Continuous-variable systems, Quantum advantage

1 Introduction

Learning and characterizing a physical system is a crucial task in science and technology. Over the past few years, there has been a huge interest in studying quantum advantage in learning a quantum system. Many of the previous results discovered a quantum advantage in learning using quantum memory in the sense that learning schemes allowed the use of entanglement with quantum memory to provide an exponential sample complexity advantage over any schemes without quantum memory. Specifically, Refs. [1, 2] establish a framework for proving exponential separation in sample complexity between learning with and without a coherently controllable quantum memory.

However, most learning tasks studied so far are restricted to discrete-variable (DV) systems. It is natural to ask whether entanglement-enabled advantage can also be realized for learning properties of bosonic continuous-variable (CV) systems. This is particularly important because CV systems are ubiquitous in nature and have many applications, such as quantum sensing. The main obstacle for generalizing the results in DV systems to CV systems is that the latter has an infinite-dimensional Hilbert space, making it challenging to formulate rigorous results concerning the complexity of learning properties of these systems. Recent progress has been achieved in studies of entanglement-enhanced learning of CV-state characteristic functions [3]; however, the lower bounds obtained so far apply to a restricted class of learning strategies rather than to general entanglement-free schemes.

In this work, we rigorously prove an entanglement-enabled advantage in learning an n-mode bosonic random displacement channel. Specifically, we show that any schemes without ancillary quantum memory require an exponential number of samples in n to learn the characteristic functions of the channel with reasonably good precision and high success probability. In stark contrast, we present a simple scheme utilizing entanglement with ancillary quantum memory (i.e., entanglement-assisted) that can complete the same learning task with a sample complexity independent of n, given access to two-mode squeezed vacuum (TMSV) states with sufficiently large squeezing parameter and Bell measurements (BM). This establishes an exponential separation between learning with and without entanglement in bosonic systems. The two learning scenarios are illustrated in Fig. 1. We emphasize that our hardness results hold for arbitrarily high-energy input states and arbitrary measurements, while the presented entanglement-assisted scheme only requires a finite-energy TMSV and BM.

2 Results

2.1 Main result

Our main result is to prove the exponential separation of sample complexity between two types of learning schemes, (i) entanglement-free scheme and (ii) entanglement-assisted scheme, for the random displacement channel, as illustrated in Fig. 1. The main

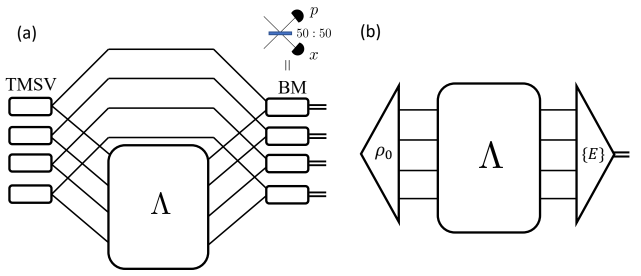

Figure 1: Schemes for learning an n-mode random displacement channel Λ. (a) TMSV+BM, a specific entanglement-assisted (EA) scheme. (b) General entanglement-free (EF) scheme (see the main text).

result is obtained by combining Theorem 1, proving the upper-bound of sample complexity for the proposed entanglement-assisted scheme and Theorem 2, proving the lower-bound of sample complexity for any entanglement-free schemes. Here, an entanglement-free scheme is (i) ancilla-free, i.e., not allowed to use ancillary memory, (ii) concatenation-free, i.e., the output of the channel is measured destructively after each channel use, but (iii) adaptive, i.e., for each channel use, the input to the channel and the measurement performed on the output may depend on measurement outcomes obtained in earlier rounds. On the other hand, a particular entanglement-assisted scheme we propose is allowed to use (i) ancilla, (ii) concatenation-free, and (iii) non-adaptive.

2.2 Problem setup

We consider the task of learning an n-mode random displacement channel characterized by a probability distribution $p(\alpha)$ with $\alpha \in \mathbb{C}^n$, which transforms an input state $\hat{\rho}$ as

$$\Lambda(\hat{\rho}) = \int d^{2n}\alpha\ p(\alpha)\hat{D}(\alpha)\hat{\rho}\hat{D}^\dagger(\alpha) \tag{1}$$

$$= \frac{1}{\pi^n}\int d^{2n}\beta\ \lambda(\beta)\mathrm{Tr}[\hat{\rho}\hat{D}(\beta)]\hat{D}^\dagger(\beta), \tag{2}$$

where $\hat{D}(\alpha) \equiv \otimes_{i=1}^n \hat{D}(\alpha_i)$ and $\hat{D}(\alpha_i) \equiv \exp(\alpha_i\hat{a}_i^\dagger - \alpha_i^*\hat{a}_i)$ is the displacement operator for the ith mode. Here, the second equivalent expression is by the characteristic function of $p(\alpha)$, i.e., its Fourier transform, as

$$\lambda(\beta) \equiv \int d^{2n}\alpha\ p(\alpha)e^{\alpha^\dagger\beta-\beta^\dagger\alpha}. \tag{3}$$

Here, because of the Fourier relation, $\lambda(\beta)$ with a large β contributes to rapidly oscillating $p(\alpha)$. Since the domain of β is infinite in principle, we will focus on a restricted finite domain specified later. The goal of our learning task is to learn the channel by estimating the characteristic function $\lambda(\beta)$. We emphasize that this is different from identifying a particular displacement that is drawn from the distribution $p(\alpha)$.

2.3 Entanglement-assisted scheme

Now, we present an entanglement-assisted scheme (see Fig. 1(a)). Consider an n-mode random displacement channel Λ_B acting on the n-mode system B. To learn this channel, we prepare n CV Bell states with a finite squeezing parameter r, which is a two-mode squeezed vacuum (TMSV) state, and half of the states go through the channel while the other half stays in quantum memory. Finally, we measure the output state by CV Bell measurement (BM), which can be implemented by passing through a 50:50 beam splitter and performing homodyne measurement on output ports along different quadratures. To see how to learn a random displacement channel using this TMSV+BM scheme, we invoke the probability of obtaining outcome ζ from BM:

$$p_{EA}(\zeta) = \frac{1}{\pi^{2n}}\int d^{2n}\alpha\ \lambda(\alpha)e^{-e^{-2r}|\alpha|^2}e^{\alpha^\dagger\zeta-\zeta^\dagger\alpha}. \tag{4}$$

Fourier transforming to invert this relation, we obtain

$$\lambda(\beta) = e^{e^{-2r}|\beta|^2}\int d^{2n}\zeta\ p_{EA}(\zeta)e^{\zeta^\dagger\beta-\beta^\dagger\zeta}. \tag{5}$$

This expression indicates that, by sampling N measurement outcomes $\{\zeta^{(i)}\}_{i=1}^N$ from a TMSV+BM scheme, one can obtain an unbiased estimator $\tilde{\lambda}(\beta)$ of $\lambda(\beta)$ by defining $\tilde{\lambda}(\beta) \equiv \frac{1}{N}e^{e^{-2r}|\beta|^2}\sum_{i=1}^N e^{\zeta^{(i)\dagger}\beta-\beta^\dagger\zeta^{(i)}}$. Note that the same set of samples can be used to estimate $\lambda(\beta)$ for different values of β just by modifying the estimator. Using the Hoeffding's bound, we prove the following theorem:

Theorem 1 *For any n-mode random displacement channel Λ, after the TMSV+BM scheme with squeezing parameter r has learned from N copies of Λ, and then received a query $\beta \in \mathbb{C}^n$, it can provide an estimator $\tilde{\lambda}(\beta)$ of Λ's characteristic function $\lambda(\beta)$ such that $|\tilde{\lambda}(\beta) - \lambda(\beta)| \leq \epsilon$ with probability at least $1-\delta$, with the number of samples $N = 8e^{2e^{-2r}|\beta|^2}\epsilon^{-2}\log 4\delta^{-1}$.*

Here, if we confine the domain of β to $|\beta|^2 \leq \kappa n$ with a constant $\kappa > 0$, we obtain an upper bound on the sample complexity for achieving an error ϵ with success probability $1-\delta$ using each scheme:

$$N_{EA} = O(e^{2e^{-2r}\kappa n}\epsilon^{-2}\log\delta^{-1}),. \tag{6}$$

In particular, if we choose the squeezing parameter as $r = \Omega(\log n)$, the sample complexity $N_{EA} = O(\epsilon^{-2}\log\delta^{-1})$ of the entanglement-assisted scheme becomes independent of the number of modes n, while our lower bound on sample complexity of the entanglement-free scheme increases exponentially with n (see below). Since the accessible squeezing parameter is bounded in practice, though, we will compare the sample complexities of the two schemes when r is an n-independent constant below.

2.4 Entanglement-free schemes

We now prove an exponential sample complexity lower bound for any entanglement-free scheme using information-theoretic methods. This highlights the indispensable role of entanglement for efficiently learning bosonic random displacement channels. Our result is as follows:

Theorem 2 *Let Λ be an arbitrary n-mode random displacement channel ($n \geq 8$) and consider an entanglement-free scheme that uses N copies of Λ. After all measurements are completed, the scheme receives the query $\beta \in \mathbb{C}^n$ and returns an estimate $\tilde{\lambda}(\beta)$ of Λ's characteristic function $\lambda(\beta)$. Suppose that, with success probability at least $2/3$, $|\tilde{\lambda}(\beta) - \lambda(\beta)| \leq \epsilon \leq 0.24$ for any β such that $|\beta|^2 \leq n\kappa$. Then $N \geq 0.01\epsilon^{-2}(1 + 1.98\kappa)^n$.*

Here, the success probability $2/3$ is arbitrary and can be easily amplified. Comparing with the sample complexity of the entanglement-assisted given in Eq. (6), Theorem 2 establishes an exponential separation in n for cutoff coefficient $\kappa = O(1)$ and squeezing parameter $r = \Omega(\log n)$. The intuition underlying this theorem is that displacement operators $\hat{D}(\beta)$ do not generally commute with each other. Consequently, entanglement-free measurements can resolve $\lambda(\beta)$ for only a small portion of β space.

The main idea of the proof of the theorem is (i) to define a family of "3-peak" random displacement channels $\mathbf{\Lambda}^{\epsilon,\sigma}_{\text{3-peak}} = \{\Lambda_\gamma\}_{\gamma \in \mathbb{C}^n}$ whose characteristic functions and distributions of displacement are, respectively,

$$\lambda_\gamma(\beta) = e^{-\frac{|\beta|^2}{2\sigma^2}} + 2i\epsilon_0 e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}} - 2i\epsilon_0 e^{-\frac{|\beta+\gamma|^2}{2\sigma^2}}, \qquad (7)$$

$$p_\gamma(\alpha) \propto e^{-2\sigma^2|\alpha|^2}\left(1 + 4\epsilon_0 \sin(2(\gamma_i\alpha_r - \gamma_r\alpha_i))\right), \qquad (8)$$

where $\sigma > 0$ and $\epsilon \equiv 0.98\epsilon_0$, and (ii) to consider a binary hypothesis testing of (1) $\Lambda = \Lambda_0$; (2) $\Lambda = \Lambda_\gamma$, for Gaussian random variable γ characterized by κ. Then, we can show that (iii) given a learning scheme satisfying the assumptions of Theorem 2, Bob can guess correctly with high probability. This means that the outcome distributions of Bob's scheme under hypotheses (1) and (2) must have a sufficiently large total variation distance (TVD). Finally, (iv) we can upper bound the contribution from each use of Λ to the TVD to be exponentially small. Therefore, the number of channel uses N must be exponentially large to ensure a large enough TVD, which gives us the desired lower bound.

2.5 Effect of loss

For practical applications, we analyze how the entanglement-assisted scheme is affected by photon loss, a dominant noise source in optical platforms. We consider two different places where the loss occurs: one is before applying the channel with loss rate $1-T_b$ to model the preparation imperfection, and the other is after applying the channel and before the perfect BM with loss rate $1 - T_a$, which models the finite efficiency of detection. As before, we derive the relation between the measurement probability distribution and the characteristic function of the channel:

$$\lambda(\beta) = e^{e^{-2r_{\text{eff}}}|\beta|^2} \int d^{2n}\zeta \; p_{loss}(\zeta) e^{(\zeta^\dagger\beta - \beta^\dagger\zeta)/\sqrt{T_a}}, \qquad (9)$$

where we define an effective squeezing parameter

$$r_{\text{eff}} \equiv -\frac{1}{2}\log\left(T_b e^{-2r} + (1 - T_b) + \frac{1 - T_a}{T_a}\right), \qquad (10)$$

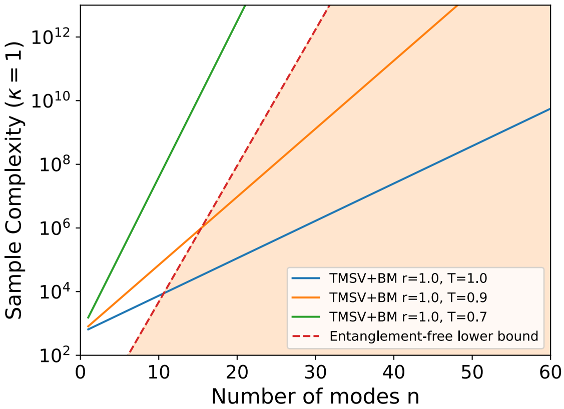

Figure 2: Comparison of TMSV+BM and the entanglement-free lower bound at $\kappa = 1$ for estimating any $\lambda(\beta)$ such that $|\beta|^2 \leq \kappa n$ with precision $\varepsilon = 0.2$ and success probability $1 - \delta = 2/3$. The orange region represents a rigorous advantage over all entanglement-free schemes.

which incorporates the loss rates. Because loss degrades the advantage from squeezing, the upper bound on sample complexity in Theorem 1 is modified as:

Theorem 3 *For the same task as in Theorem 1, a TMVS+BM scheme with squeezing parameter r and transmission rates before and after the channel to be T_b and T_a, respectively, can estimate any $\lambda(\beta)$ to error ϵ with success probability $1-\delta$ using the number of samples $N = 8e^{2e^{-2r_{\mathit{eff}}|\beta|^2}}\epsilon^{-2}\log 4\delta^{-1}$.*

Thus, when $|\beta|^2 \leq \kappa n$ with a constant $\kappa > 0$, $T_b = 1 - O(1/n)$, $T_a = 1 - O(1/n)$ and $r = \Omega(\log n)$, the sample complexity becomes $N = O(\epsilon^{-2}\log\delta^{-1})$ as in the lossless case. For practically relevant squeezing and including loss before BM, we compare the sample complexity for the lossy TMSV+BM protocol and the lossless entanglement-free lower bound in Fig. 2, finding a significant entanglement-enabled advantage in realistic experimental settings. Although the 10^9 number of samples required to achieve the advantage seems large, the state-of-the-art quantum optics experiments (e.g., Refs. [4, 5]) can attain such number of samples in a reasonable time with high sampling rate up to 160 GHz.

3 Discussion

We proved that schemes that exploit entanglement with an ancillary quantum memory can learn n-mode bosonic random displacement channels with exponentially fewer samples compared to entanglement-free schemes. Our results show that the information-theoretic framework for learning studied in DV quantum systems can be generalized to the CV setting and have powerful implications. We anticipate that these techniques can also be applied to other CV learning tasks. Besides generalizing other previous results known in DV systems, an interesting open question is to find a practical application of such an exponential advantage. We expect that it may have a direct connection to quantum sensing.

(Dated: March 1, 2024)

We show that quantum entanglement can provide an exponential advantage in learning properties of a bosonic continuous-variable (CV) system. The task we consider is estimating a probabilistic mixture of displacement operators acting on n bosonic modes, called a random displacement channel. We prove that if the n modes are not entangled with an ancillary quantum memory, then the channel must be sampled a number of times exponential in n in order to estimate its characteristic function to reasonable precision; this lower bound on sample complexity applies even if the channel inputs and measurements performed on channel outputs are chosen adaptively. On the other hand, we present a simple entanglement-assisted scheme that only requires a number of samples independent of n, given a sufficient amount of squeezing. This establishes an exponential separation in sample complexity. We then analyze the effect of photon loss and show that the entanglement-assisted scheme is still significantly more efficient than any lossless entanglement-free scheme under mild experimental conditions. Our work illuminates the role of entanglement in learning continuous-variable systems and points toward experimentally feasible demonstrations of provable entanglement-enabled advantage using CV quantum platforms.

Quantum science and technology holds promise to revolutionize how we understand and interact with nature, enabling computational speedups [1], classically impossible communication tasks [2, 3], and measurements with unprecedented sensitivity [4–6]. Rapid progress during the noisy intermediate-scale quantum (NISQ) era [7] has brought these promises closer to reality, but the challenge remains to demonstrate rigorous quantum advantage for practical problems.

Over the past few years, there has been ongoing theoretical and experimental progress in exploring quantum computational advantage [8–16]. Another recent line of research seeks quantum advantage in learning [17–24], revealing that access to quantum memory enables us to learn properties of nature more efficiently. Specifically, Refs. [18, 19] establish a framework for proving exponential separation in sample complexity between learning with and without a coherently controllable quantum memory. In contrast to its computational counterpart, this entanglement-enabled advantage in learning can be proven without invoking computational assumptions and can sometimes be more experimentally accessible. A proof-of-principle experiment has been conducted on Google's superconducting quantum processor using 40 qubits [18].

Most learning tasks studied so far are restricted to discrete-variable (DV) systems. It is natural to ask whether entanglement-enabled advantage can also be realized for learning properties of bosonic continuous-variable (CV) systems. This is particularly interesting and important because CV systems are ubiquitous in nature and have many applications in quantum information science, such as quantum sensing [6, 8, 25–27]. However, generalizing the results in DV systems to CV systems can be difficult because bosonic systems have infinite-dimensional Hilbert spaces, making it challenging to formulate rigorous results concerning the complexity of learning properties of these systems. Recent progress has been achieved in studies of entanglement-enhanced learning of CV-state characteristic functions [28]; however, the lower bounds obtained so far apply to a restricted class of learning strategies rather than to general entanglement-free schemes.

In this work, we rigorously establish an entanglement-enabled advantage in learning a probabilistic mixture of n-mode displacement operations, called a *bosonic random displacement channel*. Specifically, we show that any schemes without ancillary quantum memory require a number of samples exponential in n to learn the characteristic functions of the channel with reasonably good precision and high success probability. On the contrary, we present a simple scheme utilizing entanglement with ancillary quantum memory (*i.e.*, entanglement-assisted) that can complete the same learning task with a sample complexity independent of n, given access to two-mode squeezed vacuum (TMSV) states with sufficiently large squeezing parameter and Bell measurements (BM). This establishes an exponential separation between learning with and without entanglement in the bosonic system. The two learning scenarios are illustrated in Fig. 1. Note that our hardness results hold for arbitrarily high-energy input states and arbitrary measurements, while the presented entanglement-assisted scheme only requires a finite-energy TMSV and BM.

Furthermore, we analyze the robustness of this entanglement-enabled advantage under realistic experimental conditions. Specifically, we study the photon-loss effect, the most common noise source in optical platforms. Our results suggest that for squeezing parameters and loss rates achievable in a state-of-the-art bosonic experiment platform, the separation in sample complexity remains significant. Therefore, we anticipate that an experimental demonstration of entanglement-enabled advantage in CV quantum systems can be achieved in the near future.

Problem Setup.— We consider the task of learning an n-mode random displacement channel characterized by a probability distribution $p(\alpha)$ with $\alpha \in \mathbb{C}^n$, which transforms an input state $\hat{\rho}$ as

$$\Lambda(\hat{\rho}) = \int d^{2n}\alpha \; p(\alpha)\hat{D}(\alpha)\hat{\rho}\hat{D}^\dagger(\alpha), \tag{1}$$

where $\hat{D}(\alpha) := \otimes_{i=1}^n \hat{D}(\alpha_i)$ and $\hat{D}(\alpha_i) := \exp(\alpha_i\hat{a}_i^\dagger - \alpha_i^*\hat{a}_i)$ is the displacement operator for the ith mode. The random displacement channel can also be equivalently described by the characteristic function of $p(\alpha)$, *i.e.*, its Fourier transform, as (see SM S1 [29] for the derivation)

$$\Lambda(\hat{\rho}) = \frac{1}{\pi^n}\int d^{2n}\beta \; \lambda(\beta)\,\mathrm{Tr}[\hat{\rho}\hat{D}(\beta)]\hat{D}^\dagger(\beta), \tag{2}$$

$$\lambda(\beta) := \int d^{2n}\alpha \; p(\alpha)e^{\alpha^\dagger\beta - \beta^\dagger\alpha}. \tag{3}$$

Here, because of the Fourier relation, $\lambda(\beta)$ with a large β contributes to rapidly oscillating $p(\alpha)$. Since the domain of β is infinite in principle, we will focus on a restricted finite domain specified later. The goal is to learn the channel by estimating the characteristic function $\lambda(\beta)$. We emphasize that the goal is to characterize the channel, as opposed to identifying a particular displacement that is drawn from the distribution $p(\alpha)$. The value of β for which $\lambda(\beta)$ is to be estimated is revealed only after all measurements are completed.

We focus on the separation between two types of learning schemes for the random displacement channel distinguished by whether or not the scheme uses entanglement between the system and an ancilla, as illustrated in Fig. 1. Throughout this work, we define an entanglement-free scheme to be both ancilla-free and concatenation-free, i.e., the output of the channel is measured destructively after each channel use. However, the entanglement-free scheme is allowed to be adaptive; for each channel use, the input to the channel and the measurement performed on the output may depend on measurement outcomes obtained in earlier rounds. This scenario is similar to Refs. [17, 22]. Several recent works have obtained lower bounds on learning DV channels that hold even with concatenation [23, 30, 31], but we will not analyze the consequences of concatenating CV channels in this work for simplicity.

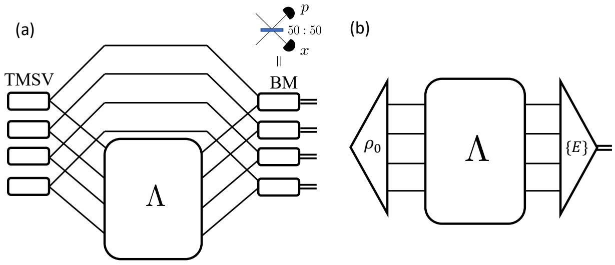

FIG. 1. Schemes for learning an n-mode random displacement channel Λ. (a) TMSV+BM, a specific entanglement-assisted (EA) scheme. (b) General entanglement-free (EF) scheme. Here we assume no concatenation is allowed, i.e., each copy of the channel acts on some input state ρ_0 and is measured destructively by some POVM $\{E\}$. The input state and measurement are allowed to be adaptively chosen depending on previous outcomes. An example of EF scheme is Vacuum+Heterodyne (see the main text).

Schemes.— Now, we present an entanglement-assisted scheme (see Fig. 1) inspired by a similar scheme to which has been proposed in DV Pauli channel estimation in Ref. [23]. Consider an n-mode random displacement channel Λ_B acting on the n-mode system B. To learn this channel, we prepare n CV Bell states with a finite squeezing parameter r, which is a two-mode squeezed vacuum (TMSV) state, and half of the states go through the channel while the other half stays in quantum memory. Finally, we measure the output state by CV Bell measurement (BM), which can be implemented by passing through a 50:50 beam splitter and performing homodyne measurement on output ports along different quadratures [27]. Formally, the BM POVM element labeled by $\{\zeta \in \mathbb{C}^n\}$ has the following form: $(I\otimes\hat{D}(\zeta))|\Psi\rangle\langle\Psi|(I\otimes\hat{D}^\dagger(\zeta))/\pi^n$; here $|\Psi\rangle$ denotes the tensor product of n infinitely squeezed TMSV states, each proportional to $\sum_{k=0}^\infty |k\rangle|k\rangle$ when expressed in the Fock basis. To see how to learn a random displacement channel using this TMSV+BM scheme, we invoke the probability of obtaining outcome ζ from BM (see SM S2 A [29] for the derivation):

$$p_{EA}(\zeta) = \frac{1}{\pi^{2n}}\int d^{2n}\alpha \; \lambda(\alpha)e^{-e^{-2r}|\alpha|^2}e^{\alpha^\dagger\zeta - \zeta^\dagger\alpha}. \tag{4}$$

Fourier transforming to invert this relation, we obtain

$$\begin{aligned}\lambda(\beta) &= e^{e^{-2r}|\beta|^2}\int d^{2n}\zeta\; p_{EA}(\zeta)e^{\zeta^\dagger\beta-\beta^\dagger\zeta} \\ &:= e^{e^{-2r}|\beta|^2}\lambda_{EA}(\beta).\end{aligned} \tag{5}$$

This expression indicates that, by sampling N measurement outcomes $\{\zeta^{(i)}\}_{i=1}^N$ from a TMSV+BM scheme, one can obtain an unbiased estimator $\tilde{\lambda}(\beta)$ of $\lambda(\beta)$ by defining $\tilde{\lambda}(\beta) := \frac{1}{N}e^{e^{-2r}|\beta|^2}\sum_{i=1}^N e^{\zeta^{(i)\dagger}\beta-\beta^\dagger\zeta^{(i)}}$. Note that the same set of samples can be used to estimate $\lambda(\beta)$ for different values of β just by modifying the estimator. Using the Hoeffding's bound, we prove the following theorem (see SM S2 A for the proof):

Theorem 1. *For any n-mode random displacement channel Λ, after the TMSV+BM scheme with squeezing parameter r has learned from N copies of Λ, and then received a query $\beta \in \mathbb{C}^n$, it can provide an estimator $\tilde{\lambda}(\beta)$ of Λ's characteristic function $\lambda(\beta)$ such that $|\tilde{\lambda}(\beta)-\lambda(\beta)| \le \epsilon$ with probability at least $1-\delta$, with the number of samples $N = 8e^{2e^{-2r}|\beta|^2}\epsilon^{-2}\log 4\delta^{-1}$.*

Let us compare the TMSV+BM scheme with a particular entanglement-free scheme that uses the vacuum state as input and heterodyne detection (Vacuum+Heterodyne). Here, heterodyne detection is defined as a projection onto the (overcomplete) basis of coherent states, i.e., $|\zeta\rangle\langle\zeta|/\pi^n$ with $\zeta \in \mathbb{C}^n$. Though it may not be the optimal entanglement-free scheme, this specific scheme helps us understand the limitations of entanglement-free schemes, which we capture more generally in Theorem 2 below.

In this scheme, the probability of obtaining POVM outcome ζ is (see SM S2 B [29])

$$p_{VH}(\zeta) = \frac{1}{\pi^{2n}}\int d^{2n}\alpha\; \lambda(\alpha)e^{\alpha^\dagger\zeta-\zeta^\dagger\alpha}e^{-|\alpha|^2}. \tag{6}$$

In fact, the Vacuum+Heterodyne scheme can be understood as the TMSV+BM scheme with $r=0$. Inverting this relation by Fourier transforming, we may express the channel's characteristic function in terms of the measurement probability distribution:

$$\lambda(\beta) = e^{|\beta|^2}\int d^{2n}\zeta\; p_{VH}(\zeta)e^{\zeta^\dagger\beta-\beta^\dagger\zeta} := e^{|\beta|^2}\lambda_{VH}(\beta), \tag{7}$$

which yields another unbiased estimator $\tilde{\lambda}(\beta) := \frac{1}{N}e^{|\beta|^2}\sum_{i=1}^N e^{\zeta^{(i)\dagger}\beta-\beta^\dagger\zeta^{(i)}}$ given N samples $\{\zeta^{(i)}\}_{i=1}^N$. Comparing to (5), we see that the r-dependent prefactor is missing from (7). Specifically, if we confine β to $|\beta|^2 \le \kappa n$ with a constant $\kappa > 0$, we obtain upper bounds on the sample complexity for achieving an error ϵ with success probability $1-\delta$ using each scheme:

$$N_{EA} = O(e^{2e^{-2r}\kappa n}\epsilon^{-2}\log\delta^{-1}), \tag{8}$$

$$N_{VH} = O(e^{2\kappa n}\epsilon^{-2}\log\delta^{-1}). \tag{9}$$

In particular, if we choose the squeezing parameter as $r = \Omega(\log n)$, the sample complexity $N_{EA} = O(\epsilon^{-2}\log\delta^{-1})$ of the entanglement-assisted scheme becomes independent of the number of modes n, while our upper bound on sample complexity of the entanglement-free scheme increases exponentially with n. Since the accessible squeezing parameter is bounded in practice, though, we will compare the sample complexities of the two schemes when r is an n-independent constant below.

To illustrate the difference, we compare TMSV+BM and Vacuum+Heterodyne strategies with an example in Fig. 2. We consider a single-mode channel for ease of visualization, characterized by

$$\begin{aligned}p(\alpha) = \frac{2\sigma^2}{\pi}e^{-2\sigma^2|\alpha|^2}[&\cos^2(\alpha_r\gamma_i-\alpha_i\gamma_r) \\ &+\sin^2(\alpha_r\gamma_r+\alpha_i\gamma_i)],\end{aligned} \tag{10}$$

$$\begin{aligned}\lambda(\beta) = e^{-\frac{|\beta|^2}{2\sigma^2}} &+ \frac{1}{4}e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}} + \frac{1}{4}e^{-\frac{|\beta+\gamma|^2}{2\sigma^2}} \\ &- \frac{1}{4}e^{-\frac{|\beta-i\gamma|^2}{2\sigma^2}} - \frac{1}{4}e^{-\frac{|\beta+i\gamma|^2}{2\sigma^2}},\end{aligned} \tag{11}$$

with $\sigma = 0.3$, $\gamma_r = 1.6$, $\gamma_i = 0$ ($\gamma := \gamma_r + i\gamma_i$), and $r = 2$ for the TMSV+BM scheme. The figure, where we present the underlying output probability distributions and their characteristic functions from Eqs. (4),(5),(6), and (7), clearly shows that in the TMSV+BM scheme with a sufficiently large squeezing parameter, the resultant probability distribution and characteristic function are almost identical to the ideal case. However, for the Vacuum+Heterodyne scheme, the vacuum noise distorts the initial probability distribution so significantly that we cannot see the signal clearly, which thus makes it harder to estimate the original characteristic function.

Lower bound.— Our upper bound on the sample complexity of the Vacuum+Heterodyne scheme scales exponentially with n. Can this scaling be improved using more advanced entanglement-free schemes, such as homodyne or general-dyne detection [27, 32], or by non-Gaussian resources like GKP states [33] or photon-number resolving measurements [34]? Here, using information-theoretic methods, we prove an exponential sample complexity lower bound for any entanglement-free scheme. This highlights the indispensable role of entanglement for efficiently learning bosonic random displacement channels. Our result is as follows:

Theorem 2. *Let Λ be an arbitrary n-mode random displacement channel ($n \ge 8$) and consider an entanglement-free scheme that uses N copies of Λ. After all measurements are completed, the scheme receives the query $\beta \in \mathbb{C}^n$ and returns an estimate $\tilde{\lambda}(\beta)$ of Λ's characteristic function $\lambda(\beta)$. Suppose that, with success probability at least 2/3, $|\tilde{\lambda}(\beta)-\lambda(\beta)| \le \epsilon \le 0.24$ for all β such that $|\beta|^2 \le n\kappa$. Then $N \ge 0.01\epsilon^{-2}(1+1.98\kappa)^n$.*

Here, the choice of success probability 2/3 is arbitrary and can be easily amplified. Comparing with the

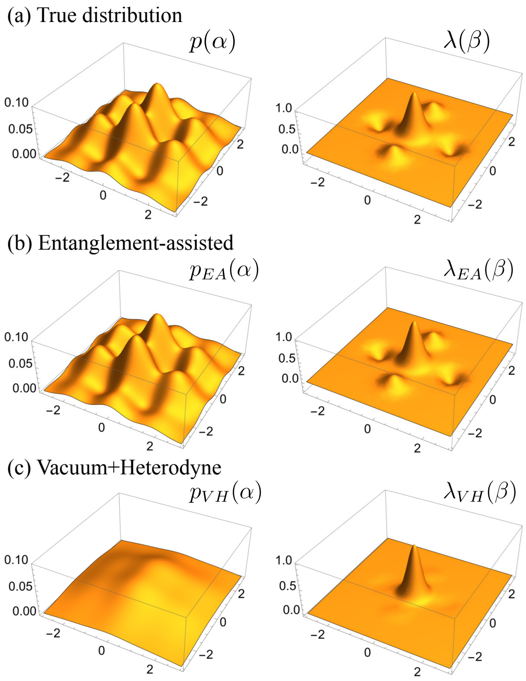

FIG. 2. Comparison between (a) the true distribution, (b) TMSV+BM, and (c) Vacuum+Heterodyne strategies. The left panel represents the probability distribution of the true distribution and measurement probability distributions for each scheme. The right panel represents the characteristic function of probability distributions.

entanglement-assisted sample complexity given in Eq. (8), Theorem 2 establishes a separation exponential in n for cutoff coefficient $\kappa = O(1)$ and squeezing parameter $r = \Omega(\log n)$. The intuition underlying this theorem is that displacement operators $\hat{D}(\beta)$ do not generally commute with each other. Consequently, entanglement-free measurements can resolve $\lambda(\beta)$ for only a small portion of β space. We sketch the proof below and leave the full details to SM S3 [29].

Proof Sketch. Our proof extends the techniques of Refs. [18, 23] to the CV case. We begin by defining the following family of "3-peak" random displacement channels $\mathbf{\Lambda}^{\epsilon,\sigma}_{\text{3-peak}} = \{\Lambda_\gamma\}_{\gamma\in\mathbb{C}^n}$ whose characteristic functions and distributions of displacement are, respectively,

$$\lambda_\gamma(\beta) = e^{-\frac{|\beta|^2}{2\sigma^2}} + 2i\epsilon_0 e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}} - 2i\epsilon_0 e^{-\frac{|\beta+\gamma|^2}{2\sigma^2}}, \qquad (12)$$

$$p_\gamma(\alpha) \propto e^{-2\sigma^2|\alpha|^2}\left(1 + 4\epsilon_0 \sin(2(\gamma_i\alpha_r - \gamma_r\alpha_i))\right). \qquad (13)$$

with positive parameters σ and $\epsilon := 0.98\epsilon_0$. We will show that, even with the prior knowledge that the channel is from this family, it is still hard for entanglement-free schemes to complete the learning tasks.

The key idea is to reduce learning to binary hypothesis testing. Consider the following game between Alice and Bob: Alice chooses one of two hypotheses with equal probability: (1) Set $\Lambda = \Lambda_0$; (2) Set $\Lambda = \Lambda_\gamma$, for γ sampled from a zero-mean homogeneous Gaussian distribution whose variance is determined by κ. Next, Alice allows Bob to use the channel Λ N times, and Bob uses his favorite entanglement-free scheme to learn from these channel uses. After Bob has finished all quantum measurements and keeps only classical data, Alice reveals some auxiliary information to Bob, who is then asked to decide whether Alice has chosen (1) or (2).

Given a learning scheme satisfying the assumptions of Theorem 2, Bob can guess correctly with high probability. This means that the outcome distributions of Bob's scheme under hypotheses (1) and (2) must have a sufficiently large total variation distance (TVD). On the other hand, we can upper bound the contribution from each use of Λ to the TVD to be exponentially small, where we use a technique inspired by Ref. [35] which derived the maximum fidelity of Gaussian random displacement channels. Therefore, the number of channel uses N must be exponentially large to ensure a large enough TVD, which gives us the desired lower bound. □

Effect of loss.— Now, for practical applications, we study how the entanglement-assisted scheme is affected by photon loss, a dominant noise source in optical platforms (see SM S2 D for a discussion of more general noise models, such as phase diffusion). Photon loss transforms the relevant bosonic operator $\hat{a}$ to $\sqrt{T}\hat{a} + \sqrt{1-T}\hat{e}$, where T is the transmission rate and $\hat{e}$ is the environmental mode, i.e., $1-T$ is the loss rate. We consider two different places where the loss occurs: one is before applying the channel with loss rate $1-T_b$ to model the preparation imperfection, and the other is after applying the channel and before the perfect BM with loss rate $1-T_a$, which models the finite efficiency of detection, *i.e.*, an imperfect BM [27]. As before, we derive the relation between the measurement probability distribution and the characteristic function of the channel (with appropriate rescaling of the phase):

$$\lambda(\beta) = e^{e^{-2r_{\text{eff}}}|\beta|^2} \int d^{2n}\zeta\; p_{loss}(\zeta) e^{(\zeta^\dagger\beta - \beta^\dagger\zeta)/\sqrt{T_a}}, \qquad (14)$$

where we define an effective squeezing parameter

$$r_{\text{eff}} := -\frac{1}{2}\log\left(T_b e^{-2r} + (1-T_b) + \frac{1-T_a}{T_a}\right), \qquad (15)$$

which incorporates the loss rates. Because loss degrades the advantage from squeezing, the upper bound on sample complexity in Theorem 1 is modified in the presence of loss (see SM S2 C for the proof):

Theorem 3. *For the same task as in Theorem 1, a TMVS+BM scheme with squeezing parameter r and transmission rates before and after the channel to be T_b and T_a, respectively, can estimate any $\lambda(\beta)$ to error ϵ with success probability $1-\delta$ using the number of samples*

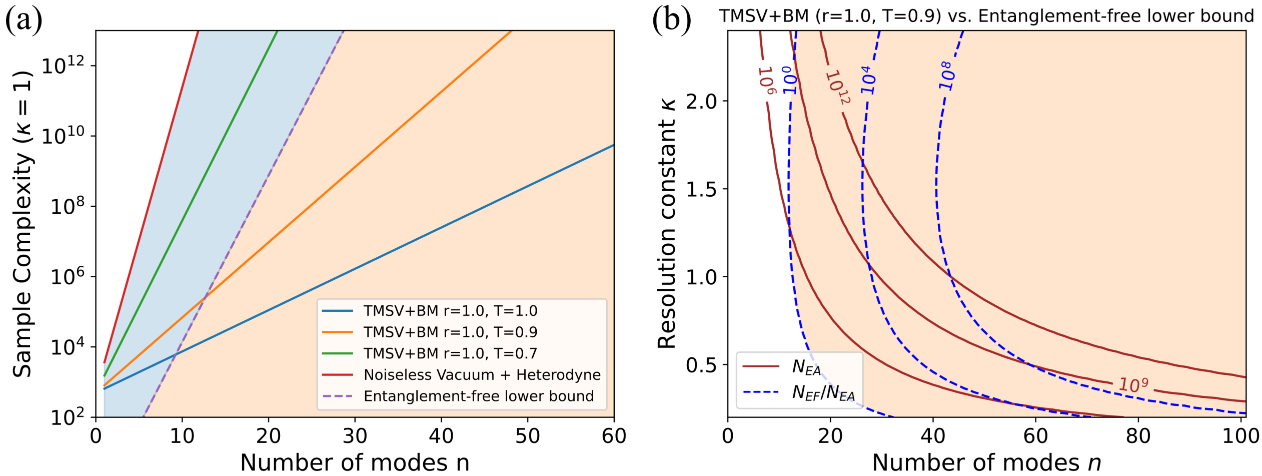

FIG. 3. (a) Comparison of TMSV+BM (with different loss rates), Vacuum+Heterodyne, and the entanglement-free lower bound at $\kappa = 1$. The task is to estimate any $\lambda(\beta)$ such that $|\beta|^2 \le \kappa n$ with precision $\varepsilon = 0.2$ and success probability $1 - \delta = 2/3$. The orange region represents a rigorous advantage over all entanglement-free schemes. The blue region represents an advantage over noiseless Vacuum+Heterodyne. (b) Comparison of the TMSV+BM scheme with squeezing parameter $r = 1.0$ and loss rate $1 - T = 0.1$ with the entanglement-free lower bound of Theorem 2. (See SM S3 A for further practical considerations.) The task is the same as (a). The brown solid contour lines represent the sample complexity of TMSV+BM given by Theorem 3. The blue dashed contour lines represent the ratio of sample complexity between the entanglement-free lower bound and TMSV+BM, indicating the entanglement-enabled advantage.

$N = 8e^{2e^{-2r_{\mathit{eff}}|\beta|^2}}\epsilon^{-2}\log 4\delta^{-1}$, *where* $r_{\rm eff}$ *is defined according to Eq.* (15).

Thus, when $|\beta|^2 \le \kappa n$ with a constant $\kappa > 0$, $T_b = 1 - O(1/n)$, $T_a = 1 - O(1/n)$ and $r = \Omega(\log n)$, the sample complexity becomes $N = O(\epsilon^{-2}\log\delta^{-1})$ as in the lossless case. For practically relevant squeezing and including loss prior to Bell measurement, we compare the sample complexity for the lossy TMSV+BM protocol and the lossless entanglement-free lower bound in Fig. 3, finding a significant entanglement-enabled advantage in realistic experimental settings. Specifically, for reasonable parameter choices such as squeezing parameter $r = 1$, loss rate 10%, and $\kappa = O(1)$, we can achieve a factor of 10^4 (10^8) advantage for around $n = 30$ (60) modes. Although the 10^9 number of samples required to achieve the advantage seems large, the state-of-the-art quantum optics experiments (e.g., Refs. [36, 37]) can attain such number of samples in a reasonable time with high sampling rate up to 160 GHz.

Discussion.— We proved that schemes that exploit entanglement with an ancillary quantum memory can learn n-mode bosonic random displacement channels with exponentially fewer samples compared to entanglement-free schemes. Our results show that the information-theoretic framework for learning studied in DV quantum systems [17, 19] can be generalized to the CV setting and have powerful implications. We anticipate that these techniques can be applied to other CV learning tasks as well. In addition, our analysis suggests that the separation in sample complexity between entanglement-assisted and entanglement-free protocols may be realized in the near future.

Apart from their theoretical interest, random displacement channels can also be practically relevant in, *e.g.*, modeling noise in bosonic systems. As in the qubit case [38], we expect that noise tailoring methods can transform more general noise models into random displacement channels; therefore efficiently learning random displacement channels can be useful for benchmarking CV quantum systems [39, 40] and for error mitigation.

Displacement estimation is also studied in quantum metrology (see *e.g.* [41–43]). A task often considered in metrology is learning an unknown *unitary* displacement or phase transformation acting independently on each mode [36, 42, 44–47] whereas the task analyzed in this word is learning an unknown *mixture* of multimode displacements. Furthermore, while the goal in metrology is typically to learn one or a few parameters, in our case, the parameter space is very large. Therefore, the methodology in the two settings is quite different. Connections between metrology and bosonic channel learning are worthy of further exploration.

CONTENTS

S1. PRELIMINARY

In this section, we provide some identities that are frequently used in Supplemental Material (more details can be found in Refs. [1–3]). First, an elementary operator in n-mode bosonic system is n-mode displacement operator $\hat{D}(\beta) \coloneqq e^{\beta\hat{a}^\dagger - \beta^\dagger\hat{a}}$, where $\beta \coloneqq (\beta_1, \dots, \beta_n)^{\mathrm{T}} \in \mathbb{C}^n$, $\hat{a} \coloneqq$

[*] These authors contributed equally to this work: C.O. (changhun0218@gmail.com); S.C. (csenrui@uchicago.edu).
[†] liang.jiang@uchicago.edu
[‡] preskill@caltech.edu

$(\hat{a}_1, \dots, \hat{a}_n)^{\mathrm{T}}$ and $\hat{a}^\dagger \coloneqq (\hat{a}_1^\dagger, \dots, \hat{a}_n^\dagger)^{\mathrm{T}}$ are annihilation and creation operator of bosons, which follow the commutation relation $[\hat{a}_i, \hat{a}_j^\dagger] = \delta_{ij}$. Displacement operator $\hat{D}(\beta)$ forms an orthogonal basis in the operator space; thus, any operator $\hat{O}$ can be expanded by displacement operators as

$$\hat{O} = \frac{1}{\pi^n} \int d^{2n}\beta \, \mathrm{Tr}\Big[\hat{O}\hat{D}(\beta)\Big] \hat{D}^\dagger(\beta), \tag{S1}$$

where $\mathrm{Tr}[\hat{O}\hat{D}(\beta)]$ is called the characteristic function of an operator $\hat{O}$. The n-mode displacement operator has the following properties

$$\hat{D}^\dagger(\beta) = \hat{D}(-\beta), \quad \hat{D}^*(\beta) = \hat{D}(\beta^*), \quad \hat{D}^{\mathrm{T}}(\beta) = \hat{D}(-\beta^*), \quad \mathrm{Tr}\Big[\hat{D}(\beta)\Big] = \pi^n \delta^{(2n)}(\beta), \tag{S2}$$

$$\hat{D}(\beta_1)\hat{D}(\beta_2) = \hat{D}(\beta_1 + \beta_2) e^{(\beta_2^\dagger \beta_1 - \beta_1^\dagger \beta_2)/2}, \quad \hat{D}(\alpha)\hat{D}^\dagger(\beta)\hat{D}^\dagger(\alpha) = \hat{D}^\dagger(\beta) e^{\alpha^\dagger \beta - \beta^\dagger \alpha}, \tag{S3}$$

$$\int \frac{d^{2n}\beta}{\pi^n} \hat{D}(\beta) O \hat{D}^\dagger(\beta) = \mathrm{Tr}[O]\mathbb{1}, \tag{S4}$$

where the last identity is the twirling identity. We also frequently use the following identity:

$$\delta^{(2n)}(\alpha) = \frac{1}{\pi^{2n}} \int d^{2n}\beta e^{\beta^\dagger \alpha - \alpha^\dagger \beta}. \tag{S5}$$

Also, we employ the Wigner function of an operator $\hat{O}$ defined as

$$W_O(\alpha) = \frac{1}{\pi^{2n}} \int d^{2n}\beta \, \mathrm{Tr}\Big[\hat{O}\hat{D}(\beta)\Big] e^{\beta^\dagger \alpha - \alpha^\dagger \beta}. \tag{S6}$$

In Sec. S1 A, we show that for a given random displacement channel, which is defined by the probability distribution $p(\alpha)$, we can rewrite it by the Fourier transformation $\lambda(\beta)$ of $p(\alpha)$, i.e., its characteristic function, as

$$\Lambda(\hat{\rho}) \coloneqq \int d^{2n}\alpha p(\alpha) \hat{D}(\alpha) \hat{\rho} \hat{D}^\dagger(\alpha) = \frac{1}{\pi^n} \int d^{2n}\beta \lambda(\beta) \, \mathrm{Tr}\Big[\hat{\rho}\hat{D}(\beta)\Big] \hat{D}^\dagger(\beta), \tag{S7}$$

where the probability $p(\alpha)$ and the characteristic function $\lambda(\beta)$ follow the relation

$$\lambda(\beta) = \int d^{2n}\alpha \; p(\alpha) e^{\alpha^\dagger \beta - \beta^\dagger \alpha}, \quad p(\alpha) = \frac{1}{\pi^{2n}} \int d^{2n}\beta \; \lambda(\beta) e^{\beta^\dagger \alpha - \alpha^\dagger \beta}. \tag{S8}$$

A. Fourier relation

Here, we derive the expression of a random displacement channel characterized by a probability distribution $p(\alpha)$ by its characteristic function $\lambda(\beta)$. To see the relation, we use the identity (S1). Applying this for the density operator $\hat{\rho}$, we can show that

$$\Lambda(\hat{\rho}) = \int d^{2n}\alpha p(\alpha) \hat{D}(\alpha) \hat{\rho} \hat{D}^\dagger(\alpha) = \int d^{2n}\alpha p(\alpha) \hat{D}(\alpha) \left[\frac{1}{\pi^n} \int d^{2n}\beta \, \mathrm{Tr}\Big[\hat{\rho}\hat{D}(\beta)\Big] \hat{D}^\dagger(\beta)\right] \hat{D}^\dagger(\alpha) \tag{S9}$$

$$= \frac{1}{\pi^n} \int d^{2n}\alpha \int d^{2n}\beta p(\alpha) \, \mathrm{Tr}\Big[\hat{\rho}\hat{D}(\beta)\Big] \hat{D}(\alpha) \hat{D}^\dagger(\beta) \hat{D}^\dagger(\alpha) \tag{S10}$$

$$= \frac{1}{\pi^n} \int d^{2n}\alpha \int d^{2n}\beta p(\alpha) \, \mathrm{Tr}\Big[\hat{\rho}\hat{D}(\beta)\Big] \hat{D}^\dagger(\beta) e^{\alpha^\dagger \beta - \beta^\dagger \alpha} \tag{S11}$$

$$= \frac{1}{\pi^n} \int d^{2n}\beta \lambda(\beta) \, \mathrm{Tr}\Big[\hat{\rho}\hat{D}(\beta)\Big] \hat{D}^\dagger(\beta), \tag{S12}$$

where we used the identities from Eqs. (S3),(S5). Here, the last line renders the identity

$$\lambda(\beta) = \int d^{2n}\alpha p(\alpha) e^{\alpha^\dagger\beta - \beta^\dagger\alpha}. \tag{S13}$$

Thus, $\lambda(\beta)$ is the Fourier transform of $p(\alpha)$. Its inverse Fourier transformation gives

$$p(\alpha) = \frac{1}{\pi^{2n}} \int d^{2n}\beta \lambda(\beta) e^{\beta^\dagger\alpha - \alpha^\dagger\beta}. \tag{S14}$$

S2. DERIVATION OF OUTPUT PROBABILITY DISTRIBUTIONS OF EACH SCHEME

A. Entanglement-assisted (TMSV+BM) schemes

In this section, we consider the two-mode squeezed vacuum and Bell measurement (TMSV+BM) strategy (see Fig. 1(a) in the main text.) and prove Theorem 1 in the main text by deriving the sample complexity of the strategy. We assume a lossless system and a perfect Bell measurement, whereas the input squeezed state has a finite squeezing parameter r since the input squeezing parameter r is typically upper-bounded by a constant in practice. We then analyze the effect of the imperfect measurement and loss in Sec. S2 C.

We now derive the probability of outcomes of the strategy, i.e., the outcomes obtained by applying an n-mode channel Λ onto a product state of a subsystem of n TMSV states $|\tilde{\Psi}\rangle$ and measuring in the Bell basis $|\Psi(\zeta)\rangle\langle\Psi(\zeta)|/\pi^n$ with $\zeta \in \mathbb{C}^n$:

$$p_{EA}(\zeta) = \frac{1}{\pi^n} \operatorname{Tr}\Big[(|\Psi(\zeta)\rangle\langle\Psi(\zeta)|_{AB})(\mathcal{I}_A \otimes \Lambda_B)(|\tilde{\Psi}\rangle\langle\tilde{\Psi}|_{AB})\Big]. \tag{S15}$$

To simplify the expression, we rewrite a TMSV state. To do that, let us first consider a single-mode squeezed state $|r\rangle := \hat{S}(r)|0\rangle$:

$$|r\rangle\langle r| = \frac{1}{\pi}\int d^2\alpha \hat{D}^\dagger(\alpha) \operatorname{Tr}\Big[\hat{D}(\alpha)|r\rangle\langle r|\Big] := \frac{1}{\pi}\int d^2\alpha \hat{D}^\dagger(\alpha) f(\alpha, r), \tag{S16}$$

where $\hat{S}(r) := \exp\Big[r(\hat{a}^{\dagger 2} - \hat{a}^2)/2\Big]$ is the squeezing operation and we have defined

$$f(\alpha, r) := \operatorname{Tr}\Big[\hat{D}(\alpha)|r\rangle\langle r|\Big] = \langle 0|\hat{S}^\dagger(r)\hat{D}(\alpha)\hat{S}(r)|0\rangle = \langle 0|\hat{D}(\alpha\cosh r - \alpha^*\sinh r)|0\rangle \tag{S17}$$

$$= \exp\left(-\frac{1}{2}|\alpha\cosh r - \alpha^*\sinh r|^2\right). \tag{S18}$$

Here, we have used the relation, $\hat{S}^\dagger(r)\hat{a}\hat{S}(r) = \hat{a}\cosh r + \hat{a}^\dagger \sinh r$. Using the fact that a TMSV state can be generated by injecting two single-mode squeezed states into the 50:50 beam splitter, i.e., $\hat{U}_{\rm BS}(|r\rangle\langle r| \otimes |-r\rangle\langle -r|)\hat{U}_{\rm BS}^\dagger = |\tilde{\Psi}(r)\rangle\langle\tilde{\Psi}(r)|$, where $\hat{U}_{\rm BS}$ is 50:50 beam splitter, we can rewrite the TMSV state $|\tilde{\Psi}(r)\rangle$ as

$$|\tilde{\Psi}(r)\rangle\langle\tilde{\Psi}(r)| = \frac{1}{\pi^2}\int d^2\alpha_1 d^2\alpha_2 \hat{U}_{\rm BS}[\hat{D}^\dagger(\alpha_1)\otimes\hat{D}^\dagger(\alpha_2)]\hat{U}_{\rm BS}^\dagger f(\alpha_1, r) f(\alpha_2, -r) \tag{S19}$$

$$= \frac{1}{\pi^2}\int d^2\alpha_1 d^2\alpha_2 \hat{D}^\dagger\left(\frac{\alpha_1-\alpha_2}{\sqrt{2}}\right)\otimes\hat{D}^\dagger\left(\frac{\alpha_1+\alpha_2}{\sqrt{2}}\right) f(\alpha_1, r) f(\alpha_2, -r) \tag{S20}$$

$$= \frac{1}{\pi^2}\int d^2\omega_1 d^2\omega_2 \hat{D}^\dagger(\omega_1)\otimes\hat{D}^\dagger(\omega_2) f\left(\frac{\omega_1+\omega_2}{\sqrt{2}}, r\right) f\left(\frac{\omega_2-\omega_1}{\sqrt{2}}, -r\right) \tag{S21}$$

$$:= \frac{1}{\pi^2}\int d^2\omega_1 d^2\omega_2 \hat{D}^\dagger(\omega_1)\otimes\hat{D}^\dagger(\omega_2) g(w_1, w_2, r), \tag{S22}$$

where we defined

$$g(\omega_1,\omega_2,r) := f\left(\frac{\omega_1+\omega_2}{\sqrt{2}},r\right) f\left(\frac{\omega_2-\omega_1}{\sqrt{2}},-r\right) \tag{S23}$$

$$= \exp\left[-\frac{1}{2}\Big[(|\omega_1|^2+|\omega_2|^2)\cosh 2r - (\omega_1\omega_2+\omega_1^*\omega_2^*)\sinh 2r\Big]\right], \tag{S24}$$

which is the characteristic function of the TMSV state $|\tilde{\Psi}(r)\rangle$ by Eq. (S1), i.e.,

$$g(\omega_1,\omega_2,r) := \mathrm{Tr}\Big[|\tilde{\Psi}(r)\rangle\langle\tilde{\Psi}(r)|(\hat{D}(\omega_1)\otimes\hat{D}(\omega_2))\Big]. \tag{S25}$$

Multiple TMSV states are straightforward to generalize:

$$g(\omega_1,\omega_2,r) := \exp\left[-\frac{1}{2}\Big[(|\omega_1|^2+|\omega_2|^2)\cosh 2r - (\omega_1\cdot\omega_2+\omega_1^*\cdot\omega_2^*)\sinh 2r\Big]\right], \tag{S26}$$

where $\omega_{1,2}$ are now n-dimensional complex vectors. Especially when $\omega_2=\omega_1^*$, it reduces to

$$g(\omega_1,\omega_1^*,r) = \exp\Big(-e^{-2r}|\omega_1|^2\Big). \tag{S27}$$

Therefore, the input TMSV states can be written as

$$|\tilde{\Psi}(r)\rangle\langle\tilde{\Psi}(r)| = \frac{1}{\pi^{2n}}\int d^{2n}\omega_1 d^{2n}\omega_2 \hat{D}^\dagger(\omega_1)\otimes\hat{D}^\dagger(\omega_2)g(w_1,w_2,r). \tag{S28}$$

Similarly, by generalizing an entangled state with a single-mode ancilla to an entangled state with n modes and infinite squeezing, the measurement POVM of CV Bell measurement can be written as [2, 3]

$$\frac{1}{\pi^n}|\Psi(\zeta)\rangle\langle\Psi(\zeta)| = \frac{1}{\pi^n}(I\otimes\hat{D}(\zeta))|\Psi\rangle\langle\Psi|(I\otimes\hat{D}^\dagger(\zeta)) = \int\frac{d^{2n}\omega}{\pi^{2n}}e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega}\hat{D}^\dagger(\omega)\otimes\hat{D}^{\mathrm{T}}(\omega), \tag{S29}$$

where

$$|\Psi\rangle\langle\Psi| := \int\frac{d^{2n}\omega}{\pi^n}\hat{D}^\dagger(\omega)\otimes\hat{D}^{\mathrm{T}}(\omega) \tag{S30}$$

corresponds to a multimode generalization of a TMSV state with infinite squeezing parameter, i.e., $|\Psi\rangle\propto\sum_{k=0}^\infty|k\rangle|k\rangle$. Here, the normalization factor $1/\pi^n$ is introduced to ensure the completeness

$$\frac{1}{\pi^n}\int d^{2n}\zeta|\Psi(\zeta)\rangle\langle\Psi(\zeta)| = \mathbb{1}\otimes\mathbb{1}. \tag{S31}$$

We now simplify the expression of the output probability distribution of the scheme:

$$p_{EA}(\zeta)$$
$$= \frac{1}{\pi^n}\mathrm{Tr}\left[(|\Psi(\zeta)\rangle\langle\Psi(\zeta)|_{AB})(\mathcal{I}_A\otimes\Lambda_B)(|\tilde{\Psi}\rangle\langle\tilde{\Psi}|_{AB})\right] \tag{S32}$$
$$= \frac{1}{\pi^n}\mathrm{Tr}\left[\int\frac{d^{2n}\omega}{\pi^n}\frac{d^{2n}\beta_1 d^{2n}\beta_2}{\pi^{2n}}g(\beta_1,\beta_2,r)e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega}\hat{D}^\dagger(\omega)_A\otimes\hat{D}^{\mathrm{T}}(\omega)_B(\mathcal{I}_A\otimes\Lambda_B)(\hat{D}^\dagger(\beta_1)_A\otimes\hat{D}^\dagger(\beta_2)_B)\right]. \tag{S33}$$

Here, we have

$$(\mathcal{I}_A\otimes\Lambda_B)(\hat{D}^\dagger(\beta_1)_A\otimes\hat{D}^\dagger(\beta_2)_B) = \hat{D}^\dagger(\beta_1)_A\otimes\frac{1}{\pi^n}\int d^{2n}\omega\lambda(\omega)\,\mathrm{Tr}\Big[\hat{D}^\dagger(\beta_2)_B\hat{D}(\omega)_B\Big]\hat{D}^\dagger(\omega)_B \tag{S34}$$
$$= \hat{D}^\dagger(\beta_1)_A\otimes\int d^{2n}\omega\lambda(\omega)\delta(\omega-\beta_2)\hat{D}^\dagger(\omega)_B \tag{S35}$$
$$= \lambda(\beta_2)\hat{D}^\dagger(\beta_1)_A\otimes\hat{D}^\dagger(\beta_2)_B. \tag{S36}$$

Thus, we can simplify Eq. (S32) as

$$\frac{1}{\pi^n}\operatorname{Tr}\left[\int \frac{d^{2n}\omega}{\pi^n}\frac{d^{2n}\beta_1 d^{2n}\beta_2}{\pi^{2n}} g(\beta_1,\beta_2,r)e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega}\hat{D}^\dagger(\omega)_A\otimes\hat{D}^{\mathrm{T}}(\omega)_B(\mathcal{I}_A\otimes\Lambda_B)(\hat{D}^\dagger(\beta_1)_A\otimes\hat{D}^\dagger(\beta_2)_B)\right] \tag{S37}$$

$$= \frac{1}{\pi^n}\int \frac{d^{2n}\omega}{\pi^n}\frac{d^{2n}\beta_1 d^{2n}\beta_2}{\pi^{2n}}\lambda(\beta_2) g(\beta_1,\beta_2,r)e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega}\operatorname{Tr}\Big[\hat{D}^\dagger(\omega)_A\hat{D}^\dagger(\beta_1)_A\Big]\operatorname{Tr}\Big[\hat{D}^{\mathrm{T}}(\omega)_B\hat{D}^\dagger(\beta_2)_B\Big] \tag{S38}$$

$$= \frac{1}{\pi^{2n}}\int d^{2n}\omega d^{2n}\beta_1 d^{2n}\beta_2\lambda(\beta_2)g(\beta_1,\beta_2,r)e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega}\delta(\omega+\beta_1)\delta(\omega^*+\beta_2) \tag{S39}$$

$$= \frac{1}{\pi^{2n}}\int d^{2n}\omega\lambda(-\omega^*)g(-\omega,-\omega^*,r)e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega}. \tag{S40}$$

Hence, we finally obtain the probability of obtaining ζ from Bell measurement with an initial Bell state with finite squeezing:

$$p_{EA}(\zeta) = \frac{1}{\pi^{2n}}\int d^{2n}\omega\lambda(-\omega^*)g(-\omega,-\omega^*,r)e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega} = \frac{1}{\pi^{2n}}\int d^{2n}\omega\lambda(-\omega^*)e^{-e^{-2r}|\omega|^2}e^{\zeta^*\cdot\omega^*-\zeta\cdot\omega}. \tag{S41}$$

By inverting the relation using Fourier transformation,

$$\int d^{2n}\zeta p_{EA}(\zeta)e^{\zeta^\dagger\beta-\beta^\dagger\zeta} = \frac{1}{\pi^{2n}}\int d^{2n}\omega\lambda(-\omega^*)g(-\omega,-\omega^*,r)e^{(\omega^*+\beta)\cdot\zeta^*-(\omega^*+\beta)^*\cdot\zeta} \tag{S42}$$

$$= \lambda(\beta)g(\beta^*,\beta,r), \tag{S43}$$

we obtain the relation between the characteristic function of the channel $\lambda(\beta)$ and the probability distribution of outcomes $p_{EA}(\zeta)$:

$$\lambda(\beta) = \frac{1}{g(\beta^*,\beta,r)}\int d^{2n}\zeta p_{EA}(\zeta)e^{\zeta^\dagger\beta-\beta^\dagger\zeta} = \exp\Big(e^{-2r}|\beta|^2\Big)\int d^{2n}\zeta p_{EA}(\zeta)e^{\zeta^\dagger\beta-\beta^\dagger\zeta}. \tag{S44}$$

The expression shows that by obtaining samples ζ's following the probability distribution using sampling in experiment and taking Fourier transformation, one can obtain the estimate of $\lambda(\beta)$. Now, we show the number of samples $N \geq \frac{8}{\epsilon^2}\log\frac{4}{\delta}e^{2e^{-2r}|\beta|^2} = O(e^{2e^{-2r}|\beta|^2}\epsilon^{-2}\log\delta^{-1})$ suffices to have a good precision ϵ with a high probability $1-\delta$. As observed above, for N number of samples, $\{\zeta^{(i)}\}_{i=1}^N$, we set the estimator of $\lambda(\beta)$ to be $\tilde{\lambda}(\beta) = \frac{1}{N}\sum_{i=1}^N \exp(e^{-2r}|\beta|^2)e^{\zeta^{(i)\dagger}\beta-\beta^\dagger\zeta^{(i)}}$ for measurement outcome ζ and apply the Hoeffding bound for the estimator. To do that, we find the bound for real part and imaginary part, respectively and combine them. We first obtain two different probabilities' bound by the Hoeffding bound such that

$$\Pr[|\tilde{\lambda}_r(\beta)-\lambda_r(\beta)|\leq\epsilon/2]\geq 1-2e^{-\frac{N\epsilon^2}{8}e^{-2e^{-2r}|\beta|^2}},\ \Pr[|\tilde{\lambda}_i(\beta)-\lambda_i(\beta)|\leq\epsilon/2]\geq 1-2e^{-\frac{N\epsilon^2}{8}e^{-2e^{-2r}|\beta|^2}}, \tag{S45}$$

where $\lambda_r = \mathrm{Re}(\lambda)$ and $\lambda_i = \mathrm{Im}(\lambda)$ and similar for $\tilde{\lambda}$. Applying the union bound and the triangle inequality, we obtain

$$\Pr[|\tilde{\lambda}(\beta)-\lambda(\beta)|\leq\epsilon]\geq 1-4e^{-\frac{N\epsilon^2}{8}e^{-2e^{-2r}|\beta|^2}}. \tag{S46}$$

Thus, if we choose the number of samples to be

$$N \geq \frac{8}{\epsilon^2}\log\frac{4}{\delta}e^{2e^{-2r}|\beta|^2} = O(e^{2e^{-2r}|\beta|^2}\epsilon^{-2}\log\delta^{-1}) \tag{S47}$$

the estimation error is upper-bounded by ϵ with high probability $1-\delta$. This completes the proof of Theorem 1 in the main text.

Note that in an ideal case where the input squeezing parameter r can be chosen to be arbitrarily large, the sample complexity can be reduced to $N = O(1/\epsilon^2)$ for any β.

B. Entanglement-free (Vacuum+Heterodyne) schemes

Now, let us consider the entanglement-free scheme with vacuum input and heterodyne detection (Vacuum+Heterodyne). In general, denoting Π_ϕ as a POVM with an outcome ϕ and $|\phi_0\rangle\langle\phi_0|$ as an input state, the probability of a classical scheme is written as

$$\begin{aligned}
p_{EF}(\phi) &= \mathrm{Tr}[\Pi_\phi \Lambda(|\phi_0\rangle\langle\phi_0|)] && \text{(S48)}\\
&= \frac{1}{\pi^{2n}} \int d^{2n}\alpha d^{2n}\beta \, \mathrm{Tr}\Big[\hat{D}(\alpha)\Lambda(\hat{D}^\dagger(\beta))\Big] \, \mathrm{Tr}\Big[\Pi_\phi \hat{D}^\dagger(\alpha)\Big] \, \mathrm{Tr}\Big[|\phi_0\rangle\langle\phi_0|\hat{D}(\beta)\Big] && \text{(S49)}\\
&= \frac{1}{\pi^{n}} \int d^{2n}\alpha d^{2n}\beta \lambda(\beta)\delta(\alpha-\beta) \, \mathrm{Tr}\Big[\Pi_\phi \hat{D}^\dagger(\alpha)\Big] \, \mathrm{Tr}\Big[|\phi_0\rangle\langle\phi_0|\hat{D}(\beta)\Big] && \text{(S50)}\\
&= \frac{1}{\pi^{n}} \int d^{2n}\beta \lambda(\beta) \, \mathrm{Tr}\Big[\Pi_\phi \hat{D}^\dagger(\beta)\Big] \, \mathrm{Tr}\Big[|\phi_0\rangle\langle\phi_0|\hat{D}(\beta)\Big]. && \text{(S51)}
\end{aligned}$$

For the Vacuum+Heterodyne scheme, we employ vacuum state input $|\phi_0\rangle = |0\rangle$ and heterodyne detection, whose POVM elements are described by projectors onto the (overcomplete) basis of coherent states, $|\zeta\rangle\langle\zeta|/\pi^n$, where $|\zeta\rangle$ is a coherent state with complex amplitude $\zeta \in \mathbb{C}^n$. Note that such a scheme is informationally complete in the sense that it provides distinct probability distributions for different channels. For this scheme, we can obtain the probability distribution

$$p_{VH}(\zeta) = \frac{1}{\pi^{2n}} \int d^{2n}\alpha \lambda(\alpha) \, \mathrm{Tr}\Big[|\zeta\rangle\langle\zeta|\hat{D}^\dagger(\alpha)\Big] \, \mathrm{Tr}\Big[|0\rangle\langle 0|\hat{D}(\alpha)\Big] = \frac{1}{\pi^{2n}} \int d^{2n}\alpha \lambda(\alpha) e^{\alpha^\dagger\zeta - \zeta^\dagger\alpha} e^{-|\alpha|^2}. \tag{S52}$$

Again, by inverting the probability distribution as

$$\int d^{2n}\zeta p_{VH}(\zeta) e^{\zeta^\dagger\beta - \beta^\dagger\zeta} = \frac{1}{\pi^{2n}} \int d^{2n}\zeta d^{2n}\alpha \lambda(\alpha) e^{\zeta^\dagger(\beta-\alpha) - (\beta-\alpha)^\dagger\zeta} e^{-|\alpha|^2} = \lambda(\beta) e^{-|\beta|^2}, \tag{S53}$$

we obtain the final relation between the measurement probability distribution and the characteristic function of the channel:

$$\lambda(\beta) = e^{|\beta|^2} \int d^{2n}\xi p_{VH}(\zeta) e^{\zeta^\dagger\beta - \beta^\dagger\zeta}. \tag{S54}$$

It clearly shows the difference from the quantum strategies, which is the prefactor $e^{|\beta|^2}$. Thus, similarly, after sampling ζ from experiments following $p_{EF}(\zeta)$ and averaging $e^{|\beta|^2} e^{\zeta^\dagger\beta - \beta^\dagger\zeta}$ over the samples, we obtain the estimate of $\lambda(\beta)$. As for the entanglement-assisted case, for N samples, $\{\zeta^{(i)}\}_{i=1}^N$, by setting the estimator $\tilde{\lambda}(\beta) = \frac{1}{N}\sum_{i=1}^N e^{|\beta|^2} e^{\zeta^{(i)\dagger}\beta - \beta^\dagger\zeta^{(i)}}$ and using the Hoeffding bound, we obtain

$$\Pr[|\tilde{\lambda}(\beta) - \lambda(\beta)| \leq \epsilon] \geq 1 - 4e^{-\frac{N\epsilon^2}{8}e^{-2|\beta|^2}}. \tag{S55}$$

Thus, in this case, it indicates that the sufficient number of samples is

$$N \geq \frac{8}{\epsilon^2} \log\frac{4}{\delta} e^{2|\beta|^2} = O(e^{2|\beta|^2}\epsilon^{-2}\log\delta^{-1}) \tag{S56}$$

for the estimation error to be upper-bounded by ϵ with high probability $1-\delta$. It clearly shows the significant difference of the sample complexity from the entanglement-assisted case.

C. Entanglement-assisted scheme with imperfection

We now consider the effect of imperfections and prove Theorem 3 in the main text. More specifically, we consider the cases where photon loss occurs before and after applying the random displacement channel we want to learn and a regularized Bell measurement. Here, the photon loss before and after the random displacement channel models an imperfect input state preparation and imperfect Bell measurement. On the other hand, we introduce parameter s to regularize the Bell measurement POVM by a general-dyne measurement POVM, where we recover the perfect Bell measurement by taking $s \to \infty$. By considering the regularized Bell measurement POVM, we assume the same condition as the lower bound in Sec. S3 in that the measurement POVM is normalizable, i.e., its norm is finite.

Let us first consider the effect of the loss channel on a single-mode displacement operator. Using the equivalent description of a loss channel $\mathcal{L}$ by a beam splitter interaction with a vacuum environment, we can show that

$$\mathcal{L}[\hat{D}^\dagger(\alpha)_S] = \mathrm{Tr}_E[U_T(\hat{D}^\dagger(\alpha)_S \otimes |0\rangle\langle 0|_E)U_T^\dagger] \tag{S57}$$

$$= \int \frac{d^2z}{\pi^n} e^{-\frac{1}{2}|z|^2}\, \mathrm{Tr}_E[U_T\hat{D}^\dagger(\alpha)_S \otimes \hat{D}^\dagger(z)_E U_T^\dagger] \tag{S58}$$

$$= \int \frac{d^2z}{\pi^n} e^{-\frac{1}{2}|z|^2}\, \mathrm{Tr}_E[\hat{D}^\dagger(\sqrt{T}\alpha - \sqrt{1-T}z)_S \otimes \hat{D}^\dagger(\sqrt{T}z + \sqrt{1-T}\alpha)_E] \tag{S59}$$

$$= T^{-1}e^{-\frac{1-T}{2T}|\alpha|^2}\hat{D}^\dagger(\alpha/\sqrt{T})_S, \tag{S60}$$

where $\hat{U}_T$ is the beam splitter interaction with the environment with the transmission rate T, and thus $1-T$ is the loss rate. Here, we used the identity [1]

$$|0\rangle\langle 0| = \int \frac{d^{2n}z}{\pi^n} e^{-\frac{1}{2}|z|^2}\hat{D}^\dagger(z). \tag{S61}$$

Recall that the input state is two-mode squeezed states with a finite squeezing parameter, which is written as

$$|\tilde{\Psi}(r)\rangle\langle\tilde{\Psi}(r)| = \frac{1}{\pi^{2n}}\int d^{2n}\omega_1 d^{2n}\omega_2 g(w_1, w_2, r)\hat{D}^\dagger(\omega_1)\otimes\hat{D}^\dagger(\omega_2). \tag{S62}$$

Let us first study how the displacement operator transforms over the channels.

First, after a loss channel with loss rate $1-T_b$, the random displacement channel Λ and another loss channel with loss rate $1-T_a$, an n-mode displacement operator transforms as

$$\mathcal{L}^{T_a}_{AB}(\mathcal{I}_A\otimes\Lambda_B)\mathcal{L}^{T_b}_{AB}(\hat{D}^\dagger(\omega_1)_A\otimes\hat{D}^\dagger(\omega_2)_B) \tag{S63}$$

$$= T_b^{-2n}e^{-\frac{1-T_b}{2T_b}(|\omega_1|^2+|\omega_2|^2)}\mathcal{L}^{T_a}_{AB}(\mathcal{I}_A\otimes\Lambda_B)(\hat{D}^\dagger(\omega_1/\sqrt{T_b})_A\otimes\hat{D}^\dagger(\omega_2/\sqrt{T_b})_B) \tag{S64}$$

$$= T_b^{-2n}e^{-\frac{1-T_b}{2T_b}(|\omega_1|^2+|\omega_2|^2)}\lambda(\omega_2/\sqrt{T_b})\mathcal{L}^{T_a}_{AB}(\hat{D}^\dagger(\omega_1/\sqrt{T_b})_A\otimes\hat{D}^\dagger(\omega_2/\sqrt{T_b})_B) \tag{S65}$$

$$= (T_bT_a)^{-2n}e^{-\frac{1-T_b}{2T_b}(|\omega_1|^2+|\omega_2|^2)}e^{-\frac{1-T_a}{2T_aT_b}(|\omega_1|^2+|\omega_2|^2)}\lambda(\omega_2/\sqrt{T_b})(\hat{D}^\dagger(\omega_1/\sqrt{T_bT_a})_A\otimes\hat{D}^\dagger(\omega_2/\sqrt{T_bT_a})_B). \tag{S66}$$

Now we implement the regularized Bell measurement. Recall that the perfect Bell measurement can be conducted by applying a 50:50 beam splitter and then performing homodyne detection. Here, we will regularize the homodyne detection by general-dyne detection and tracing out some quadratures.

After 50:50 beam splitters $\hat{U}_{\mathrm{BS}}$, the displacement operators transform as

$$\hat{D}^\dagger(\omega_1/\sqrt{T_bT_a})_A\otimes\hat{D}^\dagger(\omega_2/\sqrt{T_bT_a})_B \to \hat{D}^\dagger\left(\frac{\omega_1-\omega_2}{\sqrt{2T_bT_a}}\right)_A\otimes\hat{D}^\dagger\left(\frac{\omega_1+\omega_2}{\sqrt{2T_bT_a}}\right)_B. \tag{S67}$$

We then perform measurements described by the following POVM:

$$\{\hat{\Pi}^A_\alpha(-s) \otimes \hat{\Pi}^B_\beta(s)\}_{\alpha,\beta} \quad \text{where} \quad \hat{\Pi}_\gamma(s) \coloneqq \frac{1}{\pi^n} \hat{D}(\gamma) \left|s\right\rangle\!\left\langle s\right| \hat{D}^\dagger(\gamma), \tag{S68}$$

where $s \geq 0$ is the squeezing parameter for the Bell measurement. We note that this measurement corresponds to a special type of general-dyne measurement [3] and that when $s \to \infty$, we recover the Bell measurement studied in Sec. S2 A. Then, the output probability is written as

$$q(\alpha, \beta) \coloneqq \frac{1}{\pi^{2n}} \int d^{2n}\omega g(\omega_1, \omega_2, r) \operatorname{Tr}\Big[\hat{\Pi}^A_\alpha(-s) \otimes \hat{\Pi}^B_\beta(s) \hat{U}_{BS} \left(\mathcal{L}^{T_a}_{AB}(\mathcal{I}_A \otimes \Lambda_B)\mathcal{L}^{T_b}_{AB}(\hat{D}^\dagger(\omega_1)_A \otimes \hat{D}^\dagger(\omega_2)_B)\right) \hat{U}^\dagger_{BS}\Big]. \tag{S69}$$

Here, we have

$$\operatorname{Tr}\Big[\hat{\Pi}_\alpha(-s)\hat{D}^\dagger(\omega)\Big] = \frac{1}{\pi^n}\langle -s|\hat{D}^\dagger(\alpha)\hat{D}^\dagger(\omega)\hat{D}(\alpha)| - s\rangle = \frac{1}{\pi^n} e^{-\frac{1}{2}(|\omega|^2 \cosh 2s + (\omega^2 + \omega^{*2}) \sinh 2s/2)} e^{\omega^\dagger \alpha - \alpha^\dagger \omega}, \tag{S70}$$

$$\operatorname{Tr}\Big[\hat{\Pi}_\beta(s)\hat{D}^\dagger(\omega)\Big] = \frac{1}{\pi^n} e^{-\frac{1}{2}(|\omega|^2 \cosh 2s - (\omega^2 + \omega^{*2}) \sinh 2s/2)} e^{\omega^\dagger \beta - \beta^\dagger \omega}, \tag{S71}$$

and

$$\operatorname{Tr}\left[\hat{\Pi}_\alpha(-s)\hat{D}^\dagger\left(\frac{\omega_1 - \omega_2}{\sqrt{2T_aT_b}}\right)\right] \operatorname{Tr}\left[\hat{\Pi}_\beta(s)\hat{D}^\dagger\left(\frac{\omega_1 + \omega_2}{\sqrt{2T_aT_b}}\right)\right] \tag{S72}$$

$$= \frac{1}{\pi^{2n}} e^{-\frac{1}{2}\left[(|\omega_1|^2 + |\omega_2|^2)\frac{\cosh 2s}{T_aT_b} - (\omega_1 \cdot \omega_2 + \omega_1^* \cdot \omega_2^*)\frac{\sinh 2s}{T_aT_b}\right]} \exp\left[\omega_1^*\left(\frac{\alpha + \beta}{\sqrt{2T_aT_b}}\right) + \omega_2^*\left(\frac{\beta - \alpha}{\sqrt{2T_aT_b}}\right) - c.c.\right] \tag{S73}$$

$$= \frac{1}{\pi^{2n}} g(\omega_1/\sqrt{T_aT_b}, \omega_2/\sqrt{T_aT_b}, s) \exp\left[\omega_1^\dagger\left(\frac{\alpha + \beta}{\sqrt{2T_aT_b}}\right) + \omega_2^\dagger\left(\frac{\beta - \alpha}{\sqrt{2T_aT_b}}\right) - c.c.\right]. \tag{S74}$$

We now trace out one of two quadratures for each mode. To do that, we take integral over the imaginary part of α and the real part of β. Here, we define $\alpha \coloneqq \alpha_r + i\alpha_i$ and $\beta \coloneqq \beta_r + i\beta_i$. If we take the integral, the relevant part reduces to

$$\frac{1}{\pi^n}\int d^n\alpha_i \exp\left[\alpha\left(\frac{\omega_1^* - \omega_2^*}{\sqrt{2T_aT_b}}\right) - \alpha^*\left(\frac{\omega_1 - \omega_2}{\sqrt{2T_aT_b}}\right)\right] = \delta(\operatorname{Re}(\omega_1 - \omega_2)/\sqrt{2T_aT_b}) e^{-i\sqrt{2}\operatorname{Im}(\omega_1 - \omega_2)\alpha_r/\sqrt{T_aT_b}}, \tag{S75}$$

$$\frac{1}{\pi^n}\int d^n\beta_r \exp\left[\beta\left(\frac{\omega_1^* + \omega_2^*}{\sqrt{2T_aT_b}}\right) - \beta^*\left(\frac{\omega_1 + \omega_2}{\sqrt{2T_aT_b}}\right)\right] = \delta(\operatorname{Im}(\omega_1 + \omega_2)/\sqrt{2T_aT_b}) e^{i\sqrt{2}\operatorname{Re}(\omega_1 + \omega_2)\beta_i/\sqrt{T_aT_b}}, \tag{S76}$$

where the delta function gives us $\omega_2 = \omega_1^*$. Thus,

$$\int d^n\alpha_i d^n\beta_r \operatorname{Tr}\left[\hat{\Pi}_\alpha(-s)\hat{D}^\dagger\left(\frac{\omega_1 - \omega_2}{\sqrt{2T_aT_b}}\right)\right] \operatorname{Tr}\left[\hat{\Pi}_\beta(s)\hat{D}^\dagger\left(\frac{\omega_1 + \omega_2}{\sqrt{2T_aT_b}}\right)\right] \tag{S77}$$

$$= g(\omega_1/\sqrt{T_aT_b}, \omega_2/\sqrt{T_aT_b}, s)\delta\left(\frac{\omega_1 - \omega_2^*}{\sqrt{2T_aT_b}}\right) e^{-i\sqrt{2}\operatorname{Im}(\omega_1 - \omega_2)\alpha_r/\sqrt{T_aT_b}} e^{i\sqrt{2}\operatorname{Re}(\omega_1 + \omega_2)\beta_i/\sqrt{T_aT_b}}. \tag{S78}$$

Thus, the output probability is, by defining the measurement output variable as $\xi = -\alpha_r + i\beta_i$, given by

$$\begin{aligned}
&q(\xi) \qquad \text{(S79)}\\
&= \int d^n\alpha_i d^n\beta_r q(\alpha,\beta) \qquad \text{(S80)}\\
&= \frac{1}{\pi^{2n}}\int d^n\alpha_i d^n\beta_r d^{2n}\omega_1 d^{2n}\omega_2 (T_bT_a)^{-n} e^{-(\frac{1-T_b}{2T_b}+\frac{1-T_a}{2T_aT_b})(|\omega_1|^2+|\omega_2|^2)} g(\omega_1,\omega_2,r)\lambda(\omega_2/\sqrt{T_b})\\
&\qquad\qquad \times \mathrm{Tr}\left[\hat{\Pi}_\alpha(-s)\hat{D}^\dagger\left(\frac{\omega_1-\omega_2}{\sqrt{2T_aT_b}}\right)\right]\mathrm{Tr}\left[\hat{\Pi}_\beta(s)\hat{D}^\dagger\left(\frac{\omega_1+\omega_2}{\sqrt{2T_aT_b}}\right)\right] \qquad \text{(S81)}\\
&= \frac{1}{\pi^{2n}}\int d^{2n}\omega_1 d^{2n}\omega_2 (T_bT_a)^{-2n} e^{-(\frac{1-T_b}{2T_b}+\frac{1-T_a}{2T_aT_b})(|\omega_1|^2+|\omega_2|^2)} \lambda(\omega_2/\sqrt{T_b}) g(\omega_1,\omega_2^*,r) g(\omega_1/\sqrt{T_aT_b},\omega_2/\sqrt{T_aT_b},s)\\
&\qquad\qquad \times \delta\left(\frac{\omega_1-\omega_2^*}{\sqrt{2T_aT_b}}\right) e^{-i\sqrt{2}\,\mathrm{Im}(\omega_1-\omega_2)\alpha_r/\sqrt{T_aT_b}} e^{i\sqrt{2}\,\mathrm{Re}(\omega_1+\omega_2)\beta_i/\sqrt{T_aT_b}} \qquad \text{(S82)}\\
&= \left(\frac{2}{T_aT_b}\right)^n \frac{1}{\pi^{2n}}\int d^{2n}\omega e^{-(\frac{1-T_b}{T_b}+\frac{1-T_a}{T_aT_b})|\omega|^2} \lambda(\omega^*/\sqrt{T_b}) g(\omega,\omega^*,r) g(\omega/\sqrt{T_aT_b},\omega^*/\sqrt{T_aT_b},s) e^{\sqrt{2}(\xi\cdot\omega-\omega^*\cdot\xi^*)/\sqrt{T_aT_b}}\\
&\qquad \text{(S83)}\\
&= \left(\frac{2}{T_aT_b}\right)^n \frac{1}{\pi^{2n}}\int d^{2n}\omega e^{-(\frac{1-T_b}{T_b}+\frac{1-T_a}{T_aT_b})|\omega|^2} \lambda(\omega^*/\sqrt{T_b}) e^{-(e^{-2r}+e^{-2s}/T_aT_b)|\omega|^2} e^{\sqrt{2}(\xi\cdot\omega-\omega^*\cdot\xi^*)/\sqrt{T_aT_b}}\\
&\qquad \text{(S84)}\\
&= \left(\frac{2}{T_a}\right)^n \frac{1}{\pi^{2n}}\int d^{2n}\omega e^{-((1-T_b)+\frac{1-T_a}{T_a})|\omega|^2} \lambda(\omega^*) e^{\sqrt{2}(\xi\cdot\omega-\omega^*\cdot\xi^*)/\sqrt{T_a}}. \qquad \text{(S85)}
\end{aligned}$$

Here, for consistency with Sec. S2 A, we rescale $\sqrt{2}\xi = \zeta$ and define $p_{loss}(\zeta)$ such that

$$p_{loss}(\zeta) = \left(\frac{1}{T_a}\right)^n \frac{1}{\pi^{2n}}\int d^{2n}\omega e^{-((1-T_b)+\frac{1-T_a}{T_a})|\omega|^2} \lambda(\omega^*) e^{-(T_be^{-2r}+e^{-2s}/T_a)|\omega|^2} e^{(\omega\cdot\zeta-\omega^*\cdot\zeta^*)/\sqrt{T_a}}, \tag{S86}$$

where 2^n factor is canceled because of the relation $2^n d^{2n}\xi = d^{2n}\zeta$ (This rescaling is because the convention of Bell measurement outcome ζ in Sec. S2 A is different from ξ in this section by $\sqrt{2}$ factor.). Therefore, after Fourier transformation, we obtain

$$\int d^{2n}\zeta p_{loss}(\zeta) e^{(\zeta^\dagger\beta-\beta^\dagger\zeta)/\sqrt{T_a}} = \lambda(\beta) e^{-(T_be^{-2r}+e^{-2s}/T_a)|\beta|^2} e^{-(1-T_b)|\beta|^2} e^{-\frac{1-T_a}{T_a}|\beta|^2}. \tag{S87}$$

Consequently, the characteristic function is written by the probability distribution as

$$\begin{aligned}
\lambda(\beta) &= e^{(T_be^{-2r}+e^{-2s}/T_a)|\beta|^2} e^{(1-T_b)|\beta|^2} e^{\frac{1-T_a}{T_a}|\beta|^2} \int d^{2n}\zeta p_{loss}(\zeta) e^{(\zeta^\dagger\beta-\beta^\dagger\zeta)/\sqrt{T_a}}, \qquad \text{(S88)}\\
&= e^{e^{-2r_{\mathrm{eff}}}|\beta|^2} \int d^{2n}\zeta p_{loss}(\zeta) e^{(\zeta^\dagger\beta-\beta^\dagger\zeta)/\sqrt{T_a}}. \qquad \text{(S89)}
\end{aligned}$$

where we defined an effective squeezing parameter r_{eff} due to all kinds of imperfections via

$$e^{-2r_{\mathrm{eff}}} := (T_be^{-2r} + T_a^{-1}e^{-2s}) + (1-T_b) + \frac{1-T_a}{T_a}. \tag{S90}$$

In order to estimate any $\lambda(\beta)$, one simply obtains N samples $\{\zeta^{(i)}\}_{i=1}^N$ from $p(\zeta)$ and set the estimator to be $\tilde{\lambda}(\beta) := \frac{1}{N}\sum_{i=1}^N e^{e^{-2r_{\mathrm{eff}}}|\beta|^2} e^{(\zeta^{(i)\dagger}\beta-\beta^\dagger\zeta^{(i)})/\sqrt{T_b}}$. According to the Hoeffding's inequality as the ideal case, averaging over $N \geq 8/\epsilon^2 \log(4/\delta) e^{2e^{-2r_{\mathrm{eff}}}|\beta|^2}$ copies is sufficient to estimate $\lambda(\beta)$ to ϵ additive error with high probability.

Meanwhile, the effects of imperfections are thus the envelope of Fourier transforms. Especially when $s \to \infty$, the effective squeezing parameter under loss is given by

$$r_{\mathrm{eff}} = -\frac{1}{2}\log\left(T_be^{-2r} + (1-T_b) + \frac{1-T_a}{T_a}\right). \tag{S91}$$

This completes the proof of Theorem 3 in the main text.

To be clearer, for photon loss before the channel without any other imperfections, i.e., $s \to \infty$ and $T_a = 1$, the envelope is given by

$$e^{[T_b e^{-2r}+(1-T_b)]|\beta|^2}, \tag{S92}$$

and for photon loss after the channel without other imperfections, the envelope is given by

$$e^{[e^{-2r}+(1-T_a)/T_a]|\beta|^2}. \tag{S93}$$

D. Discussion on more general input states

In this section, we study more general sources of noise other than finite squeezing and photon loss. To begin with, consider the case where we use an arbitrary input state while the CV Bell measurement is still employed. To this end, note that Eq. (S44) from Sec. S2 A does not use any special properties of TMSV, and actually holds for any $2n$-mode input state, *i.e.*,

$$\lambda(\beta) = \frac{1}{g_{\hat{\rho}}(\beta^*, \beta)} \int d^{2n}\zeta p_{EA}(\zeta) e^{\zeta^\dagger \beta - \beta^\dagger \zeta}, \tag{S94}$$

where g is the characteristic function of the input state $\hat{\rho}$:

$$g_{\hat{\rho}}(w_1, w_2) = \mathrm{Tr}\Big[\hat{\rho}\hat{D}(\omega_1) \otimes \hat{D}(\omega_2)\Big]. \tag{S95}$$

The fact that the same relation holds by replacing the g function properly indicates that for different types of input states, we still have a very similar form of an unbiased estimator for N samples:

$$\tilde{\lambda}(\beta) = \frac{1}{N}\sum_{i=1}^{N} \frac{1}{g_{\hat{\rho}}(\beta^*, \beta)} e^{\zeta^{(i)\dagger}\beta - \beta^\dagger \zeta^{(i)}}. \tag{S96}$$

It implies that the sampling complexity is determined by the function $g_{\hat{\rho}}(\beta^*, \beta)$. More specifically, by the Hoeffding inequality, the number of samples to achieve an error ϵ with high probability $1-\delta$ is given by

$$N = O(|g_{\hat{\rho}}(\beta^*, \beta)|^{-2}\epsilon^{-2}\log\delta^{-1}). \tag{S97}$$

For example, for TMSV states, this function reduces to

$$g_{\tilde{\Psi}}(\beta^*, \beta) = \exp\Big(-e^{-2r}|\beta|^2\Big). \tag{S98}$$

Therefore, as long as the function g of the input state is sufficiently large for the β of interest, we can still expect the scheme to be sample efficient.

Such a general form enables us to analyze the effect of general noise on input states. Let us again focus on TMSV states but assume a noise channel $\mathcal{N}$. Then, the characteristic function g of the noisy TMSV states can be written as

$$g_{\mathcal{N}(\tilde{\Psi})}(w_1, w_2) = \mathrm{Tr}\Big[\mathcal{N}(|\tilde{\Psi}(r)\rangle\langle\tilde{\Psi}(r)|)\hat{D}(\omega_1) \otimes \hat{D}(\omega_2)\Big]. \tag{S99}$$

As discussed, it suffices to analyze how the characteristic function changes by noise to ensure that a significant advantage is still maintained for noisy states. In typical experiments, while the CV Bell measurement noise can be modeled by photon loss, as we considered already in the previous section, other types of noise may exist in the TMSV state preparation procedure. An example is

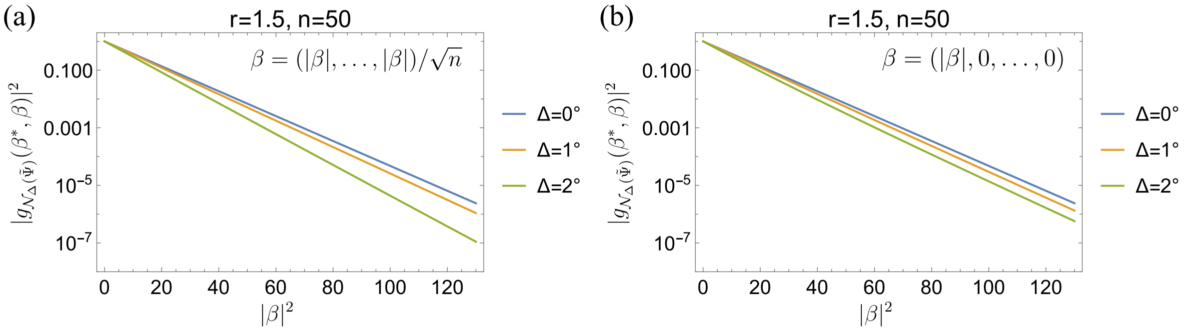

FIG. S1. Effect of phase diffusion on the squared characteristic function $|g_{\mathcal{N}_\Delta(\hat{\rho})}(\beta^*, \beta)|^2$, where we choose a specific form of $\beta \in \mathbb{C}^n$ as (a) $\beta := (|\beta|/\sqrt{n}, \ldots, |\beta|/\sqrt{n})$ and (b) $\beta := (|\beta|, 0, \ldots, 0)$ for two extreme cases with a given $|\beta|^2$. We fix the squeezing parameter $r = 1.5$ of the input TMSV states and set the number of modes $n = 50$. For the standard deviation $\Delta = 1°$ of phase noise, following Gaussian distributions, one may observe that the characteristic function is almost identical to the noiseless case ($\Delta = 0°$). For the standard deviation $\Delta = 2°$ as well, the effect is not very significant.

phase diffusion, which can be modeled by a photon-number-dependent random phase following a Gaussian distribution. For $2n$-mode state input, we can write the noise channel as

$$\mathcal{N}_\Delta(\hat{\rho}) \tag{S100}$$

$$= \int d^n\phi_A d^n\phi_B \frac{e^{-\frac{|\phi_A|^2+|\phi_B|^2}{2\Delta^2}}}{(2\pi\Delta^2)^n} e^{-i\phi_A\cdot\hat{n}_A - i\phi_B\cdot\hat{n}_B} \hat{\rho} e^{i\phi_A\cdot\hat{n}_A + i\phi_B\cdot\hat{n}_B} \tag{S101}$$

$$= \frac{1}{\pi^{2n}} \int d^{2n}\omega_1 d^{2n}\omega_2 g_{\hat{\rho}}(\omega_1, \omega_2) \int d^n\phi_A d^n\phi_B \frac{e^{-\frac{|\phi_A|^2+|\phi_B|^2}{2\Delta^2}}}{(2\pi\Delta^2)^n} e^{-i\phi_A\cdot\hat{n}_A - i\phi_B\cdot\hat{n}_B} [\hat{D}^\dagger(\omega_1) \otimes \hat{D}^\dagger(\omega_2)] e^{i\phi_A\cdot\hat{n}_A + i\phi_B\cdot\hat{n}_B}, \tag{S102}$$

where ϕ_A and ϕ_B are n-dimensional real vectors and $\hat{n}_A$ and $\hat{n}_B$ are photon number operator vectors for A and B parts, respectively. Then, noting that

$$e^{-i\phi_A\cdot\hat{n}_A - i\phi_B\cdot\hat{n}_B} [\hat{D}^\dagger(\omega_1) \otimes \hat{D}^\dagger(\omega_2)] e^{i\phi_A\cdot\hat{n}_A + i\phi_B\cdot\hat{n}_B} = \hat{D}^\dagger(\omega_1 e^{-i\phi_A}) \otimes \hat{D}^\dagger(\omega_2 e^{-i\phi_B}), \tag{S103}$$

where $\omega_1 e^{-i\phi_A}$ and $\omega_2 e^{-i\phi_B}$ are interpreted as vectors obtained by an elementwise product, the corresponding g function for TMSV states is written as

$$g_{\mathcal{N}(\tilde{\Psi})}(w_1, w_2) \tag{S104}$$

$$= \mathrm{Tr}\Big[\mathcal{N}_\Delta(|\tilde{\Psi}(r)\rangle\langle\tilde{\Psi}(r)|) \hat{D}(\omega_1) \otimes \hat{D}(\omega_2)\Big] \tag{S105}$$

$$= \frac{1}{\pi^{2n}} \int d^{2n}\beta_1 d^{2n}\beta_2 g_{\tilde{\Psi}}(\beta_1, \beta_2) \int d^n\phi_A d^n\phi_B \frac{e^{-\frac{|\phi_A|^2+|\phi_B|^2}{2\Delta^2}}}{(2\pi\Delta^2)^n} \mathrm{Tr}\Big[\hat{D}^\dagger(\beta_1 e^{-i\phi_A}) \otimes \hat{D}^\dagger(\beta_2 e^{-i\phi_B}) \hat{D}(\omega_1) \otimes \hat{D}(\omega_2)\Big] \tag{S106}$$

$$= \int d^{2n}\beta_1 d^{2n}\beta_2 g_{\tilde{\Psi}}(\beta_1, \beta_2) \int d^n\phi_A d^n\phi_B \frac{e^{-\frac{|\phi_A|^2+|\phi_B|^2}{2\Delta^2}}}{(2\pi\Delta^2)^n} \delta(\omega_1 - \beta_1 e^{-i\phi_A}) \delta(\omega_2 - \beta_2 e^{-i\phi_B}) \tag{S107}$$

$$= \int d^n\phi_A d^n\phi_B \frac{e^{-\frac{|\phi_A|^2+|\phi_B|^2}{2\Delta^2}}}{(2\pi\Delta^2)^n} g_{\tilde{\Psi}}(\omega_1 e^{i\phi_A}, \omega_2 e^{i\phi_B}). \tag{S108}$$

Thus, the effect of phase noise is to transform the g function as a mixture with random phases. We present examples to illustrate the effect of the phase noise on the sample complexity in Fig. S1.

We have chosen the parameters $\beta \in \mathbb{C}^n$ of two extreme cases as $\beta := (|\beta|/\sqrt{n}, \dots, |\beta|/\sqrt{n})$ and $\beta := (|\beta|, 0, \dots, 0)$. Recall that the typical choice of the regime of interest in the main text is $|\beta|^2 \leq \kappa n$; here, the range $|\beta|^2 \in [0, 130]$ in the figure covers up to $\kappa = 2.5$ for $n = 50$. We see that the advantages of the entanglement-assisted scheme look robust against small-phase diffusion noise.

S3. FUNDAMENTAL LIMITS FOR ENTANGLEMENT-FREE SCHEMES

In this section, we prove the fundamental limit on general entanglement-free schemes for learning n-mode random displacement channels. In this work, we will focus on the ancilla-free schemes without concatenation. This means that, for each copy of the channel, we act it on some input state and apply a destructive POVM measurement right after. The input states and measurements can be adaptively chosen depending on previous measurement outcomes. See Fig. S2. Bounds for such schemes have been investigated in different tasks [4–6]. One can also study ancilla-free protocols with concatenation, the lower bounds for which have been obtained in several recent works [6–8], but we leave that for future study as continuous-variable system puts an additional level of complexity. Throughout this work, we assume entanglement-free schemes to have no concatenation.

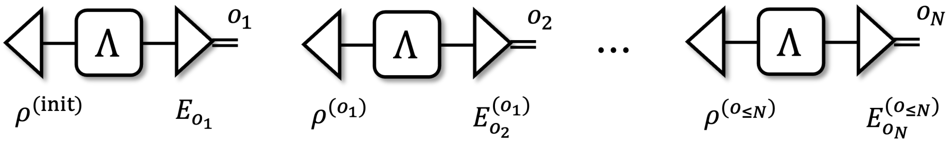

FIG. S2. Schematics for entanglement-free schemes. In this work we assume no concatenation is allowed. Such a scheme can be completely specificed by a collection of input states and POVM measurements that adaptively depend on the measurement outcomes from the previous round.

Theorem S1. *Let Λ be an arbitrary n-mode random displacement channel ($n \geq 8$) and consider an entanglement-free scheme that uses N copies of Λ. After all measurements are completed, the scheme receives the query $\beta \in \mathbb{C}^n$ and returns an estimate $\tilde{\lambda}(\beta)$ of Λ's characteristic function $\lambda(\beta)$. Suppose that, with success probability at least 2/3, $|\tilde{\lambda}(\beta) - \lambda(\beta)| \leq \epsilon \leq 0.24$ for all β such that $|\beta|^2 \leq n\kappa$. Then $N \geq 0.01\epsilon^{-2}(1 + 1.98\kappa)^n$.*

Recall that an entanglement-assisted scheme can achieve the same task using $O(\epsilon^{-2})$ copies of channels given sufficient squeezing and $\kappa = O(1)$. Therefore, we establish an exponential separation between learning bosonic random displacement channels with and without entanglement. In the following, we start proving this result in Sec. S3 A and present a core lemma in Sec. S3 B. We also prove a bound for learning with Gaussian schemes in Sec. S3 C, which might be of independent interest.

Before proceeding, let us specify some regularization conditions. We will only work with proper vectors (i.e., normalizable vector) in the Hilbert space and bounded operator acting on the Hilbert space. That is to say, all the quantum states we considered can be expressed as a density operator $\hat{\rho}$ with trace 1, and all the POVM element $\hat{E}$ is a bounded positive semi-definite operator satisfying $\hat{E} \leq \hat{I}$. Perhaps the most representative example that does not admit the above form is the perfect homodyne detection projector $|x\rangle\langle x|$, which represents projection onto the quadrature x. While $|x\rangle$ is not a proper vector in the relevant Hilbert space, it can be treated as a limit of proper vectors in any physical setting. Concretely, homodyne detection is implemented by applying a 50:50 beam splitter between the input state and a strong local oscillator [3], and the above improper projector $|x\rangle\langle x|$ is obtained by taking the limit where the power of the oscillator goes to infinity. Therefore, in a reasonable physical setup, the actual projector is constructed with a proper vector in the Hilbert space, thus satisfying our assumptions. We emphasize that our entanglement-assisted strategy also satisfies the same assumption as we regularize the Bell measurements with general-dyne detection with a parameter $s < \infty$, see Sec. S2 C.

A. Lower bound for entanglement-free schemes

Given positive number $n \geq 8$ and $\epsilon \leq 0.24$, we introduce a family of "3-peak" random displacement channels, defined by their characteristic functions,

$$\Lambda_\gamma : \ \lambda_\gamma(\beta) \coloneqq e^{-\frac{|\beta|^2}{2\sigma^2}} + 2i\epsilon_0 e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}} - 2i\epsilon_0 e^{-\frac{|\beta+\gamma|^2}{2\sigma^2}}, \quad \gamma \in \mathbb{C}^n, \tag{S109}$$

where $\epsilon_0 \coloneqq \epsilon/0.98 \leq 0.25$. The corresponding distributions of displacements, computed via Fourier transformation, are

$$\Lambda_\gamma : \ p_\gamma(\alpha) = \left(\frac{2\sigma^2}{\pi}\right)^n e^{-2\sigma^2|\alpha|^2} \left(1 + 4\epsilon_0 \sin(2(\operatorname{Im}[\gamma]\operatorname{Re}[\alpha] - \operatorname{Re}[\gamma]\operatorname{Im}[\alpha]))\right), \tag{S110}$$

from which we see that the typical strength of displacement is of order $1/\sigma$. Roughly, the smaller σ is, the larger energy the channel carries. We define $\Lambda_{\text{dep}} \coloneqq \Lambda_0$ as the CV analogy of the depolarizing channel, and the other Λ_γ can be viewed as perturbed depolarizing channels. The set of 3-peak channels with parameters (ϵ, σ) is denoted as $\mathbf{\Lambda}^{\epsilon,\sigma}_{\text{3-peak}}$. With this, we are going to prove a strictly stronger result than Theorem S1. That is, even if one knows the channel to be estimated is from the restricted family, $\mathbf{\Lambda}^{\epsilon,\sigma}_{\text{3-peak}}$, an exponential lower bound still applies.

Theorem S2. *Given positive numbers $n, \sigma, \kappa, \epsilon$ such that*

$$2\sigma^2 \leq \max\left\{1 - 1.98\kappa,\ 0.99\kappa\left(\sqrt{1 + (0.99\kappa)^{-2}} - 1\right)\right\}, \quad n \geq 8, \quad \epsilon \leq 0.24. \tag{S111}$$

If there exists an entanglement-free scheme such that, after learning from N copies of an n-mode random displacement channel $\Lambda \in \mathbf{\Lambda}^{\epsilon,\sigma}_{\text{3-peak}}$, and then receiving a query $\beta \in \mathbb{C}^n$, can return an estimate $\tilde{\lambda}(\beta)$ of $\lambda(\beta)$ such that $|\tilde{\lambda}(\beta) - \lambda(\beta)| \leq \epsilon$ with probability at least $2/3$ for all β such that $|\beta|^2 \leq n\kappa$, then

$$N \geq 0.01\epsilon^{-2}\left(1 + \frac{1.98\kappa}{1 + 2\sigma^2}\right)^n. \tag{S112}$$

It is not hard to see that a $\sigma > 0$ satisfying the assumptions can always be found for any $\kappa > 0$. Indeed, Theorem S1 follows from Theorem S2 by choosing $\sigma \to 0$. Note that Theorem S2 does not place any constraint on the input state and measurement. This means that learning a finite-energy random displacement channel is hard without ancilla even given energy-unbounded input state and measurement. Also, Theorem S2 enables an experimental test, as it only requires generating finite displacement with high probability. The practical performance of this bound with $\sigma = 0.3$ is shown in Fig. S3.

Proof of Theorem S2. Now we introduce the following game between Alice and Bob that helps reduce the learning task to a partially-revealed hypothesis testing task [9]. First, Alice samples $s \in \{\pm 1\}$ with equal probability and $\gamma \in \mathbb{C}^n$ according to the multivariate normal distribution $q(\gamma)$ defined as

$$q(\gamma) \coloneqq \left(\frac{1}{2\pi\sigma_\gamma^2}\right)^n e^{-\frac{|\gamma|^2}{2\sigma_\gamma^2}}, \tag{S113}$$

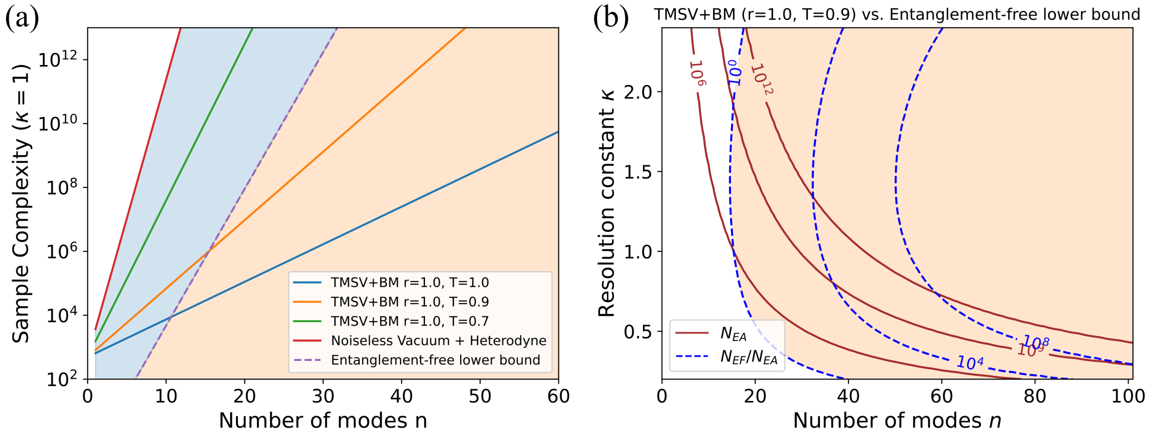

FIG. S3. Learning random displacement channels from the family with $\sigma = 0.3$ as in Theorem S2. (In the main text, we set $\sigma = 0$.) All κ shown in the figure satisfies Eq. (S111). (a) Comparison of TMSV+BM (with different loss rates), Vacuum+Heterodyne, and the entanglement-free lower bound at $\kappa = 1$. The task is to estimate any $\lambda(\beta)$ such that $|\beta|^2 \leq \kappa n$ with precision $\varepsilon = 0.2$ and success probability $1 - \delta = 2/3$. The orange region represents a rigorous advantage over any entanglement-free schemes. The blue region represents an advantage over Vacuum+heterodyne. (b) Comparison of the TMSV+BM scheme with squeezing parameter $r = 1.0$ and loss rate $1 - T = 0.1$ with the entanglement-free lower bound of Theorem 2. The task is the same as (a). The brown solid contour lines represent the sample complexity of TMSV+BM given by Theorem 3. The blue dashed contour lines represent the ratio of sample complexity between the entanglement-free lower bound and TMSV+BM, which clearly indicates the entanglement-enabled advantages.

where we will set $2\sigma_\gamma^2 := 0.99\kappa$ to ensure the tail probability, i.e., $\Pr(|\gamma|^2 > \kappa n)$, to be sufficiently small. Next, Alice does one of the following with equal probability:

1. Prepare N copies of Λ_{dep} for Bob;

2. Prepare N copies of $\Lambda_{s\gamma}$ for Bob.

Bob then measures the N copies of the channels Alice prepared. After Bob has finished the measurements and retains only classical information, Alice reveals the value of γ to Bob. Now Bob is asked to distinguish between the two hypotheses: whether Alice has prepared copies of Λ_{dep} or $\Lambda_{s\gamma}$. Crucially, Bob must have completed all quantum measurements before Alice reveals γ, and can only perform classical post-processing after that.

We first argue that if there is a scheme satisfying the assumptions of Theorem S2, then Bob can use it to win the game with an average probability much better than random guess. Bob's strategy is as follows: If the γ he received satisfies $2\sigma^2 < |\gamma|^2 \leq \kappa n$, use the scheme to query $\lambda(\gamma)$. Note that for any $\gamma \in \mathbb{C}^n$:

$$|\lambda_{\text{dep}}(\gamma) - \lambda_{\pm\gamma}(\gamma)| = \frac{1}{2}|\lambda_\gamma(\gamma) - \lambda_{-\gamma}(\gamma)| = 2\epsilon_0 \left|1 - e^{-\frac{4|\gamma|^2}{2\sigma^2}}\right|. \tag{S114}$$

For $|\gamma|^2 > 2\sigma^2$, the R.H.S. is lower bounded by $2\epsilon_0 \times 0.98 = 2\epsilon$. By assumption, this allows Bob to distinguish among $\{\Lambda_{\text{dep}}, \Lambda_\gamma, \Lambda_{-\gamma}\}$ and thus guess correctly with at least $2/3$ chance; For other γ, Bob just makes a uniformly random guess. Note that

$$\Pr\left(2\sigma^2 < |\gamma|^2 \leq \kappa n\right) = 1 - \Pr\Big(|\gamma|^2 > \kappa n\Big) - \Pr\Big(|\gamma|^2 \leq 2\sigma^2\Big) \tag{S115}$$

$$= 1 - \left(\frac{\Gamma(n, n/0.99)}{\Gamma(n)}\right) - \left(1 - \frac{\Gamma(n, \sigma^2/\sigma_\gamma^2)}{\Gamma(n)}\right) \tag{S116}$$

$$\geq \frac{1}{2} - \left(1 - \frac{\Gamma(n, \sigma^2/\sigma_\gamma^2)}{\Gamma(n)}\right) \tag{S117}$$

$$= \frac{1}{2} - \frac{\int_0^{\sigma^2/\sigma_\gamma^2} t^{n-1} e^{-t} dt}{(n-1)!} \tag{S118}$$

$$\geq 0.49987. \tag{S119}$$

The first inequality is shown in Sec. S4. The second inequality requires $n \geq 8$ and $2\sigma^2 \leq 0.99\kappa := 2\sigma_\gamma^2$. Bob's average success probability is lower bounded by

$$\Pr[\text{Success}] \geq \Pr\left(2\sigma^2 < |\gamma|^2 \leq \kappa n\right) \times 2/3 + \left(1 - \Pr\left(2\sigma^2 < |\gamma|^2 \leq \kappa n\right)\right) \times 1/2. \tag{S120}$$

Now we investigate the probability distribution of Bob's measurement outcomes for any γ. For any adaptive entanglement-free strategy, one specifies an input state and a POVM for the ith copy of Λ that can depend on previous measurement outcomes. We denote the ith measurement outcomes as o_i and the outcomes up to the ith round as $o_{<i} = [o_1, ..., o_{i-1}]$. The latter is added as a superscript to the ith input states $\rho^{o_{<i}}$ and POVM element $E_{o_i}^{o_{<i}}$ to emphasize their adaptive nature. With these notations, the probability of obtaining outcomes $o_{1:N}$ on N copies of Λ is

$$p(o_{1:N}|\Lambda) = \prod_{k=1}^{N} \mathrm{Tr}\Big[\hat{E}_{o_i}^{o_{<i}} \Lambda(\hat{\rho}^{o_{<i}})\Big]. \tag{S121}$$

For a fixed γ, let $p_1(o_{1:N}) := p(o_{1:N}|\Lambda_{\text{dep}})$, $p_{2,\gamma}(o_{1:N}) := \mathbb{E}_{s=\pm1} p(o_{1:N}|\Lambda_{s\gamma})$, which is the distribution of Bob's outcomes under the two hypotheses, respectively, conditioned on the γ he received. According to the property of total variation distance, the maximal probability that Bob can distinguish p_1 and $p_{2,\gamma}$ is bounded by

$$\Pr[\text{Success}|\gamma] \leq \frac{1}{2}(1 + \mathrm{TVD}(p_1, p_{2,\gamma})), \tag{S122}$$

where TVD is the *total variation distance* defined as

$$\mathrm{TVD}(p_1, p_{2,\gamma}) := \sum_{o_{1:N}} \max\left\{0,\ p_1(o_{1:N}) - p_{2,\gamma}(o_{1:N})\right\}. \tag{S123}$$

We note that the sum over $o_{1:N}$ should be understood as integral for continuous-variable outcomes. Thus, the average probability that Bob can win the game is upper bounded by

$$\Pr[\text{Success}] = \mathbb{E}_{\gamma\sim q} \Pr[\text{Success}|\gamma] \leq \frac{1}{2}(1 + \mathbb{E}_\gamma \mathrm{TVD}(p_1, p_{2,\gamma})). \tag{S124}$$

Combining Eq. (S120) and Eq. (S124), we get

$$\mathbb{E}_\gamma \mathrm{TVD}(p_1, p_{2,\gamma}) \geq 0.1666. \tag{S125}$$

In the following, we show by direct calculation that this is impossible unless N is exponentially large in n, which yields a desired lower bound for the sample complexity.

Thanks to convexity, we assume pure input states and rank-1 measurement without decreasing the TVD, i.e., the kth round's input state and POVM are written as $|A^{o_{<k}}\rangle$ and $\{|B^{o_{<k}}_{o_k}\rangle\langle B^{o_{<k}}_{o_k}|\}$, which are conditioned on the previous measurement outcomes $o_{<k}$. Here, the input state has unit length and $\sum_{o_k}|B^{o_{<k}}_{o_k}\rangle\langle B^{o_{<k}}_{o_k}| = \mathbb{1}$. We note that since any density matrix is trace-class, a spectrum decomposition always exists. On the other hand, the POVM element can be non-compact operator and might not have spectrum decomposition, but it is known that they can always be composed into rank-1 projectors with positive coefficients (see [10, Theorem 6]). Thus, making both the input state and measurement projector to be rank-1 is indeed justified.

Now, let us rewrite the probabilities as

$$\begin{aligned} p_1(o_{1:N}) &= \prod_{k=1}^{N} \langle B^{o_{<k}}_{o_k}|\Lambda_{\mathrm{dep}}(|A^{o_{<k}}\rangle\langle A^{o_{<k}}|)|B^{o_{<k}}_{o_k}\rangle \qquad \text{(S126)}\\ &= \prod_{k=1}^{N}\left(\frac{1}{\pi^n}\int d^{2n}\beta_k \lambda_{\mathrm{dep}}(\beta_k)\langle B^{o_{<k}}_{o_k}|\hat{D}^\dagger(\beta_k)|B^{o_{<k}}_{o_k}\rangle\langle A^{o_{<k}}|\hat{D}(\beta_k)|A^{o_{<k}}\rangle\right), \qquad \text{(S127)}\\ p_{2,\gamma}(o_{1:N}) &= \mathbb{E}_{s=\pm1}\prod_{k=1}^{N}\langle B^{o_{<k}}_{o_k}|\Lambda_{s\gamma}(|A^{o_{<k}}\rangle\langle A^{o_{<k}}|)|B^{o_{<k}}_{o_k}\rangle \qquad \text{(S128)}\\ &= \mathbb{E}_{s=\pm1}\prod_{k=1}^{N}\left(\frac{1}{\pi^n}\int d^{2n}\beta_k \lambda_{s\gamma}(\beta_k)\langle B^{o_{<k}}_{o_k}|\hat{D}^\dagger(\beta_k)|B^{o_{<k}}_{o_k}\rangle\langle A^{o_{<k}}|\hat{D}(\beta_k)|A^{o_{<k}}\rangle\right). \qquad \text{(S129)} \end{aligned}$$

Let $\lambda^{\mathrm{add}}_{\gamma}(\beta_k) := \lambda_\gamma(\beta_k) - \lambda_{\mathrm{dep}}(\beta_k)$. The difference of the probabilities can then be written as

$$\begin{aligned} &p_1(o_{1:N}) - p_{2,\gamma}(o_{1:N}) \qquad \text{(S130)}\\ =&p_1(o_{1:N})\left(1-\frac{p_{2,\gamma}(o_{1:N})}{p_1(o_{1:N})}\right) \qquad \text{(S131)}\\ =&p_1(o_{1:N})\left(1-\mathbb{E}_{s=\pm1}\prod_{k=1}^{N}\left(1+\frac{\frac{1}{\pi^n}\int d^{2n}\beta_k\lambda^{\mathrm{add}}_{s\gamma}(\beta_k)\langle B^{o_{<k}}_{o_k}|\hat{D}^\dagger(\beta_k)|B^{o_{<k}}_{o_k}\rangle\langle A^{o_{<k}}|\hat{D}(\beta_k)|A^{o_{<k}}\rangle}{\frac{1}{\pi^n}\int d^{2n}\beta_k\lambda_{\mathrm{dep}}(\beta_k)\langle B^{o_{<k}}_{o_k}|\hat{D}^\dagger(\beta_k)|B^{o_{<k}}_{o_k}\rangle\langle A^{o_{<k}}|\hat{D}(\beta_k)|A^{o_{<k}}\rangle}\right)\right) \qquad \text{(S132)}\\ =&p_1(o_{1:N})\left(1-\mathbb{E}_{s=\pm1}\prod_{k=1}^{N}\left(1-4\epsilon_0\,\mathrm{Im}\,G^{o_{\le k}}_{\sigma}(s\gamma)\right)\right), \qquad \text{(S133)} \end{aligned}$$

where we have defined

$$G^{o_{\le k}}_{\sigma}(\gamma) := \frac{\int d^{2n}\beta e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}}G^{o_{\le k}}(\beta)}{\int d^{2n}\beta' e^{-\frac{|\beta'|^2}{2\sigma^2}}G^{o_{\le k}}(\beta')}, \tag{S134}$$

where

$$G^{o_{\le k}}(\beta) := \frac{\langle B^{o_{<k}}_{o_k}|\hat{D}^\dagger(\beta)|B^{o_{<k}}_{o_k}\rangle}{\langle B^{o_{<k}}_{o_k}|B^{o_{<k}}_{o_k}\rangle}\cdot\langle A^{o_{<k}}|\hat{D}(\beta)|A^{o_{<k}}\rangle, \tag{S135}$$

which satisfies $G^{o_{\le k}}(\gamma) = G^{o_{\le k}}(-\gamma)^*$.

We thus have

$$\mathbb{E}_\gamma \mathrm{TVD}(p_1, p_{2,\gamma}) = \mathbb{E}_\gamma\sum_{o_{1:N}} p_1(o_{1:N})\max\left\{0,\ 1-\mathbb{E}_{s=\pm1}\prod_{k=1}^{N}\left(1-4\epsilon_0\,\mathrm{Im}\,G^{o_{\le k}}_{\sigma}(s\gamma)\right)\right\}. \tag{S136}$$

Now we can lower bound the following term,

$$\mathbb{E}_{s=\pm1}\prod_{k=1}^{N}\left(1-4\epsilon_0\,\mathrm{Im}\,G_\sigma^{o_{\leq k}}(s\gamma)\right) \tag{S137}$$

$$\geq \prod_{k=1}^{N}\sqrt{\left(1-4\epsilon_0\,\mathrm{Im}\,G_\sigma^{o_{\leq k}}(+\gamma)\right)\left(1-4\epsilon_0\,\mathrm{Im}\,G_\sigma^{o_{\leq k}}(-\gamma)\right)} \tag{S138}$$

$$= \prod_{k=1}^{N}\sqrt{1-16\epsilon_0^2\left(\mathrm{Im}\,G_\sigma^{o_{\leq k}}(\gamma)\right)^2} \tag{S139}$$

$$\geq \prod_{k=1}^{N}\left(1-16\epsilon_0^2\left(\mathrm{Im}G_\sigma^{o_{\leq k}}(\gamma)\right)^2\right) \tag{S140}$$

$$\geq 1-\sum_{k=1}^{N}16\epsilon_0^2|G_\sigma^{o_{\leq k}}(\gamma)|^2, \tag{S141}$$

where the second line uses the AM-GM inequality and the fact that the expression inside the bracket is the ratio of two conditional probabilities and is thus non-negative; the third line uses the fact that $\mathrm{Im}\,G_\sigma^{o_{\leq k}}(\gamma) = -\,\mathrm{Im}\,G_\sigma^{o_{\leq k}}(-\gamma)$; the fourth line uses $\sqrt{1-x}\geq 1-x, \forall\, 0\leq x\leq 1$; and the final line uses the inequality $\prod_i(1-x_i)\geq 1-\sum_i x_i$ for all $0\leq x_i\leq 1$. Thus, we can get rid of the maximum in the expression of the average TVD as

$$\mathbb{E}_\gamma \mathrm{TVD}(p_1,p_{2,\gamma}) \leq \sum_{o_{1:N}} p_1(o_{1:N})\sum_{k=1}^{N}16\epsilon_0^2\mathbb{E}_\gamma|G_\sigma^{o_{\leq k}}(\gamma)|^2. \tag{S142}$$

To further upper bound the R.H.S., we need the following Lemma S1. The lemma is analogous to Pauli twirling in discrete-variable systems but also takes finite energy into consideration. The proof of Lemma S1 is given in Sec. S3 B; Alternatively, when the input states and measurements are restricted to be Gaussian, a more straightforward calculation is possible, yielding different bounds, which we will present in Sec. S3 C.

Lemma S1. *For any* $|A^{o_{<k}}\rangle, |B_{o_k}^{o_{<k}}\rangle$ *we have*

$$\mathbb{E}_\gamma|G_\sigma^{o_{\leq k}}(\gamma)|^2 \leq \left(\frac{1+2\sigma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^n, \tag{S143}$$

given that $\sigma^2 \leq \max\left\{\frac{1}{2}-2\sigma_\gamma^2,\ \sigma_\gamma^2\left(\sqrt{1+\frac{1}{4\sigma_\gamma^4}}-1\right)\right\}$.

Thanks to Lemma S1, we get the following upper bound

$$\mathbb{E}_\gamma \mathrm{TVD}(p_1,p_{2,\gamma}) \leq \sum_{o_{1:N}} p_1(o_{1:N})\sum_{k=1}^{N}16\epsilon_0^2\left(\frac{1+2\sigma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^n = 16N\epsilon_0^2\left(\frac{1+2\sigma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^n. \tag{S144}$$

Combining this with the lower bound in Eq. (S125) and substituting $\epsilon = 0.98\epsilon_0$,

$$N \geq 0.01\epsilon^{-2}\left(1+\frac{4\sigma_\gamma^2}{1+2\sigma^2}\right)^n. \tag{S145}$$

By substituting $2\sigma_\gamma^2 = 0.99\kappa$, we obtain the lower bound as claimed in Theorem S2. □

In Fig. S3, we compare the upper bound of the TMSV+BM scheme to the derived lower bound of entanglement-free schemes. In contrast to the main text, we set $\sigma = 0.3$ to consider a more practical case for experimental realization in the near future. To see how much energy is required to realize the 3-peak channel, one can easily check that for a given σ, the corresponding single-mode depolarizing channel Λ_0 transforms a vacuum input state to a thermal state of mean photon number $1/2\sigma^2$. Since this channel is a product channel, it implies that we need $1/2\sigma^2$ average photons per mode. For our choice $\sigma = 0.3$, $1/2\sigma^2 \approx 5.56$. Since the envelope determined by σ has a larger contribution than γ that determines the oscillation, we are required to produce approximately $1/2\sigma^2$ photon number on average. It is worth emphasizing that for $\kappa \leq 2.5$, the choice satisfies the condition of Theorem S2.

B. Proof of Lemma S1

In this section we prove Lemma S1. Let $|A\rangle, |B\rangle$ be arbitrary normalized pure states in the n-mode bosonic Hilbert space. Define

$$G(\beta) \coloneqq \langle B|\hat{D}^\dagger(\beta)|B\rangle\langle A|\hat{D}(\beta)|A\rangle, \tag{S146}$$

$$G_\sigma(\gamma) \coloneqq \frac{[\mathcal{N}_\sigma * G](\gamma)}{[\mathcal{N}_\sigma * G](0)} \coloneqq \frac{\int d^{2n}\beta \exp(-|\beta-\gamma|^2/2\sigma^2)G(\beta)}{\int d^{2n}\beta \exp(-|\beta|^2/2\sigma^2)G(\beta)}. \tag{S147}$$

Here $*$ stands for convolution. We are going to prove the following inequality

$$\mathbb{E}_\gamma|G_\sigma(\gamma)|^2 = \frac{\mathbb{E}_\gamma|[\mathcal{N}_\sigma * G](\gamma)|^2}{|[\mathcal{N}_\sigma * G](0)|^2} \leq \left(\frac{1+2\sigma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^n, \tag{S148}$$

where $\gamma \sim q(\gamma) \coloneqq \left(\frac{1}{2\pi\sigma_\gamma^2}\right)^n \exp\left(-\frac{|\gamma|^2}{2\sigma_\gamma^2}\right)$ and $\sigma^2 \leq \max\left\{\frac{1}{2} - 2\sigma_\gamma^2,\ \sigma_\gamma^2\left(\sqrt{1+\frac{1}{4\sigma_\gamma^4}} - 1\right)\right\}$.

First of all, write the following expression in the Fourier basis

$$[\mathcal{N}_\sigma * G](\gamma) = \frac{1}{\pi^{2n}}\int d^{2n}\omega e^{\omega^\dagger\gamma-\gamma^\dagger\omega}F_{[\mathcal{N}_\sigma * G]}(\omega) = \frac{1}{\pi^{2n}}\int d^{2n}\omega e^{\omega^\dagger\gamma-\gamma^\dagger\omega}F_{\mathcal{N}_\sigma}(\omega)F_G(\omega), \tag{S149}$$

where the last equality uses the convolution theorem [11]. The Fourier component of $\mathcal{N}_\sigma$ is

$$F_{\mathcal{N}_\sigma}(\omega) = \int d^{2n}\beta e^{-\frac{|\beta|^2}{2\sigma^2}} e^{\beta^\dagger\omega-\omega^\dagger\beta} = (2\pi\sigma^2)^n e^{-2\sigma^2|\omega|^2}. \tag{S150}$$

The Fourier component of G can be computed as

$$F_G(\omega) = \int d^{2n}\beta \langle B|\hat{D}^\dagger(\beta)|B\rangle\langle A|\hat{D}(\beta)|A\rangle e^{\beta^\dagger\omega-\omega^\dagger\beta} \tag{S151}$$

$$= \int d^{2n}\beta \langle B|\hat{D}^\dagger(\beta)|B\rangle\langle A|\hat{D}^\dagger(\omega)\hat{D}(\beta)\hat{D}(\omega)|A\rangle \tag{S152}$$

$$= \pi^n|\langle B|\hat{D}(\omega)|A\rangle|^2, \tag{S153}$$

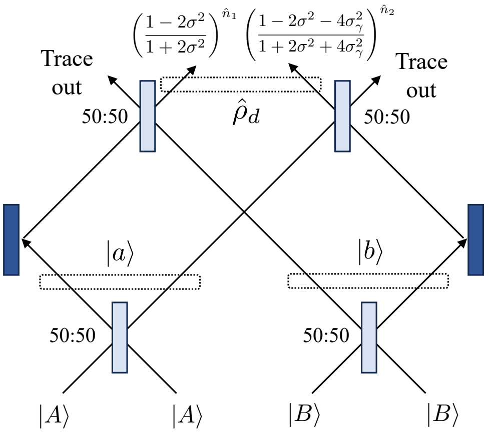
where the second line uses $\hat{D}^\dagger(\omega)\hat{D}(\beta)\hat{D}(\omega) = e^{\beta^\dagger\omega-\omega^\dagger\beta}\hat{D}(\beta)$, and the last line is by Eq. (S1). Thus,

$$|[\mathcal{N}_\sigma * G](\gamma)|^2 \tag{S154}$$

$$= \left|\frac{1}{\pi^{2n}}\int d^{2n}\omega e^{\omega^\dagger\gamma-\gamma^\dagger\omega}F_{\mathcal{N}_\sigma}(\omega)F_G(\omega)\right|^2 \tag{S155}$$

$$= \frac{1}{\pi^{4n}}\int d^{2n}\omega d^{2n}\omega' e^{(\omega-\omega')^\dagger\gamma-\gamma^\dagger(\omega-\omega')}F_{\mathcal{N}_\sigma}(\omega)F^*_{\mathcal{N}_\sigma}(\omega')F_G(\omega)F^*_G(\omega') \tag{S156}$$

$$= (2\sigma^2)^{2n}\int d^{2n}\omega d^{2n}\omega' e^{(\omega-\omega')^\dagger\gamma-\gamma^\dagger(\omega-\omega')}e^{-2\sigma^2(|\omega|^2+|\omega'|^2)}|\langle B,B|\hat{D}(\omega)\otimes\hat{D}(\omega')|A,A\rangle|^2. \tag{S157}$$



$\left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1}$
$\left(\frac{1-2\sigma^2-4\sigma_\gamma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^{\hat{n}_2}$

FIG. S4. Schematics for Eq. (S164) to (S169). Here, each line represents n-mode state, and we omit the phase factors for simplicity.

After averaging over Gaussian distribution of γ, we obtain the numerator

$$\mathbb{E}_\gamma|[\mathcal{N}_\sigma * G](\gamma)|^2 = (2\sigma^2)^{2n}\int d^{2n}\omega d^{2n}\omega' e^{-2\sigma_\gamma^2|\omega-\omega'|^2}e^{-2\sigma^2(|\omega|^2+|\omega'|^2)}|\langle B,B|\hat{D}(\omega)\otimes\hat{D}(\omega')|A,A\rangle|^2 \tag{S158}$$

$$= (2\sigma^2)^{2n}\int d^{2n}\alpha d^{2n}\beta e^{-4\sigma_\gamma^2|\beta|^2}e^{-2\sigma^2(|\alpha|^2+|\beta|^2)}|\langle B,B|\hat{U}_{\text{BS}}^\dagger\hat{D}(\alpha)\otimes\hat{D}(\beta)\hat{U}_{\text{BS}}|A,A\rangle|^2. \tag{S159}$$

Here, we changed the variable as $\omega = (\alpha+\beta)/\sqrt{2}$ and $\omega' = (\alpha-\beta)/\sqrt{2}$, i.e., $(\omega+\omega')/\sqrt{2} = \alpha$ and $(\omega-\omega')/\sqrt{2} = \beta$ and chose the 50:50 beam splitter such that

$$\hat{U}_{\text{BS}}^\dagger\hat{D}(\alpha)\otimes\hat{D}(\beta)\hat{U}_{\text{BS}} = \hat{D}((\alpha+\beta)/\sqrt{2})\otimes\hat{D}((\alpha-\beta)/\sqrt{2}). \tag{S160}$$

The denominator follows similarly from Eq. (S157) as

$$|[\mathcal{N}_\sigma * G](0)|^2 = (2\sigma^2)^{2n}\int d^{2n}\omega d^{2n}\omega' e^{-2\sigma^2(|\omega|^2+|\omega'|^2)}|\langle B,B|\hat{D}(\omega)\otimes\hat{D}(\omega')|A,A\rangle|^2 \tag{S161}$$

$$= (2\sigma^2)^{2n}\int d^{2n}\alpha d^{2n}\beta e^{-2\sigma^2(|\alpha|^2+|\beta|^2)}|\langle B,B|\hat{U}_{\text{BS}}^\dagger\hat{D}(\alpha)\otimes\hat{D}(\beta)\hat{U}_{\text{BS}}|A,A\rangle|^2. \tag{S162}$$

To further simplify the expressions, note that by applying the convolution theorem to Eq. (S151), we have

$$\frac{1}{\pi^n}|\langle B|\hat{D}(\alpha)|A\rangle|^2 = \int d^{2n}\beta W_A(\beta)W_B(\beta-\alpha), \tag{S163}$$

where W_A and W_B are the Wigner functions of the states $|A\rangle$ and $|B\rangle$, respectively. Here, note the sign in the arguments due to the complex conjugate of the characteristic function, $\langle B|\hat{D}^\dagger(\beta)|B\rangle$, in

Eq. (S151). Thus, by defining the $2n$-mode states $|a\rangle := \hat{U}_{\mathrm{BS}}|A, A\rangle$ and $|b\rangle := \hat{U}_{\mathrm{BS}}|B, B\rangle$, we have

$$\int d^{2n}\alpha d^{2n}\beta e^{-4\sigma_\gamma^2|\beta|^2} e^{-2\sigma^2(|\alpha|^2+|\beta|^2)} |\langle B, B|\hat{U}_{\mathrm{BS}}^\dagger \hat{D}(\alpha) \otimes \hat{D}(\beta)\hat{U}_{\mathrm{BS}}|A, A\rangle|^2 \tag{S164}$$

$$= \pi^{2n} \int d^{2n}\omega_1 d^{2n}\omega_2 d^{2n}\alpha d^{2n}\beta e^{-2\sigma^2|\alpha|^2} e^{-(4\sigma_\gamma^2+2\sigma^2)|\beta|^2} W_a(\omega_1, \omega_2) W_b(\omega_1 - \alpha, \omega_2 - \beta) \tag{S165}$$

$$= \pi^{2n} \int d^{2n}\omega_1 d^{2n}\omega_2 d^{2n}\gamma_1 d^{2n}\gamma_2 e^{-2\sigma^2|\omega_1-\gamma_1|^2} e^{-(4\sigma_\gamma^2+2\sigma^2)|\omega_2-\gamma_2|^2} W_a(\omega_1, \omega_2) W_b(\gamma_1, \gamma_2) \tag{S166}$$

$$= \pi^{2n} \int d^{2n}\alpha_1 d^{2n}\alpha_2 d^{2n}\beta_1 d^{2n}\beta_2 e^{-4\sigma^2|\alpha_1|^2} e^{-(8\sigma_\gamma^2+4\sigma^2)|\alpha_2|^2} W_a\left(\frac{\alpha_1+\beta_1}{\sqrt{2}}, \frac{\alpha_2+\beta_2}{\sqrt{2}}\right) W_b\left(\frac{\beta_1-\alpha_1}{\sqrt{2}}, \frac{\beta_2-\alpha_2}{\sqrt{2}}\right) \tag{S167}$$

$$= \pi^{2n} \int d^{2n}\alpha_1 d^{2n}\alpha_2 e^{-4\sigma^2|\alpha_1|^2} e^{-(8\sigma_\gamma^2+4\sigma^2)|\alpha_2|^2} W_d(\alpha_1, \alpha_2) \tag{S168}$$

$$= \pi^{2n}(1+2\sigma^2)^{-n}(1+2\sigma^2+4\sigma_\gamma^2)^{-n} \operatorname{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2-4\sigma_\gamma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^{\hat{n}_2}\right], \tag{S169}$$

where we used the convolution theorem for the first equality, and we changed the variables for the second and third equalities, and

$$W_d(\alpha_1, \alpha_2) = \int d^{2n}\beta_1 d^{2n}\beta_2 W_a\left(\frac{\alpha_1+\beta_1}{\sqrt{2}}, \frac{\alpha_2+\beta_2}{\sqrt{2}}\right) W_b\left(\frac{\beta_1-\alpha_1}{\sqrt{2}}, \frac{\beta_2-\alpha_2}{\sqrt{2}}\right) \tag{S170}$$

is the Wigner function of the state $\hat{\rho}_d$ obtained by applying a 50:50 beam splitter to the state $|a\rangle$ and $|b\rangle$ and tracing out half of the output. For the last equality, $\hat{n}_1$ and $\hat{n}_2$ are the sum of the photon number operators for the first and second n modes, respectively, and we use the following correspondence between the Wigner function and the operator

$$\frac{e^{-4x|\alpha|^2}}{\pi^n} \iff \frac{[(1-2x)/(1+2x)]^{\hat{n}}}{(1+2x)^n}, \tag{S171}$$

for any $x > 0$ (see e.g. [12, Eq. (3.6.39)]). Note that, when $x > 1/2$ the R.H.S. is proportional to a thermal state. Similar methods have been used to prove the maximum fidelity of Gaussian channels [13]. We illustrate the procedure in Fig. S4. With the same logic, we have

$$\int d^{2n}\alpha d^{2n}\beta e^{-2\sigma^2(|\alpha|^2+|\beta|^2)} |\langle B, B|\hat{U}_{\mathrm{BS}}^\dagger \hat{D}(\alpha) \otimes \hat{D}(\beta)\hat{U}_{\mathrm{BS}}|A, A\rangle|^2 \tag{S172}$$

$$= \pi^{2n}(1+2\sigma^2)^{-2n} \operatorname{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_2}\right]. \tag{S173}$$

Hence, we have

$$\mathbb{E}_\gamma |G_\sigma(\gamma)|^2 = \left(\frac{1+2\sigma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^n \frac{\operatorname{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2-4\sigma_\gamma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^{\hat{n}_2}\right]}{\operatorname{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_2}\right]}. \tag{S174}$$

We now consider two parameter regimes. First, if $2\sigma^2 + 4\sigma_\gamma^2 \leq 1$, the operators on the R.H.S. are positive-semidefinite, and it is not hard to see, by monotonicity, that

$$\frac{\operatorname{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2-4\sigma_\gamma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^{\hat{n}_2}\right]}{\operatorname{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_2}\right]} \leq 1. \tag{S175}$$

Second, if $2\sigma^2 + 4\sigma_\gamma^2 > 1$ but $2\sigma^2 \leq 2\sigma_\gamma^2 \left(\sqrt{1+\frac{1}{4\sigma_\gamma^4}} - 1\right) \leq 1$ (the last inequality holds for all $\sigma_\gamma > 0$), the above can be bounded as

$$\frac{\mathrm{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2-4\sigma_\gamma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^{\hat{n}_2}\right]}{\mathrm{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_2}\right]} \leq \frac{\mathrm{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left|\frac{1-2\sigma^2-4\sigma_\gamma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right|^{\hat{n}_2}\right]}{\mathrm{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_2}\right]} \tag{S176}$$

$$= \frac{\mathrm{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\Sigma^2}{1+2\Sigma^2}\right)^{\hat{n}_2}\right]}{\mathrm{Tr}\left[\hat{\rho}_d \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_1} \otimes \left(\frac{1-2\sigma^2}{1+2\sigma^2}\right)^{\hat{n}_2}\right]} \tag{S177}$$

$$\leq 1, \tag{S178}$$

where, in the second line, we define $-\frac{1-2\sigma^2-4\sigma_\gamma^2}{1+2\sigma^2+4\sigma_\gamma^2} := \frac{1-2\Sigma^2}{1+2\Sigma^2}$, i.e., $\Sigma^2 = \frac{1}{4(\sigma^2+2\sigma_\gamma^2)}$. In the third line, we use $\Sigma^2 \geq \sigma^2$, which can be easily verified under our assumptions for σ. Therefore, as long as $\sigma^2 \leq \max\left\{\frac{1}{2} - 2\sigma_\gamma^2,\ \sigma_\gamma^2\left(\sqrt{1+\frac{1}{4\sigma_\gamma^4}} - 1\right)\right\}$, we have the following bound

$$\mathbb{E}_\gamma |G_\sigma(\gamma)|^2 \leq \left(\frac{1+2\sigma^2}{1+2\sigma^2+4\sigma_\gamma^2}\right)^n. \tag{S179}$$

This completes the proof of Lemma S1. Note that the equality can be achieved if $\hat{\rho}_d$ is chosen to be the vacuum state. One can verify this holds when $|A\rangle = |B\rangle = |\alpha\rangle$ for some coherent state $|\alpha\rangle$.

C. Lower bound for entanglement-free Gaussian schemes

In this section, we give a lower bound for a specific class of scheme, the *Gaussian schemes*, which may be of independent interest. An ancilla-free Gaussian scheme is specified by collections of adaptively chosen Gaussian input state and Gaussian measurements. Again, thanks to convexity, we again consider only pure input states and rank-1 POVM measurements. A Gaussian input state can be expressed as $|A\rangle = \hat{D}(\omega)|\bar{A}\rangle$, where $|\bar{A}\rangle$ is a centered (*i.e.*, zero-mean) Gaussian state; A Gaussian POVM can be written as

$$\hat{\Pi}(\alpha) = |B\rangle\langle B| = \frac{1}{\pi^n}\hat{D}(\alpha)|\bar{B}\rangle\langle\bar{B}|\hat{D}^\dagger(\alpha), \tag{S180}$$

for outcomes $\alpha \in \mathbb{C}^n$, where $|\bar{B}\rangle$ is a centered Gaussian state. We refer the readers to Ref. [1–3] for more details about Gaussian quantum information.

Proposition S3. *Given positive numbers $n, \sigma, \kappa, \epsilon$ such that*

$$n \geq 8, \quad \epsilon \leq 0.24. \tag{S181}$$

If there exists an entanglement-free Gaussian scheme such that, after learning from N copies of an n-mode random displacement channel $\Lambda \in \mathbf{\Lambda}^{\epsilon,\sigma}_{\text{3-peak}}$, and then receiving a query $\beta \in \mathbb{C}^n$, can return an estimate $\tilde{\lambda}(\beta)$ of $\lambda(\beta)$ such that $|\tilde{\lambda}(\beta) - \lambda(\beta)| \leq \epsilon$ with probability at least $2/3$ for all β such that $|\beta|^2 \leq n\kappa$, then

$$N \geq 0.01\epsilon^{-2}\min\left\{\left(1+\frac{0.99\kappa}{\sigma^2}\right)^{n/2},\ \left(1+\frac{1.98\kappa}{1+2\sigma^2}\right)^n\right\}. \tag{S182}$$

A few remarks before presenting the proof: When $\kappa = O(1)$ and $\sigma^2 \ll \kappa$, the second expression in the minimization dominates, and we recover Theorem S2. On the other hand, the bound for Gaussian schemes also holds for arbitrarily large σ, though the upper bound will enter a different branch and the separation with entanglement-assisted schemes becomes weaker.

Proof. Consider the same partially-revealed hypothesis-testing task and the same strategy used by Bob in the proof of Theorem S2. Recall that the average TVD under the two hypotheses is lower bounded by

$$\mathbb{E}_\gamma \mathrm{TVD}(p_1, p_{2,\gamma}) \geq 0.1666. \tag{S183}$$

To upper bound the average TVD, recall the following bound derived in Eq. (S142),

$$\mathbb{E}_\gamma \mathrm{TVD}(p_1, p_{2,\gamma}) \leq \sum_{o_{1:N}} p_1(o_{1:N}) \sum_{k=1}^{N} 16\epsilon_0^2 \mathbb{E}_\gamma |G_\sigma^{o_{\leq k}}(\gamma)|^2, \tag{S184}$$

with $G_\sigma^{o_{\leq k}}$ defined as

$$G_\sigma^{o_{\leq k}}(\gamma) = \frac{\int d^{2n}\beta e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}} G^{o_{\leq k}}(\beta)}{\int d^{2n}\beta' e^{-\frac{|\beta'|^2}{2\sigma^2}} G^{o_{\leq k}}(\beta')}, \tag{S185}$$

$$G^{o_{\leq k}}(\beta) = \frac{\langle B_{o_k}^{o_{<k}} | \hat{D}^\dagger(\beta) | B_{o_k}^{o_{<k}} \rangle}{\langle B_{o_k}^{o_{<k}} | B_{o_k}^{o_{<k}} \rangle} \cdot \langle A^{o_{<k}} | \hat{D}(\beta) | A^{o_{<k}} \rangle, \tag{S186}$$

Note that this bound holds for any σ. Now we calculate the R.H.S. with Gaussian schemes. First compute $G^{o_{\leq k}}(\beta)$,

$$G^{o_{\leq k}}(\beta) = \langle \bar{B} | \hat{D}^\dagger(\alpha) \hat{D}^\dagger(\beta) \hat{D}(\alpha) | \bar{B} \rangle \langle A | \hat{D}(\beta) | A \rangle = \langle \bar{B} | \hat{D}^\dagger(\beta) | \bar{B} \rangle \langle \bar{A} | \hat{D}(\beta) | \bar{A} \rangle e^{\beta^\dagger(\alpha-\omega)-(\alpha-\omega)^\dagger\beta}, \tag{S187}$$

Here, without loss of generality, we can always write $|\bar{A}\rangle = \hat{U}_{\mathrm{BS}_A} \hat{U}_{\mathrm{sq}_A} |0\rangle$, where $\hat{U}_{\mathrm{BS}_A}$ represents the unitary operator for a beam-splitter network and $\hat{U}_{\mathrm{sq}_A}$ represents the product of single-mode squeezing operations. Similarly, $|\bar{B}\rangle = \hat{U}_{\mathrm{BS}_B} \hat{U}_{\mathrm{sq}_B} |0\rangle$.

To simplify $G^{o_{\leq k}}(\beta)$, using $\hat{a} := (\hat{x} + i\hat{p})/\sqrt{2}$, we can rewrite the displacement operator as

$$\hat{D}(\beta) := \exp\Big(\beta \hat{a}^\dagger - \beta^\dagger \hat{a}\Big) = \exp\Big(\sqrt{2}i \operatorname{Im}\beta \hat{x} - \sqrt{2}i \operatorname{Re}\beta \hat{p}\Big) = \exp\Big(\sqrt{2}iv \cdot \hat{q}\Big), \tag{S188}$$

where $\hat{q} := (\hat{x}_1, \ldots, \hat{x}_n, \hat{p}_1, \ldots, \hat{p}_n)^{\mathrm{T}}$ and $v(\beta) := (\operatorname{Im}\beta_1, \ldots, \operatorname{Im}\beta_n, \operatorname{Re}\beta_1, \ldots, \operatorname{Re}\beta_n)^{\mathrm{T}}$. And

$$\langle 0 | \hat{D}(\beta) | 0 \rangle = e^{-\frac{1}{2}|\beta|^2} = e^{-\frac{1}{2}|v|^2}. \tag{S189}$$

Now, let us introduce the symplectic matrix S that describes the dynamics of quadrature operators under Gaussian unitary operation $\hat{U}$:

$$\hat{U}^\dagger \hat{q}_i \hat{U} = (S\hat{q})_i. \tag{S190}$$

Since the Gaussian unitary operation we consider is written as $\hat{U}_{\mathrm{BS}} \hat{U}_{\mathrm{sq}}$, the symplectic matrix can be decomposed as $S = S_{\mathrm{BS}} S_{\mathrm{sq}}$. Here, S_{BS} is an orthogonal matrix and $\hat{S}_{\mathrm{sq}}$ can be explicitly written as $\mathrm{diag}(e^{r_1}, \ldots, e^{r_n}, e^{-r_1}, \ldots, e^{-r_n})$, where $r_1, \ldots, r_n \geq 0$ represent squeezing parameters for each mode. We use r for squeezing parameters for $|A\rangle$ and s for $|\bar{B}\rangle$. After the symplectic transformation S, the displacement operator transforms as

$$\exp\Big(\sqrt{2}iv^{\mathrm{T}}\hat{q}\Big) \to \exp\Big(\sqrt{2}iv\cdot(S\hat{q})\Big) = \exp\Big(\sqrt{2}i(S^{\mathrm{T}}v)\cdot\hat{q}\Big), \tag{S191}$$

and

$$\langle 0|\exp\Big(\sqrt{2}i(S^{\mathrm{T}}v)\cdot\hat{q}\Big)|0\rangle = e^{-\frac{1}{2}|S^{\mathrm{T}}v|^2} \tag{S192}$$

Thus,

$$\langle\bar{A}|\hat{D}(\beta)|\bar{A}\rangle = \langle 0|\hat{U}^{\dagger}_{\mathrm{sq}_A}\hat{U}^{\dagger}_{\mathrm{BS}_A}\hat{D}(\beta)\hat{U}_{\mathrm{BS}_A}\hat{U}_{\mathrm{sq}_A}|0\rangle = e^{-\frac{1}{2}|S_A^{\mathrm{T}}v|^2}, \tag{S193}$$

and

$$\langle\bar{B}|\hat{D}^{\dagger}(\beta)|\bar{B}\rangle = \langle\bar{B}|\hat{D}(\beta)|\bar{B}\rangle = e^{-\frac{1}{2}|S_B^{\mathrm{T}}v'|^2} = e^{-\frac{1}{2}|S_B^{\mathrm{T}}v|^2}, \tag{S194}$$

where $v \coloneqq v(\beta)$. The first equality is due to the fact that $\langle\bar{B}|\hat{D}^{\dagger}(\beta)|\bar{B}\rangle$ is real. And we can write the phase factor as

$$\exp\left(\beta^{\dagger}(\alpha-\omega)-\beta(\alpha-\omega)^{\dagger}\right) = \exp\Big(2iv^{\mathrm{T}}u\Big), \tag{S195}$$

where $u \coloneqq (-\operatorname{Re}(\alpha_1-\omega_1),\ldots,-\operatorname{Re}(\alpha_n-\omega_n),\operatorname{Im}(\alpha_1-\omega_1),\ldots,\operatorname{Im}(\alpha_n-\omega_n))^{\mathrm{T}}$. Thus,

$$G^{o_{\leq k}}(\beta) = \langle\bar{B}|\hat{D}^{\dagger}(\beta)|\bar{B}\rangle\langle\bar{A}|\hat{D}(\beta)|\bar{A}\rangle e^{\beta^{\dagger}(\alpha-\omega)-(\alpha-\omega)^{\dagger}\beta} \tag{S196}$$

$$= \exp\left[-\frac{1}{2}v^{\mathrm{T}}(S_AS_A^{\mathrm{T}}+S_BS_B^{\mathrm{T}})v + 2iv^{\mathrm{T}}u\right] \tag{S197}$$

$$\coloneqq \exp\left[-\frac{1}{2}v^{\mathrm{T}}\Sigma v + 2iv^{\mathrm{T}}u\right] \tag{S198}$$

$$= \exp\left[-\frac{1}{2}(Ov)^{\mathrm{T}}D(Ov) + 2i(Ov)^{\mathrm{T}}\cdot(Ou)\right] \tag{S199}$$

$$= \prod_{i=1}^{2n}\exp\left[-\frac{d_i}{2}\left(v_i'-\frac{2i}{d_i}u_i'\right)^2-\frac{2u_i'^2}{d_i}\right], \tag{S200}$$

where $\Sigma \coloneqq S_AS_A^{\mathrm{T}}+S_BS_B^{\mathrm{T}} > 0$ is diagonalized as $\Sigma = O^{\mathrm{T}}DO$ with diagonal matrix $D = \operatorname{diag}(d_1,\ldots,d_{2n}) > 0$, and $v' \coloneqq Ov$, $u' \coloneqq Ou$. Let us analyze the spectrum of D. Note that since $S_AS_A^{\mathrm{T}}$ and $S_BS_B^{\mathrm{T}}$ are physical covariance matrices, $S_AS_A^{\mathrm{T}} \geq i\Omega$, $S_BS_B^{\mathrm{T}} \geq i\Omega$, and thus $\Sigma \geq 2i\Omega$ [3], where

$$\Omega = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \otimes \mathbb{1}_M. \tag{S201}$$

Hence, by the Williamson decomposition [3], the spectrum of Σ is composed of pairs such that the product of the ith and $(i+n)$th eigenvalues of this matrix is no smaller than 4. Without loss of generality, we label the eigenvalues $d_1,\ldots,d_{2n}$ in such a way that $d_id_{i+n} \geq 4$ for all $1 \leq i \leq n$.

Now let us compute $G_{\sigma}^{o_{\leq k}}(\gamma)$.

$$G_{\sigma}^{o_{\leq k}}(\gamma) = \frac{\int d^{2n}\beta e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}}G^{o_{\leq k}}(\beta)/(2\pi\sigma^2)^n}{\int d^{2n}\beta' e^{-\frac{|\beta'|^2}{2\sigma^2}}G^{o_{\leq k}}(\beta')/(2\pi\sigma^2)^n} \tag{S202}$$

By defining $z \coloneqq (\operatorname{Im}\gamma_1, \dots, \operatorname{Im}\gamma_n, \operatorname{Re}\gamma_1, \dots, \operatorname{Re}\gamma_n)$, and $z' \coloneqq Oz$, we have

$$\begin{aligned}
&\frac{1}{(2\pi\sigma^2)^n}\int d^{2n}\beta e^{-\frac{|\beta-\gamma|^2}{2\sigma^2}} G^{o_{\le k}}(\beta) \qquad \text{(S203)}\\
=\ &\frac{1}{(2\pi\sigma^2)^n}\int d^{2n}v' \prod_{i=1}^{2n}\exp\left[-\frac{(v_i'-z_i')^2}{2\sigma^2} - \frac{d_i}{2}\left(v_i' - \frac{2i}{d_i}u_i'\right)^2 - \frac{2u_i'^2}{d_i}\right] \qquad \text{(S204)}\\
=\ &\prod_{i=1}^{2n}\left[\frac{1}{\sqrt{1+d_i\sigma^2}}\exp\left(-\frac{2u_i'^2\sigma^2}{1+d_i\sigma^2}\right)\exp\left(\frac{1}{2}\left(\frac{-d_iz_i'^2+4iu_iz_i'}{1+d_i\sigma^2}\right)\right)\right], \qquad \text{(S205)}
\end{aligned}$$

Therefore, we obtain

$$G_\sigma^{o_{\le k}}(\gamma) = \prod_{i=1}^{2n}\exp\left[\frac{1}{2}\left(\frac{-d_iz_i'^2+4iu_iz_i'}{1+d_i\sigma^2}\right)\right], \quad \text{and} \quad |G_\sigma^{o_{\le k}}(\gamma)| = \prod_{i=1}^{2n}\exp\left[\frac{-d_iz_i'^2}{2(1+d_i\sigma^2)}\right]. \tag{S206}$$

Thus, after taking the average over γ, we obtain

$$\mathbb{E}_\gamma|G_\sigma^{o_{\le k}}(\gamma)|^2 = \int d^{2n}z' \frac{e^{-\frac{|z|^2}{2\sigma_\gamma^2}}}{(2\pi\sigma_\gamma^2)^n}\prod_{i=1}^{2n}\exp\left[\frac{-d_iz_i'^2}{(1+d_i\sigma^2)}\right] = \prod_{i=1}^{2n}\sqrt{\frac{1}{1+2d_i\sigma_\gamma^2/(1+d_i\sigma^2))}}. \tag{S207}$$

Substituting this back to Eq. (S184), we obtain the following upper bound for the average TVD

$$\mathbb{E}_\gamma \mathrm{TVD}(p_1, p_{2,\gamma}) \le 16N\epsilon_0^2\prod_{i=1}^{2n}\sqrt{\frac{1}{1+2d_i\sigma_\gamma^2/(1+d_i\sigma^2))}}, \tag{S208}$$

which, combined with the lower bound Eq. (S183) and substituting $\epsilon_0 = \epsilon/0.98$, yields the following sample complexity bound

$$N \ge 0.01\epsilon^{-2}\left(\prod_{i=1}^{2n}\sqrt{1+\frac{2d_i\sigma_\gamma^2}{1+d_i\sigma^2}}\right). \tag{S209}$$

To find a lower bound independent of d_i's, focus on the following product, for any $1 \le i \le n$,

$$\left(1+\frac{2d_i\sigma_\gamma^2}{1+d_i\sigma^2}\right)\left(1+\frac{2d_{i+n}\sigma_\gamma^2}{1+d_{i+n}\sigma^2}\right) \tag{S210}$$

This is an increasing function in d_i and d_{i+n}. We know the spectrum satisfies $d_id_{i+n} \ge 4$. Hence, we can lower bound it by setting $d_{i+n}/2 = 2/d_i \coloneqq d > 0$, which leads to

$$\left(1+\frac{2d_i\sigma_\gamma^2}{1+d_i\sigma^2}\right)\left(1+\frac{2d_{i+n}\sigma_\gamma^2}{1+d_{i+n}\sigma^2}\right) \ge \frac{(d+2\sigma^2+4\sigma_\gamma^2)(1+2d(\sigma^2+2\sigma_\gamma^2))}{(d+2\sigma^2)(1+2d\sigma^2)}. \tag{S211}$$

The R.H.S. is differentiable in d, with its only extreme value at $d=1$ being

$$\left(1+\frac{4\sigma_\gamma^2}{1+2\sigma^2}\right)^2. \tag{S212}$$

Meanwhile, when $d \to 0$ or $d \to \infty$, it becomes $1+2\sigma_\gamma^2/\sigma^2$. We thus have the following lower bound,

$$\left(1+\frac{2d_i\sigma_\gamma^2}{1+d_i\sigma^2}\right)\left(1+\frac{2d_{i+n}\sigma_\gamma^2}{1+d_{i+n}\sigma^2}\right) \ge \min\left\{1+\frac{2\sigma_\gamma^2}{\sigma^2}, \left(1+\frac{4\sigma_\gamma^2}{1+2\sigma^2}\right)^2\right\}, \tag{S213}$$

which gives us the following sample complexity lower bound:

$$N \geq 0.01\epsilon^{-2} \min\left\{\left(1+\frac{2\sigma_\gamma^2}{\sigma^2}\right)^{n/2}, \left(1+\frac{4\sigma_\gamma^2}{1+2\sigma^2}\right)^n\right\}. \tag{S214}$$

Substituting $2\sigma_\gamma^2 = 0.99\kappa$ completes the proof of Proposition S3.

□

S4. GAUSSIAN TAIL EFFECT

In this section, we find the condition that the effect of truncating a multivariate normal distribution is smaller than 0.5, which is used to derive the lower bound for entanglement-free schemes. Consider a multivariate normal distribution:

$$q(\boldsymbol{x}) = \left(\frac{1}{2\pi\sigma^2}\right)^n \exp\left(-\frac{|\boldsymbol{x}|^2}{2\sigma^2}\right), \tag{S215}$$

where $\boldsymbol{x} \in \mathbb{R}^{2n}$. Note that in the main text, while we consider $\gamma \in \mathbb{C}^n$, they are equivalent. Now, we consider a truncated distribution with $|\boldsymbol{x}|^2 \leq R^2$ with a given R:

$$\begin{aligned}\int_{|\boldsymbol{x}|\leq R} d\boldsymbol{x} q(\boldsymbol{x}) &= \int_{|\boldsymbol{x}|\leq R} d\boldsymbol{x} \left(\frac{1}{2\pi\sigma^2}\right)^n \exp\left(-\frac{|\boldsymbol{x}|^2}{2\sigma^2}\right) &\text{(S216)}\\ &= \left(\frac{1}{2\pi\sigma^2}\right)^n \int_0^R dr \int d\Omega_{2n} r^{2n-1} \exp\left(-\frac{r^2}{2\sigma^2}\right) &\text{(S217)}\\ &= 1 - \frac{\Gamma\left(n, \frac{R^2}{2\sigma^2}\right)}{\Gamma(n)}. &\text{(S218)}\end{aligned}$$

where we have used the following integrals:

$$\int d\Omega_n = \frac{2\pi^{n/2}}{\Gamma(n/2)}, \qquad \int_0^R dr r^{2n-1} \exp\left(-\frac{r^2}{2\sigma^2}\right) = 2^{n-1}\sigma^{2n}\left[\Gamma(n) - \Gamma\left(n, \frac{R^2}{2\sigma^2}\right)\right], \tag{S219}$$

and

$$\Gamma(n,x) = \int_x^\infty t^{n-1} e^{-t} dt \tag{S220}$$

is the (upper) incomplete gamma function and $\Gamma(n) = \Gamma(n,0)$. Therefore, the tail probability is given by $\Gamma\left(n, \frac{R^2}{2\sigma^2}\right)/\Gamma(n)$. In the main text and the proof of sample complexity lower bound of entanglement-free schemes, we choose $2\sigma^2 = 0.99\kappa$ and $R^2 = \kappa n$. For our purpose, it suffices to show that $\frac{\Gamma(n,n/0.99)}{\Gamma(n)} \leq 0.5$. To see this, we use the following inequality [14]:

$$\frac{\Gamma(n,kn)}{\Gamma(n)} \leq (ke^{1-k})^n, \quad \forall\ k > 1. \tag{S221}$$

First notice that for $k = 1/0.99$ and $n = 14000$, $(ke^{1-k})^n \leq 0.492$. Now, for every $n < 14000$, one can numerically verify $\frac{\Gamma(n,n/0.99)}{\Gamma(n)} \leq 0.5$ (see Fig. S5); For $n > 14000$, the upper bound $(ke^{1-k})^n$ monotonically decreases with n, so we also have $\frac{\Gamma(n,n/0.99)}{\Gamma(n)} \leq 0.492$. Combining these two cases completes the proof.

Abstract. Wave-particle duality, the cornerstone of quantum mechanics, illustrates essential trade-offs between two complementary aspects of quantum systems. In this work, from the perspective of coherence resource manipulation, we uncover a novel duality relation between quantum coherence and distinguishability in ensembles of mutually orthogonal pure states, treating them as two complementary resources. We demonstrate that the sum of 'co-bits', coherence preserved after discrimination, and classical bits, distinguishability extracted through perfect discrimination is bounded. One cannot simultaneously extract all classical information and preserve coherence. Such duality relation exposes an inherent trade-off between quantum coherence and classical distinguishability resources. Our findings offer a fresh perspective and advance our understanding of the intrinsic complementary relationship between quantum and classical resources. Note: A technical version of this work is attached.

Keywords: Quantum coherence, wave-particle duality, quantum resource theory, quantum state discrimination.

Background. Wave-particle duality, a fundamental principle in quantum mechanics, deeply relates with foundational phenomena such as uncertainty relations [1–3] and Wheeler's delayed-choice experiments [4], as well as to innovative quantum imaging techniques [5, 6]. It reveals an inherent trade-off relation between the display of wave and particle behavior in a single quantum particle. Such duality relation is typically demonstrated in interference experiments [7–10]. In a two-path interferometer experiment, a particle behavior is characterized by path information acquired by a which-path detector, while wave behavior is determined by the visibility of the interference pattern. Quantitative statements of wave-particle duality in two-path interferometer experiments [11, 12], such as the famous inequality by Englert [13] and Jaeger *et al.* [14], are formulated as

$$D^2 + V^2 \leq 1, \tag{1}$$

where D measures path distinguishability, characterizing particle behavior, and V is the visibility of the interference fringe, determining wave behavior.

Furthermore, in extending wave-particle duality relation to multipath interferometers [15, 16], such relation has been reformulated in the context of quantum information theory. These reformulations [17–20] leverage resource theory of coherence [21–24] and quantum state discrimination (QSD) [25], a fundamental quantum information task. By entangling particle and detector states within an interferometer, Eq. (1) was formulated by a duality relation between some coherence measure [26], which substitutes visibility to identify wave properties, and the distinguishability among detector states providing which-path information.

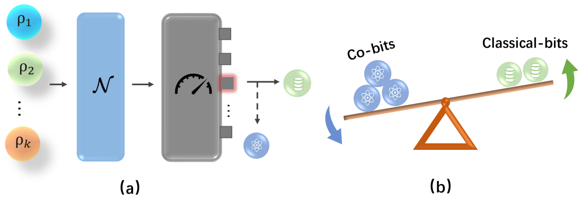

Figure 1: (a) Quantum state discrimination via free operations. The discrimination procedure consists of applying a free operation $\mathcal{N}$ w.r.t. a quantum resource theory and measuring the state in a computational basis. (b) Coherence-distinguishability duality relation. There is an inherent trade-off between the quantum coherence resource ('co-bits') and the classical distinguishability resource ('c-bits').

Coherence stands as a typical quantum resource generating quantum superposition promoting quantum computation algorithms [27, 28] and intrinsic randomness vital in quantum cryptography [29–31]. While distinguishability, contrasted with coherence, acts as a classical resource revealing deterministic classical information encoded in quantum systems [32–34]. The above reformulation caught a glimpse of the deep complementary correlation between quantum and classical resources.

Following up this quantum information perspective, wave-particle duality has been extended into quantum many-body systems [35–37]. An operational meaning of wave-particle duality has also been demonstrated [38]. However, all of these investigations are rooted in interference scenarios. Can we further discern a similar duality relationship between coherence and distinguishability resources in broader and more fundamental quantum scenarios, transcending typical interference experiments? Such inquiry aids in elucidating the intrinsic connection between these two resources themselves from a theoretical perspective for quantum foundations.

Overview of results: This work aims to investigate the manipulation of coherence resources within the context of quantum state discrimination (QSD), offering a fresh perspective on wave-particle duality through the lens of quantum resource theory. Specifically, we establish the following:

1. We propose a general paradigm for quantum state discrimination via quantum channels, enabling the exploration of **quantum resource manipulation** within QSD.

2. We reveal a **coherence-distinguishability duality relation**, quantitatively captured by a bounded sum of 'co-bits' (preserved coherence) and classical bits (extracted distinguishability). This relation highlights a **resource-theoretic nature** of wave-particle duality.

3. We analyze **extreme cases** in this coherence-distinguishability duality relation. First, we show that this duality relation is **tight** by a special case. Secondly, we demonstrate that One cannot simultaneously extract all classical bits and preserve coherence. These observations hint again at the underlying **wave-particle duality relationship** between coherence and distinguishability resource.

Quantum state discrimination via free operations: Our first contribution is to propose a general quantum state discrimination paradigm via quantum channels, which contributes to explore quantum resource manipulation within QSD.

Recall that for the minimum-error state discrimination, one aims to find a Positive Operator-Valued Measure (POVM) $\{E_j\}_{j=0}^{k-1}$ to maximize the average success probability of discriminating a state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$ with $\sum_{j=0}^{k-1} p_j = 1, \rho_j \in \mathcal{D}(\mathcal{H}_A)$:

$$P_{\mathrm{suc}}(\Omega) = \max_{\{E_j\}_j} \sum_j p_j \operatorname{Tr}(E_j \rho_j). \tag{2}$$

To investigate the quantum resource manipulation in QSD, we reconsider a general paradigm for discriminating $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$ as the following steps in order: (I) Receive an unknown state ρ_j with prior probability p_j. (II) Apply a quantum channel $\mathcal{N}_{A\to BA'}$ to ρ_j, yielding $\omega_{BA'}^{(j)} = \mathcal{N}_{A\to BA'}(\rho_j)$ where $A' \cong A$ and $\dim \mathcal{H}_B = k$. (III) Measure $\omega_{BA'}^{(j)}$ on the subsystem B in computational basis. If the outcome is i, decide the received state is ρ_i.

We call the above quantum channel $\mathcal{N}_{A\to BA'}$ a *discrimination channel.* This paradigm provides an intuitive approach to evaluate the 'resourcefulness' of the discrimination channel, which is crucial for understanding resource dynamics and manipulation within a discrimination task. Specifically, for a given quantum resource theory $(\mathcal{F}, \mathcal{O})$, we introduce the optimal average success probability by free operations as follows.

$$\begin{aligned}\widetilde{P}_{\mathrm{suc},\mathcal{O}}(\Omega) = &\max \sum_{j=0}^{k-1} p_j \operatorname{Tr}[\mathcal{N}_{A\to BA'}(\rho_j)(|j\rangle\langle j|_B \otimes I_{A'})]\\ &\text{s.t. } \mathcal{N}_{A\to BA'} \in \mathcal{O}\end{aligned}$$

Furthermore, we denote $\widetilde{P}_{\mathrm{suc}}(\Omega)$ as the maximal average success probability attainable through operations $\mathcal{N}_{A\to BA'}$ without constraints on their availability. Note if there is an optimal $\mathcal{N}_{A\to BA'} \in \mathcal{L}(\mathcal{H}_A, \mathcal{H}_{BA'})$ such that $\widetilde{P}_{\mathrm{suc}}(\Omega) = P_{\mathrm{suc}}(\Omega)$, we say $\mathcal{N}_{A\to BA'}$ can optimally discriminate Ω.

Proposition 1 *For a d-dimensional state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$, the optimal discrimination probability $P_{\mathrm{suc}}(\Omega)$ can be achieved by incoherent operations.*

Proposition 1 reveals that the process of optimally discriminating an ensemble Ω does not consume additional quantum coherence. This pivotal finding aligns with the intuition from the wave-particle duality relation that distinguishability cannot increase with an increase in coherence, where they are complementary.

Coherence-distinguishability duality: Our second contribution is to reveal an inherent trade-off between preserved coherence and achievable perfect distinguishability within ensembles of mutually

	Wave-Particle Duality	**Coherence-Distinguishability Duality**
Scenario	Multi-interference experiment	Coherence resource manipulation in QSD
Quantitative Relation	$D^2 + V^2 \leq 1$	$\mathbf{C}_{\text{MIO}}(\Omega) + \mathbf{S}(\Omega) \leq \log d$
Particle behavior	D: Path distinguishability	$\mathbf{S}(\Omega)$: Classical distinguishability bits
Wave behavior	V: Interference fringe visibility	$\mathbf{C}_{\text{MIO}}(\Omega)$: Post-discrimination 'co-bits'
Extreme Case	Perfect path distinguishability $D = 1$ $\Longrightarrow$ No interference $V = 0$	Full classical bit extraction $\mathbf{S}(\Omega) = \log d$ $\Longrightarrow$ No 'co-bits' preserved $\mathbf{C}_{\text{MIO}}(\Omega) = 0$
Equality holding condition	Pure detector states	Maximally coherent states

Table 1: Comparison between Wave-Particle Duality (Eq. (1)) and Coherence-Distinguishability Duality ((Eq. (3))

orthogonal pure states, highlighting the resource-theoretic nature of wave-particle duality.

For coherence analysis, we consider the maximum relative entropy of coherence $C_{\max}(\rho)$ as a coherence measure [22, 39, 40]. The maximal possible value of $C_{\max}(\cdot)$ for a d-dimensional state is achieved by Ψ_d with $C_{\max}(\Psi_d) = \log d$ [41], corresponding with $\log d$ coherent bits (co-bits) [42]. Then, we introduce the *post-disrimination coherence* as the maximum average *co-bits* that can be preserved after a perfect discrimination procedure.

Definition 2 (Post-discrimination coherence) *For a mutually orthogonal d-dimensional state ensemble* $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$, *the post-discrimination coherence under maximally incoherent operations is defined as* $\mathbf{C}_{\text{MIO}}(\Omega) := \log(1+\eta)$ *where*

$$\eta = \max\left\{\sum_{j=0}^{k-1} p_j C_R(\sigma_j) : \mathcal{M}(\rho_j) = |j\rangle\langle j| \otimes \sigma_j, \right.$$
$$\left. \sigma_j \in \mathcal{D}(\mathcal{H}_d),\, \forall j,\, \mathcal{M} \in \text{MIO}\right\}.$$

Proposition 1 indicates that there is always a feasible MIO $\mathcal{M}$ for $\mathbf{C}_{\text{MIO}}(\Omega)$.

We recall that the distinguishability emerges from a pure state ensemble $\Omega = \{(p_j, |\psi_j\rangle)\}_{j=0}^{k-1}$ can be characterized by the von-Neumann entropy defined on it [32], i.e., $\mathbf{S}(\Omega) := S(\hat{\omega})$ where $S(\cdot)$ is the von-Neumann entropy of a state and $\hat{\omega} = \sum_j p_j |\psi_j\rangle\langle\psi_j|$ denotes the average state of Ω. In Theorem 3, we demonstrate the duality relation between these two quantities $\mathbf{S}(\Omega)$ and $\mathbf{C}_{\text{MIO}}(\Omega)$.

Theorem 3 (Coherence-distinguishability duality) *For a mutually orthogonal d-dimensional pure-state ensemble* $\Omega = \{(1/k, |\psi_j\rangle)\}_{j=0}^{k-1}$,

$$\mathbf{C}_{MIO}(\Omega) + \mathbf{S}(\Omega) \leq \log d. \tag{3}$$

Theorem 3 gives a novel wave-particle duality relation through the lens of quantum resource theory. It reveals an intriguing fact that the more classical bits ('c-bits') you want to decode, the fewer 'co-bits' can be preserved after extracting all classical information.

Boundary cases of duality relation: Our third contribution is to analyze extreme cases of this duality relation. We demonstrate the tightness of Eq. (3) and the fact that one cannot simultaneously extract all classical information and preserve coherence.

Proposition 4 *Let* $|\phi_j\rangle = HX^j|0\rangle$ *where* H, X *are the d-dimensional Hadamard gate and generalized Pauli X gate. For* $\Omega = \{(1/k, |\phi_j\rangle)\}_{j=0}^{k-1}$, $k \leq d$,

$$\mathbf{C}_{MIO}(\Omega) + \mathbf{S}(\Omega) = \log d. \tag{4}$$

Proposition 4 shows that an ensemble of k mutually orthogonal maximally coherent states exactly achieves the upper bound in Eq. (3), which identifies the tightness of this trade-off relation. This finding underscores a novel role for maximally coherent states beyond their established status as golden resources within the quantum resource theory of coherence.

Furthermore, as another boundary case of Theorem 3, we note that when the cardinality of the set Ω is equal to the dimension d, $\mathbf{C}_{\text{MIO}}(\Omega)$ vanishes, indicating that no coherence resource could be preserved after perfect discrimination. The total similarity comparisons between Wave-Particle Duality (Eq. (1)) and Coherence-Distinguishability Duality ((Eq. (3)) are shown in Table 1.

Concluding remarks: In this work, we explore the quantum coherence manipulation within quantum state discrimination and uncover a significant duality relation between quantum coherence and classical distinguishability resources. Our result opens a new avenue for studying wave-particle duality and the uncertainty principle through the lens of quantum resource theories, offering insights to both quantum foundations and quantum information theory.

Wave-particle duality, a fundamental principle of quantum mechanics, encapsulates the complementary relationship between the wave and particle behaviors of quantum systems. In this paper, we uncover a novel manifestation of this duality by establishing a trade-off between quantum coherence and classical distinguishability through the lens of quantum state discrimination under incoherent operations. We prove that in an ensemble of mutually orthogonal pure states, the sum of 'co-bits', quantifying the coherence preserved under incoherent free operations, and classical bits, representing the distinguishability extracted via quantum state discrimination, is bounded. This coherence-distinguishability duality relation exposes an inherent limitation on the simultaneous preservation of a system's quantum coherence (wave-like property) and extraction of its classical distinguishability (particle-like property). Our findings provide a fresh perspective on wave-particle duality through the paradigm of quantum resource theories, offering fundamental insights into the manipulation of quantum and classical resources, with implications for quantum foundations and quantum technologies.

Introduction.— Can all physical observables of a system be sharply determined simultaneously, or say is there any trade-off relation among them? Heisenberg answered this pivotal question with his famous uncertainty principle [1]. This fundamental principle states that the more accurately one measures the position of a particle, the less accurately one can measure its momentum, and vice versa. Uncertainty principles deeply reveal an inherent knowledge trade-off between two complementary observables of a quantum system [2]. Under a modern formulation in terms of entropy [3–5], uncertainty relation is further shown to be equivalent to another intriguing and fundamental phenomenon in quantum mechanics, namely wave-particle duality.

Wave-particle duality stated by Bohr's complementarity principle [6] also reveals an inherent trade-off relation between two conjugate properties of a quantum object. This describes a competition phenomenon between the display of wave and particle behavior for a single quantum particle. Such duality relation is typically demonstrated in interference experiments [7–10], such as the double-slit experiment or two-path interferometer. In such experiments, a particle behavior is characterized by path information acquired by a which-path detector, while wave behavior is determined by the visibility of the interference pattern. Quantitative statements of wave-particle duality [11, 12], such as the famous inequality by Englert [13] and Jaeger *et al.* [14], are formulated as

$$D^2 + V^2 \leq 1, \tag{1}$$

where D represents path distinguishability and V denotes visibility of the interference fringe. Perfect path distinguishability ($D = 1$) corresponds to complete particle behavior, thus no interference pattern will exhibit ($V = 0$).

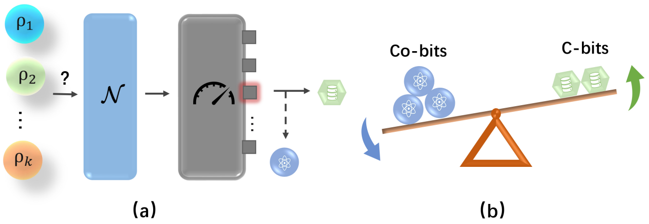

Fig 1. (a) Quantum state discrimination via free operations. The discrimination procedure consists of applying a free operation $\mathcal{N}$ w.r.t. a quantum resource theory and measuring the state on a computational basis. (b) Coherence-distinguishability duality relation. There is a trade-off between the quantum coherence resource ('co-bits') and the classical distinguishability resource ('c-bits').

Furthermore, in extending wave-particle duality relation to multipath interferometers [15, 16], such relation has been reformulated within the context of quantum information theory. These reformulations [17–20] leverage the resource theory of coherence [21–24] and quantum state discrimination (QSD) [25], a fundamental task in quantum information theory. By entangling particle and detector states within an interferometer, Eq. (1) was formulated by a duality relation between some coherence measure [26] replacing visibility to identifying wave property, and the distinguishability among detector states providing which-path information. In this context, perfect distinguishability of mutually orthogonal detector states implies full path information and the absence of coherence.

Coherence stands as a typical quantum resource generating quantum superposition promoting quantum computation

[*] Zhiping Liu and Chengkai Zhu contributed equally to this work.
[†] felixxinwang@hkust-gz.edu.cn

algorithms [27, 28] and intrinsic randomness vital in quantum cryptography [29–31]. While distinguishability, contrasted with coherence, acts as a classical resource revealing deterministic classical information encoded in quantum systems [32–34]. The above reformulation caught a glimpse of the deep complementary correlation between quantum and classical resources.

Following up this quantum information perspective, wave-particle duality has been extended into complicated quantum many-body systems [35–37]. An operational meaning of wave-particle duality has also been demonstrated within discrimination games [38]. However, all of these investigations are rooted in interference scenarios, where the path of particles is entangled with corresponding detector states within an interferometer. Can we further discern a similar duality relationship between coherence and distinguishability resources in broader and more fundamental quantum scenarios, transcending typical interference experiments? Such inquiry aids in elucidating the intrinsic connection between these two resources themselves from a theoretical perspective for quantum foundations.

In this work, we uncover a novel coherence-distinguishability duality relation within mutually orthogonal pure-state ensembles. Different from supposing a multipath interferometer scenario as previous works, our discovery stems from exploring coherence resource manipulation by introducing a new paradigm for QSD via free operations (see Fig. 1(a)). This duality relation shows that the more one extracts classical information by discriminating states in the ensemble, the less one can preserve the coherence, and vice versa. It unveils an inherent trade-off between the coherence resource preserved after discrimination and the achievable perfect distinguishability within these ensembles (see Fig. 1(b)).

In particular, we present two intriguing cases derived from our coherence-distinguishability duality relation. Firstly, we reveal that our duality relation is tight. When considering mutually orthogonal maximally coherent states, the sum of the maximum co-bits left and the classical bits we can extract achieves the bound $\log d$. Secondly, we demonstrate that in discriminating a complete orthonormal basis of a d-dimensional Hilbert space, no coherence can be preserved while extracting $\log d$ classical bits. This is a mutually exclusive extreme situation within our duality relation. Our work establishes a profound connection between coherence and distinguishability as fundamental resources, generalizing the wave-particle duality relation into a new scenario within the realm of quantum resource theory.

Quantum state discrimination via free operations.— We begin with an introduction to quantum resource theories and quantum state discrimination. Let $\mathcal{L}(\mathcal{H}_A, \mathcal{H}_B)$ denote the set of linear operations from a d_A-dimensional Hilbert space $\mathcal{H}_A$ to $\mathcal{H}_B$. Let $\mathcal{D}(\mathcal{H}_A)$ be the set of density operators acting on $\mathcal{H}_A$, and $\mathcal{N}_{A\to B}$ be a quantum operation from system A to B which is a completely positive and trace-preserving map. A quantum resource theory of states is defined as a tuple $(\mathcal{F}, \mathcal{O})$ where $\mathcal{F}$ is the set of free states; $\mathcal{O}$ is the set of free operations that preserve free states, i.e., $\mathcal{N}(\rho) \in \mathcal{F}, \forall \mathcal{N} \in \mathcal{O}, \forall \rho \in \mathcal{F}$. For $(\mathcal{F}, \mathcal{O})$, a reasonable resource measure $\mathcal{R}(\rho) \in \mathbb{R}, \forall \rho \in \mathcal{D}(\mathcal{H}_A)$ satisfies monotonicity $\mathcal{R}(\mathcal{N}(\rho)) \le \mathcal{R}(\rho)$ and positivity $\mathcal{R}(\rho) \ge 0, \forall \rho \in \mathcal{D}(\mathcal{H}_A), \forall \mathcal{N} \in \mathcal{O}$. Such a quantum resource theory intuitively arises when there is a restricted set of operations $\mathcal{O}$ that are significantly easier to implement than the others, e.g., local operations and classical communication (LOCC) in entanglement theory [39], Clifford operations in the quantum resource theory of magic states [40, 41].

For coherence, we start by fixing the incoherent basis as the computational basis $\{|i\rangle\}_i$ when considering circuit-based quantum computation, since the encoding and decoding of the information will be reduced to the classical application of stochastic matrices onto probability vectors if there is no coherence involved. We denote by $\mathcal{I}$ the set of incoherent states, i.e., those diagonal in $\{|i\rangle\}_i$. For a given dimension d, we denote $|\Psi_d\rangle = \frac{1}{\sqrt{d}} \sum_{i=0}^{d-1} |i\rangle$ as the maximally coherent state, and denote $\Psi_d = |\Psi_d\rangle\langle\Psi_d|$. The maximal set of operations that map incoherent states to incoherent states is called the maximally incoherent operations (MIO) [42]. Other common free operations include incoherent operations (IO) [26], dephasing-covariant incoherent operations (DIO) [43, 44] and strictly incoherent operations (SIO) [21]. There are hierarchies among these free operations: SIO $\subsetneq$ IO $\subsetneq$ MIO, SIO $\subsetneq$ DIO $\subsetneq$ MIO [43]. More details about QRT of coherence can be found in the appendix.

Recall that for the minimum-error state discrimination, one aims to find a Positive Operator-Valued Measure (POVM) $\{E_j\}_{j=0}^{k-1}$ to maximize the average success probability of discriminating a state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$ with $\sum_j p_j = 1, \rho_j \in \mathcal{D}(\mathcal{H}_A)$:

$$P_{\rm suc}(\Omega) = \max_{\{E_j\}_j} \sum_j p_j \operatorname{Tr}(E_j \rho_j). \tag{2}$$

Numerous studies have been carried out to understand the limits of such a task when measurements are restricted to different classes, including POVMs with locality constraints [45–53] (i.e., LOCC, separable, PPT POVMs), incoherent [54], stabilizer measurement [55], all of which are considered within the context of different quantum resource theories.

To investigate the quantum resource manipulation in QSD, we reconsider a general paradigm for discriminating $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$ as the following steps in order: (I) Receive an unknown state ρ_j with prior probability p_j. (II) Apply a quantum channel $\mathcal{N}_{A\to BA'}$ to ρ_j, yielding $\omega_{BA'}^{(j)} = \mathcal{N}_{A\to BA'}(\rho_j)$ where $A' \cong A$ and $\dim \mathcal{H}_B = k$. (III) Measure $\omega_{BA'}^{(j)}$ on the subsystem B in computational basis. If the outcome is i, decide the received state is ρ_i.

We call the above quantum channel $\mathcal{N}_{A\to BA'}$ a *discrimination channel*. This paradigm provides an intuitive approach to evaluate the 'resourcefulness' of the discrimination channel, which is crucial for understanding resource dynamics and manipulation within a discrimination task. Specifically, for a given quantum state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$ and a quantum resource theory $(\mathcal{F}, \mathcal{O})$, we introduce the optimal average success probability by free operations as follows.

$$\widetilde{P}_{\text{suc},\mathcal{O}}(\Omega) = \max \sum_{j=0}^{k-1} p_j \operatorname{Tr}[\mathcal{N}_{A\to BA'}(\rho_j)(|j\rangle\langle j|_B \otimes I_{A'})]$$
$$\text{s.t. } \mathcal{N}_{A\to BA'} \in \mathcal{O}$$

Furthermore, we denote $\widetilde{P}_{\text{suc}}(\Omega)$ as the maximal average success probability attainable through operations $\mathcal{N}_{A\to BA'}$ without constraints on their availability. It is worth noting that $\widetilde{P}_{\text{suc},\mathcal{O}}(\Omega)$ can be equivalently characterized by optimization over operations $\mathcal{N}_{A\to B} \in \mathcal{O}$, since discarding the subsystem A' typically constitutes a free operation. However, the inclusion of the reference system A' facilitates a comprehensive examination of resource dynamics during the discrimination process. This concept is elaborated further in Theorem 2. Note if there is an optimal $\mathcal{N}_{A\to BA'} \in \mathcal{L}(\mathcal{H}_A, \mathcal{H}_{BA'})$ such that $\widetilde{P}_{\text{suc}}(\Omega) = P_{\text{suc}}(\Omega)$, we say $\mathcal{N}_{A\to BA'}$ can optimally discriminate Ω.

Coherence manipulation in state discrimination.— Now, in the context of quantum coherence manipulation in QSD, we present our first result that the process of optimally discriminating an ensemble Ω does not necessitate the consumption of additional quantum coherence. We establish this by demonstrating that the optimal average success probability, typically associated with unrestricted general POVMs, can be realized through free operations within the prescribed paradigm of a discrimination process.

Proposition 1 *For a d-dimensional state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$, the optimal discrimination probability $P_{\text{suc}}(\Omega)$ can be achieved by incoherent operations.*

Proposition 1 is established by proving $P_{\text{suc}}(\Omega) = \widetilde{P}_{\text{suc,IO}}(\Omega) = \widetilde{P}_{\text{suc,MIO}}(\Omega)$, with the detailed proof deferred to appendix. The wave-particle duality relation reminds us that an increase in visibility pattern always implies a decrease in path discrimination. This pivotal finding aligns with the intuition from the wave-particle duality relation that distinguishability cannot increase with an increase in coherence, where they are complementary.

This result also highlights the importance of exploring QSD tasks within the context of dynamical quantum resources, as proposed in our paradigm, rather than focusing solely on restrictions on POVMs. From the perspective of resource theories of measurements [54, 56–58], the 'free measurements' for coherence are previously considered as incoherent measurements, which are diagonal in the fixed basis $\{|i\rangle\}_i$. However, this characterization yields a limited understanding of QSD tasks in the context of resource theories. We establish that QSD performed by incoherent measurements is merely equivalent to our aforementioned process with a discrimination channel belonging to DIO (SIO), a strict subset of MIO (IO), as shown in the appendix. Hence, incoherent measurements generally fall short of achieving optimal discrimination by Proposition 1. This analysis suggests that MIO possesses an intrinsic advantage over DIO in the task of coherent state discrimination, which can be quantified by the generalized robustness of incoherent measurements [54, 56]. This insight establishes a strict hierarchy between MIO and DIO on the optimal discrimination of coherent states.

When optimal discrimination associated with global POVMs is not achievable through free measurements alone, it is intuitive to consider employing ancillary resource states to enhance discrimination capabilities [59–61]. In this way, the resource cost for a QSD task is quantified by the minimal number of copies of the resource state required for reaching optimal global discrimination. However, examining the resource cost of QSD via DIO (SIO), which is tantamount to performing incoherent measurements, reveals a subtlety. For any optimal channel $\mathcal{N} \in \mathcal{O}$ that attains $\widetilde{P}_{\text{suc},\mathcal{O}}(\Omega)$, applying the dephasing channel Δ before or after $\mathcal{N}$ yields the same outcome when $\mathcal{N}$ is DIO (SIO), i.e., $\Delta \circ \mathcal{N}(\rho \otimes \Psi_d) = \mathcal{N} \circ \Delta(\rho \otimes \Psi_d), \forall \rho$. Thus, Ψ_d does not assist in simulating any more powerful discrimination channel through DIO (SIO). This insight implies a no-go case for reaching optimal global discrimination via DIO (SIO) in discriminating general coherent state ensembles.

Coherence-distinguishability duality.— Given that optimal discrimination does not involve additional consumption of coherence, it is reasonable to postulate that the process may consume the coherence present within the state ensemble itself, owing to the decoherence effect of the discrimination task. Then it prompts intriguing questions: how much coherence can be maximally preserved after a discrimination process? By characterizing this maximally preserved coherence, can we establish a duality relation between the distinguishability and coherence resources?

To address this question, we start with the problem of discriminating an ensemble of mutually orthogonal pure states. For coherence analysis, we consider the maximum relative entropy of coherence as a coherence measure [62]. It is denoted as $C_{\max}(\rho) = \log(1 + C_R(\rho))$ where $C_R(\rho) = \min_{\sigma\in\mathcal{D}(\mathcal{H}_d)}\{s \geq 0 | \frac{\rho+s\sigma}{1+s} := \tau \in \mathcal{I}\}$ is the robustness of coherence [22, 63]. The logarithm is taken under the base of two throughout the paper. The maximal value of $C_{\max}(\cdot)$ for a d-dimensional state is achieved by Ψ_d with $C_{\max}(\Psi_d) = \log d$ [64], corresponding with $\log d$ coherent bits (co-bits) [65]. Then, we introduce the *post-disrimination coherence* as the maximum average *co-bits* that can be preserved after a perfect discrimination procedure.

Definition 1 (Post-discrimination coherence) *For a mutually orthogonal d-dimensional state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$, the post-discrimination coherence under maximally incoherent operations is defined as $\mathbf{C}_{\text{MIO}}(\Omega) := \log(1+\eta)$ where*

$$\eta = \max\Big\{\sum_{j=0}^{k-1} p_j C_R(\sigma_j) : \mathcal{M}(\rho_j) = |j\rangle\langle j| \otimes \sigma_j,$$
$$\sigma_j \in \mathcal{D}(\mathcal{H}_d),\ \forall j,\ \mathcal{M} \in \text{MIO}\Big\}.$$

It is worth noting that, by Proposition 1, there is always a feasible maximally incoherent operation $\mathcal{M}$ for $\mathbf{C}_{\text{MIO}}(\Omega)$.

The constraint $\mathcal{M}(\rho_j) = |j\rangle\langle j| \otimes \sigma_j$ corresponds to the criterion for perfect discrimination of a mutually orthogonal state ensemble, wherein $\{\sigma_j\}_{j=0}^{k-1}$ act as memory states that restore coherence. This quantity evaluates the average resource retained in the quantum states after a discrimination process by maximally incoherent operations. Notably, it can be efficiently computed by semidefinite programming (SDP), which is a powerful tool in quantum information theory [66, 67].

To characterize the distinguishability, we recall that the distinguishability emerges from a pure state ensemble $\Omega = \{(p_j, |\psi_j\rangle)\}_{j=0}^{k-1}$ can be characterized by the von-Neumann entropy defined on it [32], i.e., $\mathbf{S}(\Omega) := S(\hat{\omega})$ where $S(\cdot)$ is the von-Neumann entropy of a state and $\hat{\omega} = \sum_j p_j |\psi_j\rangle\langle\psi_j|$ denotes the average state of Ω. We are now ready to present our main result of the relationship between these two quantities $\mathbf{S}(\Omega)$ and $\mathbf{C}_{\text{MIO}}(\Omega)$, for a mutually orthogonal pure-state ensemble Ω.

Theorem 2 (Coherence-distinguishability duality) *For a mutually orthogonal d-dimensional pure-state ensemble $\Omega = \{(1/k, |\psi_j\rangle)\}_{j=0}^{k-1}$,*

$$\mathbf{C}_{MIO}(\Omega) + \mathbf{S}(\Omega) \leq \log d. \tag{3}$$

Notice that from the state ensemble Ω, one can distill $\mathbf{S}(\Omega)$ bits of classical information by perfectly discriminating any given unknown state within the ensemble. For such a fixed state ensemble Ω, the maximum number of co-bits that can be left after perfect discrimination has an upper bound directly related to the von-Neunman entropy of Ω. Moreover, this theorem reveals an intriguing and crucial fact that the more classical bits (‘c-bits’) you want to decode, the fewer ‘co-bits’ can be preserved after extracting all classical information. The proof of Theorem 2 is deferred to the appendix.

We note that Theorem 2 is not entirely a prior unexpected, as a discrimination procedure appears to introduce decoherence. However, remarkably, this quantitative relationship gives a novel wave-particle duality relation as the following. Since we are dealing with a d-dimensional Hilbert space, we can further normalize the post-discrimination coherence $\mathbf{C}_{\text{MIO}}(\Omega)$ and the von-Neunman entropy $\mathbf{S}(\Omega)$ of an ensemble at the same time by $\widetilde{V}^2 = \mathbf{C}_{\text{MIO}}(\Omega)/\log d$ and $\widetilde{D}^2 = \mathbf{S}(\Omega)/\log d$. Thus, we uncover a wave-particle duality-like relation as follows.

$$\widetilde{V}^2 + \widetilde{D}^2 \leq 1, \tag{4}$$

which is akin to the form of Eq. (1). This relation is an inherent duality property of a state ensemble containing mutually orthogonal pure states prepared with equal probability.

More generally, we can extend this duality relation into the state ensemble with non-uniform distribution. If we characterize the distinguishability with the min-entropy of $\mathbf{S}_{\min}(\Omega) := -H_{\max}(\hat{\omega}||\mathbb{I}) = \mathbf{S}_{\min}(\hat{\omega})$, where $\hat{\omega}$ denotes the average state of Ω and $\mathbf{S}_{\min}(\hat{\omega}) = -\log p_{\max}$ is the min-entropy of $\hat{\omega}$ [68], then for a mutually orthogonal d-dimensional pure-state ensemble $\Omega = \{(p_j, |\psi_j\rangle)\}_{j=0}^{k-1}$,

$$\mathbf{C}_{\text{MIO}}(\Omega) + \mathbf{S}_{\min}(\Omega) \leq \log d. \tag{5}$$

The relative proof remains in the appendix. This duality relation reveals that the sum of ‘co-bits’ maximally preserved and ‘c-bits’ at least gained is also bounded, although this bound is not generally tight.

Boundary cases of duality.— To deepen our understanding of the coherence-distinguishability duality relation, we explore two specific instances illuminating its fundamental aspects. Firstly, analogous to how squeezed coherent states in quantum optics reach the Heisenberg uncertainty limit [69], we identify a particular state ensemble that makes the equality in Eq. (3) hold. Let H denote the d-dimensional Hadamard gate, given by $H = \frac{1}{\sqrt{d}} \sum_{i,j=0}^{d-1} \omega^{kj} |k\rangle\langle j|$ where $\omega = e^{i2\pi/d}$, and X denote the d-dimensional generalized Pauli X gate, given by $X = \sum_{i=0}^{d-1} |i+1\rangle\langle i|$. Then we have the following.

Proposition 3 *Let $|\phi_j\rangle = HX^j|0\rangle$ where H, X are the d-dimensional Hadamard gate and generalized Pauli X gate. For $\Omega = \{(1/k, |\phi_j\rangle)\}_{j=0}^{k-1}$, $k \leq d$,*

$$\mathbf{C}_{MIO}(\Omega) + \mathbf{S}(\Omega) = \log d. \tag{6}$$

Proposition 3 shows that an ensemble of k mutually orthogonal maximally coherent states exactly achieves the upper bound in Eq. (3), which identifies the tightness of this trade-off relation. The proof is provided in the appendix. This finding underscores a novel role for maximally coherent states beyond their established status as golden resources within the quantum resource theory of coherence. It is also interesting to seek other non-trivial ensemble cases saturating the coherence-distinguishability duality relation. A necessary condition for those ensembles to achieve the upper bound can be found in the appendix.

Furthermore, as another boundary case of Theorem 2, we note that when the cardinality of the set Ω is equal to the dimension d, $\mathbf{C}_{\text{MIO}}(\Omega)$ vanishes, indicating that no coherence could be preserved after perfect discrimination. Equivalently, this states that if a quantum channel $\mathcal{N} \in$ MIO exists such that $\mathcal{N}(|\psi_j\rangle\langle\psi_j|) = |j\rangle\langle j| \otimes \sigma_j$, $\sigma_j \in \mathcal{H}_d$ for each $j = 0, 1, ..., d-1$, then each σ_j must be an incoherent state. It illustrates an extreme case in which it is inherently unfeasible to completely extract all c-bits encoded in a complete orthonormal basis of the Hilbert space through MIO while concurrently maintaining any co-bit. This scenario reveals a mutual exclusion between coherence and distinguishability within the ensemble of mutually orthogonal pure states, analogous to the situation described by $D = 1$ and $V = 0$ in Eq. (1). Another extreme situation arises when the ensemble Ω contains only one state ρ, where no distinguishability can be obtained and the coherence of ρ remains completely preserved, as $\mathbf{C}_{\text{MIO}}(\Omega) = C_{\max}(\rho)$. These observations hint again at an underlying wave-particle duality relationship within these ensembles.

Concluding remarks.— In this work, we explore the manipulation of quantum coherence within quantum state discrimination by proposing a general QSD paradigm via quantum operations. Leveraging this new paradigm of QSD, we treat coherence and distinguishability as two complementary resources and then uncover a significant coherence-distinguishability duality relation. This relation emerges from a mutually orthogonal pure-state ensemble where free operations cannot simultaneously accomplish the extraction of all c-bits and the preservation of the co-bits.

Note that the seminal work [17] also established a duality between coherence and path distinguishability via unambiguous state discrimination, focusing on extending the wave-particle duality to multipath interference. In their setting, the particle states and path detector states are entangled within the interferometer forming a total system state. Coherence is quantified with tracing out the detector states, while distinguishability arises from an ensemble of detector states that allow unambiguous discrimination. Orthogonal detector states signify complete distinguishability and the absence of coherence. Our work, however, derives a duality relation from orthogonal state ensembles, presenting a fresh perspective on resource manipulation that contrasts with the interference scenarios addressed in prior research.

We anticipate that our paradigm for QSD may be applied to advance the understanding of the interplay between classical distinguishability and other quantum resources, such as entanglement, magic, thermodynamics [70, 71] and imaginarity [72]. There is a possibility of exploring other duality relations between every two potential complementary resources. Furthermore, it is interesting to study if there is any uncertainty relation formulation of our coherence-distinguishability duality relation, considering that wave-particle duality relation is a special case of uncertainty relation.

Acknowledgments.– We thank Bartosz Regula for the suggestion of extending the duality relation into a pure state ensemble with non-uniform distribution and for other helpful discussions. We also thank Ranyiliu Chen, Kun Wang, and Benchi Zhao for their helpful comments. Supplemental Material for: **Quantum Coherence and Distinguishability: A Resource-Theoretic Perspective on Wave-Particle Duality**

In this Supplemental Material, we offer detailed proofs of the theorems and propositions in the manuscript "Quantum Coherence and Distinguishability: A Resource-Theoretic Perspective on Wave-Particle Duality". In Appendix I, we demonstrate two paradigms of quantum state discrimination via free operations and free POVMs respectively. In Appendix II, we cover the basics of the quantum resource theory of coherence. In Appendix III, we first present the detailed proofs for Proposition 1 and Proposition S2, which characterize the capability difference of different classes of incoherent free operations in state discrimination tasks, respectively. In Appendix IV, we provide detailed proofs of Theorem 2 and Proposition 3, which reveal the coherence-distinguishability duality relation and demonstrate its tightness with a special case. Additionally, we present a necessary condition for the duality relation to achieve equality.

I. QUANTUM STATE DISCRIMINATION VIA FREE OPERATIONS

Given a quantum state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$ where $\sum_j p_j = 1, \rho_j \in \mathcal{D}(\mathcal{H}_A)$, $d_A = d$ and $k \leq d$, and a free states set $\mathcal{F}$ with corresponding free operations set $\mathcal{O}$, we introduce the *quantum state discrimination via channel*

1. Receive an unknown state ρ_j with prior probability p_j.
2. Apply a quantum operation $\mathcal{N}_{A\to A'B}$ to ρ_j yielding $\tau_{A'B}^{(j)} = \mathcal{N}_{A\to A'B}(\rho_j)$ where $A' \cong A$ and $\dim \mathcal{H}_B = k$.
3. Measure $\tau_{A'B}^{(i)}$ on subsystem B in basis $\{|i\rangle\}_{i=0}^{k-1}$. If the outcome is i, decide the received state is ρ_i.

POVM

$$P_{\text{suc}}(\Omega) = \max_{\{E_j\}} \sum_{j=0}^{k-1} p_j \operatorname{Tr}(\rho_j E_j)$$
$$\text{s.t.} \quad \sum_{j=0}^{k-1} E_j = I, E_j \geq 0, \forall j,$$

Quantum channel

$$\widetilde{P}_{\text{suc}}(\Omega) = \max \sum_{j=0}^{k-1} p_j \operatorname{Tr}[\mathcal{N}_{A\to BA'}(\rho_j)(|j\rangle\langle j|_B \otimes I_{A'})]$$
$$\text{s.t.} \quad \mathcal{N}_{A\to BA'} \in \text{CPTP}.$$

We call $\mathcal{N}_{A\to BA'}$ the *discrimination channel*, where subsystem A' is introduced to further investigate the resource left after discrimination process. When $\mathcal{N}_{A\to BA'}$ is chosen from a set of free operation $\mathcal{O}$ of some quantum resource theory, we call this task *quantum state discrimination via free operations*. And we denote the optimal average success probability via free operations with $\widetilde{P}_{\text{suc},\mathcal{O}}(\Omega)$. In the following, we discard the subsystem A' and consider $\mathcal{N}_{A\to B} \in \mathcal{O}$ without affecting the attainment of $\widetilde{P}_{\text{suc},\mathcal{O}}(\Omega)$.

Besides, we denote a set of restricted resourceless POVMs with $\mathcal{M}_{\mathcal{F}}$, when $\mathbf{E} = \{E_j\}_j \in \mathcal{M}_{\mathcal{F}}$ for some resource theory, we call the task *quantum state discrimination via free POVMs* and denote the optimal average success probability via free POVMs with $P_{\text{suc},\mathcal{M}_{\mathcal{F}}}(\Omega)$.

II. QUANTUM RESOURCE THEORY OF COHERENCE

We briefly introduce the quantum resource theory (QRT) of coherence [73, 74]. Throughout this Letter, we denote Hilbert space with d-dimension as $\mathcal{H}_d$. Let $\mathcal{L}(\mathcal{H}_d)$ be the space of linear operators mapping $\mathcal{H}_d$ to itself and $\mathcal{D}(\mathcal{H}_d)$ be the set of density operators acting on $\mathcal{H}_d$. We define dephasing operations Δ as follows:

$$\Delta(\rho) = \sum_{i=0}^{d-1} |i\rangle\langle i|\rho|i\rangle\langle i| \tag{S1}$$

The set of free states in QRT of coherence is defined as $\mathcal{I} := \{\rho \geq 0 | \Delta(\rho) = \rho\}$.

In the following, we introduce several free operations in QRT of coherence. The maximally incoherent operations (MIO) is the largest class of incoherent operations, which map $\mathcal{I}$ onto itself. The incoherent operations (IO) [26] admit a set of Kraus operators $\{K_n\}_n$ such that:

$$\frac{K_n \rho K_n^\dagger}{\mathrm{Tr}[K_n \rho K_n^\dagger]} \in \mathcal{I}, \quad \sum_n K_n^\dagger K_n = \mathbb{I},\ \forall n, \rho \in \mathcal{I} \tag{S2}$$

Dephasing-covariant incoherent operations (DIO) [43, 44] are those quantum operations $\mathcal{E}$ which commute with the dephasing operations Δ for any quantum state ρ such that: $[\Delta, \mathcal{E}] = 0$. The strictly incoherent operations (SIO) [21] fulfill $\langle i|K_n \rho K_n^\dagger|i\rangle = \langle i|K_n \Delta[\rho] K_n^\dagger|i\rangle\ \forall n, i$. There are hierarchies among these free operations: SIO $\subsetneq$ IO $\subsetneq$ MIO, SIO $\subsetneq$ DIO $\subsetneq$ MIO [43]. In a d-dimensional Hilbert space $\mathcal{H}_d$, a maximally coherent state is:

$$|\Psi_d\rangle = \frac{1}{\sqrt{d}} \sum_{i=0}^{d-1} |i\rangle. \tag{S3}$$

We denote $|\Psi_d\rangle\langle\Psi_d|$ with Ψ_d in the following.

A good coherence measure is expected to satisfy the following three conditions under MIO:

- $C(\rho) = 0\ \forall \rho \in \mathcal{I}$;
- $C(\rho) \geq C(\mathcal{T}(\rho))$ for all incoherent CPTP maps $\mathcal{T}$;
- Convexity: $\sum_j p_j C(\rho_j) \geq C(\sum_j p_j \rho_j)$, which is not necessary.

Definition S1 *(Robustness of coherence [22, 75]) The robustness of coherence of a quantum state $\rho \in \mathcal{D}(\mathcal{H}_d)$ is defined as:*

$$C_R(\rho) = \min_{\tau \in \mathcal{D}(\mathcal{H}_d)} \left\{ s \geq 0 \,\middle|\, \frac{\rho + s\tau}{1+s} := \delta \in \mathcal{I} \right\}, \tag{S4}$$

which can be transformed into a simple semidefinite program (SDP) [22]:

$$\begin{aligned} C_R(\rho) = \max\ & \mathrm{Tr}(W\rho) && \text{(S5)}\\ \text{s.t.}\ & \Delta(W) \leq 0, && \text{(S6)}\\ & W \geq -I, && \text{(S7)} \end{aligned}$$

where the Hermitian operator $M = -W$ fulfills $M \geq 0$ if and only if $\mathrm{Tr}(\rho M) = \mathrm{Tr}(\rho \Delta(M))$ for all incoherent states $\rho \in \mathcal{I}$. Such an observable M serves as a coherence witness, where $\mathrm{Tr}(\rho M) \leq 0$ indicates coherence in the state ρ. Robustness of coherence is multiplicative under the tensor product of states:

$$1 + C_R(\rho_1 \otimes \rho_2) = (1 + C_R(\rho_1))(1 + C_R(\rho_2)) \tag{S8}$$

Another main advantage of the robustness of coherence is that it can be estimated in the laboratory as an expected value of observable M with respect to ρ. An operational interpretation of the robustness of coherence is that: it quantifies the advantage enabled by a quantum state in a *phase discrimination task*.

Another equivalent primal standard form of the above SDP [75] is:

$$1 + C_R(\rho) = \min \left\{ \lambda \,|\, \rho \leq \lambda\sigma, \sigma \in \mathcal{I} \right\} \tag{S9}$$

and the dual form is given by

$$1 + C_R(\rho) = \max \left\{ \mathrm{Tr}(\rho S) \,|\, S \geq 0, S_{ii} = 1,\ \forall i \right\} \tag{S10}$$

Definition S2 *(Maximum relative entropy of coherence) [62] The maximum relative entropy of coherence of a state ρ is defined as:*

$$C_{\max}(\rho) = \min_{\sigma \in \mathcal{I}} D_{\max}(\rho||\sigma), \tag{S11}$$

where $\mathcal{I}$ is the set of incoherent states in $\mathcal{D}(\mathcal{H}_d)$ and $D_{\max}(\rho||\sigma)$ denotes the maximum relative entropy of ρ with respect to σ and $D_{\max}(\rho||\sigma) := \min\{\lambda \,|\, \rho \leq 2^\lambda \sigma\}$.

It is obvious that $D_{\max}(\rho||\sigma)$ is the upper bound of the maximum relative entropy of coherence. Note that $2^{C_{\max}(\rho)} = 1 + C_R(\rho)$.

III. COHERENCE MANIPULATION WITHIN QSD

Lemma S1 *For a d-dimensional state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$ and a resource theory of states $(\mathcal{F}, \mathcal{O})$, there exist quantum-classical channels $\mathcal{N}^{qc} \in \mathcal{O}$ achieving the optimal discrimination probability via free operations $\widetilde{P}_{\mathrm{suc},\mathcal{O}}(\Omega)$.*

Proof We consider QSD via free operations in some quantum resource theory with $\mathcal{N} \in \mathcal{O}$. Suppose $\mathcal{N}$ is the optimal channel achieving $\widetilde{P}_{\mathrm{suc},\mathcal{O}}(\Omega)$. It follows

$$\widetilde{P}_{\mathrm{suc},\mathcal{O}}(\Omega) = \sum_{j=0}^{k-1} p_j \operatorname{Tr}(\mathcal{N}(\rho_j)|j\rangle\langle j|) \tag{S12a}$$

$$= \sum_{j=0}^{k-1} p_j \operatorname{Tr}\left(\mathcal{N}(\rho_j)\Delta(|j\rangle\langle j|)\right) \tag{S12b}$$

$$= \sum_{j=0}^{k-1} p_j \operatorname{Tr}(\Delta \circ \mathcal{N}(\rho_j)|j\rangle\langle j|), \tag{S12c}$$

where we use the fact that the adjoint map of a fully dephasing channel $\Delta(\cdot)$ is itself. Note that $\mathcal{N} \in \mathcal{O}$ is a free operation in some resource theory, it holds that $\mathcal{N}(\rho) \in \mathcal{F}$, $\forall \rho \in \mathcal{F}$, where $\mathcal{F}$ denotes the set of free states. Obviously, we have $\Delta \circ \mathcal{N}(\rho) \in \mathcal{F}$, $\forall \rho \in \mathcal{F}$. Thus, it holds $\Delta \circ \mathcal{N} \in \mathcal{O}$. Then we conclude that $\Delta \circ \mathcal{N}$ is also an optimal free channel achieving $\widetilde{P}_{\mathrm{suc},\mathcal{O}}(\Omega)$. Then we show that $\Delta \circ \mathcal{N}$ is a quantum-classical channel. We express $J_{\mathcal{N}} = \sum_{i,i'} |i\rangle\langle i'| \otimes \mathcal{N}(|i\rangle\langle i'|)$ and deduce that

$$J_{\Delta\circ\mathcal{N}} = \sum_{i,i'} |i\rangle\langle i'| \otimes \Delta \circ \mathcal{N}(|i\rangle\langle i'|) \tag{S13a}$$

$$= \sum_{i,i',q} p_{i,i',q}|i\rangle\langle i'| \otimes |q\rangle\langle q|) \tag{S13b}$$

$$= \sum_{q} Q_q \otimes |q\rangle\langle q| \tag{S13c}$$

Then we express the Choi operator of $\Delta \circ \mathcal{N}$ as $J_{\Delta\circ\mathcal{N}} = \sum_q Q_q \otimes |q\rangle\langle q|$, where $Q_q = \sum_{i,i'} p_{i,i',q}|i\rangle\langle i'|$, $\sum_q Q_q = I$ and $Q_q \geq 0$ due to $\Delta \circ \mathcal{N}$ is a CPTP map. We can choose $Q_q = M_q^T$ and conclude $\{M_q\}_{q=0}^{k-1}$ is a POVM. Thus, $\Delta \circ \mathcal{N}$ is a quantum-classical channel $\mathcal{N}^{\mathrm{qc}}$. Such conclusion also holds when $\mathcal{N} \in$ CPTP without considering any resource theory, and indicates that $\widetilde{P}_{\mathrm{suc}}(\Omega) \leq P_{\mathrm{suc}}(\Omega)$. ■

Proposition 1 *For a d-dimensional state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$, the optimal discrimination probability $P_{\mathrm{suc}}(\Omega)$ can be achieved by quantum state discrimination via incoherent operations.*

Proof We prove this proposition by demonstrating that $P_{\mathrm{suc}}(\Omega) = \widetilde{P}_{\mathrm{suc,IO}}(\Omega)$. First, we will show $P_{\mathrm{suc}}(\Omega) \leq \widetilde{P}_{\mathrm{suc,IO}}(\Omega)$. Suppose the optimal POVM for $P_{\mathrm{suc}}(\Omega)$ is $\{E_j\}_{j=0}^{k-1}$. We can obtain a quantum-classical channel

$$\mathcal{M}_{A\to B}(\rho_A) = \sum_{j=0}^{k-1} \operatorname{Tr}(\rho_A E_j)|j\rangle\langle j|. \tag{S14}$$

In the following, we show that quantum-classical channel $\mathcal{M}_{A\to B}$ is an IO. Suppose the spectral decomposition of E_q is

$$E_q = \sum_{i=1}^{r_q} \lambda_i^q |\psi_i^q\rangle\langle\psi_i^q|, \tag{S15}$$

where r_q is the rank of E_q. Then we can express the Kraus operators of the quantum-classical channel as $K_i^q = \sqrt{\lambda_i^q}|q\rangle\langle\psi_i^q|$. We can check that for any $|j\rangle$:

$$K_i^q|j\rangle\langle j|(K_i^q)^\dagger = \lambda_i^q|q\rangle\langle\psi_i^q|j\rangle\langle j|\psi_i^q\rangle\langle q| = \lambda_i^q|\langle j|\psi_i^q\rangle|^2|q\rangle\langle q|. \tag{S16}$$

$K_i^q|j\rangle\langle j|(K_i^q)^\dagger \in \mathcal{I}$. Thus, we can conclude that $\mathcal{M}_{A\to A'} \in$ IO. Then we have

$$\widetilde{P}_{\text{suc,IO}}(\Omega) \geq \sum_{j=0}^{k-1} p_j \operatorname{Tr}(\mathcal{M}(\rho_j)|j\rangle\langle j|) = \sum_{j=0}^{k-1} p_j \operatorname{Tr}(\rho_j E_j) = P_{\text{suc}}(\Omega). \tag{S17}$$

Second, we are going to prove $P_{\text{suc}}(\Omega) \geq \widetilde{P}_{\text{suc,IO}}(\Omega)$. Recall that $\widetilde{P}_{\text{suc,IO}}(\Omega)$ can always be achieved by a quantum-classical channel $\mathcal{N}'$ according to the Lemma S1. Note that we have shown that the quantum-classical channel is an IO. Suppose that $J_{N'} = \sum_q M_q^T \otimes |q\rangle\langle q|$ and we can conclude that $\widetilde{P}_{\text{suc,IO}}(\Omega)$ is equivalently achieved by a POVM $\{M_q\}_0^{k-1}$. Thus, $P_{\text{suc}}(\Omega) \geq \widetilde{P}_{\text{suc,IO}}(\Omega)$.

In conclusion, we have $P_{\text{suc}}(\Omega) = \widetilde{P}_{\text{suc,IO}}(\Omega)$, which means optimal discrimination probability via free operations can be achieved with IO. The result also holds for MIO because IO $\subsetneq$ MIO. ■

Definition S3 *(Incoherent measurement [54]) A d-dimentional POVM $\{E_m\}_{m=0}^{k-1}$ is called an incoherent measurement if $\Delta(E_m) = E_m$ for all m.*

Incoherent measurements can be regarded as POVMs analog of incoherent states, which are diagonal in the fixed basis and can be expressed as $E_m = \sum_{i=0}^{d-1} p(m|i)|i\rangle\langle i|$. We denote the set of incoherent measurements as $\mathcal{M}_{\mathcal{I}}$.

Proposition S2 *For a d-dimensional state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$, we have*

$$P_{\text{suc},\mathcal{M}_{\mathcal{I}}}(\Omega) = \widetilde{P}_{\text{suc,SIO}}(\Omega). \tag{S18}$$

Proof First, we show that $P_{\text{suc},\mathcal{M}_{\mathcal{I}}}(\Omega) \geq \widetilde{P}_{\text{suc,DIO}}(\Omega)$. Recall that the discrimination channel $\mathcal{N} \in$ DIO reaching $\widetilde{P}_{\text{suc,DIO}}(\Omega)$ can be a quantum-classical channel. We denote the quantum-classical channel $\mathcal{N}$ by $\mathcal{N}(\cdot) = \sum_{j=0}^{k-1} \operatorname{Tr}(E_j \cdot)|j\rangle\langle j|$, where $\{E_j\}_{j=0}^{k-1}$ is the corresponding POVM. Note that $\mathcal{N} \in$ DIO and $\forall \rho$, we have

$$\mathcal{N}(\rho) = \Delta \circ \mathcal{N}(\rho) = \mathcal{N} \circ \Delta(\rho) = \sum_{j=0}^{k-1} \operatorname{Tr}(E_j \Delta(\rho))|j\rangle\langle j| = \sum_{j=0}^{k-1} \operatorname{Tr}(\Delta(E_j)\rho)|j\rangle\langle j|. \tag{S19}$$

Obviously, $\{\Delta(E_j)\}_{j=0}^{k-1}$ is an incoherent measurement with $\sum_{j=0}^{k-1} \Delta(E_j) = I$ and $\Delta(E_j) \geq 0$. Thus, we can directly let $E_j = \sum_i p_{i,j}|i\rangle\langle i|$ and $\{E_j\}_{j=0}^{k-1} \in \mathcal{M}_{\mathcal{I}}$. Thus, we conclude that $P_{\text{suc},\mathcal{M}_{\mathcal{I}}}(\Omega) \geq \widetilde{P}_{\text{suc,DIO}}(\Omega)$.

Conversely, if we distinguish Ω via incoherent measurements, and the optimal discrimination probability under such constraints is achieved by an incoherent measurement $\{E_j\}_{j=0}^{d-1}$, where $E_j = \sum_i p_{i,j}|i\rangle\langle i|$. We can construct a channel $\widetilde{\mathcal{N}} \in$ DIO with its Choi operator being $J_{\widetilde{\mathcal{N}}} == \sum_j E_j \otimes |j\rangle\langle j| = \sum_{i,j} p_{i,j}|i\rangle\langle i| \otimes |j\rangle\langle j|$, which means $P_{\text{suc},\mathcal{M}_{\mathcal{I}}}(\Omega) \leq \widetilde{P}_{\text{suc,DIO}}(\Omega)$. We can further reduce the DIO into SIO. We have shown that the Choi operator of the quantum-classical channel of incoherent measurements can be expressed as $J_{\widetilde{\mathcal{N}}} = \sum_{i,j} p_{i,j}|i\rangle\langle i| \otimes |j\rangle\langle j|$ with $E_j = \sum_j p_{i,j}|i\rangle\langle i|$. Then we can express the Kraus operators of $J_{\widetilde{\mathcal{N}}}$ as $K_i^j = \sqrt{p_{i,j}}|j\rangle\langle i|$. We can check that

$$K_i^j|q\rangle\langle q'|(K_i^j)^\dagger = p_{i,j}|j\rangle\langle i|q\rangle\langle q'|i\rangle\langle j| = p_{i,j}\delta_{i,q}\delta_{i,q'}|j\rangle\langle j| \tag{S20a}$$

If $q = q'$, we obtain that $K_i^j|q\rangle\langle q|(K_i^j)^\dagger = p_{i,j}\delta_{i,q}|j\rangle\langle j|$; and if $q \neq q'$, we obtain that $K_i^j|q\rangle\langle q'|(K_i^j)^\dagger = 0$. Thus $\widetilde{\mathcal{N}}$ discussed above belongs to SIO. Thus, we have $P_{\text{suc},\mathcal{M}_{\mathcal{I}}}(\Omega) = \widetilde{P}_{\text{suc,SIO}}(\Omega)$. It also holds for $P_{\text{suc},\mathcal{M}_{\mathcal{I}}}(\Omega) = \widetilde{P}_{\text{suc,DIO}}(\Omega)$. ■

Remark 1 Until now, we have demonstrated the significant difference between MIO and DIO in QSD tasks. Using the paradigm of QSD via free operations, we can implement the global optimal POVMs equivalently through MIO (IO), but only achieve the incoherent measurements equivalently through DIO (SIO). Thus, we can argue that MIO (IO) provides a maximal advantage over DIO (SIO) in the QSD task, as discussed in Ref. [54, 56]. This advantage is fully identified by the quantifier called robustness for incoherent measurements $\mathcal{R}_{\mathcal{M}_{\mathcal{I}}}$ as follows:

$$\mathcal{R}_{\mathcal{M}_{\mathcal{I}}}(\mathbf{M}) = \max_{\Omega_0} \frac{p_{\text{suc}}(\Omega_0, \mathbf{M})}{\max_{\mathbf{N}\in\mathcal{M}_{\mathcal{I}}} p_{\text{suc}}(\Omega_0, \mathbf{N})} - 1, \tag{S21}$$

where $p_{\text{suc}}(\Omega_0, \mathbf{E}) = \sum_j p_j \operatorname{Tr}(E_j \rho_j)$ with $\mathbf{E} = \{E_j\}_{j=0}^{k-1}$, $\mathbf{M}$ is a global POVM, $\mathbf{N}$ is an incoherent measurement, and $\Omega_0 = \{p_j, \rho_j\}_{j=0}^{k-1}$ denotes a quantum state ensemble. Note that $\mathcal{R}_{\mathcal{M}_{\mathcal{I}}}(\mathbf{M}) \geq 0$ and when $\mathbf{M} \nsubseteq \mathcal{M}_{\mathcal{I}}$, $\exists\, \Omega_0$ let $\mathcal{R}_{\mathcal{M}_{\mathcal{I}}}(\mathbf{M}) > 0$. We can conclude that QSD via free operation in the QRT of coherence can identify a strict hierarchy between MIO and DIO on the optimal discrimination probability.

IV. COHERENCE-DISTINGUISHABILITY DUALITY RELATION

Lemma S3 *For a mutually orthogonal d-dimensional state ensemble $\Omega = \{(p_j, \rho_j)\}_{j=0}^{k-1}$, if the post-discrimination coherence under maximally incoherent operations $\mathbf{C}_{\text{MIO}}(\Omega)$ is achieved by some MIO $\mathcal{N}$, then $\mathbf{C}_{\text{MIO}}(\Omega) = C_{\max}(\mathcal{N}(\hat{\omega}))$ with $\hat{\omega} = \sum_{j=0}^{k-1} p_j \rho_j$.*

Proof According to the definition, the MIO $\mathcal{N}$ achieving $\mathbf{C}_{\text{MIO}}(\Omega)$ satisfies $\mathcal{N}(\rho_j) = |j\rangle\langle j| \otimes \sigma_j, \forall \rho_j \in \Omega$. Then we have

$$\begin{align}
\mathbf{C}_{\text{MIO}}(\Omega) &= \log[1+\eta] \tag{S22a}\\
&= \log[1 + \sum_{j=0}^{k-1} p_j C_R(\sigma_j)] \tag{S22b}\\
&= \log[1 + \sum_{j=0}^{k-1} p_j C_R(|j\rangle\langle j| \otimes \sigma_j)] \tag{S22c}\\
&= \log\left[1 + C_R\Big(\sum_{j=0}^{k-1} p_j |j\rangle\langle j| \otimes \sigma_j\Big)\right] \tag{S22d}\\
&= \log\left[1 + C_R\Big(\sum_{j=0}^{k-1} p_j \mathcal{N}(\rho_j)\Big)\right] \tag{S22e}\\
&= \log[1 + C_R(\mathcal{N}(\hat{\omega})], \tag{S22f}
\end{align}$$

where $\hat{\omega} = \sum_{j=0}^{k-1} p_j \rho_j$. We drive Eq. (S22c) from Eq. (S22b) because robustness of coherence is multiplicative under the tensor product of states. And Eq. (S22d) is driven from Eq. (S22c) because the robustness of coherence is convex linear on classical-quantum states [76]. ■

Theorem S4 *For a mutually orthogonal d-dimensional pure-state ensemble $\Omega = \{(p_i, |\psi_i\rangle)\}_{i=0}^{k-1}$,*

$$\mathbf{C}_{MIO}(\Omega) + \mathbf{S}_{\min}(\Omega) \leq \log d, \tag{S23}$$

Proof Denote by $\mathcal{E} = \{|\psi_i\rangle\}_{i=0}^{d-1}$ an orthogonal basis of $\mathcal{H}_A$ with $d_A = k$, and $\mathcal{N}(|\psi_i\rangle\langle\psi_i|) = |i\rangle\langle i| \otimes \sigma_i$, where $|i\rangle\langle i| \in \mathcal{D}(\mathcal{H}_B)$, $d_B = k$ and $i = 0, \cdots, k-1$. For these states $|\psi_j\rangle, j = k, \cdots, d-1$, i.e., $|\psi_j\rangle \in \mathcal{E}$ but $|\psi_j\rangle \notin \Omega$, we directly assume:

$$\mathcal{N}(|\psi_j\rangle\langle\psi_j|) = \left(\sum_{n=0}^{k-1} q_n^j |n\rangle\langle n|\right) \otimes \rho_j, \quad j = k, \cdots d-1, \tag{S24}$$

where $\sum_{n=0}^{k-1} q_n^j = 1$, $\rho_j \in \mathcal{D}(\mathcal{H}_{A'})$ and $d_{A'} = d$, and we use the conclusion that $(\Delta \otimes I) \circ \mathcal{N}$ is also the optimal channel achieving $\mathbf{C}_{\text{MIO}}(\Omega)$. Then we have,

$$\begin{aligned}
\mathcal{N}\left(\frac{I}{d}\right) &= \mathcal{N}\left(\frac{1}{d}\sum_{i=0}^{d-1} |\psi_i\rangle\langle\psi_i|\right)\\
&= \frac{1}{d}\left(\sum_{i=0}^{k-1} \mathcal{N}(|\psi_i\rangle\langle\psi_i|) + \sum_{j=k}^{d-1} \mathcal{N}(|\psi_j\rangle\langle\psi_j|)\right)\\
&= \frac{1}{d}\left(\sum_{i=0}^{k-1} |i\rangle\langle i| \otimes \sigma_i + \sum_{j=k}^{d-1}\left(\sum_{n=0}^{k-1} q_n^j |n\rangle\langle n|\right) \otimes \rho_j\right)\\
&= \frac{1}{d}\left(\sum_{i=0}^{k-1} |i\rangle\langle i| \otimes \left(\sigma_i + \sum_{j=k}^{d-1} q_i^j \rho_j\right)\right)
\end{aligned} \tag{S25}$$

Notice that $\mathcal{N}$ is a MIO which yields $\mathcal{N}\left(\frac{I}{d}\right)$ is incoherent. Thus, we have $\sigma_i + \sum_{j=k}^{d-1} q_i^j \rho_j$ is an incoherent state (unnormalized) for $i = 0, \cdots, k-1$. We can conclude that $C_R(\sigma_i) \leq \sum_{j=k}^{d-1} q_i^j$. Therefore,

$$\eta = \sum_{i=0}^{k-1} p_i C_R(\sigma_i) \leq \max \sum_{i=0}^{k-1} p_i \sum_{j=k}^{d-1} q_i^j. \tag{S26}$$

If each $|\psi_i\rangle$ in Ω is given with probability p_i, we have $\sum_{i=0}^{k-1}\sum_{j=k}^{d-1} p_i q_i^j \leq \sum_{j=k}^{d-1}\sum_{i=0}^{k-1} p_{\max} q_i^j \leq (d-k)p_{\max}$, where $p_{\max} = \max\{p_0, p_1, ..., p_{k-1}\}$). Thus, we have $\mathbf{C}_{\mathrm{MIO}}(\Omega) = \log(1+\eta) \leq \log[(d-k)p_{\max}+1] \leq \log d + \log(p_{\max})$ and conclude

$$\mathbf{C}_{\mathrm{MIO}}(\Omega) + \mathbf{S}_{\min}(\Omega) \leq \log d, \tag{S27}$$

where $\mathbf{S}_{\min}(\Omega)$ is defined as the min-entropy of the average state of Ω with $\hat{\omega} = \sum_i p_i |\psi_i\rangle\langle\psi_i|$ and $\mathbf{S}_{\min}(\Omega) = \mathbf{S}_{\min}(\hat{\omega}) = -\log(p_{\max})$.

■

Theorem 2 *For a mutually orthogonal d-dimensional pure-state ensemble $\Omega = \{(1/k, |\psi_i\rangle)\}_{i=0}^{k-1}$,*

$$\mathbf{C}_{MIO}(\Omega) + \mathbf{S}(\Omega) \leq \log d, \tag{S28}$$

Proof Note that for the $\Omega = \{(1/k, |\psi_i\rangle)\}_{i=0}^{k-1}$, $\mathbf{S}(\Omega) = \mathbf{S}_{\min}(\Omega) = \log k$, we arrive the conclusion immediately, combined with the Theorem S4. ■

This bound can be achieved in the following example.

Proposition 3 *Let $|\phi_i\rangle = HX^i|0\rangle$ where H, X are the d-dimensional Hadamard gate and generalized Pauli X gate. For $\Omega = \{(1/k, |\phi_i\rangle)\}_{i=0}^{k-1}$, $k \leq d$,*

$$\mathbf{C}_{MIO}(\Omega) + \mathbf{S}(\Omega) = \log d. \tag{S29}$$

Proof We construct an MIO channel $\mathcal{N}$ to show the equality sign can be achieved in Eq. (S26) for this ensemble containing k mutually orthogonal maximally coherent states. Here, d-dimensional Hadamard gate H and d-dimensional Pauli X gate are defined as $H = \frac{1}{\sqrt{d}}\sum_{i,j=0}^{d-1}\omega^{kj}|k\rangle\langle j|$ and $X = \sum_{i=0}^{d-1}|i+1\rangle\langle i|$ respectively, where $\{|i\rangle\}_{i=0}^{d-1}$ denotes computational basis and $\omega = e^{i2\pi/d}$. We denote $|\phi_i\rangle\langle\phi_i|$ with Ψ_i in the following, and construct the MIO channel $\mathcal{N}$ as follows:

$$\mathcal{N}(\rho) = \sum_{i=0}^{k-1}\mathrm{Tr}(\Psi_i\rho)|i\rangle\langle i| \otimes \mathcal{D}_p(Z^{\dagger i}\rho Z^i) + \sum_{j=k}^{d-1}\mathrm{Tr}(\Psi_j\rho)\Pi \otimes [(Z^{\dagger j}\rho Z^j)\circ U], \quad \forall\rho, \tag{S30}$$

where $\Pi = 1/k\sum_{i=0}^{k-1}|i\rangle\langle i|$, Z denotes d-dimensional Pauli Z operator with $Z = \sum_{j=0}^{d-1}\omega^j|j\rangle\langle j|$, $U = I + \frac{1}{d-1}\sum_{i<j}(e^{i\pi}|i\rangle\langle j| + e^{-i\pi}|j\rangle\langle i|)$ and $\tau \circ U$ is the Hadamard product with $(\tau\circ U)_{ij} = -\tau_{ij}/(d-1)$, for $i \neq j$ and a given state τ. Note that $\tau \to \tau\circ U$ is also an MIO. And $\mathcal{D}_p(\rho) = (1-p)\rho + p\frac{I}{d}$ denotes the p-depolarizing channel, with $p = 1 - \frac{d-k}{k(d-1)}$. First, we can check $\mathcal{N}$ is a MIO with $\mathcal{N}(|m\rangle\langle m|) = \Delta[\mathcal{N}(|m\rangle\langle m|)]$ with $m = 0, \cdots, k-1$. Then we can check that:

$$\mathcal{N}(\Psi_i) = |i\rangle\langle i| \otimes \sigma, \quad i = 0, \cdots, k-1, \tag{S31}$$

where $\sigma = I/d + \sum_{m\neq n}\frac{d-k}{k(d-1)d}|m\rangle\langle n|$. Thus, $\mathbf{C}_{\mathrm{MIO}}(\Omega) \geq \sum_{i=0}^{k-1} C_R(\sigma)/k = (d-k)/k$. Combined with the upper bound provided by the Theorem 2, we can conclude that $\mathbf{C}_{\mathrm{MIO}}(\Omega) = (d-k)/k$ and $\mathbf{C}_{\mathrm{MIO}}(\Omega) = \log(d/k) = \log d - \mathbf{S}(\Omega)$. ■

Proposition S5 *For a mutually orthogonal d-dimensional pure-state ensemble $\Omega = \{(1/k, |\psi_i\rangle)\}_{i=0}^{k-1}$ with $k < d$, the necessary condition for Ω to saturate the coherence-distinguishability duality relation is*

$$C_{\max}(\hat{\omega}) + S(\hat{\omega}) \geq \log d, \tag{S32}$$

where $\hat{\omega} = \sum_{i=0}^{k-1} 1/k|\psi_i\rangle\langle\psi_i|$.

Proof Saturating the coherence-distinguishability duality relation with a given Ω means $\mathbf{C}_{\mathrm{MIO}}(\Omega) + \mathbf{S}(\Omega) = \log d$. Note that we restrict $k < d$ and avoid the trivial case of extracting all $\log d$ c-bits from Ω, namely $\mathbf{S}(\Omega) = \log d$. Suppose the MIO achieving $\mathbf{C}_{\mathrm{MIO}}(\Omega)$ is $\mathcal{N}$, combined with Lemma S3, if $C_{\max}(\hat{\omega}) + S(\hat{\omega}) < \log d$, we have

$$\begin{aligned}
\mathbf{C}_{\mathrm{MIO}}(\Omega) + \mathbf{S}(\Omega) &= C_{\max}(\mathcal{N}(\hat{\omega})) + \mathbf{S}(\Omega) && \text{(S33)}\\
&= C_{\max}(\mathcal{N}(\hat{\omega})) + S(\hat{\omega}) && \text{(S34)}\\
&\leq C_{\max}(\hat{\omega}) + S(\hat{\omega}) && \text{(S35)}\\
&< \log d. && \text{(S36)}
\end{aligned}$$

Then it is impossible for Ω to saturate the coherence-distinguishability duality relation. Thus, we conclude that $C_{\max}(\hat{\omega}) + S(\hat{\omega}) \geq \log d$ is the necessary condition. ■

Nonlocality-driven certification without locality requirements

Ivan Supic[1] *

[1] *Sorbonne University*

Abstract. In recent years, quantum technologies have experienced rapid growth and maturation. As quantum devices become capable of specific tasks, ensuring their proper functioning is crucial, necessitating reliable certification techniques. Certification became one of the most important topics in the field as it addresses concerns related to noise and decoherence, ensuring that devices align effectively with blueprints. In this talk I will discuss possible answers to the question: How can certification methods, which rely on the robustness of quantum correlations, be applied to quantum computing platforms? Self-testing as the most important primitive for device-independent certification is constructed within the framework of the Bell scenario, which entails two or more spatially separated parties. While this setup is advantageous for demonstrating foundational proofs of quantumness, its application to computing platforms poses challenges due to the inherent integrality of such platforms, making them incompatible with Bell-type scenarios. I will describe two approaches to dealing with this problem. In the first one I give some answers stemming from using quantum homomorphic encryption to bypass the locality requirement. In the second one I describe plethora of self-testing results that can be proven in the case when some amount of communication is allowed among the parties.

Self-testing: Capabilities and Limitations

Laura Mančinska[1] *

[1] *QMATH, University of Copenhagen*

Abstract. In this talk, I will introduce the concept of self-testing, which aims to address the fundamental question of how can we certify the proper functioning of black-box quantum devices. Self-testing represents the strongest form of quantum functionality certification, enabling a classical user to infer the quantum state and measurements used to produce the observed measurement statistics.

I will survey key self-testing results and discuss outstanding questions in the field. As an example, we will examine a recent protocol that allows for self-testing of arbitrary real projective measurements in the simplest two-party Bell scenario.

Regarding limitations, I will highlight common assumptions in existing self-testing results, pointing out their potential weaknesses, especially in the context of cryptographic applications. To address these limitations, I will present a general theorem that promotes most existing self-testing results to their assumption-free variants. However, we will also see that in some scenarios assumptions cannot be lifted. To illustrate this point, I will present a simple quantum correlation that qualifies as a self-test only under certain assumptions.

Abstract. Quantum optical platforms, essential for quantum communication and computation, are typically affected by photon loss and dephasing noise. Our paper addresses the crucial problem of determining for which regime of loss and dephasing the noise can be corrected. Our results, refuting a known conjecture, show that quantum error correction and reliable quantum communication are impossible in a large region of parameter space of loss and dephasing. On the positive side, however, we prove that if the sender and the receiver are assisted by two-way classical communication, then reliable quantum communication becomes possible even for arbitrarily high levels of loss and dephasing.

Keywords: Continuous-variable systems, Bosonic loss-dephasing channel, Quantum Shannon Theory

1 Introduction

Quantum optical platforms play a crucial role in both quantum communication and quantum computation. However, one of the most serious problems plaguing these platforms is the presence of noise due to *photon loss* and *bosonic dephasing* [1, 2, 3], which have been both extensively analysed separately [4, 5, 6, 7]. Loss dissipates energy, whereas dephasing works to transform coherent superpositions into probabilistic mixtures. Although loss and dephasing sources can simultaneously affect bosonic systems [8, 9, 10, 11, 12], the existing literature provides only partial results about their combined effect [12], modelled by the so-called loss-dephasing channel. Understanding the combined effect of loss and dephasing is challenging due to the conflicting behaviours they exhibit: loss takes a simple form when written in the coherent state basis but is complicated to analyse in the Fock basis [13], whereas dephasing demonstrates the opposite pattern, making the analysis of their combined effect quite intricate.

Consider an optical link or a quantum memory affected by both loss and dephasing. Can the overall noise be corrected? In other words, does the corresponding channel have non-zero quantum capacity? Answering this question is crucial for determining the specific conditions under which quantum communication and quantum computation can be successfully achieved in optical platforms. This question is intimately related to the *anti-degradability* condition in Quantum Shannon Theory: if a noise channel is anti-degradable [14, 15], there are no quantum communication protocols or quantum error-correcting codes capable of overcoming it. Consequently, it is crucial to understand whether the combined effect of loss and dephasing results in an anti-degradable channel. This has been a puzzling problem, to the point that in [12] it was conjectured that the combined loss-dephasing noise results in an anti-degradable channel if and only if the loss is above 50%.

In our paper [16] we refute the above conjecture; specifically, for any value of the photon loss, we explicitly find a *critical value* of the dephasing above which the resulting loss-dephasing channel is anti-degradable. Our result identifies a large region of the loss-dephasing parameter space where correcting the noise and achieving quantum communication is impossible. On the more positive side, however, we also prove that if the sender and the receiver are assisted by two-way classical communication, then quantum communication — and thus quantum key distribution — is always possible, even in scenarios characterised by arbitrarily high levels of loss and dephasing.

On the technical level, **we devise a new method to analyse anti-degradability of bosonic channels**, and we use it to derive the first analytical results characterising the transmission and storage of quantum information in the presence of both loss and dephasing noise. We believe that this constitutes a significant technical as well as conceptual innovation because *all* other known tools to analyse quantum capacities (e.g. degradability [15], PPT-ness [17], teleportation simulability [18, 19], entanglement breaking-ness [15]) **fail completely** for this channel [12, 16]. We are thus confident that our analysis, which is a first of its kind, will be of wide interest to the community interested in quantum communication at large, beyond the specific niche of those interested in bosonic systems.

2 Preliminaries

The *quantum capacity* $Q(\mathcal{N})$ of a channel $\mathcal{N}$ quantifies the efficiency in transmitting qubits reliably across $\mathcal{N}$ [14, 15]. The condition $Q(\mathcal{N}) = 0$ implies that there exist neither reliable quantum communication protocols across $\mathcal{N}$ nor codes capable of correcting the errors induced by $\mathcal{N}$. By definition, $\mathcal{N}$ is anti-degradable if there exists a channel $\mathcal{A}$ — called the *anti-degrading map* — such that $\mathcal{A} \circ \mathcal{N}^{\mathrm{c}} = \mathcal{N}$, where $\mathcal{N}^{\mathrm{c}}$ is a complementary channel of $\mathcal{N}$ [14]. Importantly, if $\mathcal{N}$ is *anti-degradable*

*francesco.mele@sns.it

†farzin.salek@gmail.com

‡vittorio.giovannetti@sns.it

§ludovico.lami@gmail.com

then $Q(\mathcal{N}) = 0$ [14].

The phenomenon of photon loss can be modelled by the well-known *pure-loss channel* $\mathcal{E}_\lambda$ of transmissivity $\lambda \in [0, 1]$ [13, 20]. When $\lambda = 1$ the pure-loss channel is noiseless, while when $\lambda = 0$ it is completely noisy. It is known that $\mathcal{E}_\lambda$ is anti-degradable for $\lambda \in [0, \frac{1}{2}]$ [21, 22, 23, 24]. The phenomenon of bosonic dephasing can be described by the *bosonic dephasing channel* $\mathcal{D}_\gamma$ [12, 7, 25], which maps the state $\rho = \sum_{m,n=0}^{\infty} \rho_{mn} |m\rangle\langle n|$, written in the Fock basis, to $\mathcal{D}_\gamma(\rho) := \sum_{m,n=0}^{\infty} \rho_{mn}\, e^{-\frac{\gamma}{2}(m-n)^2} |m\rangle\langle n|$, resulting in a reduction in magnitude of the off-diagonal elements. When $\gamma = 0$, the bosonic dephasing channel is noiseless. In contrast, when $\gamma \to \infty$, it completely annihilates all off-diagonal components of the input density matrix, reducing it to an incoherent probabilistic mixture of Fock states. Moreover, $\mathcal{D}_\gamma$ is never anti-degradable [25].

Consider an optical system undergoing simultaneous loss and dephasing over a time interval. At each instant, the system is susceptible to both an infinitesimal pure-loss channel and an infinitesimal bosonic dephasing channel. Hence, the overall channel, which describes the simultaneous effect of loss and dephasing, results in a suitable composition of numerous concatenations between infinitesimal pure-loss and bosonic dephasing channels. However, given that (i) the pure-loss channel and the bosonic dephasing channel commute, $\mathcal{E}_\lambda \circ \mathcal{D}_\gamma = \mathcal{D}_\gamma \circ \mathcal{E}_\lambda$; (ii) the composition of pure-loss channels is a pure-loss channel, $\mathcal{E}_{\lambda_1} \circ \mathcal{E}_{\lambda_2} = \mathcal{E}_{\lambda_1\lambda_2}$; and (iii) the composition of bosonic dephasing channels is a bosonic dephasing channel, $\mathcal{D}_{\gamma_1} \circ \mathcal{D}_{\gamma_2} = \mathcal{D}_{\gamma_1+\gamma_2}$; it follows that the combined effect of loss and dephasing can be modelled by the composition $\mathcal{N}_{\lambda,\gamma} := \mathcal{E}_\lambda \circ \mathcal{D}_\gamma$, which we will refer to as the *bosonic loss-dephasing channel.*

3 Results

Prior to this work, the only result on the anti-degradability of the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ was that it is anti-degradable if the transmissivity λ is below $\frac{1}{2}$ [12]. (This result trivially follows from the anti-degradability of $\mathcal{E}_\lambda$ for $\lambda \leq \frac{1}{2}$). Notably, in the regime $\lambda > \frac{1}{2}$, it was an open question to understand whether $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable for some values of the dephasing γ, and in [12] the answer was conjectured to be negative. However, in the forthcoming Theorem 1, we show that the latter conjecture is incorrect.

Theorem 1 *The bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable if the transmissivity λ and the dephasing γ fall within one of the following regions: (i) $\lambda \in [0, \frac{1}{2}]$ and $\gamma \geq 0$; (ii) $\lambda \in (\frac{1}{2}, 1)$ and γ such that $\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \leq \frac{3}{2}$, where $\theta(x, y) := \sum_{n=0}^{\infty} x^{n^2} y^n$. A weaker but simpler condition that implies anti-degradability is $\lambda \leq \max\left(\frac{1}{2}, \frac{1}{1+9e^{-\gamma}}\right)$.*

Proof. [Proof sketch] A single-mode channel $\mathcal{N}$ is anti-degradable if and only if its generalised Choi state is *two-extendible* [26, 27], i.e. there exists a tripartite state $\rho_{AB_1B_2}$ such that the reduced states on AB_1 and AB_2 both coincide with the generalised Choi state: $\mathrm{Tr}_{B_2}[\rho_{AB_1B_2}] = \mathrm{Tr}_{B_1}[\rho_{AB_1B_2}] = C_{AB}(\mathcal{N}) := \mathrm{Id}_A \otimes \mathcal{N}_{A'\to B}(\Psi_{AA'})$, with $\Psi_{AA'}$ being a two-mode squeezed vacuum state [13]. The crux of our proof is to find a two-extension of $C_{AB}(\mathcal{N}_{\lambda,\gamma})$ in the region identified by condition (ii). We do this in two steps.

First, after scrutinising $C_{AB}(\mathcal{N}_{\lambda,\gamma})$ in the Fock basis, we construct a tripartite state $\tau_{AB_1B_2}$ such that the reduced states on AB_1 and AB_2 have the same diagonal as $C_{AB}(\mathcal{N}_{\lambda,\gamma})$, and the same pattern of vanishing off-diagonal entries. We construct $\tau_{AB_1B_2}$ by applying several channels — namely, beam splitter unitaries, squeezing unitary, partial trace, and a three mode controlled-add-add isometry — to a 4-mode vacuum state.

The second step consists in transforming $\tau_{AB_1B_2}$ into a two-extension of $C_{AB}(\mathcal{N}_{\lambda,\gamma})$ by tweaking its off-diagonal entries. This is done by using the toolbox of *Hadamard maps* [15], whose employment here constitutes **one of our main technical innovations**. For any matrix $A := (a_{mn})_{m,n\in\mathbb{N}}$, the associated Hadamard map $H^{(A)}$ is defined by $H^{(A)}(|m\rangle\langle n|) = a_{mn}|m\rangle\langle n|$ for all m, n [15]. In practice, $H^{(A)}$ acts on the input density matrix by multiplying each (m, n) entry by the corresponding coefficient a_{mn}. Importantly, $H^{(A)}$ is a quantum channel if and only if A is Hermitian, positive semi-definite, and has all 1's on the main diagonal [15]. The crucial observation is that it is always possible to find an infinite matrix $A_{\lambda,\gamma}$, which is Hermitian and has all 1's on the main diagonal, such that the operator $\mathrm{Id}_A \otimes H_{B_1}^{(A_{\lambda,\gamma})} \otimes H_{B_2}^{(A_{\lambda,\gamma})}(\tau_{AB_1B_2})$ coincides with $C_{AB}(\mathcal{N}_{\lambda,\gamma})$ when tracing out either B_1 or B_2.

This however does not mean that we have found a two-extension of C_{AB}, because the above operator is not necessarily a state — it may fail to be positive semi-definite. It *is* a state, however, whenever $H^{(A_{\lambda,\gamma})}$ is a quantum channel, i.e. when the infinite matrix $A_{\lambda,\gamma}$ is positive semi-definite, in formula $A_{\lambda,\gamma} \geq 0$. Therefore, a sufficient condition on the anti-degradability of $\mathcal{N}_{\lambda,\gamma}$ is that $A_{\lambda,\gamma} \geq 0$. The rest of the proof consists in showing that under condition (ii) one indeed finds $A_{\lambda,\gamma} \geq 0$. This is not straightforward to check, because $A_{\lambda,\gamma}$ is an *infinite* matrix, and it cannot be diagonalised analytically nor numerically. To by-pass this last hurdle we had the idea to employ the **theory of diagonally dominant matrices**, and in particular the statement that if a matrix A is such that $|a_{nn}| - \sum_{m:\, m\mathbb{N}eqn} |a_{mn}| \geq 0$ for all n, then necessarily $A \geq 0$ [28, Chapter 6]. □

Theorem 1 identifies a region of the parameter space (λ, γ), illustrated in Fig. 1, where the channel is anti-degradable, thereby implying the absence of viable error correcting codes for quantum data transfer and storage. In Fig. 1, we plot other relevant regions, e.g. a region where $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable, and another region where the quantum capacity of $\mathcal{N}_{\lambda,\gamma}$ is strictly positive.

As we have just seen, (unassisted) quantum communication is not possible when the combined effects of loss and dephasing are too strong. However, as we show in the technical manuscript, if Alice (the sender) and Bob (the receiver) have access to a *two-way* classical communication line, then quantum communication, entanglement distribution, and quantum-key distribution [29] become again achievable for any value of loss and dephasing, even when Alice's input signals are constrained to have limited energy. In particular, this implies that the bosonic loss-dephasing channel is never entanglement breaking [14, 15].

Let us conclude with a quite shocking observation. Theorem 1 implies that even if $\lambda > \frac{1}{2}$ one can pick γ large enough so that there exists an anti-degrading map achieving the transformation $\mathcal{N}^{c}_{\lambda,\gamma}(|n\rangle\langle n|_F) \longrightarrow \mathcal{N}_{\lambda,\gamma}(|n\rangle\langle n|_F)$, which can be expressed as

$$\mathcal{E}_{1-\lambda}(|n\rangle\langle n|_F) \otimes |\sqrt{\gamma}n\rangle\langle\sqrt{\gamma}n|_C \longrightarrow \mathcal{E}_{\lambda}(|n\rangle\langle n|_F)\,, \qquad (1)$$

where $|n\rangle_F$ denotes the nth Fock state and $|\sqrt{\gamma}n\rangle_C$ denotes a coherent state [13] (see the technical manuscript for an explicit construction of such anti-degrading map). This entails the following remarkable fact: for $\lambda > 1/2$ and large enough γ there exists an *n-independent* strategy to convert the lossy Fock state $\mathcal{E}_{1-\lambda}(|n\rangle\langle n|_F)$ into the less lossy Fock state $\mathcal{E}_{\lambda}(|n\rangle\langle n|_F)$ using the coherent state $|\sqrt{\gamma}n\rangle_C$ as a resource. In other words, one can undo part of the loss on $|n\rangle_F$ if one has a coherent state that contains some information on n, sufficiently amplified so that that information is accessible enough. The nontrivial and somewhat surprising nature of this exact conversion strategy arises from the fact that the coherent states $\{|\sqrt{\gamma}n\rangle_C\}_{n\in\mathbb{N}}$ are not orthogonal, meaning that the strategy that consists in measuring the coherent state, guessing n, and re-preparing $\mathcal{E}_{\lambda}(|n\rangle\langle n|_F)$ cannot succeed with probability 1.

4 Discussion

In our paper, we have provided the first analytical investigation of the quantum communication capabilities of the bosonic loss-dephasing channel, a much more realistic model of noise than dephasing and loss treated separately. Refuting a conjecture put forth in [12], we showed that the bosonic loss-dephasing channel is anti-degradable in a large region of the loss-dephasing parameter space, entailing that neither quantum communication nor quantum error correcting codes are possible in this region. On the positive side, we also showed that if two-way classical communication is suitably exploited, then quantum communication is always achievable, even in scenarios characterised by high levels of loss and dephasing, and even in the presence of stringent energy constraints.

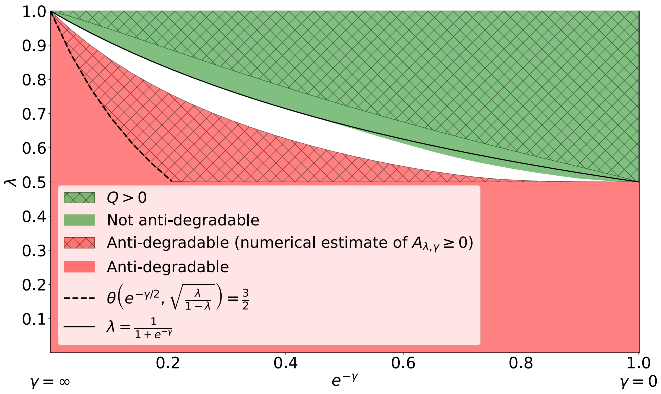

Figure 1: The vertical axis represents the transmissivity λ, while the horizontal axis corresponds to $e^{-\gamma}$, where γ is the dephasing parameter. **1)** In the red region, identified in Theorem 1, the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable, and hence there are neither quantum error correction codes nor quantum communication protocols. **2)** The crossed red region is a numerical estimate of the region where the infinite matrix $A_{\lambda,\gamma}$ is positive semi-definite, implying the anti-degradability of $\mathcal{N}_{\lambda,\gamma}$, as explained in Theorem 1. This estimate is derived by examining the positive semi-definiteness of the $d \times d$ top-left corner of $A_{\lambda,\gamma}$ for large d (increasing d already beyond $d \geq 20$ yields no discernible change in the plot). **3)** In the crossed green region, the quantum capacity of $\mathcal{N}_{\lambda,\gamma}$ is strictly positive, allowing for quantum communication and quantum error correction. We show this by optimising the coherent information [15, 14] over input states of the form $\rho_p := p|0\rangle\langle 0| + (1-p)|1\rangle\langle 1|$. **4)** In the green region, $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable. This is derived by observing that the action of $\mathcal{N}_{\lambda,\gamma}$ can only subtract and never add any photons. Specifically, if the input state to $\mathcal{N}_{\lambda,\gamma}$ is supported on the span of the first d Fock states, so is the output state. This restriction defines a qu*d*it-to-qu*d*it channel $\mathcal{N}^{(d)}_{\lambda,\gamma}$, analysing which can yield some insights into $\mathcal{N}_{\lambda,\gamma}$ itself. First, if $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is *not* anti-degradable then the same is true of $\mathcal{N}_{\lambda,\gamma}$; secondly, the anti-degradability of $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is equivalent to the *two-extendibility* of the corresponding Choi state [26], and for moderate values of d this latter condition can be efficiently checked numerically via *semi-definite programming* [30, 15]. The restriction $\mathcal{N}^{(6)}_{\lambda,\gamma}$ is anti-degradable if and only if λ and γ fall within the green region, explaining why $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable here. **5)** Interestingly, the qubit restriction $\mathcal{N}^{(2)}_{\lambda,\gamma}$, equivalent to the composition between the amplitude damping channel and the qubit dephasing channel [15], yields the analytical result: *If* $\lambda > \frac{1}{1+e^{-\gamma}}$, *then* $\mathcal{N}_{\lambda,\gamma}$ *is not anti-degradable.*

Quantum optical systems are typically affected by two types of noise: photon loss and dephasing. Despite extensive research on each noise process individually, a comprehensive understanding of their combined effect is still lacking. A crucial problem lies in determining the values of loss and dephasing for which the resulting loss-dephasing channel is anti-degradable, implying the absence of codes capable of correcting its effect or, alternatively, capable of enabling quantum communication. A conjecture in [Quantum 6, 821 (2022)] suggested that the bosonic loss-dephasing channel is not anti-degradable if the loss is below 50%. In this paper we refute this conjecture, specifically proving that for any value of the loss, if the dephasing is above a critical value, then the bosonic loss-dephasing channel is anti-degradable. While our result identifies a large parameter region where quantum communication is not possible, we also prove that if two-way classical communication is available, then quantum communication — and thus quantum key distribution — is always achievable, even for high values of loss and dephasing.

Quantum optical platforms are key elements of quantum technologies, contributing significantly to both quantum communication and quantum computation [1–9]. Since the potential benefits of quantum technologies are hindered by the presence of decoherence [10], the investigation of decoherence sources affecting bosonic systems and the development of bosonic quantum error-correcting codes have been extensively analysed in recent years [11–22]. The primary noise processes in bosonic systems that act as dominant sources of decoherence are *photon loss* and *bosonic dephasing* [23–25], which have been both extensively analysed [13, 26–28]. Loss affects the system by causing it to dissipate some of its energy, whereas dephasing works to transform coherent superpositions into probabilistic mixtures. Although loss and dephasing sources can simultaneously affect bosonic systems [15, 29], such as in superconducting systems [30, 31], the existing literature provides only partial results about their combined effect [32]. On a technical level, understanding the combined effect of loss and dephasing is challenging due to the conflicting behaviours they exhibit: the action of loss takes a simple form when written in the coherent state basis but is complicated to analyse in the Fock basis [2], whereas dephasing demonstrates the opposite pattern, making the analysis of their combined effect quite intricate.

Consider an optical link (e.g. an optical fibre or a free-space link) or a quantum memory affected by both loss and dephasing, where the link is used for quantum communication and the memory for quantum computation. A crucial challenge is to determine the conditions under which there exist protocols capable of enabling reliable quantum communication across the optical link or capable of mitigating the combined noise affecting the quantum memory. This problem is closely related to the anti-degradability condition in quantum Shannon theory: if a noise channel is *anti-degradable* [33, 34], there are no quantum communication protocols for reliable information transmission or quantum error-correcting codes capable of overcoming it. Consequently, it is crucial to understand whether the combined effect of loss and dephasing results in an anti-degradable channel. This has been a puzzling problem, to the point that in [32] it was conjectured that the combined loss-dephasing noise does not result in an anti-degradable channel if the loss is below 50%.

In this paper we refute the above conjecture; specifically, we prove that for any value of the photon loss there exists a *critical value* of the dephasing above which the resulting loss-dephasing channel is anti-degradable. Our discovery thus identifies a large region of the loss-dephasing parameter space where correcting the noise and achieving reliable quantum communication is impossible. On the more positive side, however, we also prove that if the sender and the receiver are assisted by two-way classical communication, then reliable quantum communication — and thus quantum key distribution — is always possible, even in scenarios characterised by arbitrarily high levels of loss and dephasing. Ours are the first analytical results to characterise the transmission of quantum information in the presence of both loss and dephasing noise.

***Preliminaries*.**— The *quantum capacity* $Q(\mathcal{N})$ of a quantum channel $\mathcal{N}$ quantifies the efficiency in transmitting qubits reliably across $\mathcal{N}$ [33, 34]. The condition $Q(\mathcal{N}) = 0$ implies that there exist neither reliable quantum communication protocols across $\mathcal{N}$ nor codes capable of correcting the errors induced by $\mathcal{N}$. Accordingly, if $\mathcal{N}$ is *anti-degradable* its quantum capacity vanishes [33]. This underscores the significance of determining whether a channel is anti-degradable, as the noise associated with such a channel cannot be corrected. By definition, a channel $\mathcal{N}$ is anti-degradable if there exists a channel $\mathcal{A}$ — called the *anti-degrading map* — such that $\mathcal{A} \circ \mathcal{N}^{c} = \mathcal{N}$, where $\mathcal{N}^{c}$ denotes a complementary channel of $\mathcal{N}$ [33]. Conversely, a channel $\mathcal{N}$ is degradable if there exists a channel $\mathcal{D}$ such that $\mathcal{D} \circ \mathcal{N} = \mathcal{N}^{c}$. Degradable channels are theoretically important because their quantum capacity can be calculated as the single-letter coherent information of the channel [33–35].

The phenomenon of photon loss is mathematically modelled by the *pure-loss channel* $\mathcal{E}_\lambda$ [2, 4], a single-mode continuous-variable channel that acts on the input state ρ by mixing it with an environmental vacuum state in a beam splitter of transmissivity $\lambda \in [0, 1]$:

$$\mathcal{E}_\lambda(\rho) := \mathrm{Tr}_E \left[U_\lambda \left(\rho_S \otimes |0\rangle\!\langle 0|_E \right) U_\lambda^\dagger \right] , \tag{1}$$

where $U_\lambda := \exp\left[\arccos\!\left(\sqrt{\lambda}\right)(\hat{a}^\dagger \hat{e} - \hat{a}\,\hat{e}^\dagger)\right]$ is the beam splitter unitary, $\hat{a}$ and $\hat{e}$ are the annihilation operators of the input system S and of the environment E, and Tr_E is the partial trace w.r.t. E. When a single photon is fed into $\mathcal{E}_\lambda$, it is transmitted to the output with probability λ, while it is lost to the environment with probability $1 - \lambda$. More generally, if n photons are fed into the channel, the output is given by the binomial probability mixture $\mathcal{E}_\lambda(|n\rangle\!\langle n|) = \sum_{\ell=0}^{n} \binom{n}{l} (1-\lambda)^\ell \lambda^{n-\ell} \, |n-\ell\rangle\!\langle n-\ell|$, where $|n\rangle$ denotes the Fock state with n photons [2]. When $\lambda = 1$ the pure-loss channel is noiseless, while when $\lambda = 0$ it is completely noisy — it maps any state into the vacuum. It is known that the pure-loss channel is anti-degradable for $\lambda \in [0, \frac{1}{2}]$ and degradable for $\lambda \in [\frac{1}{2}, 1]$ [36–39].

The phenomenon of bosonic dephasing is mathematically described by the *bosonic dephasing channel* $\mathcal{D}_\gamma$ [28, 32, 40], which maps the state $\rho = \sum_{m,n=0}^{\infty} \rho_{mn} \, |m\rangle\!\langle n|$, written in the Fock basis, to

$$\mathcal{D}_\gamma(\rho) := \sum_{m,n=0}^{\infty} \rho_{mn} e^{-\frac{\gamma}{2}(m-n)^2} \, |m\rangle\!\langle n| \ , \tag{2}$$

resulting in a reduction in magnitude of the off-diagonal elements. When $\gamma = 0$, the bosonic dephasing channel is noiseless. In contrast, when $\gamma \to \infty$, it completely annihilates all off-diagonal components of the input density matrix, reducing it to an incoherent probabilistic mixture of Fock states. Moreover, the bosonic dephasing channel is never anti-degradable and it is always degradable [40].

Consider an optical system undergoing simultaneous loss and dephasing over a finite time interval. At each instant, the system is susceptible to both an infinitesimal pure-loss channel and an infinitesimal bosonic dephasing channel. Hence, the overall channel, which describes the simultaneous effect of loss and dephasing, results in a suitable composition of numerous concatenations between infinitesimal pure-loss and bosonic dephasing channels. However, given that (i) the pure-loss channel and the bosonic dephasing channel commute, $\mathcal{E}_\lambda \circ \mathcal{D}_\gamma = \mathcal{D}_\gamma \circ \mathcal{E}_\lambda$; (ii) the composition of pure-loss channels is a pure-loss channel, $\mathcal{E}_{\lambda_1} \circ \mathcal{E}_{\lambda_2} = \mathcal{E}_{\lambda_1 \lambda_2}$; and (iii) the composition of bosonic dephasing channels is a bosonic dephasing channel, $\mathcal{D}_{\gamma_1} \circ \mathcal{D}_{\gamma_2} = \mathcal{D}_{\gamma_1 + \gamma_2}$; it follows that the combined effect of loss and dephasing can be modelled by the composition

$$\mathcal{N}_{\lambda,\gamma} := \mathcal{E}_\lambda \circ \mathcal{D}_\gamma \ , \tag{3}$$

which we will refer to as the *bosonic loss-dephasing channel* [41].

Anti-degradability.— Prior to this work, the only result on the anti-degradability of the bosonic loss-dephasing channel was that it is anti-degradable if the transmissivity is below $\frac{1}{2}$ [32]. (This result trivially follows from the anti-degradability of the pure-loss channel for transmissivities below $\frac{1}{2}$, and the fact that the composition of an anti-degradable channel with another channel inherits the property of being anti-degradable [41]). Notably, in the regime $\lambda > \frac{1}{2}$, it was an open question to understand whether or not the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable for some values of the dephasing γ, and in [32] the answer was conjectured to be negative. However, in the forthcoming Theorem 1, we show that the latter conjecture is incorrect, specifically, we prove that for all $\lambda \in [0, 1)$, if γ is sufficiently large, then $\mathcal{N}_{\lambda,\gamma}$ becomes anti-degradable [41, Theorem 27].

Theorem 1. *The bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable if the transmissivity λ and the dephasing γ fall within one of the following regions: (i) $\lambda \in [0, \frac{1}{2}]$ and $\gamma \geq 0$; (ii) $\lambda \in (\frac{1}{2}, 1)$ and γ such that $\theta\!\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \leq \frac{3}{2}$, where $\theta(x, y) := \sum_{n=0}^{\infty} x^{n^2} y^n$. A weaker but simpler sufficient condition that implies anti-degradability is given by $\lambda \leq \max\!\left(\frac{1}{2}, \frac{1}{1+9e^{-\gamma}}\right)$.*

Proof sketch. Any finite dimensional channel $\mathcal{N}$ is anti-degradable if and only if its Choi state is *two-extendible* [42], meaning that there exists a tripartite state $\rho_{AB_1B_2}$ such that the reduced states on AB_1 and AB_2 both coincide with the Choi state:

$$\begin{aligned} \mathrm{Tr}_{B_2}\left[\rho_{AB_1B_2}\right] &= C_{AB_1}(\mathcal{N}) \, , \\ \mathrm{Tr}_{B_1}\left[\rho_{AB_1B_2}\right] &= C_{AB_2}(\mathcal{N}) \, , \end{aligned} \tag{4}$$

where the Choi state is defined as $C_{AB}(\mathcal{N}) := \mathrm{id}_A \otimes \mathcal{N}_{A' \to B}(\Phi_{AA'})$, with $\Phi_{AA'}$ being the maximally entangled state. Such a characterisation extends to infinite dimension by considering the generalised Choi state

$C^{(r)}_{AB}(\mathcal{N}) := \mathrm{id}_A \otimes \mathcal{N}_{A'\to B}\big(\Psi^{(r)}_{AA'}\big)$ [43], obtained by replacing $\Phi_{AA'}$ by the two-mode squeezed vacuum state $\Psi^{(r)}_{AA'}$ with squeezing parameter $r > 0$ [2]. The crux of our proof is to find a two-extension of $C^{(r)}_{AB}(\mathcal{N}_{\lambda,\gamma})$ in the region identified by condition (ii). We do this in two steps.

First, after scrutinising the matrix $C^{(r)}_{AB}(\mathcal{N}_{\lambda,\gamma})$ written in the Fock basis, we construct a tripartite state $\tau_{AB_1B_2}$ such that the reduced states on AB_1 and AB_2 have the same diagonal as $C^{(r)}_{AB}(\mathcal{N}_{\lambda,\gamma})$, and the same pattern of vanishing off-diagonal entries. The construction of this tripartite state involves applying several channels — namely, beam splitter unitaries, squeezing unitary, partial trace, and a three mode controlled-add-add isometry — to a 4-mode vacuum state.

The second step consists in transforming $\tau_{AB_1B_2}$ into a two-extension of $C^{(r)}_{AB}(\mathcal{N}_{\lambda,\gamma})$ by tweaking its off-diagonal entries. This is done by using the toolbox of *Hadamard maps* [34]. For any matrix $A := (a_{mn})_{m,n\in\mathbb{N}}$, the associated Hadamard map $H^{(A)}$ is defined by

$$H^{(A)}(|m\rangle\!\langle n|) = a_{mn}\,|m\rangle\!\langle n| \tag{5}$$

for all m, n [34]. In practice, $H^{(A)}$ acts on the input density matrix by multiplying each (m, n) entry by the corresponding coefficient a_{mn}. Importantly, $H^{(A)}$ is a quantum channel if and only if A is Hermitian, positive semi-definite, and has all 1's on the main diagonal [34]. The crucial observation is that it is always possible to find an infinite matrix $A_{\lambda,\gamma}$ (possibly not positive semi-definite), which is real, symmetric, and has all 1's on the main diagonal, such that the operator $\mathrm{id}_A \otimes H^{(A_{\lambda,\gamma})}_{B_1} \otimes H^{(A_{\lambda,\gamma})}_{B_2}(\tau_{AB_1B_2})$ coincides with $C^{(r)}_{AB}(\mathcal{N}_{\lambda,\gamma})$ when tracing out either B_1 or B_2.

This however does not mean that we have found a two-extension of $C^{(r)}_{AB}$, because the above operator is not necessarily a state — it may fail to be positive semi-definite. It *is* a state, however, whenever $H^{(A_{\lambda,\gamma})}$ is a quantum channel, i.e. when the infinite matrix $A_{\lambda,\gamma}$ is positive semi-definite, in formula $A_{\lambda,\gamma} \geq 0$. Therefore, a sufficient condition on the anti-degradability of $\mathcal{N}_{\lambda,\gamma}$ is that $A_{\lambda,\gamma} \geq 0$.

The rest of the proof consists in showing that under condition (ii) one indeed finds $A_{\lambda,\gamma} \geq 0$. This is not straightforward to check, because $A_{\lambda,\gamma}$ is an *infinite* matrix, and it cannot be diagonalised analytically nor numerically. To by-pass this last hurdle we employ the theory of diagonally dominant matrices, and in particular the statement that if a matrix A is such that $a_{nn} - \sum_{m:\,m\neq n}|a_{mn}| \geq 0$ for all n, then necessarily $A \geq 0$ [44, Chapter 6]. We demonstrate that if λ and γ satisfy condition (ii), then $A_{\lambda,\gamma}$ satisfies this condition, which establishes that $A_{\lambda,\gamma} \geq 0$ and hence concludes the proof [41]. □

Theorem 1 identifies a region of the parameter space (λ, γ), with λ identifying the transmissivity and γ the dephasing, where the channel is anti-degradable and thus its quantum capacity vanishes, thereby implying the absence of viable error correcting codes for quantum data transfer and storage. This region is illustrated in Fig. 1. Interestingly, Theorem 1 implies that even if $\lambda > \frac{1}{2}$ one can pick γ large enough so that there exists an anti-degrading map achieving the transformation $\mathcal{N}^{\mathrm{c}}_{\lambda,\gamma}(|n\rangle\!\langle n|_F) \longrightarrow \mathcal{N}_{\lambda,\gamma}(|n\rangle\!\langle n|_F)$, which can be expressed as [41, Subsection I G]

$$\mathcal{E}_{1-\lambda}(|n\rangle\!\langle n|_F) \otimes \big|\sqrt{\gamma}n\big\rangle\!\big\langle\sqrt{\gamma}n\big|_C \longrightarrow \mathcal{E}_{\lambda}(|n\rangle\!\langle n|_F)\,, \tag{6}$$

where $|n\rangle_F$ denotes the nth Fock state and $\big|\sqrt{\gamma}n\big\rangle_C$ denotes a coherent state [2] (see [41, Theorem 29] for an explicit construction of such anti-degrading map). This entails the following remarkable fact: for $\lambda > 1/2$ and large enough γ there exists an *n-independent* strategy to convert the lossy Fock state $\mathcal{E}_{1-\lambda}(|n\rangle\!\langle n|_F)$ into the less lossy Fock state $\mathcal{E}_{\lambda}(|n\rangle\!\langle n|_F)$ using the coherent state $\big|\sqrt{\gamma}n\big\rangle_C$ as a resource. In other words, one can undo part of the loss on $|n\rangle_F$ if one has a coherent state that contains some information on n, sufficiently amplified so that that information is accessible enough. The nontrivial and somewhat surprising nature of this exact conversion strategy arises from the fact that the coherent states $\{\big|\sqrt{\gamma}n\big\rangle_C\}_{n\in\mathbb{N}}$ are not orthogonal, meaning that the strategy that consists in measuring the coherent state, guessing n, and re-preparing $\mathcal{E}_{\lambda}(|n\rangle\!\langle n|_F)$ cannot succeed with probability 1.

Theorem 1 does not identify the entire anti-degradability region of $\mathcal{N}_{\lambda,\gamma}$, but only a subset of it. One way to improve this approximation is to determine numerically the region where the infinite matrix $A_{\lambda,\gamma}$ introduced in the proof sketch of Theorem 1 is positive semi-definite. In Fig. 1 we depict a numerical estimate of this region (see the crossed red part of the plot).

So far we have been concerned with inner approximations of the anti-degradability region. To obtain outer approximations, instead, one can start by observing that the action of $\mathcal{N}_{\lambda,\gamma}$ can only subtract and never add any photons. Mathematically, if the input state to $\mathcal{N}_{\lambda,\gamma}$ is supported on the span of the first d Fock states, so is the output state [41]. This restriction defines a qu$d$it-to-qu$d$it channel $\mathcal{N}^{(d)}_{\lambda,\gamma}$, analysing which can yield some insights into $\mathcal{N}_{\lambda,\gamma}$ itself. First, if $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is *not* anti-degradable then the same is true of $\mathcal{N}_{\lambda,\gamma}$ [41]; secondly, as discussed above the anti-degradability of $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is equivalent to the two-extendibility of the corresponding Choi state [42], and for moderate values of d this latter condition can be efficiently checked numerically via *semi-definite programming* [34, 41, 45]. In this way, we can numerically determine a parameter region (see green region of Fig. 1) where $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable. Interestingly, already the qubit restriction $\mathcal{N}^{(2)}_{\lambda,\gamma}$, which coincides with the composition between the amplitude damping channel and the qubit dephasing channel [34], yields the necessary condition $\lambda \leq \frac{1}{1+e^{-\gamma}}$ on the anti-degradability of $\mathcal{N}_{\lambda,\gamma}$, as shown in the forthcoming Theorem 2. Based on the analysis of the qudit restrictions [41], we conjecture that, if γ is sufficiently large, the latter condition $\lambda \leq \frac{1}{1+e^{-\gamma}}$ is not only necessary but also sufficient.

Theorem 2. *If $\lambda > \frac{1}{1+e^{-\gamma}}$ then $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable.*

Proof sketch. A qubit channel $\mathcal{N}$ is anti-degradable if and only if

$$\frac{1}{4}\operatorname{Tr}\left[\mathcal{N}(\mathbb{1}_2)^2\right] \geq \operatorname{Tr}\left[C(\mathcal{N})^2\right] - 4\sqrt{\det[C(\mathcal{N})]}, \qquad (7)$$

where $C(\mathcal{N})$ is the Choi state [42, 46, 47]. When focusing on the qubit restriction $\mathcal{N}^{(2)}_{\lambda,\gamma}$, Eq. (7) is equivalent to the condition $\lambda \leq \frac{1}{1+e^{-\gamma}}$. □

We are interested in the anti-degradability of the loss-dephasing channel because it implies that the quantum capacity vanishes, entailing the impossibility of quantum communication. We now look at the complementary question: when is the quantum capacity $Q(\mathcal{N}_{\lambda,\gamma})$ strictly positive? A simple sufficient condition can be obtained by optimising the coherent information [33, 34] of $\mathcal{N}_{\lambda,\gamma}$ over input states of the form $\rho_p := p\,|0\rangle\!\langle 0| + (1-p)\,|1\rangle\!\langle 1|$. By doing so we identify a region of the (λ,γ) parameter space where $Q(\mathcal{N}_{\lambda,\gamma}) > 0$ (see the crossed green region in Fig. 1). In this region quantum communication and quantum error correction become feasible.

Two-way quantum communication.— As we have just seen, (unassisted) quantum communication is not possible when the combined effects of loss and dephasing are too strong. However, in the forthcoming Theorem 3 we show that if Alice (the sender) and Bob (the receiver) have access to a *two-way* classical communication line, then quantum communication, entanglement distribution, and quantum-key distribution [48] become again achievable for any value of loss and dephasing, even when Alice's input signals are constrained to have limited energy.

In this two-way communication setting the relevant notion of capacity is the *two-way quantum capacity* $Q_2(\mathcal{N})$ [33, 34], defined as the maximum achievable rate of qubits that can be reliably transmitted across $\mathcal{N}$ with the aid of two-way classical communication. Since in practice Alice has only a limited amount of energy to produce her input signals, one usually defines the so-called *energy-constrained* two-way quantum capacity [49, 50], denoted as $Q_2(\mathcal{N}, N_s)$. Here, N_s denotes the mean photon number constraint at the input of the channel. Now, we are ready to state the main result of this section [41, Section III].

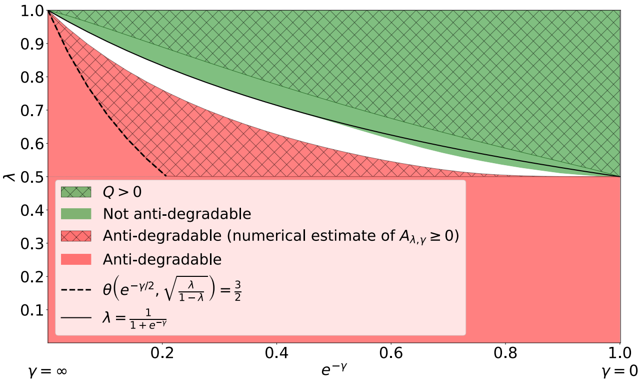

FIG. 1. Summary of results on the anti-degradability of the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$. The vertical axis represents the transmissivity λ, while the horizontal axis corresponds to $e^{-\gamma}$, where γ is the dephasing parameter. In the green region $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable, while in the red region it is anti-degradable. In the crossed green region, the quantum capacity of $\mathcal{N}_{\lambda,\gamma}$ is strictly positive. The crossed red region is a numerical estimate of the region where the infinite matrix $A_{\lambda,\gamma}$ is positive semi-definite, a condition implying that $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable, as explained in the proof sketch of Theorem 1. Such an estimate can be obtained by examining the positive semi-definiteness of the $d \times d$ top-left corner of $A_{\lambda,\gamma}$ for large values of d (here we employ $d = 30$, but increasing d already beyond $d \geq 20$ yields no discernible change in the plot). The restriction $\mathcal{N}^{(6)}_{\lambda,\gamma}$ is anti-degradable if and only if λ and γ fall within the green region, and this is the reason why $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable in the green region. Below the curve $\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) = \frac{3}{2}$, the channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable, as stated in Theorem 1. Above the curve $\lambda = \frac{1}{1+e^{-\gamma}}$, the channel is not anti-degradable, as guaranteed by Theorem 2.

Theorem 3. *For all $N_s > 0$, $\lambda \in (0,1]$, and $\gamma \geq 0$, the energy-constrained two-way quantum capacity of the bosonic loss-dephasing channel is strictly positive, i.e. $Q_2(\mathcal{N}_{\lambda,\gamma}, N_s) > 0$. In particular, $\mathcal{N}_{\lambda,\gamma}$ is not entanglement breaking. An explicit lower bound is*

$$Q_2(\mathcal{N}_{\lambda,\gamma}, N_s) \geq \frac{\lambda^N}{k}\left[\log_2\binom{N+k-1}{N} - S\left(\rho_{N,k,\gamma}\right)\right] \qquad (8)$$

for any $N, k \in \mathbb{N}_+$ satisfying $\frac{N}{k} \leq N_s$. Here, $S(\cdot)$ is the von Neumann entropy, $\rho_{N,k,\gamma}$ is a $\binom{N+k-1}{N}$-dimensional state defined by

$$\rho_{N,k,\gamma} := \binom{N+k-1}{N}^{-1} \sum_{p,q \in \Pi(N,k)} e^{-\frac{\gamma}{2}\|p-q\|_2^2}\,|p\rangle\!\langle q|\,, \qquad (9)$$

where $\Pi(N,k) := \left\{p \in \mathbb{N}^k : \sum_{i=1}^{k} p_i = N\right\}$ represents the set of partitions of a set of N elements into k parts, and the vectors $\{|p\rangle\}_{p\in\Pi(N,k)}$ are orthonormal.

Proof sketch. The proof exploits entanglement transmission protected by a particular error correction technique, *rail encoding*. In a k-mode bosonic system, consider the subspace $V_{N,k}$ corresponding to a total photon number N. We can use this subspace, whose dimension is $d_{N,k} := \dim V_{N,k} = \binom{N+k-1}{N}$, as an error correction code that protects against the detrimental action of $\mathcal{N}_{\lambda,\gamma}$. To this end, we prepare a maximally entangled state of dimension $d_{N,k}$ and send one share of it through k copies of the channel $\mathcal{N}_{\lambda,\gamma}$, one per mode. Since under the action of $\mathcal{N}_{\lambda,\gamma}$ photons can only be lost and never added, and each photon has a probability λ of being transmitted, the probability that an N-photon state will retain all of its photons at the output of the channel is exactly λ^N. If this happens to be the case, which — crucially — can be certified by a total photon number measurement at the output, then the input state has been subjected to no loss and only dephasing. The entanglement of the resulting, maximally correlated state can be distilled via an explicit protocol known as the hashing protocol [34, 51], resulting in $\log_2 d_{N,k} - S(\rho_{N,k,\gamma}) > 0$ singlet (a.k.a. ebit, i.e. unit of entanglement) yield. The strict positivity of this yield follows by observing that $\rho_{N,k,\gamma}$ is a $d_{N,k}$-dimensional mixed state that is not maximally mixed [41].

□

Degradability.— The bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is never degradable, except in the simple cases when either $\lambda = 1$ or $\gamma = 0$ and $\lambda \geq 1/2$ [32]. This in turn implies that no single-letter formula for its quantum capacity is known outside of the anti-degradability region studied here, where the capacity vanishes. The failure of degradability has been demonstrated in [32] through a lengthy proof; we are now in position to provide an alternative, much simpler argument. The key ideas are as follows: (i) If the qubit restriction $\mathcal{N}^{(2)}_{\lambda,\gamma}$ is not degradable, then $\mathcal{N}_{\lambda,\gamma}$ is not degradable either [41]; and (ii) if the rank of the Choi state of a qubit channel is greater or equal to 3 than such channel is not degradable [52, Theorem 4]. The result then follows by observing that the rank of the Choi state of the qubit channel $\mathcal{N}^{(2)}_{\lambda,\gamma}$ is exactly 3 (for a detailed proof see [41, Theorem 34]).

Conclusion.— In this paper we have provided the first analytical investigation of the quantum communication capabilities of the bosonic loss-dephasing channel, a much more realistic model of noise than dephasing and loss treated separately. Refuting a conjecture put forth in [32], we showed that the bosonic loss-dephasing channel is anti-degradable in a large region of the loss-dephasing parameter space, entailing that neither quantum communication nor quantum error correcting codes are possible in this region. On the positive side, we also showed that if two-way classical communication is suitably exploited, then quantum communication is always achievable, even in scenarios characterised by high levels of loss and dephasing, and even in the presence of stringent energy constraints.

Two fundamental technical innovations are key to our approach. First, a new method to analyse anti-degradability of bosonic channels, based on a two-stage construction of a symmetric extension of the Choi state. The introduction of this technique is crucial here also on the conceptual level, as *all* other known tools to analyse quantum capacities (e.g. degradability [34], PPT-ness [53], or teleportation simulability [54, 55]) fail completely for the loss-dephasing channel [32]. We envision that our technique could also be applied to other cases, e.g. to analyse the anti-degradability of the composition between the pure-loss channel and a *general* bosonic dephasing channel [41, Section V]. The second innovation we introduce is based on the use of rail encoding to investigate two-way assisted entanglement generation on the loss-dephasing channel. This technique, which we anticipate may be used to study general processes where photon loss is involved, has the additional benefit of yielding an explicit entanglement generation protocol.

Although the capacities of the dephasing channel and the pure-loss channel (separately) have been determined [28, 38, 39, 54, 56–59], the capacities of the channel resulting from their combined action remain unknown. An intriguing open problem is to calculate or approximate these capacities.

CONTENTS

I. PRELIMINARIES AND NOTATION

A. Quantum states and Channels

In this subsection, we present a summary of the notation and fundamental properties used in the paper, drawing from the conventions established in standard quantum information theory textbooks [1–4]. Every quantum system is associated with a separable complex Hilbert space $\mathcal{H}$ whose dimension is denoted by $|\mathcal{H}|$. We use subscripts to denote the system associated to a Hilbert space and also systems on which the operators act. The composite quantum systems A and B exist within the tensor product of their individual Hilbert spaces $\mathcal{H}_A \otimes \mathcal{H}_B$ which is also denoted by $\mathcal{H}_{AB}$.

We shall use $\mathbb{1}$ to denote the identity operator on $\mathcal{H}$. The operator norm of a linear operator $\Theta : \mathcal{H} \longrightarrow \mathcal{H}$ is defined as

$$\|\Theta\|_\infty := \sup_{|\psi\rangle\in\mathcal{H}:\, \langle\psi|\psi\rangle=1} \sqrt{\langle\psi|\Theta^\dagger\Theta|\psi\rangle}\,. \tag{S1}$$

An alternative (but equivalent) definition of the operator norm is as follows:

$$\|\Theta\|_\infty := \sup_{|v\rangle,|w\rangle\in\mathcal{H},\, \langle v|v\rangle=\langle w|w\rangle=1} |\langle v|\,\Theta\,|w\rangle|\ . \tag{S2}$$

An operator is called bounded if its operator norm is bounded, i.e. $\|\Theta\|_\infty < \infty$. A bounded operator Θ is positive semi-definite if $\langle\psi|\,\Theta\,|\psi\rangle \geq 0, \forall\, |\psi\rangle \in \mathcal{H}$, while it is positive definite if $\langle\psi|\,\Theta\,|\psi\rangle > 0,\, \forall\, |\psi\rangle \in \mathcal{H}$. The trace norm of a linear operator $\Theta : \mathcal{H} \to \mathcal{H}$ is defined as $\|\Theta\|_1 := \mathrm{Tr}\,\sqrt{\Theta^\dagger\Theta}$. The set of trace class operators, denoted as $\mathcal{T}(\mathcal{H})$, is the set of all the linear operators on $\mathcal{H}$ such that their trace norm is finite, i.e. $\|\Theta\|_1 < \infty$. The operator and trace norm satisfy $\|\Theta\|_\infty \leq \|\Theta\|_1$. The set of quantum states (density operators), denoted as $\mathcal{P}(\mathcal{H})$, is the set of positive semi-definite trace class operators on $\mathcal{H}$ with unit trace. The *fidelity* between two quantum states $\rho, \sigma \in \mathcal{P}(\mathcal{H})$ is defined as $F(\rho,\sigma) := \mathrm{Tr}\left[\sqrt{\sqrt{\rho}\sigma\sqrt{\rho}}\right]$.

A superoperator is a linear map between spaces of linear operators. The identity superoperator will be denoted as id. Quantum channels are completely-positive trace-preserving (cptp) superoperators. In this paper, we will use two different representations of a quantum channel that are known as Stinespring and Choi–Jamiołkowski representation. A quantum channel $\mathcal{N}_{A'\to B}$ can be represented in Stinespring representation as

$$\mathcal{N}_{A'\to B}(\cdot) = \mathrm{Tr}_E\left[U_{A'E\to BE}(\cdot \otimes |0\rangle\langle 0|_E)U^\dagger_{A'E\to BE}\right].$$

Here, E is an environment system, $|0\rangle_E$ is a pure state of the environment, and $U_{A'E\to BE}$ is an isometry that takes as input the systems A' and E and outputs the systems B, E. The associated complementary channel $\mathcal{N}^{\mathrm{c}}_{A'\to B}$ is given by

$$\mathcal{N}^{\mathrm{c}}_{A'\to E}(\cdot) = \mathrm{Tr}_B\left[U_{A'E\to BE}(\cdot \otimes |0\rangle\langle 0|_E)U^\dagger_{A'E\to BE}\right].$$

A channel $\mathcal{N}$ is called degradable if there exist a quantum channel $\mathcal{J}$, such that when is used after $\mathcal{N}$, we get back to the complementary channel $\mathcal{N}^{\mathrm{c}}$, i.e. $\mathcal{J} \circ \mathcal{N} = \mathcal{N}^{\mathrm{c}}$. On the other hand, a channel is called anti-degradable if there is another quantum channel $\mathcal{A}$, such that using it after the complementary channel, gives back the original channel, i.e. $\mathcal{A} \circ \mathcal{N}^{\mathrm{c}} = \mathcal{N}$. The channels $\mathcal{J}$ and $\mathcal{A}$ are usually called the degrading map and the anti-degrading map of $\mathcal{N}$, respectively.

The Choi–Jamiołkowski representation of the channel $\mathcal{N}_{A'\to B}$ is the operator $C(\mathcal{N}) \in \mathcal{T}(\mathcal{H}_A \otimes \mathcal{H}_B)$ that is defined as

$$C(\mathcal{N}) := \mathrm{id}_A \otimes \mathcal{N}_{A'\to B}(|\Phi\rangle\langle\Phi|_{AA'}), \tag{S3}$$

where $|\Phi\rangle = \frac{1}{\sqrt{|\mathcal{H}_A|}}\sum_{i=0}^{|\mathcal{H}_A|-1} |i\rangle_A \otimes |i\rangle_{A'}$ is a maximally entangled state of schmidt rank $|\mathcal{H}_A|$, the set of states $\{|i\rangle\}_{i=0,\ldots,|\mathcal{H}_A|-1}$ forms a basis for $\mathcal{H}_A$, and $\mathcal{H}_A = \mathcal{H}_{A'}$. It is a well-established fact that the superoperator $\mathcal{N}$ is a quantum channel if and only if $C(\mathcal{N}) \geq 0$ and $\mathrm{Tr}_B\, C(\mathcal{N}) = \mathbb{1}_A/|\mathcal{H}_A|$ [2].

Definition 1. *A bipartite state ρ_{AB} is symmetric two-extendible on B if there exists a tripartite state $\tau_{AB_1B_2}$ such that*

- $F_{B_1B_2}\tau_{AB_1B_2}F^\dagger_{B_1B_2} = \tau_{AB_1B_2}$
- $\mathrm{Tr}_{B_1}\,\tau_{AB_1B_2} = \rho_{AB}$,

where B_1 and B_2 are two copies of the system B, the operator $F_{B_1B_2} := \sum_{i,j} |i\rangle\langle j|_{B_1} \otimes |j\rangle\langle i|_{B_2}$ denotes the swap unitary, and $\{|i\rangle_{B_1}\}_i$ and $\{|i\rangle_{B_2}\}_i$ form an orthonormal basis. The state $\tau_{AB_1B_2}$ is called a symmetric two-extension of ρ_{AB} on B.

Definition 2. *A bipartite state ρ_{AB} is called two-extendible on B if there exists a tripartite state $\tau_{AB_1B_2}$ such that*

$$\mathrm{Tr}_{B_1}\,\tau_{AB_1B_2} = \mathrm{Tr}_{B_2}\,\tau_{AB_1B_2} = \rho_{AB}\,, \tag{S4}$$

where B_1 and B_2 are two copies of the system B.

Lemma 3 [5]**.** *A bipartite state ρ_{AB} is two-extendible on B if and only if it is symmetric two-extendible on B .*

Proof. First, assume ρ_{AB} is symmetric two-extendible on B. Since $F_{B_1B_2}\tau_{AB_1B_2}F^\dagger_{B_1B_2} = \tau_{AB_1B_2}$, it holds that $\mathrm{Tr}_{B_2}\,\tau_{AB_1B_2} = \mathrm{Tr}_{B_1}\,\tau_{AB_1B_2}$. This implies that ρ_{AB} is two-extendible on B. Second, let ρ_{AB} be two-extendible on B. One can easily check that the state $1/2(\tau_{AB_1B_2} + F_{B_1B_2}\tau_{AB_1B_2}F^\dagger_{B_1B_2})$ is a symmetric two-extension of ρ_{AB}. □

It has been demonstrated that a quantum channel is anti-degradable if and only if its Choi state is two-extendible on the output system [6]. This equivalence leads to a simple necessary and sufficient condition for the anti-degradability of qubit channels:

Lemma 4. *[7, Corollary 4](See also [6, 8]) Any qubit quantum channel $\mathcal{N}$ is anti-degradable if and only if it satisfies*

$$\mathrm{Tr}\left[\left(\mathcal{N}\left(\frac{\mathbb{1}_2}{2}\right)\right)^2\right] \geq \mathrm{Tr}\left[(C(\mathcal{N}))^2\right] - 4\sqrt{\det(C(\mathcal{N}))},$$

where $\mathbb{1}_2$ denotes the identity operator on the qubit Hilbert space.

B. Bosonic systems

In this subsection, we will provide an overview of relevant definitions and properties concerning quantum information with continuous variable systems; refer to [9] for detailed explanations. A single-mode of electromagnetic radiation with definite frequency and polarisation is represented by the Hilbert space $L^2(\mathbb{R})$, which comprises all square-integrable complex-valued functions over $\mathbb{R}$. Let $\mathbb{N}_+$ be the set of strictly positive integers and let $\mathbb{N} := \{0\} \cup \mathbb{N}_+$. For any $n \in \mathbb{N}$, the construction of the *Fock state* $|n\rangle$ (the quantum state with n photons) involves the application of the bosonic creation operator $\hat{a}^\dagger$ to the *vacuum state* $|0\rangle$:

$$|n\rangle := \frac{1}{\sqrt{n!}}(\hat{a}^\dagger)^n |0\rangle \, . \tag{S5}$$

The Fock states $\{|n\rangle\}_{n\in\mathbb{N}}$ form an orthonormal basis of $L^2(\mathbb{R})$. The bosonic annihilation operator $\hat{a}$ and creation operator $\hat{a}^\dagger$ satisfy the well-known canonical commutation relation $[\hat{a}, \hat{a}^\dagger] = \mathbb{1}$.

Let $\mathbb{C}$ be the set of complex numbers. For any $\alpha \in \mathbb{C}$, let $D(\alpha) := e^{\alpha\hat{a}^\dagger - \alpha^*\hat{a}}$ be the displacement operator. A coherent state of parameter α, denoted by $|\alpha\rangle$, is defined by applying the displacement operator $D(\alpha)$ to the vacuum state, i.e. $|\alpha\rangle := D(\alpha)|0\rangle$. The overlap between coherent states is given by

$$\langle\alpha|\beta\rangle = e^{-\frac{1}{2}(|\alpha|^2+|\beta|^2-2\alpha^*\beta)} \, . \tag{S6}$$

Quantum channels acting on bosonic systems are sometimes called bosonic channels. Similar to finite-dimensional channels, bosonic channels admit a Choi–Jamiołkowski representation, usually referred to as *generalised* Choi–Jamiołkowski representation [10, 11]. Consider isomorphic Hilbert spaces $\mathcal{H}_A, \mathcal{H}_{A'}$ which are possibly infinite dimensional. Let $|\psi\rangle_{AA'}$ be a pure state satisfying $\mathrm{Tr}_{A'}\left[|\psi\rangle\langle\psi|_{AA'}\right] > 0$ (See [12, Lemma 26]). The generalised Choi state is constructed by applying the channel to the subsystem A' of $|\psi\rangle_{A'A}$ (see Lemma 49 in the Appendix): $\mathrm{id}_A \otimes \mathcal{N}_{A'\to B}(|\psi\rangle\langle\psi|_{AA'})$. The construction of the generalised Choi state usually utilises the two-mode squeezed vacuum state with squeezing parameter $r > 0$, defined as follows [9]:

$$|\psi(r)\rangle_{AA'} := \frac{1}{\cosh(r)} \sum_{n=0}^{\infty} \tanh^n(r) \, |n\rangle_A \, |n\rangle_{A'} \, . \tag{S7}$$

The equivalence between anti-degradability of a channel and two-extendibility of its Choi state extends to the infinite-dimensional channels [13]. We provide a detailed proof of this equivalence in Lemma 50 in the Appendix as it helps us in developing our intuition in inventing an explicit example of an anti-degrading map of the bosonic loss-dephasing channel.

C. Hadamard maps

Let $A = (a_{mn})_{m,n\in\mathbb{N}}$, $a_{mn} \in \mathbb{C}$, be an infinite matrix of complex numbers. Consider the superoperator H on $\mathcal{T}\left(L^2(\mathbb{R})\right)$, recognised as the *Hadamard map*, whose action on rank one operator $|m\rangle\langle n|$ is defined as follows:

$$H(|m\rangle\langle n|) = a_{mn} \, |m\rangle\langle n| \, , \quad \forall \, m, n \in \mathbb{N} \, .$$

In Section IV A in the Appendix, we provide an overview of relevant properties of Hadamard maps. In particular, by combining known results about Hadamard maps and matrix analysis, in Lemma 47 in the Appendix, we show that given an infinite matrix $A = (a_{mn})_{m,n\in\mathbb{N}}$, $a_{mn} \in \mathbb{C}$, the associated Hadamard map is a quantum channel if

- A is Hermitian
- $a_{nn} = 1, \forall n \in \mathbb{N}$
- A is diagonally dominant, i.e. $\sum_{\substack{m=0 \\ m\neq n}}^{\infty} |a_{mn}| \leq 1, \, \forall \, n \in \mathbb{N} \, .$

D. Beam splitter

A beam splitter serves as a linear optical tool employed for creating quantum entanglement between two modes, referred to as the *system* mode (denoted as S) and the *environment* mode (denoted as E). A depiction of a beam splitter is reported in Fig 1.

Definition 5. *Let $\mathcal{H}_S, \mathcal{H}_E := L^2(\mathbb{R})$. Let $\hat{a}$ and $\hat{e}$ denote the annihilation operator of $\mathcal{H}_S$ and $\mathcal{H}_E$, respectively. For all $\lambda \in [0,1]$, the beam splitter unitary of transmissivity λ is given by*

$$U_\lambda^{SE} := \exp\left[\arccos\sqrt{\lambda}\left(\hat{a}^\dagger\hat{e} - \hat{a}\,\hat{e}^\dagger\right)\right] . \tag{S8}$$

Lemma 6. *For all $\lambda \in [0,1]$, it holds that*

$$\begin{aligned}(U_\lambda^{SE})^\dagger \hat{a}\, U_\lambda^{SE} &= \sqrt{\lambda}\,\hat{a} + \sqrt{1-\lambda}\,\hat{e}\,,\\ U_\lambda^{SE}\hat{a}\,(U_\lambda^{SE})^\dagger &= \sqrt{\lambda}\,\hat{a} - \sqrt{1-\lambda}\,\hat{e}\,,\\ (U_\lambda^{SE})^\dagger \hat{e}\, U_\lambda^{SE} &= -\sqrt{1-\lambda}\,\hat{a} + \sqrt{\lambda}\,\hat{e}\,,\\ U_\lambda^{SE}\hat{e}\,(U_\lambda^{SE})^\dagger &= \sqrt{1-\lambda}\,\hat{a} + \sqrt{\lambda}\,\hat{e}\,.\end{aligned} \tag{S9}$$

Proof. These identities can be readily proved by applying the Baker-Campbell-Hausdorff formula. For an alternative proof see [14, Lemma A.2]. □

Lemma 7. *For all $\lambda \in [0,1]$ and all $n \in \mathbb{N}$, it holds that*

$$U_\lambda^{SE}\,|n\rangle_S \otimes |0\rangle_E = \sum_{l=0}^{n}(-1)^l\sqrt{\binom{n}{l}}\lambda^{\frac{n-l}{2}}(1-\lambda)^{\frac{l}{2}}\,|n-l\rangle_S \otimes |l\rangle_E\ , \tag{S10}$$

$$U_\lambda^{SE}\,|0\rangle_S \otimes |n\rangle_E = \sum_{l=0}^{n}\sqrt{\binom{n}{l}}(1-\lambda)^{\frac{l}{2}}\lambda^{\frac{n-l}{2}}\,|l\rangle_S \otimes |n-l\rangle_E\ . \tag{S11}$$

Proof. Thanks to Lemma (6), we have that $U_\lambda^{SE}\hat{a}\left(U_\lambda^{SE}\right)^\dagger = \sqrt{\lambda}\hat{a} - \sqrt{1-\lambda}\hat{e}$. Consequently, it holds that

$$\begin{aligned}U_\lambda^{SE}\,|n\rangle_S \otimes |0\rangle_E &= \frac{1}{\sqrt{n!}}U_\lambda^{SE}(a^\dagger)^n\,|0\rangle_S \otimes |0\rangle_E\\ &= \frac{1}{\sqrt{n!}}\left(U_\lambda^{SE}a^\dagger\left(U_\lambda^{SE}\right)^\dagger\right)^n |0\rangle_S \otimes |0\rangle_E\\ &= \frac{1}{\sqrt{n!}}\left(\sqrt{\lambda}a^\dagger - \sqrt{1-\lambda}b^\dagger\right)^n |0\rangle_S \otimes |0\rangle_E\\ &= \frac{1}{\sqrt{n!}}\sum_{l=0}^{n}(-1)^l\binom{n}{l}\lambda^{\frac{n-l}{2}}(1-\lambda)^{\frac{l}{2}}(a^\dagger)^{n-l}\,|0\rangle_S \otimes (b^\dagger)^l\,|0\rangle_E\\ &= \sum_{l=0}^{n}(-1)^l\sqrt{\binom{n}{l}}\lambda^{\frac{n-l}{2}}(1-\lambda)^{\frac{l}{2}}\,|n-l\rangle_S \otimes |l\rangle_E\ .\end{aligned} \tag{S12}$$

Analogously, one can show the validity of (S11) by exploiting $U_\lambda^{SE}\hat{e}\,(U_\lambda^{SE})^\dagger = \sqrt{1-\lambda}\,\hat{a} + \sqrt{\lambda}\,\hat{e}$. □

Remark 8. *It is easily seen that Eq.* (S10) *is equivalent to*

$$U_\lambda^{SE}\,|n\rangle_S \otimes |0\rangle_E = (-1)^n\sum_{l=0}^{n}(-1)^l\sqrt{\binom{n}{l}}\lambda^{\frac{l}{2}}(1-\lambda)^{\frac{n-l}{2}}\,|l\rangle_S \otimes |n-l\rangle_E\ .$$

E. Pure-loss channel

In optical platforms, the most common source of noise is photon loss, which is modelled by the *pure-loss channel* [9]. For any $\lambda \in [0,1]$, the pure-loss channel $\mathcal{E}_\lambda$ of transmissivity λ is a single-mode bosonic channel which acts on the input system by mixing it in a beam splitter of transmissivity λ with an environmental vacuum state; see Fig 1. In this model, the input signal is partially transmitted and partially reflected by the beam splitter, representing the loss of photons (or energy) in the channel. When $\lambda = 1$, the pure-loss channel is noiseless (it equals the identity superoperator). Conversely, when $\lambda = 0$, the pure-loss channel is completely noisy (specifically, it is a constant channel that maps any state in $|0\rangle\langle 0|$).

$\mathcal{E}^c_\lambda(\rho) = \mathcal{E}_{1-\lambda}\big((-1)^{\hat{a}^\dagger\hat{a}}\rho(-1)^{\hat{a}^\dagger\hat{a}}\big)$

FIG. 1. Stinespring representation of the pure-loss channel $\mathcal{E}_\lambda$. The pure-loss channel $\mathcal{E}_\lambda$ acts on the input state ρ by mixing it in a beam splitter of transmissivity λ (represented by the grey box) with an environmental vacuum state $|0\rangle$. Moreover, $\hat{a}$ and $\hat{e}$ are the annihilation operators of the input mode and the environmental mode, respectively. The complementary channel of the pure-loss channel is given by $\mathcal{E}^c_\lambda(\rho) = \mathcal{E}_{1-\lambda}\big((-1)^{\hat{a}^\dagger\hat{a}}\rho(-1)^{\hat{a}^\dagger\hat{a}}\big)$.

Definition 9. *Let $\mathcal{H}_S, \mathcal{H}_E := L^2(\mathbb{R})$. For all $\lambda \in [0,1]$, the pure-loss channel of transmissivity λ is a quantum channel $\mathcal{E}_\lambda : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_S)$ defined as follows:*

$$\mathcal{E}_\lambda(\rho) := \mathrm{Tr}_E\left[U^{SE}_\lambda(\rho_S \otimes |0\rangle\langle 0|_E)(U^{SE}_\lambda)^\dagger\right], \quad \forall\, \rho \in \mathcal{T}(\mathcal{H}_S),$$

where $|0\rangle\langle 0|_E$ denotes the vacuum state of $\mathcal{H}_E$ and U^{SE}_λ denotes the beam splitter unitary defined in (S8)*.*

Lemma 10. *For all $\lambda \in [0,1]$ and all $n, m \in \mathbb{N}$, it holds that*

$$\mathcal{E}_\lambda(|m\rangle\langle n|) = \sum_{\ell=0}^{\min(n,m)} \sqrt{\binom{m}{\ell}\binom{n}{\ell}}\,(1-\lambda)^\ell \lambda^{\frac{n+m}{2}-\ell}\,|m-\ell\rangle\langle n-\ell|\,.$$

Proof. This is a direct consequence of (S10) and of the definition of pure-loss channel. □

Lemma 11. *For all $\lambda \in [0,1]$, a complementary channel $\mathcal{E}^c_\lambda : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_E)$ of the pure-loss channel $\mathcal{E}_\lambda : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_S)$ is given by*

$$\mathcal{E}^c_\lambda(\rho) := \mathrm{Tr}_S\left[U^{SE}_\lambda(\rho_S \otimes |0\rangle\langle 0|_E)\left(U^{SE}_\lambda\right)^\dagger\right] = \mathcal{E}_{1-\lambda} \circ \mathcal{R}(\rho), \qquad \forall\, \rho \in \mathcal{T}(\mathcal{H}_S), \tag{S13}$$

where $\mathcal{R}(\cdot) := V \cdot V^\dagger$ with $V := (-1)^{\hat{a}^\dagger\hat{a}}$.

Proof. By linearity, it suffices to show the identity in (S13) for rank-one Fock operators of the form $|m\rangle\langle n|$ for any $n, m \in \mathbb{N}$, i.e.

$$\mathrm{Tr}_S\left[U^{SE}_\lambda(\,|m\rangle\langle n|_S \otimes |0\rangle\langle 0|_E\,)\left(U^{SE}_\lambda\right)^\dagger\right] = \mathcal{E}_{1-\lambda} \circ \mathcal{R}(|m\rangle\langle n|)\,. \tag{S14}$$

This follows directly from (S10). □

Proposition 12. *[15, 16] The pure-loss channel $\mathcal{E}_\lambda$ is degradable if and only if $\lambda \in [\frac{1}{2}, 1]$, and it is anti-degradable if and only if $\lambda \in [0, \frac{1}{2}]$.*

Lemma 13. *[14, Lemma A.7] For all $\lambda_1, \lambda_2 \in [0,1]$ it holds that $\mathcal{E}_{\lambda_1} \circ \mathcal{E}_{\lambda_2} = \mathcal{E}_{\lambda_1\lambda_2}$.*

F. Bosonic dephasing channel

Another main source of noise in optical platforms is bosonic dephasing, which serves as a prominent example of a non-Gaussian channel [17, 18].

Definition 14. *Let $\mathcal{H}_S := L^2(\mathbb{R})$ and let $\hat{a}$ be the corresponding annihilation operator. For all $\gamma \geq 0$, the bosonic dephasing channel $\mathcal{D}_\gamma : \mathcal{T}(\mathcal{H}_S) \longrightarrow \mathcal{T}(\mathcal{H}_S)$ is a quantum channel defined as follows:*

$$\mathcal{D}_\gamma(\rho) := \frac{1}{\sqrt{2\pi\gamma}} \int_{-\infty}^{\infty} \mathrm{d}\phi\, e^{-\frac{\phi^2}{2\gamma}}\, e^{i\phi \hat{a}^\dagger \hat{a}}\, \rho\, e^{-i\phi\hat{a}^\dagger\hat{a}}, \quad \forall\, \rho \in \mathcal{T}(\mathcal{H}_S)\,.$$

In other words, $\mathcal{D}_\gamma$ is a convex combination of phase space rotations $\rho \longmapsto e^{i\phi\hat{a}^\dagger\hat{a}}\, \rho\, e^{-i\phi\hat{a}^\dagger\hat{a}}$, where the random variable ϕ follows a centered Gaussian distribution with a variance of γ.

Lemma 15. *For all $\gamma \geq 0$ and all $n, m \in \mathbb{N}$, it holds that*

$$\mathcal{D}_\gamma(|m\rangle\!\langle n|) = e^{-\frac{1}{2}\gamma(n-m)^2}\, |m\rangle\!\langle n|\,.$$

Proof. This result follows from the Fourier transform of the Gaussian function:

$$\frac{1}{\sqrt{2\pi\gamma}} \int_{-\infty}^{\infty} \mathrm{d}\phi\, e^{-\frac{\phi^2}{2\gamma}} e^{i\phi k} = e^{-\frac{1}{2}\gamma k^2}, \quad \forall\, k \in \mathbb{R}\,. \tag{S15}$$

□

When $\gamma = 0$, the bosonic dephasing channel is noiseless. In contrast, when $\gamma \longrightarrow \infty$ it annihilates all off-diagonal components of the input density matrix, reducing it to an incoherent probabilistic mixture of Fock states. We now present a Stinespring dilation of the bosonic dephasing channel.

Lemma 16. *Let $\mathcal{H}_S = \mathcal{H}_E := L^2(\mathbb{R})$ and let $\hat{a}$ and $\hat{e}$ be annihilation operators on $\mathcal{H}_S$ and $\mathcal{H}_E$, respectively. For all $\gamma > 0$, the bosonic dephasing channel $\mathcal{D}_\gamma : \mathcal{T}(\mathcal{H}_S) \longrightarrow \mathcal{T}(\mathcal{H}_S)$ can be expressed in Stinespring representation as*

$$\mathcal{D}_\gamma(\rho) = \mathrm{Tr}_E\left[V_\gamma^{SE}(\rho_S \otimes |0\rangle\!\langle 0|_E)(V_\gamma^{SE})^\dagger\right], \qquad \forall\, \rho \in \mathcal{T}(\mathcal{H}_S)\,, \tag{S16}$$

where V_γ^{SE} denotes the conditional displacement unitary defined by

$$V_\gamma^{SE} := \exp\left[\sqrt{\gamma}\, \hat{a}^\dagger\hat{a} \otimes (\hat{e}^\dagger - \hat{e})\right] = \sum_{n=0}^{\infty} |n\rangle\!\langle n|_S \otimes D(\sqrt{\gamma}n). \tag{S17}$$

Proof. For any $n, m \in \mathbb{N}$ it holds that

$$\begin{aligned} &\mathrm{Tr}_E\left[V_\gamma^{SE}(\,|m\rangle\!\langle n|_S \otimes |0\rangle\!\langle 0|_E\,)(V_\gamma^{SE})^\dagger\right] \\ &\overset{\text{(i)}}{=} \mathrm{Tr}_E\left[|m\rangle\!\langle n|_S \otimes \left|\sqrt{\gamma}n\right\rangle\!\left\langle\sqrt{\gamma}m\right|_E\right] \\ &\overset{\text{(ii)}}{=} e^{-\frac{\gamma}{2}(n-m)^2}\, |m\rangle\!\langle n| \\ &\overset{\text{(iii)}}{=} \mathcal{D}_\gamma(|m\rangle\!\langle n|)\,. \end{aligned} \tag{S18}$$

Here, in (i) we used that $V_\gamma^{SE}\,|n\rangle_S \otimes |0\rangle_E = |n\rangle_S \otimes \left|\sqrt{\gamma}n\right\rangle_E$, where $\left|\sqrt{\gamma}n\right\rangle_E$ denotes the coherent state with parameter $\sqrt{\gamma}n$. In (ii), we exploited the formula for the overlap between coherent states provided in (S6), and in (iii) we used Lemma 15. The proof is completed by linearity. □

Remark 17. *A different approach to dilating the bosonic dephasing channel, as outlined in the existing literature [17, 19, 20], is as follows:*

$$\tilde{V}_\gamma^{SE} = \exp\left[-i\sqrt{\gamma}\, \hat{a}^\dagger\hat{a}\,(\hat{e}^\dagger + \hat{e})\right].$$

This unitary transformation is achieved by rotating the environmental mode of the unitary operator V_γ^{SE} in (S17) *by $\frac{\pi}{2}$, that is $\tilde{V}_\gamma^{SE} = e^{i\frac{\pi}{2}\hat{e}^\dagger\hat{e}} V_\gamma^{SE} e^{-i\frac{\pi}{2}\hat{e}^\dagger\hat{e}}$. These dilations yield the same dephasing channel, as all dilations are equivalent up to unitary transformations.*

Proposition 18 [21]**.** *The bosonic dephasing channel $\mathcal{D}_\gamma$ is degradable for all $\gamma \geq 0$.*

Proposition 19 [21]**.** *The bosonic dephasing channel $\mathcal{D}_\gamma$ is never anti-degradable.*

Lemma 20. *For all $\gamma_1, \gamma_2 \geq 0$, the composition of bosonic dephasing channels is given by $\mathcal{D}_{\gamma_1} \circ \mathcal{D}_{\gamma_2} = \mathcal{D}_{\gamma_1+\gamma_2}$.*

Proof. This can be shown by leveraging Lemma 15. □

G. Bosonic loss-dephasing channel

Consider an optical system undergoing simultaneous loss and dephasing over a finite time interval. At each instant, the system is susceptible to both an infinitesimal pure-loss channel and an infinitesimal bosonic dephasing channel. Hence, the overall channel describing the simultaneous effect of loss and dephasing results in a suitable composition of numerous concatenations between infinitesimal pure-loss and bosonic dephasing channels. However, given that:

- The pure-loss channel and the bosonic dephasing channel commute, i.e. $\mathcal{E}_\lambda \circ \mathcal{D}_\gamma = \mathcal{D}_\gamma \circ \mathcal{E}_\lambda$, as implied by Lemma 10 and Lemma 15;
- The composition of pure-loss channels is a pure-loss channel, $\mathcal{E}_{\lambda_1} \circ \mathcal{E}_{\lambda_2} = \mathcal{E}_{\lambda_1 \lambda_2}$ (Lemma 13);
- The composition of bosonic dephasing channels is a bosonic dephasing channel, $\mathcal{D}_{\gamma_1} \circ \mathcal{D}_{\gamma_2} = \mathcal{D}_{\gamma_1+\gamma_2}$ (Lemma 20);

it follows that the combined effect of loss and dephasing can be modelled by the composition between pure-loss channel and bosonic dephasing channel,

$$\mathcal{N}_{\lambda,\gamma} := \mathcal{E}_\lambda \circ \mathcal{D}_\gamma \,, \tag{S19}$$

dubbed the *bosonic loss-dephasing channel*.

Definition 21. *For all $\gamma \geq 0$ and $\lambda \in [0,1]$, the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is a quantum channel defined by the composition between pure-loss channel and bosonic dephasing channel: $\mathcal{N}_{\lambda,\gamma} := \mathcal{D}_\gamma \circ \mathcal{E}_\lambda$.*

Lemma 22. *For all $\lambda \in [0,1]$ and $\gamma \geq 0$, it holds that $\mathcal{N}_{\lambda,\gamma} := \mathcal{D}_\gamma \circ \mathcal{E}_\lambda = \mathcal{E}_\lambda \circ \mathcal{D}_\gamma$. Moreover, for all $n, m \in \mathbb{N}$ it holds that*

$$\begin{aligned}\mathcal{N}_{\lambda,\gamma}(|m\rangle\!\langle n|) &= e^{-\frac{1}{2}\gamma(n-m)^2}\mathcal{E}_\lambda(|m\rangle\!\langle n|)\\ &= e^{-\frac{1}{2}\gamma(n-m)^2}\sum_{\ell=0}^{\min(n,m)}\sqrt{\binom{n}{\ell}\binom{m}{\ell}}(1-\lambda)^\ell\lambda^{\frac{n+m}{2}-\ell}\,|m-\ell\rangle\!\langle n-\ell| \,.\end{aligned}$$

Proof. It follows from Lemma 10 and Lemma 15. □

Lemma 23. *Let $\mathcal{H}_S, \mathcal{H}_{E_1}, \mathcal{H}_{E_2} := L^2(\mathbb{R})$. For all $\lambda \in [0,1]$ and all $\gamma \geq 0$, the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma} : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_S)$ admits the following Stinespring representation:*

$$\mathcal{N}_{\lambda,\gamma}(\rho) = \mathrm{Tr}_{E_1E_2}\left[U_\lambda^{SE_1}V_\gamma^{SE_2}(\rho_S\otimes|0\rangle\!\langle 0|_{E_1}\otimes|0\rangle\!\langle 0|_{E_2})\left(U_\lambda^{SE_1}V_\gamma^{SE_2}\right)^\dagger\right], \qquad \forall\,\rho\in\mathcal{T}(\mathcal{H}_S),$$

The associated complementary channel $\mathcal{N}^c_{\lambda,\gamma} : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_{E_1}\otimes\mathcal{H}_{E_2})$ is defined as follows:

$$\mathcal{N}^c_{\lambda,\gamma}(\rho) := \mathrm{Tr}_S\left[U_\lambda^{SE_1}V_\gamma^{SE_2}(\rho_S\otimes|0\rangle\!\langle 0|_{E_1}\otimes|0\rangle\!\langle 0|_{E_2})\left(U_\lambda^{SE_1}V_\gamma^{SE_2}\right)^\dagger\right], \qquad \forall\,\rho\in\mathcal{T}(\mathcal{H}_S).$$

In particular,

$$\mathcal{N}^c_{\lambda,\gamma}(|m\rangle\!\langle n|) = (-1)^{m-n}\mathcal{E}_{1-\lambda}\left(|m\rangle\!\langle n|_{E_1}\right)\otimes\left|\sqrt{\gamma}m\right\rangle\!\left\langle\sqrt{\gamma}n\right|_{E_2}, \qquad \forall\, m,n\in\mathbb{N}\,, \tag{S20}$$

where $\left|\sqrt{\gamma}n\right\rangle_{E_2}$ denotes the coherent state with parameter $\sqrt{\gamma}n$.

Proof. The Eq. (S20) is derived by first applying (S13) and subsequently utilising the dilation of the bosonic dephasing channel. Finally, the non-environment mode of the bosonic dephasing channel is traced out. □

Lemma 24. *Consider the Hilbert spaces $\mathcal{H}_S$, $\mathcal{H}_{E_1}$, and $\mathcal{H}_{E_2}$, all isomorphic to $L^2(\mathbb{R})$. Let $\lambda \in [0,1]$ and $\gamma \geq 0$. The bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma} : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_S)$ exhibits anti-degradability if and only if there exists a quantum channel $\mathcal{A}_{\lambda,\gamma} : \mathcal{T}(\mathcal{H}_{E_{out}}) \to \mathcal{T}(\mathcal{H}_S)$ satisfying the following condition:*

$$\mathcal{A}_{\lambda,\gamma}\circ\mathcal{N}^c_{\lambda,\gamma}(|m\rangle\!\langle n|) = \mathcal{N}_{\lambda,\gamma}(|m\rangle\!\langle n|), \quad \forall\, m,n\in\mathbb{N}\,, \tag{S21}$$

where $\mathcal{N}^c_{\lambda,\gamma} : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_{E_{out}})$ denotes the complementary channel reported in (S20)*, and $\mathcal{H}_{E_{out}} \subset \mathcal{H}_{E_1}\otimes\mathcal{H}_{E_2}$ is defined in* (S42)*. Moreover, the condition in* (S21) *is equivalent to*

$$\mathcal{A}_{\lambda,\gamma}\left(\mathcal{E}_{1-\lambda}\left(|m\rangle\!\langle n|\right)\otimes\left|\sqrt{\gamma}m\right\rangle\!\left\langle\sqrt{\gamma}n\right|\right) = (-1)^{m-n}e^{-\frac{\gamma}{2}(m-n)^2}\mathcal{E}_\lambda(|m\rangle\!\langle n|), \quad \forall\, m,n\in\mathbb{N}\,, \tag{S22}$$

where $\left|\sqrt{\gamma}n\right\rangle$ denotes the coherent state with parameter $\sqrt{\gamma}n$.

Proof. $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable if and only if there exists a quantum channel $\mathcal{A}_{\lambda,\gamma} : \mathcal{T}(\mathcal{H}_{E_{\text{out}}}) \to \mathcal{T}(\mathcal{H}_S)$ such that

$$\mathcal{A}_{\lambda,\gamma} \circ \mathcal{N}^{\text{c}}_{\lambda,\gamma}(\rho) = \mathcal{N}_{\lambda,\gamma}(\rho), \qquad \forall\, \rho \in \mathcal{T}(\mathcal{H}_S)\,. \tag{S23}$$

By linearity, it suffices to show the condition in (S21), i.e. which corresponds to the condition in (S23) restricted to rank-one Fock operators of the form $\rho = |m\rangle\!\langle n|$ with $m, n \in \mathbb{N}$. Moreover, by exploiting Lemma 22 and S20, the condition in (S21) is equivalent to (S22). □

Lemma 25. *For all $\gamma_1, \gamma_2 \geq 0$ and all λ_1, λ_2 it holds that $\mathcal{N}_{\lambda_1,\gamma_1} \circ \mathcal{N}_{\lambda_2,\gamma_2} = \mathcal{N}_{\lambda_1\lambda_2\,,\,\gamma_1+\gamma_2}$.*

Proof. This can be shown by exploiting Lemma 13 and Lemma 20. □

H. Preliminaries on capacities of quantum channels

Quantum channels can be suitably exploited in order to transfer information from their input port to a possibly distant output port, a crucial task in quantum information theory [1, 3]. In particular, quantum Shannon theory [2, 4] primarily helps us understand the fundamental limits of quantum communication using a quantum channel $\mathcal{N}$. These limits are called *capacities* and tell us the ultimate amount of information we can send through the channel when we use it many times [2, 4]. Different capacities are defined based on the type of information that is being sent down the channel. For example, classical and quantum capacities of a quantum channel correspond to its ultimate capability of transmission of classical and quantum information, respectively. A channel can also be used to generate secret bits and the relevant capacity in this context is the so-called secret-key capacity. Each of the above-mentioned capacities might be endowed with other resources such as initial shared entanglement between the sender and the receiver or (possibly interactive) classical communication over a noiseless but public channel. This latter scenario gives rise to the notion of two-way capacities.

Specifically, the *quantum capacity* $Q(\mathcal{N})$ of a quantum channel $\mathcal{N}$ is the maximum rate at which qubits can be reliably transmitted through $\mathcal{N}$ [4]. We can further assume that both the sender, Alice, and the receiver, Bob, have free access to a public, noiseless two-way classical channel. In this two-way communication setting, the relevant notion of capacities are the *two-way quantum capacity* $Q_2(\mathcal{N})$ and the *secret-key capacity* $K(\mathcal{N})$ [2, 4], defined as the maximum achievable rate of qubits and secret-key bits, respectively, that can be reliably transmitted across $\mathcal{N}$ with the aid of two-way classical communication. Since an ebit (i.e. a maximally entangled state of Schmidt rank 2) can always be used to generate one bit of secret key [22], a trivial bound relates these capacities: $Q_2(\mathcal{N}) \leq K(\mathcal{N})$.

In practical scenarios, it is important to consider that the input state prepared by Alice can not have unlimited energy and it adheres to specific energy constraints. In bosonic systems, it is common to limit the average photon number of any input state ρ as $\mathrm{Tr}\left[\hat{a}^\dagger\hat{a}\rho\right] \leq N_s$, where $N_s > 0$ is a given energy constraint. For any $N_s > 0$, the energy-constrained (EC) two-way capacities for transmitting qubits and secret-key bits, denoted as $Q_2(\mathcal{N}, N_s)$ and $K(\mathcal{N}, N_s)$ respectively, are defined similarly to the unconstrained capacities with the difference that now the optimisation is performed over those strategies that exploit input states that adhere to the specified energy constraint. As in the unconstrained scenario, the relation between EC two-way capacities continue to hold, i.e. $Q_2(\mathcal{N}, N_s) \leq K(\mathcal{N}, N_s)$. Moreover, the unconstrained capacities are upper bounds for the corresponding energy constrained capacities and they become equal in the limit $N_s \to \infty$.

Two-way capacities of a quantum channel are closely related to another important information-processing task, namely, entanglement distillation over a quantum channel. Suppose Alice generates n copies of a state $\rho_{A'A}$ and sends the A' subsystems to Bob using the channel $\mathcal{N}$ for n times. Now, Alice and Bob share n copies of the state $\rho'_{AB} := \mathrm{id}_A \otimes \mathcal{N}_{A'\to B}(\rho_{AA'})$. The task of an entanglement distillation protocol concerns identifying the largest number m of ebits that can be extracted using n copies of ρ'_{AB} via LOCC (Local Operations and Classical Communication) operations. The rate of an entanglement distillation protocol is defined by the ratio m/n. The distillable entanglement $E_d(\rho'_{AB})$ of ρ'_{AB} is defined as the maximum rate over all the possible entanglement distillation protocols [23] [4, Chapter 8]. Note that without extra classical communication, entanglement distillation is not possible [24]. The following lemma establishes a link between the two-way quantum capacity, secret-key capacity, and distillable entanglement.

Lemma 26. *Let $\mathcal{H}_A, \mathcal{H}_{A'}, \mathcal{H}_B := L^2(\mathbb{R})$. Let $\mathcal{N} : \mathcal{H}_{A'} \to \mathcal{H}_B$ be a quantum channel. Let $N_s > 0$ be the energy constaint, and let $\rho_{A'A} \in \mathcal{P}(\mathcal{H}_A \otimes \mathcal{H}_{A'})$ be a two-mode state satisfying the energy constraint $\mathrm{Tr}\left[(\hat{a}^\dagger\hat{a} \otimes \mathrm{id}_A)\rho_{A'A}\right] \leq N_s$, where $\hat{a}$ denotes the annihilation operator on $\mathcal{H}_{A'}$. Then, it holds that*

$$K(\mathcal{N}, N_s) \geq Q_2(\mathcal{N}, N_s) \geq E_d(\mathrm{id}_A \otimes \mathcal{N}(\rho_{AA'}))\ , \tag{S24}$$

where $K(\mathcal{N}, N_s)$ denotes the energy-constrained secret-key capacity of $\mathcal{N}$, $Q_2(\mathcal{N}, N_s)$ denotes the energy-constrained two-way quantum capacity of $\mathcal{N}$, and $E_d(\mathrm{id}_A \otimes \mathcal{N}(\rho_{AA'}))$ denotes the distillable entanglement of the state $\mathrm{id}_A \otimes \mathcal{N}(\rho_{AA'})$.

The proof idea of the above lemma is the following. Suppose that Alice produces n copies of a state $\rho_{AA'}$ such that the energy constraint is satisfied. Then, she can use the channel n times to send all subsystems A' to Bob. Then, Alice and Bob share n copies of $\mathrm{id}_A \otimes \mathcal{N}(\rho_{AA'})$, which can now be used to generate $\approx n\, E_d(\mathrm{id}_A \otimes \mathcal{N}(\rho_{AA'}))$ ebits by means of a suitable entanglement distillation protocol. The ebit rate of this protocol is thus $E_d(\mathrm{id}_A \otimes \mathcal{N}(\rho_{AA'}))$, which provides a lower bound on $Q_2(\mathcal{N}, N_s)$ thanks to quantum teleportation [25]. In addition, it holds that $K(\mathcal{N}, N_s) \geq Q_2(\mathcal{N}, N_s)$ because an ebit can generate a secret-key bit [22]. Consequently, (S24) holds.

II. ANTI-DEGRADABILITY AND DEGRADABILITY OF BOSONIC LOSS-DEPHASING CHANNEL

This section is split into two parts based on the observation that if the input state to the bosonic loss-dephasing channel is chosen from a finite-dimensional subspace, the bosonic loss-dephasing channel effectively becomes a finite-dimensional channel, a fact we show in Lemma 33. This property allows us to apply established insights about the finite-dimensional channels to the bosonic loss-dephasing channel. In subsection II A, we present our study of the bosonic loss-dephasing channel when the input resides in the entire infinite-dimensional space, while subsection II B is dedicated to the findings resulting from analysis of finite-dimensional restrictions of the bosonic loss-dephasing channel.

A. Sufficient condition on anti-degradability

It is known that the bosonic dephasing channel $\mathcal{D}_\gamma$ is degradable across all dephasing parameter range $\gamma \geq 0$ and also it is never anti-degradable [17]. The pure-loss channel $\mathcal{E}_\lambda$ displays the peculiar characteristic of being anti-degradable for transmissivity values within the range $\lambda \in [0, \frac{1}{2}]$ and degradable for $\lambda \in [\frac{1}{2}, 1]$ [15, 16]. It turns out that when an anti-degradable channel is concatenated with another channel, the resulting channel inherits the property of being anti-degradable (see Lemma 51). This implies the following: if $\lambda \in [0, \frac{1}{2}]$ and $\gamma \geq 0$, then the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable [21]. The authors of [21] left as an open question to understand whether or not the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable in the region $\lambda \in (\frac{1}{2}, 1]$. In particular, they conjecture that $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable for all transmissivity values $\lambda \in (\frac{1}{2}, 1]$ and for all $\gamma \geq 0$. In the following theorem, we refute this conjecture by explicitly finding values of $\lambda \in (\frac{1}{2}, 1]$ and $\gamma \geq 0$ where the channel is anti-degradable. Our approach also yields an explicit expression for an anti-degrading map of the bosonic loss-dephasing channel.

Theorem 27. *Each of the following is a sufficient condition for the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ to exhibit anti-degradability:*

(i) $\lambda \in [0, \frac{1}{2}]$ and $\gamma \geq 0$.

(ii) $\lambda \in (\frac{1}{2}, 1)$ and $\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \leq \frac{3}{2}$, where θ is defined as $\theta(x, y) := \sum_{n=0}^{\infty} x^{n^2} y^n$, $\forall\, x, y \in [0, 1)$.

In particular, $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable if $\lambda \leq \max\left(\frac{1}{2}, \frac{1}{1+9e^{-\gamma}}\right)$.

Proof. The proof of the sufficient condition (i) follows directly from the observation that the composition of a pure-loss channel with transmissivity $\lambda \in [0, \frac{1}{2}]$ with any other channel inherits the anti-degradability from the pure-loss channel (see Lemma 51).

The proof of the sufficient condition (ii) is more involved, and it is the main technical contribution of our work. We rely on the equivalence between anti-degradability of a quantum channel and the two-extendibility of its Choi state [6, 13]. To provide a comprehensive and intuitive understanding of this idea and to aid in the construction of an anti-degrading map of the bosonic loss-dephasing channel, we present this equivalence in Lemma 50 within the Appendix.

Assume $\lambda \in (\frac{1}{2}, 1)$ and $\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \leq \frac{3}{2}$. Let $\mathcal{H}_A, \mathcal{H}_B, \mathcal{H}_{B_1}, \mathcal{H}_{B_2} = L^2(\mathbb{R})$ and suppose that the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is a quantum channel from the system A' to B. We want to show that the generalised Choi state of $\mathcal{N}_{\lambda,\gamma}$ is two-extendible on B. In other words, we want to show that there exists a tripartite state $\rho_{AB_1B_2}$ such that

$$\begin{aligned} \mathrm{Tr}_{B_2}\left[\rho_{AB_1B_2}\right] &= \tau_{AB_1}\,, \\ \mathrm{Tr}_{B_1}\left[\rho_{AB_1B_2}\right] &= \tau_{AB_2}\,, \end{aligned} \tag{S25}$$

where $\tau_{AB} := \mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}(|\psi(r)\rangle\langle\psi(r)|_{AA'})$ is the generalised Choi state of $\mathcal{N}_{\lambda,\gamma}$, and $|\psi(r)\rangle_{AA'}$ is the two-mode squeezed vacuum state with squeezing parameter $r > 0$ defined in (S7). By Lemma (22), the generalised Choi state of the bosonic loss-dephasing channel can be expressed as follows:

$$\tau_{AB} = \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell=0}^{\min(m,n)} (\tanh(r))^{m+n} e^{-\frac{\gamma}{2}(m-n)^2} \sqrt{\mathcal{B}_\ell(m,1-\lambda)\,\mathcal{B}_\ell(n,1-\lambda)}\, |m\rangle\langle n|_A \otimes |m-\ell\rangle\langle n-\ell|_B \;, \tag{S26}$$

where $\mathcal{B}_\ell(n,\lambda) := \binom{n}{\ell}\lambda^\ell(1-\lambda)^{n-\ell}$. We observe that τ_{AB} is a linear combination of $|m\rangle\langle n|\otimes|j_1\rangle\langle j_2|$, where $m,n,j_1,j_2 \in \mathbb{N}$, $j_1 \le n_1$, $j_2 \le n$, and $m-n = j_1 - j_2$. This insight leads to the following educated guess about the structure of a potential two-extension:

$$\tilde{\rho}_{AB_1B_2} = \sum_{m,n=0}^{\infty} \sum_{\ell_1=0}^{m} \sum_{\ell_2=0}^{n} \sum_{k=0}^{\min(m-\ell_1,n-\ell_2)} c(m,n,\ell_1,\ell_2,k)\, |m\rangle\langle n|_A \otimes |m-\ell_1\rangle\langle n-\ell_2|_{B_1} \otimes |\ell_1+k\rangle\langle \ell_2+k|_{B_2} \;, \tag{S27}$$

where $\{c(m,n,\ell_1,\ell_2,k)\}_{m,n,\ell_1,\ell_2,k}$ are some suitable coefficients. The soundness of this guess is confirmed by the fact that both $\mathrm{Tr}_{B_2}[\tilde{\rho}_{AB_1B_2}]$ and $\mathrm{Tr}_{B_1}[\tilde{\rho}_{AB_1B_2}]$ are linear combinations of $|m\rangle\langle n|\otimes|j_1\rangle\langle j_2|$ with $m,n,j_1,j_2 \in \mathbb{N}$, $j_1 \le m$, $j_2 \le n$, and $m-n = j_1 - j_2$, similar to the generalised Choi state τ_{AB} in (S26).

At this point, one could try to define the coefficients $\{c(m,n,\ell_1,\ell_2,k)\}_{m,n,\ell_1,\ell_2,k}$ so as to satisfy the required conditions of the extendibility. However, the resulting tripartite operator may not qualify as a quantum state. In order to ensure that we obtain a quantum state, our approach consists in producing the operator $\tilde{\rho}_{AB_1B_2}$ via a physical process that consists in applying a sequence of quantum channels to a quantum state.

We begin by constructing a quantum state that has the same operator structure as the operator $\tilde{\rho}_{AB_1B_2}$ in (S27). This means that at this initial stage, we only aim to build a tripartite state consisting of a linear combination of operators $|m\rangle\langle n|_A \otimes |m-\ell_1\rangle\langle n-\ell_2|_{B_1} \otimes |\ell_1+k\rangle\langle\ell_2+k|_{B_2}$ with the summation limits identical to those in (S27). This ensures that the coefficients equal to zero coincide in the two operators.

We now illustrate on each step of this construction. For a fixed $n \in \mathbb{N}$, consider the state $|n\rangle_A \otimes |n\rangle_{B_1}$. We introduce two auxiliary single-mode systems B_2 and C initially in vacuum states: $|n\rangle_A \otimes |n\rangle_{B_1} \otimes |0\rangle_{B_2} \otimes |0\rangle_C$. We next send the systems B_2 and B_1 through the ports of a beam splitter, resulting in a superposition of $|n\rangle_A \otimes |n-\ell\rangle_{B_1} \otimes |\ell\rangle_{B_2} \otimes |0\rangle_C$ for $\ell = 0,1,\ldots,n$, as implied by Lemma (7). We repeat this for systems B_1 and C, thus obtaining a superposition of $|n\rangle_A \otimes |n-\ell-k\rangle_{B_1} \otimes |\ell\rangle_{B_2} \otimes |k\rangle_C$, with $k = 0,1,\ldots,n-\ell$ and $\ell = 0,1,\ldots,n$. Consider now the isometry $W^{CB_1B_2}$ defined by

$$W^{CB_1B_2}\, |n\rangle_{B_1} \otimes |m\rangle_{B_2} \otimes |k\rangle_C = |n+k\rangle_{B_1} \otimes |m+k\rangle_{B_2} \otimes |k\rangle_C \,, \quad \forall\, n,m,k \in \mathbb{N}\,, \tag{S28}$$

dubbed *controlled-add-add isometry* (mode C is the control mode). By applying this isometry to the superposition we created by using beam splitters, we obtain a superposition of $|n\rangle_A \otimes |n-\ell\rangle_{B_1} \otimes |\ell+k\rangle_{B_2} \otimes |k\rangle_C$ with $k = 0,1,\ldots,n-\ell$ and $\ell = 0,1,\ldots,n$. Finally, by tracing out system C, we obtain the same operator structure of the operator $\tilde{\rho}_{AB_1B_2}$ in (S27). Having focused on the operator structure, we have not considered the transmissivities of the two beam splitters so far. We will see that these transmissivities can be chosen carefully such that the diagonal elements of the operator at hand becomes equal to those of the Choi state.

We now apply the outlined construction to the two-mode squeezed vacuum state with two vacuum states appended to it, i.e. $|\psi(r)\rangle_{AB_1} \otimes |0\rangle_{B_2} \otimes |0\rangle_C$. For reasons that will become clear in a moment, we choose the two beam splitter transmissivities to be λ (for the beam splitter acting on B_2B_1) and $\frac{1-\lambda}{\lambda}$ (for the one acting on CB_1). By doing so we obtain the state

$$\begin{aligned} \left|\phi\right\rangle_{AB_1B_2C} &:= W^{C,B_1B_2} U^{CB_1}_{\frac{1-\lambda}{\lambda}} U^{B_2B_1}_{\lambda}\, |\psi(r)\rangle_{AB_1} \otimes |0\rangle_{B_2} \otimes |0\rangle_C \\ &= \frac{1}{\cosh(r)} \sum_{n=0}^{\infty} \sum_{\ell=0}^{n} \sum_{k=0}^{n-\ell} \tanh^n(r) \sqrt{\mathcal{B}_\ell(n,1-\lambda)\, \mathcal{B}_k\!\left(n-\ell, \frac{2\lambda-1}{\lambda}\right)}\, |n\rangle_A \otimes |n-\ell\rangle_{B_1} \otimes |\ell+k\rangle_{B_2} \otimes |k\rangle_C \;, \end{aligned} \tag{S29}$$

where we used (S7) and Lemma 7. Note that the transmissivities of the beam splitters $U^{CB_1}_{\frac{1-\lambda}{\lambda}}$ and $U^{B_2B_1}_{\lambda}$ are chosen such that the diagonal elements of $\mathrm{Tr}_{B_2C}\left[\,|\phi\rangle\langle\phi|_{AB_1B_2C}\,\right]$ and $\mathrm{Tr}_{B_1C}\left[\,|\phi\rangle\langle\phi|_{AB_1B_2C}\,\right]$ both coincide with those of the

Choi state τ_{AB} in (S26). To verify this, let us calculate the state $\mathrm{Tr}_C\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right]$:

$$\mathrm{Tr}_C\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right] = \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell_1=0}^{m} \sum_{\ell_2=0}^{n} \sum_{k=0}^{\min(m-\ell_1,n-\ell_2)} (\tanh(r))^{m+n} \sqrt{\mathcal{B}_{\ell_1}(m,1-\lambda)\,\mathcal{B}_{\ell_2}(n,1-\lambda)}$$
$$\left[\sqrt{\mathcal{B}_k\!\left(m-\ell_1,\frac{2\lambda-1}{\lambda}\right)\,\mathcal{B}_k\!\left(n-\ell_2,\frac{2\lambda-1}{\lambda}\right)}\right] |m\rangle\!\langle n|_A \otimes |m-\ell_1\rangle\!\langle n-\ell_2|_{B_1} \otimes |\ell_1+k\rangle\!\langle \ell_2+k|_{B_2}\,.$$

Notably, the structure of the state $\mathrm{Tr}_C\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right]$ mirrors that of (S27) with specific coefficients $c(m,n,\ell_1,\ell_2,k)$. Moreover, it holds that

$$\mathrm{Tr}_{B_2C}\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right] = \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell=0}^{\min(m,n)} (\tanh(r))^{m+n} \sqrt{\mathcal{B}_{\ell}(m,1-\lambda)\,\mathcal{B}_{\ell}(n,1-\lambda)}$$
$$\left[\sum_{k=0}^{\min(m-\ell,n-\ell)} \sqrt{\mathcal{B}_k\!\left(m-\ell,\frac{2\lambda-1}{\lambda}\right)\,\mathcal{B}_k\!\left(n-\ell,\frac{2\lambda-1}{\lambda}\right)}\right] |m\rangle\!\langle n|_A \otimes |m-\ell\rangle\!\langle n-\ell|_{B_1} \tag{S30}$$

and that

$$\mathrm{Tr}_{B_1C}\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right] = \mathrm{Tr}_{B_2C}\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right]. \tag{S31}$$

In order to prove (S31), observe that

$$\begin{aligned}
\mathrm{Tr}_{B_1C}\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right] &= \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell_1=\max(m-n,0)}^{m} \sum_{k=0}^{m-\ell_1} (\tanh(r))^{m+n} \sqrt{\mathcal{B}_{\ell_1}(m,1-\lambda)\,\mathcal{B}_{n-m+\ell_1}(n,1-\lambda)} \\
&\qquad \mathcal{B}_k\!\left(m-\ell_1,\frac{2\lambda-1}{\lambda}\right) |m\rangle\!\langle n|_A \otimes |\ell_1+k\rangle\!\langle n-m+\ell_1+k|_{B_2} \\
&= \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell_1=\max(m-n,0)}^{m} \sum_{\ell=0}^{m-\ell_1} (\tanh(r))^{m+n} \sqrt{\mathcal{B}_{\ell_1}(m,1-\lambda)\,\mathcal{B}_{n-m+\ell_1}(n,1-\lambda)} \\
&\qquad \mathcal{B}_{m-\ell_1-\ell}\!\left(m-\ell_1,\frac{2\lambda-1}{\lambda}\right) |m\rangle\!\langle n|_A \otimes |m-\ell\rangle\!\langle n-\ell|_{B_2} \\
&= \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell=0}^{\min(m,n)} (\tanh(r))^{m+n} \sum_{\ell_1=\max(m-n,0)}^{m-\ell} \sqrt{\mathcal{B}_{\ell_1}(m,1-\lambda)\,\mathcal{B}_{n-m+\ell_1}(n,1-\lambda)} \\
&\qquad \mathcal{B}_{m-\ell_1-\ell}\!\left(m-\ell_1,\frac{2\lambda-1}{\lambda}\right) |m\rangle\!\langle n|_A \otimes |m-\ell\rangle\!\langle n-\ell| \\
&= \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell=0}^{\min(m,n)} (\tanh(r))^{m+n} \sum_{k=0}^{\min(n-\ell,m-\ell)} \sqrt{\mathcal{B}_{m-\ell-k}(m,1-\lambda)\,\mathcal{B}_{n-\ell-k}(n,1-\lambda)} \\
&\qquad \mathcal{B}_k\!\left(k+\ell,\frac{2\lambda-1}{\lambda}\right) |m\rangle\!\langle n|_A \otimes |m-\ell\rangle\!\langle n-\ell| \\
&\overset{\text{(i)}}{=} \frac{1}{\cosh^2(r)} \sum_{m,n=0}^{\infty} \sum_{\ell=0}^{\min(m,n)} (\tanh(r))^{m+n} \sqrt{\mathcal{B}_{\ell}(m,1-\lambda)\,\mathcal{B}_{\ell}(n,1-\lambda)} \\
&\qquad \left[\sum_{k=0}^{\min(m-\ell,n-\ell)} \sqrt{\mathcal{B}_k\!\left(m-\ell,\frac{2\lambda-1}{\lambda}\right)\,\mathcal{B}_k\!\left(n-\ell,\frac{2\lambda-1}{\lambda}\right)}\right] |m\rangle\!\langle n|_A \otimes |m-\ell\rangle\!\langle n-\ell|_{B_2} \\
&\overset{\text{(ii)}}{=} \mathrm{Tr}_{B_2C}\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right]
\end{aligned} \tag{S32}$$

Here, in (i), we used the identity

$$\begin{aligned}&\sqrt{\mathcal{B}_{m-\ell-k}(m,1-\lambda)\,\mathcal{B}_{n-\ell-k}(n,1-\lambda)}\mathcal{B}_k\left(k+\ell,\frac{2\lambda-1}{\lambda}\right)\\&\quad=\sqrt{\mathcal{B}_\ell(m,1-\lambda)\,\mathcal{B}_\ell(n,1-\lambda)}\sqrt{\mathcal{B}_k\left(m-\ell,\frac{2\lambda-1}{\lambda}\right)\,\mathcal{B}_k\left(n-\ell,\frac{2\lambda-1}{\lambda}\right)}\,,\end{aligned}\tag{S33}$$

which can be easily proved by substituting the definition $\mathcal{B}_\ell(n,\lambda) := \binom{n}{\ell}\lambda^\ell(1-\lambda)^{n-\ell}$ and by leveraging the binomial identity

$$\binom{n}{l+k}\binom{l+k}{k}=\binom{n}{l}\binom{n-l}{k}.\tag{S34}$$

Moreover, in (ii), we exploited (S30).

Note that the off-diagonal terms of the state in (S30) are not equal to those of the Choi state τ_{AB} in (S26). Specifically, the points of difference with the Choi state τ_{AB} are the presence of the term inside the square brackets and the absence of the dephasing exponent. To address these additional terms, let us use the toolbox of *Hadamard maps*. Let H be the Hadamard map, introduced in Sec. I C, associated with the infinite matrix $A := (a_{mn})_{m,n\in\mathbb{N}}$ defined as follows:

$$a_{mn} := \frac{e^{-\frac{\gamma}{2}(n-m)^2}}{\sum_{j=0}^{\min(n,m)}\sqrt{\mathcal{B}_j\left(n,\frac{2\lambda-1}{\lambda}\right)\,\mathcal{B}_j\left(m,\frac{2\lambda-1}{\lambda}\right)}}\,,\qquad\forall\, n,m\in\mathbb{N}\,.\tag{S35}$$

By construction, we have that

$$\begin{aligned}&\mathrm{id}_A\otimes H_{B_1}\left(\mathrm{Tr}_{B_2C}\left[\,|\phi\rangle\!\langle\phi|_{AB_1B_2C}\,\right]\right)\\&=\frac{1}{\cosh^2(r)}\sum_{m,n=0}^{\infty}\sum_{\ell=0}^{\min(m,n)}(\tanh(r))^{m+n}\sqrt{\mathcal{B}_\ell(m,1-\lambda)\,\mathcal{B}_\ell(n,1-\lambda)}\\&\quad\left[\sum_{k=0}^{\min(m-\ell,n-\ell)}\sqrt{\mathcal{B}_k\left(m-\ell,\frac{2\lambda-1}{\lambda}\right)\,\mathcal{B}_k\left(n-\ell,\frac{2\lambda-1}{\lambda}\right)}\right]a_{m-\ell,n-\ell}\ |m\rangle\!\langle n|_A\otimes|m-\ell\rangle\!\langle n-\ell|_{B_1}\\&=\frac{1}{\cosh^2(r)}\sum_{m,n=0}^{\infty}\sum_{\ell=0}^{\min(m,n)}(\tanh(r))^{m+n}e^{-\frac{\gamma}{2}(n-m)^2}\sqrt{\mathcal{B}_\ell(m,1-\lambda)\,\mathcal{B}_\ell(n,1-\lambda)}\,|m\rangle\!\langle n|_A\otimes|m-\ell\rangle\!\langle n-\ell|_{B_1}\\&=\tau_{AB_1}\,.\end{aligned}\tag{S36}$$

This means that the operator

$$\rho_{AB_1B_2} := \mathrm{id}_A\otimes H_{B_1}\otimes H_{B_2}\left(\mathrm{Tr}_C\left[|\phi\rangle\!\langle\phi|_{AB_1B_2C}\right]\right)\tag{S37}$$

satisfies the extendibility conditions in (S25). All that remains to prove is that $\rho_{AB_1B_2}$ is in fact a quantum state. We will do this by showing that the superoperator H is a quantum channel. In Sec. I C, we establish that a Hadamard map is a quantum channel if its defining infinite matrix is Hermitian, has diagonal elements equal to one, and is diagonally dominant. The first two properties are trivially satisfied by the infinite matrix A defined in (S35). We only need to demonstrate that for the parameter region $\lambda > \frac{1}{2}$ and $\theta\left(e^{-\gamma/2},\sqrt{\frac{\lambda}{1-\lambda}}\right)\le\frac{3}{2}$, the infinite matrix A is diagonally dominant. We recall that, by definition, A is diagonally dominant if it holds that $\sum_{\substack{m=0\\m\neq n}}^{\infty}|a_{mn}|\le 1$, $\forall\, n\in\mathbb{N}$. Note that for any $n, m \in \mathbb{N}$ we have that

$$
\begin{aligned}
|a_{nm}| &= \frac{e^{-\frac{\gamma}{2}(n-m)^2}}{\sum_{j=0}^{\min(n,m)} \sqrt{\binom{n}{j}\binom{m}{j}\left(\frac{1-\lambda}{\lambda}\right)^{n+m-2j}\left(\frac{2\lambda-1}{\lambda}\right)^{2j}}} \\
&\leq \frac{e^{-\frac{\gamma}{2}(n-m)^2}}{\sum_{j=0}^{\min(n,m)} \sqrt{\binom{\min(n,m)}{j}^2\left(\frac{1-\lambda}{\lambda}\right)^{n+m-2j}\left(\frac{2\lambda-1}{\lambda}\right)^{2j}}} \\
&= e^{-\frac{\gamma}{2}(n-m)^2}\left(\frac{\lambda}{1-\lambda}\right)^{\frac{|n-m|}{2}} .
\end{aligned}
\tag{S38}
$$

Consequently, if λ and γ are such that $\lambda > \frac{1}{2}$ and $\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \leq \frac{3}{2}$, for any $n \in \mathbb{N}$ we have that

$$
\begin{aligned}
\sum_{\substack{m=0\\ m\neq n}}^{\infty} |a_{mn}| &\leq \sum_{\substack{m=0\\ m\neq n}}^{\infty} e^{-\frac{\gamma}{2}(m-n)^2}\left(\frac{\lambda}{1-\lambda}\right)^{\frac{|m-n|}{2}} \\
&= \sum_{k=1}^{\infty} e^{-\frac{\gamma}{2}k^2}\left(\frac{\lambda}{1-\lambda}\right)^{\frac{k}{2}} + \sum_{k=1}^{n} e^{-\frac{\gamma}{2}k^2}\left(\frac{\lambda}{1-\lambda}\right)^{\frac{k}{2}} \\
&\leq 2\sum_{k=1}^{\infty} e^{-\frac{\gamma}{2}k^2}\left(\frac{\lambda}{1-\lambda}\right)^{\frac{k}{2}} \\
&= 2\,\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) - 2 \\
&\leq 1 .
\end{aligned}
\tag{S39}
$$

Therefore, the infinite matrix A is diagonally dominant if $\lambda > \frac{1}{2}$ and $\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \leq \frac{3}{2}$. This establishes that H_{B_1} and H_{B_2} are valid quantum channels in this parameter range, implying that $\rho_{AB_1B_2}$ is a valid two-extension of the Choi state of $\mathcal{N}_{\lambda,\gamma}$, and in turn entailing that $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable. Finally, note that if $\lambda > \frac{1}{2}$ the condition

$$
\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \leq \frac{3}{2}
\tag{S40}
$$

is implied by $\lambda \leq \frac{1}{1+9e^{-\gamma}}$. Indeed,

$$
\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) := \sum_{k=0}^{n} e^{-\frac{\gamma}{2}k^2}\left(\sqrt{\frac{\lambda}{1-\lambda}}\right)^{k} \leq \sum_{k=0}^{\infty}\left(\frac{e^{-\gamma}\lambda}{1-\lambda}\right)^{k/2} = \frac{1}{1-\sqrt{\frac{e^{-\gamma}\lambda}{1-\lambda}}} \leq \frac{3}{2},
$$

where the last inequality follows from $\frac{e^{-\gamma}\lambda}{1-\lambda} \leq \frac{1}{9}$, which is implied by $\lambda \leq \frac{1}{1+9e^{-\gamma}}$. □

Expanding the anti-degradability region numerically

Note that Theorem 27 does not identify the entire anti-degradability region of the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$. In fact, from the above argument it becomes clear that a way to obtain a better inner approximation of this region is to check for which values of the parameters the infinite matrix A defined by (S35) is positive semi-definite. This is established in the following theorem.

Theorem 28. *Let $\ell^2(\mathbb{N})$ be the space of square-summable complex-valued sequences (defined by* (S83) *below). For any $\lambda \in (\frac{1}{2}, 1)$ and $\gamma > 0$, let $A = (a_{mn})_{m,n\in\mathbb{N}}$ be the infinite matrix whose components are defined by* (S35)*. If $A \geq 0$ is positive semi-definite as an operator on $\ell^2(\mathbb{N})$, then the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable.*

Proof. In the proof of Theorem 27 we have seen that the bosonic loss-dephasing channel is anti-degradable if the Hadamard map associated with the infinite matrix A (given in (S35)) is a quantum channel. Since the diagonal elements of A are equal to one, from Lemma 46 we deduce that the Hadamard map associated to A is a quantum channel if and only if A is positive semi-definite. This concludes the proof. □

In Theorem 27, we showed that the above-mentioned infinite matrix A is positive semi-definite if $\theta\left(e^{-\gamma/2}, \sqrt{\lambda/(1-\lambda)}\right) \leq \frac{3}{2}$, where $\theta(x,y) \coloneqq \sum_{n=0}^{\infty} x^{n^2} y^n$. This identifies just a portion of the full region of parameters of λ and γ where the infinite matrix A is positive semi-definite.

To analyse the positive semi-definiteness of the infinite matrix A further, let $A^{(d)}$ denote its $d \times d$ top-left corner. Note that it is well-known that an infinite matrix is positive semi-definite if and only if its $d \times d$ top-left corner is positive semi-definite for all $d \in \mathbb{N}$. For modest values of d, we can numerically determine the parameter region where $A^{(d)}$ is positive semi-definite. To achieve this, we plot in Fig. 2 the quantity

$$\eta_d(\gamma) \coloneqq \max\left(\lambda \in \left(\frac{1}{2}, 1\right] : \; A^{(d)} \text{ is positive semi-definite}\right) , \tag{S41}$$

with respect to $e^{-\gamma}$ for various values of d. This quantity is relevant because $A^{(d)}$ is positive semi-definite if and only if $\lambda \leq \eta_d(\gamma)$. Moreover, the quantity $\eta_d(\gamma)$ monotonically decreases in d and converges to some $\bar{\eta}(\gamma)$ as $d \longrightarrow \infty$. Notably, the condition $\lambda \leq \bar{\eta}(\gamma)$ is necessary and sufficient for positive semi-definiteness of the infinite matrix A, and also a sufficient condition for the anti-degradability of the the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$. Our numerical investigation seems to suggest that when d is approximately 20, the quantity $\eta_d(\gamma)$ has already reached its limiting value $\bar{\eta}(\gamma)$, which can be approximated, for instance, by considering, the curve $\eta_{30}(\gamma)$.

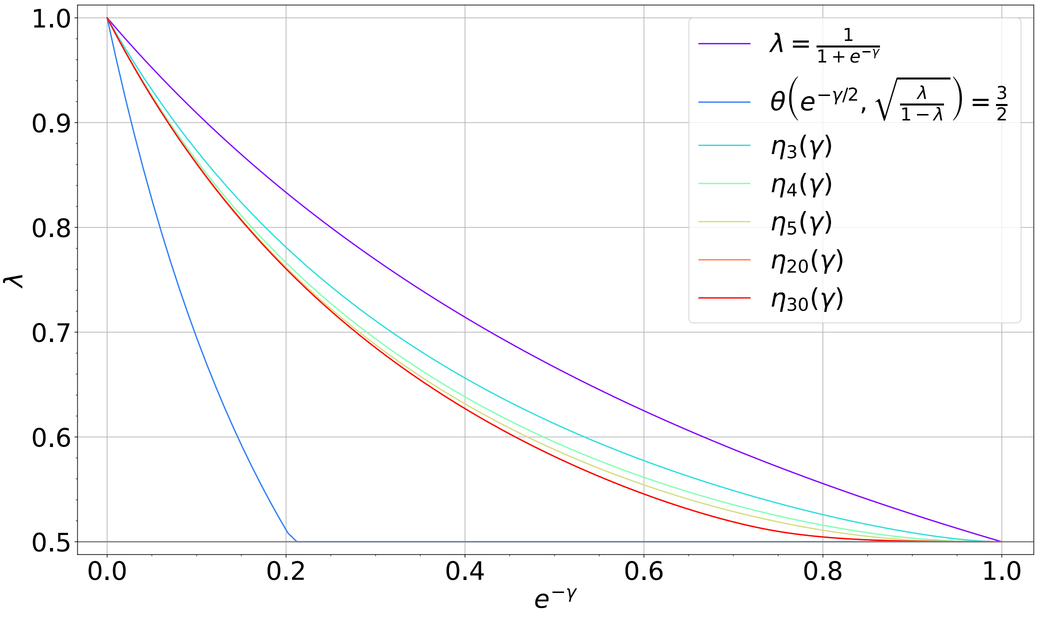

FIG. 2. Numerical estimation of the anti-degradability of the loss-dephasing channel. The horizontal axis shows the quantity $e^{-\gamma}$, varying from 0 to 1 as dephasing parameter γ decreases from ∞ to 0, while the vertical axis corresponds to the transmissivity λ. Theorem 27 establishes that below the region defined by the blue curve, corresponding to the condition $\theta(e^{-\gamma/2}, \sqrt{\lambda/(1-\lambda)}) = 3/2$, the bosonic loss-dephasing channel is anti-degradable. Moreover, Theorem 35 establishes that above the region defined by the purple curve, corresponding to $\lambda = \frac{1}{1+e^{-\gamma}}$, the bosonic loss-dephasing channel is not anti-degradable. The other curves depict the quantity $\eta_d(\gamma)$, which is defined in (S41) as the maximum value of the transmissivity where $A^{(d)}$ is positive semi-definite, for various values of d. Our numerical analysis seems to indicate that in the region below the red curve, corresponding to $\lambda \leq \eta_{30}(\gamma)$, the bosonic loss-dephasing channel is anti-degradable. Here, we employ $d = 30$, as increasing d beyond $d \geq 20$ yields no discernible change in the plot.

Theorem 27 discovers parameter regions of transmissivity λ and dephasing γ in which the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable. Although the proof of this theorem ensures the existence of anti-degrading maps for $\mathcal{N}_{\lambda,\gamma}$ within these parameter regions, it does not offer explicit constructions of such anti-degrading maps. In the forthcoming Theorem 29, we present such explicit constructions. Note that, thanks to Lemma 23, the output operators of the complementary channel $\mathcal{N}^{\mathrm{c}}_{\lambda,\gamma}$ reside within the space $\mathcal{T}(\mathcal{H}_{E_{\mathrm{out}}})$, where $\mathcal{H}_{E_{\mathrm{out}}}$ is the following subspace of the two-mode Hilbert space $\mathcal{H}_{E_1} \otimes \mathcal{H}_{E_2} = L^2(\mathbb{R}) \otimes L^2(\mathbb{R})$:

$$\mathcal{H}_{E_{\mathrm{out}}} := \mathrm{Span}\left\{ |\ell\rangle_{E_1} \otimes \left|\sqrt{\gamma} n\right\rangle_{E_2} :\ \ell \le n \text{ with } \ell, n \in \mathbb{N} \right\}, \tag{S42}$$

where $|n\rangle$ represents the nth Fock state, and $\left|\sqrt{\gamma} n\right\rangle$ denotes the coherent state with a parameter of $\sqrt{\gamma} n$. These states correspond to the environmental modes of the pure-loss and dephasing channels, respectively (we shall maintain this notation throughout).

Theorem 29. *Anti-degrading maps corresponding to each parameter region in Theorem 27 can be defined as follows. In the region (i), i.e. $\lambda \in \left[0, \frac{1}{2}\right]$ and $\gamma \ge 0$, an anti-degrading map is given by*

$$\mathcal{A}_{\lambda,\gamma} = \left(\mathcal{E}_{\frac{\lambda}{1-\lambda}} \circ \mathcal{R}_{E_1} \right) \otimes \mathrm{Tr}_{E_2}, \tag{S43}$$

where $\mathcal{R}_{E_1}(\cdot) := (-1)^{\hat{e}_1^\dagger \hat{e}_1} \cdot (-1)^{\hat{e}_1^\dagger \hat{e}_1}$, with $\hat{e}_1$ as the annihilation operator of the output mode of the pure-loss channel E_1.

In the region (ii), i.e. $\lambda \in (\frac{1}{2}, 1)$ and γ such that $\theta\left(e^{-\gamma/2}, \sqrt{\frac{\lambda}{1-\lambda}}\right) \le \frac{3}{2}$, an anti-degrading map $\mathcal{A}_{\lambda,\gamma} : \mathcal{T}(\mathcal{H}_{E_{out}}) \to \mathcal{T}(\mathcal{H}_B)$, with $\mathcal{H}_{E_{out}}$ given by (S42)*, is defined as follows. For all $\ell_1, \ell_2, n_1, n_2 \in \mathbb{N}$ with $\ell_1 \le n_1$ and $\ell_2 \le n_2$, it holds that*

$$\mathcal{A}_{\lambda,\gamma}\left(|\ell_1\rangle\langle\ell_2| \otimes \left|\sqrt{\gamma} n_1\right\rangle\left\langle\sqrt{\gamma} n_2\right|\right) := \sum_{k=0}^{\min(n_1-\ell_1, n_2-\ell_2)} c_k^{(\ell_1,\ell_2,n_1,n_2)} \, |k+\ell_1\rangle\langle k+\ell_2| \ , \tag{S44}$$

where for all $k \in \{0, 1, \ldots, \min(n_1 - \ell_1, n_2 - \ell_2)\}$ the coefficients $c_k^{(\ell_1,\ell_2,n_1,n_2)}$ are defined as

$$c_k^{(\ell_1,\ell_2,n_1,n_2)} := (-1)^{\ell_1-\ell_2} \sqrt{\mathcal{B}_k\left(n_1 - \ell_1, \frac{2\lambda - 1}{\lambda}\right) \mathcal{B}_k\left(n_2 - \ell_2, \frac{2\lambda - 1}{\lambda}\right)} \, a_{n_1-\ell_1 n_2-\ell_2} \, a_{k+\ell_1 k+\ell_2} \ , \tag{S45}$$

where $\mathcal{B}_l(n, \lambda) := \binom{n}{l} \lambda^l (1-\lambda)^{n-l}$, and a_{mn} is defined in (S35)*.*

Proof of Theorem 29. Let us suppose that λ and γ fall within the parameter region (i). A complementary channel of the pure-loss channel $\mathcal{E}_\lambda$ is given by $\mathcal{E}_\lambda^{\mathrm{c}} = \mathcal{E}_{1-\lambda} \circ \mathcal{R}$. Consequently, Lemma 13 implies that $\left(\mathcal{E}_{\frac{\lambda}{1-\lambda}} \circ \mathcal{R} \right) \circ \mathcal{E}_\lambda^{\mathrm{c}} = \mathcal{E}_\lambda$, i.e. the channel $\mathcal{E}_{\frac{\lambda}{1-\lambda}} \circ \mathcal{R}$ is an anti-degrading map of the pure-loss channel. The general construction detailed in the proof of Lemma 51 for the anti-degrading map of the composition between an anti-degradable channel and another channel demonstrates that the map given in (S43) is an anti-degrading map of $\mathcal{N}_{\lambda,\gamma}$.

Let us now suppose that λ and γ fall within the parameter region (ii). To come up with the anti-degrading map defined in (S44), we drew intuition from the proof of Lemma 50, which demonstrates the equivalence between two-extendibility of the Choi state and the existence of an anti-degrading map, while also considering the two-extension of the Choi state of $\mathcal{N}_{\lambda,\gamma}$ explicitly found in (S37). In order to show that the map $\mathcal{A}_{\lambda,\gamma}$ in (S44) is an anti-degrading map of $\mathcal{N}_{\lambda,\gamma}$, we need to show that it is a quantum channel satisfying $\mathcal{A}_{\lambda,\gamma} \circ \mathcal{N}^{\mathrm{c}}_{\lambda,\gamma} = \mathcal{N}_{\lambda,\gamma}$. We begin by proving that $\mathcal{A}_{\lambda,\gamma}$ is trace preserving. By linearity, it suffices to show that for any $\ell_1, \ell_2, n_1, n_2 \in \mathbb{N}$ with $\ell_1 \le n_1$ and $\ell_2 \le n_2$ it holds that

$$\mathrm{Tr}\left[\mathcal{A}_{\lambda,\gamma}\left(|\ell_1\rangle\langle\ell_2|_{E_1} \otimes \left|\sqrt{\gamma} n_1\right\rangle\left\langle\sqrt{\gamma} n_2\right|_{E_2} \right) \right] = \mathrm{Tr}\left[|\ell_1\rangle\langle\ell_2|_{E_1} \otimes \left|\sqrt{\gamma} n_1\right\rangle\left\langle\sqrt{\gamma} n_2\right|_{E_2} \right] \ . \tag{S46}$$

Indeed, we obtain

$$
\begin{aligned}
\mathrm{Tr}\left[\mathcal{A}_{\lambda,\gamma}\left(|\ell_1\rangle\!\langle\ell_2|_{E_1}\otimes\left|\sqrt{\gamma}m\right\rangle\!\left\langle\sqrt{\gamma}n\right|_{E_2}\right)\right] &= \delta_{\ell_1,\ell_2}\sum_{k=0}^{\min(m-\ell_1,n-\ell_1)} c_k^{(\ell_1,\ell_1,m,n)} \\
&= \delta_{\ell_1,\ell_2}\sum_{k=0}^{\min(m-\ell_1,n-\ell_1)} \sqrt{\mathcal{B}_k\left(m-\ell_1,\frac{2\lambda-1}{\lambda}\right)\mathcal{B}_k\left(n-\ell_1,\frac{2\lambda-1}{\lambda}\right)}a_{m-\ell_1,n-\ell_1}\,a_{k+\ell_1,k+\ell_1} \\
&= \delta_{\ell_1,\ell_2}e^{-\frac{\gamma}{2}(m-n)^2} \\
&= \mathrm{Tr}\left[|\ell_1\rangle\!\langle\ell_2|_{E_1}\otimes\left|\sqrt{\gamma}n_1\right\rangle\!\left\langle\sqrt{\gamma}n_2\right|_{E_2}\right]\,,
\end{aligned}
$$

where δ_{ℓ_1,ℓ_2} denotes the kronecker delta and where we have exploited the formula for the overlap between coherent states provided in (S6). Now, let us show that $\mathcal{A}_{\lambda,\gamma}$ is completely positive. To achieve this, we need to find a pure state Ψ on $\mathcal{H}_{\mathrm{anc}}\otimes\mathcal{H}_{E_{\mathrm{out}}}$, where $\mathcal{H}_{\mathrm{anc}}$ in an auxiliary reference, such that $\mathrm{Tr}_{\mathrm{anc}}[|\Psi\rangle\!\langle\Psi|]>0$ and $(\mathrm{id}_{\mathrm{anc}}\otimes\mathcal{A}_{\lambda,\gamma})(|\Psi\rangle\!\langle\Psi|)\geq 0$ [10, 11, 26]. Let $\mathcal{H}_{\mathrm{anc}}:=\mathcal{H}_A\otimes\mathcal{H}_{B_1}=L^2(\mathbb{R})\otimes L^2(\mathbb{R})$ and let us construct the pure state $|\Psi\rangle_{AB_1E_1E_2}\in\mathcal{H}_{\mathrm{anc}}\otimes\mathcal{H}_{E_{\mathrm{out}}}$ as follows:

$$
\begin{aligned}
|\Psi\rangle_{AB_1E_1E_2} &:= U_\lambda^{B_1E_1}V_\gamma^{B_1E_2}\,|\psi(r)\rangle_{AB_1}\,|0\rangle_{E_1}\,|0\rangle_{E_2} \\
&= \frac{1}{\cosh(r)}\sum_{n=0}^{\infty}\sum_{\ell=0}^{n}(-1)^{\ell}\tanh^n(r)\sqrt{\mathcal{B}_l(n,1-\lambda)}\,|n\rangle_A\,|n-\ell\rangle_{B_1}\,|\ell\rangle_{E_1}\left|\sqrt{\gamma}n\right\rangle_{E_2}\,,
\end{aligned}
\tag{S47}
$$

where $U_\lambda^{B_1E_1}$ is the beam splitter unitary, $V_\gamma^{B_1E_2}$ is the conditional displacement unitary, and $|\psi(r)\rangle_{AB_1}$ is the two-mode squeezed vacuum state with squeezing $r>0$. Let us now show that $\mathrm{Tr}_{AB_1}\left[|\Psi\rangle\!\langle\Psi|_{AB_1E_1E_2}\right]$ is positive definite on $\mathcal{H}_{E_{\mathrm{out}}}$. Let $\left|\phi\right\rangle_{E_1E_2}\in\mathcal{H}_{E_{\mathrm{out}}}$. Since there exists $\bar{\ell},\bar{n}\in\mathbb{N}$ with $\bar{l}\leq\bar{n}$ such that $\left\langle\phi\right|_{E_1E_2}\left|\bar{\ell}\right\rangle_{E_1}\otimes\left|\sqrt{\gamma}\bar{n}\right\rangle_{E_2}\neq 0$, (S47) implies that

$$
\begin{aligned}
\left\langle\phi\right|_{E_1E_2}\mathrm{Tr}_{AB_1}\left[|\Psi\rangle\!\langle\Psi|_{AB_1E_1E_2}\right]\left|\phi\right\rangle_{E_1E_2} &= \frac{1}{\cosh^2(r)}\sum_{n=0}^{\infty}\sum_{l=0}^{n}\tanh^{2n}(r)\,\mathcal{B}_\ell\left(n,1-\lambda\right)\left|\left\langle\phi\right|_{E_1E_2}|\ell\rangle_{E_1}\otimes\left|\sqrt{\gamma}n\right\rangle_{E_2}\right|^2 \\
&\geq \frac{1}{\cosh^2(r)}\tanh^{2\bar{n}}(r)\,\mathcal{B}_{\bar{l}}\left(\bar{n},1-\lambda\right)\left|\left\langle\phi\right|_{E_1E_2}\left|\bar{\ell}\right\rangle_{E_1}\otimes\left|\sqrt{\gamma}\bar{n}\right\rangle_{E_2}\right|^2 \\
&>0\,.
\end{aligned}
$$

We next show that $\mathrm{id}_{AB_1}\otimes\mathcal{A}_{\lambda,\gamma}(|\Psi\rangle\!\langle\Psi|)$ is positive semi-definite. Let B_2 denote the output system of $\mathcal{A}_{\lambda,\gamma}$. Note that

$$
\begin{aligned}
\mathrm{id}_{AB_1}\otimes\mathcal{A}_{\lambda,\gamma}(|\Psi\rangle\!\langle\Psi|_{AB_1E_1E_2}) &\overset{\text{(i)}}{=} \frac{1}{\cosh^2(r)}\sum_{m,n=0}^{\infty}\sum_{\ell_1=0}^{m}\sum_{\ell_2=0}^{n}(-1)^{\ell_1+\ell_2}[\tanh(r)]^{m+n}\sqrt{\mathcal{B}_{\ell_1}(m,1-\lambda)\mathcal{B}_{\ell_2}(n,1-\lambda)} \\
&\qquad |m\rangle\!\langle n|_A\otimes|m-\ell_1\rangle\!\langle n-\ell_2|_{B_1}\otimes\mathcal{A}_{\lambda,\gamma}\left(|\ell_1\rangle\!\langle\ell_2|_{E_1}\otimes\left|\sqrt{\gamma}m\right\rangle\!\left\langle\sqrt{\gamma}n\right|_{E_2}\right) \\
&\overset{\text{(ii)}}{=} \frac{1}{\cosh^2(r)}\sum_{m,n=0}^{\infty}\sum_{\ell_1=0}^{m}\sum_{\ell_2=0}^{n}\sum_{k=0}^{\min(m-\ell_1,n-\ell_2)}[\tanh(r)]^{m+n} \\
&\qquad \sqrt{\mathcal{B}_{\ell_1}(m,1-\lambda)\,\mathcal{B}_{\ell_2}(n,1-\lambda)\,\mathcal{B}_k\left(m-\ell_1,\frac{2\lambda-1}{\lambda}\right)\mathcal{B}_k\left(n-\ell_2,\frac{2\lambda-1}{\lambda}\right)} \\
&\qquad a_{m-\ell_1,n-\ell_2}\,a_{k+\ell_1,k+\ell_2}\,|n_1\rangle\!\langle n|_A\otimes|m-\ell_1\rangle\!\langle n-\ell_2|_{B_1}\otimes|k+\ell_1\rangle\!\langle k+\ell_2|_{B_2} \\
&\overset{\text{(iii)}}{=} \rho_{AB_1B_2}\,.
\end{aligned}
\tag{S48}
$$

Here, in (i) we used the definition of $|\Psi\rangle_{AB_1E_1E_2}$ given in (S47); in (ii) we utilised the definition of the map $\mathcal{A}_{\lambda,\gamma}$ from (S44); and in (iii) we recognised the tripartite operator $\rho_{AB_1B_2}$ defined in (S37), which is a quantum state provided that λ and γ satisfy $\theta\left(e^{-\gamma/2},\sqrt{\frac{\lambda}{1-\lambda}}\right)\leq\frac{3}{2}$. Therefore, in such a parameter region, $\mathrm{id}_{AB_1}\otimes\mathcal{A}_{\lambda,\gamma}(|\Psi\rangle\!\langle\Psi|_{AB_1E_1E_2})$

is positive semi-definite, and thus $\mathcal{A}_{\lambda,\gamma}$ is a quantum channel. Let us now verify that $\mathcal{A}_{\lambda,\gamma} \circ \mathcal{N}^{\mathrm{c}}_{\lambda,\gamma} = \mathcal{N}_{\lambda,\gamma}$. To show this, note that

$$\begin{aligned}\mathrm{id}_A \otimes \left(\mathcal{A}_{\lambda,\gamma} \circ \mathcal{N}^{\mathrm{c}}_{\lambda,\gamma}\right)(|\psi(r)\rangle\!\langle\psi(r)|_{AB_1}) &\overset{\text{(iv)}}{=} \mathrm{Tr}_{B_1}\left[\mathrm{id}_{AB_1} \otimes \mathcal{A}_{\lambda,\gamma}(|\Psi\rangle\!\langle\Psi|_{AB_1E_1E_2})\right] \\ &\overset{\text{(v)}}{=} \mathrm{Tr}_{B_1}\left[\rho_{AB_1B_2}\right] \\ &\overset{\text{(vi)}}{=} \mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}\left(|\psi(r)\rangle\!\langle\psi(r)|_{AB_2}\right),\end{aligned} \tag{S49}$$

Here, in (iv) we employed (S47); in (v) we exploited (S48); and in (vi) we used that $\rho_{AB_1B_2}$ is a two-extension of $\mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}(|\psi(r)\rangle\!\langle\psi(r)|)$, as established in the proof of Theorem 27. Finally, since the two-mode squeezed vacuum state $|\psi(r)\rangle_{AB}$ satisfies $\mathrm{Tr}_B[|\psi(r)\rangle\!\langle\psi(r)|_{AB}] > 0$, we conclude $\mathcal{A}_{\lambda,\gamma} \circ \mathcal{N}^{\mathrm{c}}_{\lambda,\gamma} = \mathcal{N}_{\lambda,\gamma}$. □

B. Analysis of the bosonic loss-dephasing channel via its finite-dimensional restrictions

Definition 30. *Let $d \in \mathbb{N}$ and let $\mathcal{H}_d := \mathrm{Span}(\{|n\rangle\}_{n=0,\ldots,d-1})$ be the subspace spanned by the first d Fock states. The qudit restriction of the bosonic loss-dephasing channel $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is a quantum channel defined by*

$$\mathcal{N}^{(d)}_{\lambda,\gamma}(\Theta) := \mathcal{N}_{\lambda,\gamma}(\Theta) \qquad \forall\, \Theta \in \mathcal{T}(\mathcal{H}_d) \tag{S50}$$

Lemma 31. *Let $\mathcal{H}_A, \mathcal{H}_B := L^2(\mathbb{R})$. Let $\mathcal{N} : \mathcal{T}(\mathcal{H}_A) \to \mathcal{T}(\mathcal{H}_B)$ be a quantum channel and let $\mathcal{N}^{(d)}$ be its qudit restriction, defined by*

$$\mathcal{N}^{(d)}(\Theta) := \mathcal{N}(\Theta) \qquad \forall\, \Theta \in \mathcal{T}(\mathcal{H}_d)\,. \tag{S51}$$

If $\mathcal{N}$ is (anti-)degradable, then its qudit restriction $\mathcal{N}^{(d)}$ is (anti-)degradable.

Proof. Let $\mathcal{N}(\cdot) = \mathrm{Tr}_E[V_{A\to BE}(\cdot)V^\dagger_{A\to BE}]$ be a Stinespring representation of $\mathcal{N}$, and let $\mathcal{N}^{\mathrm{c}}(\cdot) = \mathrm{Tr}_B[V_{A\to BE}(\cdot)V^\dagger_{A\to BE}]$ be the associated complementary channel. Note that the isometry $V_{A\to BE}$ provides a Stinespring representation also for the qudit restriction $\mathcal{N}^{(d)}$. Hence, the qudit restriction of the complementary channel $\mathcal{N}^{\mathrm{c}}$ is a complementary channel of the qudit restriction $\mathcal{N}^{(d)}$, i.e.

$$(\mathcal{N}^{(d)})^{\mathrm{c}}(\Theta) = \mathcal{N}^{\mathrm{c}}(\Theta) \qquad \forall\, \Theta \in \mathcal{T}(\mathcal{H}_d)\,. \tag{S52}$$

Moreover, note that any degrading or anti-degrading map of $\mathcal{N}$ is effective for all input states, including those restricted to $\mathcal{H}_d$. Consequently, an (anti-)degrading map of $\mathcal{N}$ is also an (anti-)degrading map of its qudit restriction $\mathcal{N}^{(d)}$. □

Corollary 32. *If the qudit restriction $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is not (anti)-degradable, then the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is also not (anti)-degradable.*

The following lemma shows that qudit restriction $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is a qu*d*it-to-qu*d*it channel, mapping the space spanned by $\{|n\rangle\}_{n=0,\ldots,d-1}$ into itself.

Lemma 33. *If the input state to the bosonic loss-dephasing channel is confined into the finite-dimensional subspace spanned by $\{|n\rangle\}_{n=0,\ldots,d-1}$, the resulting output state will similarly be confined to this subspace.*

Proof. Examining Lemma 22 reveals that the operator $|m\rangle\!\langle n|$, when acted on by the bosonic loss-dephasing channel, is transformed into linear combinations of operators $\{|\ell\rangle\!\langle k|\}_{\ell\le m, k\le n}$. This means that if the input state to the bosonic loss-dephasing channel is restricted to the d-dimensional subspace $\{|n\rangle\}_{n=0,\ldots,d-1}$, the output of the channel will reside within the same subspace. □

The qubit restriction $\mathcal{N}^{(2)}_{\lambda,\gamma}$ of the bosonic loss-dephasing channel coincides with the composition between the amplitude damping channel and the qubit dephasing channel [2, 4], which we dub *amplitude-phase damping channel*. Theorems 34 and 35 utilise the amplitude-phase damping channel $\mathcal{N}^{(2)}_{\lambda,\gamma}$ to find that the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is never degradable and, additionally, it is not anti-degradabile for $\lambda > \frac{1}{1+e^{-\gamma}}$, respectively.

The bosonic loss-dephasing channel is never degradable

The bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is never degradable, except when it coincides with either the bosonic dephasing channel ($\gamma > 0$ and $\lambda = 1$) or the degradable pure-loss channel ($\gamma = 0$ and $\lambda \geq \frac{1}{2}$), thereby complicating the derivation of its quantum capacity [21]. This result has been previously demonstrated in [21] through pages-long proof; however, here we provide a significantly simpler proof of this result.

Theorem 34. *Let $\lambda \in [0,1]$ and $\gamma \geq 0$. The bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is degradable if and only if one of the following conditions is satisfied:*

- $\gamma = 0$ *and* $\lambda \in [\frac{1}{2}, 1]$
- $\gamma \geq 0$ *and* $\lambda = 1$

Proof. Thanks to Corollary 32, a necessary condition for $\mathcal{N}_{\lambda,\gamma}$ to be degradable is the degradability of the amplitude-phase damping channel $\mathcal{N}^{(2)}_{\lambda,\gamma}$. We now apply [27, Theorem 4], which establishes a necessary condition on the degradability of any qubit channel. Specifically, the rank of the Choi state of a degradable qubit channel is necessarily less or equal to 2. By using the notation used in (S3), the matrix associated with the Choi state of the amplitude-phase damping channel $C\left(\mathcal{N}^{(2)}_{\lambda,\gamma}\right)$ in the computational basis $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$ is given by:

$$\frac{1}{2}\begin{pmatrix} 1 & 0 & 0 & \sqrt{e^{-\gamma}\lambda} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1-\lambda & 0 \\ \sqrt{e^{-\gamma}\lambda} & 0 & 0 & \lambda \end{pmatrix}. \tag{S53}$$

One can easily see that its rank is equal to 3 for $\gamma > 0$ and $\lambda \in (0,1)$. In addition, for $\lambda = 1$ the bosonic loss-dephasing channel coincides with the bosonic dephasing channel, $\mathcal{N}_{1,\gamma} = \mathcal{D}_\gamma$, which is degradable for any value of $\gamma \geq 0$ [17]. Finally, for $\gamma = 0$ the bosonic loss-dephasing channel coincides with the pure-loss channel, $\mathcal{N}_{\lambda,0} = \mathcal{E}_\lambda$, which is degradable if and only if $\lambda \in [\frac{1}{2}, 1]$ [15, 16]. □

Necessary condition on anti-degradability via qubit restriction

The next theorem establishes the parameter range where the bosonic loss-dephasing channel is not anti-degradable. We provide three different proofs for this theorem.

Theorem 35. *Let $\gamma \geq 0$. If $\lambda > \frac{1}{1+e^{-\gamma}}$, then the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable.*

Proof 1. Assume that $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable; then substituting $m = 0$ and $n = 1$ in (S22) yields

$$\mathcal{A}_{\lambda,\gamma}\left(\mathcal{E}_{1-\lambda}(|0\rangle\langle 1|) \otimes |0\rangle\langle\sqrt{\gamma}|\right) = -e^{-\frac{1}{2}\gamma}\mathcal{E}_\lambda(|0\rangle\langle 1|). \tag{S54}$$

By exploiting $\mathcal{E}_\lambda(|0\rangle\langle 1|) = \sqrt{\lambda}\,|0\rangle\langle 1|$, we have

$$\mathcal{A}_{\lambda,\gamma}\left(|0\rangle\langle 1| \otimes |0\rangle\langle\sqrt{\gamma}|\right) = -\sqrt{\frac{e^{-\gamma}\lambda}{1-\lambda}}\,|0\rangle\langle 1| \,.$$

Using Lemma 48 in the Appendix, we find $\sqrt{\frac{e^{-\gamma}\lambda}{1-\lambda}} \leq 1$, or $\lambda \leq \frac{1}{1+e^{-\gamma}}$. □

Proof 2. Assume that $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable. As a consequence of (S22) and of the data-processing inequality for the fidelity [1], we find

$$F\left(\mathcal{E}_\lambda(|0\rangle\langle 0|), \mathcal{E}_\lambda(|1\rangle\langle 1|)\right) \geq F\left(\mathcal{E}_{1-\lambda}(|0\rangle\langle 0|) \otimes |0\rangle\langle 0|\,, \mathcal{E}_{1-\lambda}(|1\rangle\langle 1|) \otimes |\sqrt{\gamma}\rangle\langle\sqrt{\gamma}|\right). \tag{S55}$$

Furthermore, we obtain

$$\begin{aligned}\sqrt{1-\lambda} &= F\big(\,|0\rangle\!\langle 0|\,,\lambda\,|1\rangle\!\langle 1| + (1-\lambda)\,|0\rangle\!\langle 0|\,\big)\\ &\overset{\text{(i)}}{=} F\big(\mathcal{E}_\lambda(|0\rangle\!\langle 0|),\mathcal{E}_\lambda(|1\rangle\!\langle 1|)\big)\\ &\overset{\text{(ii)}}{\geq} F\big(\,|0\rangle\!\langle 0|\,,\big|\sqrt{\gamma}\big\rangle\!\big\langle\sqrt{\gamma}\big|\,\big)\, F\big(\mathcal{E}_{1-\lambda}(|0\rangle\!\langle 0|),\mathcal{E}_{1-\lambda}(|1\rangle\!\langle 1|)\big)\\ &\overset{\text{(iii)}}{\geq} F\big(\,|0\rangle\!\langle 0|\,,\big|\sqrt{\gamma}\big\rangle\!\big\langle\sqrt{\gamma}\big|\,\big)\,F\big(\,|0\rangle\!\langle 0|\,, \lambda\,|0\rangle\!\langle 0| + (1-\lambda)\,|1\rangle\!\langle 1|\,\big)\\ &\overset{\text{(iv)}}{=} \sqrt{e^{-\gamma}\lambda}\,.\end{aligned} \tag{S56}$$

Here, (i) follows from Lemma 10, (ii) follows from (S55) and from the fact that the fidelity is multiplicative under tensor product [1], (iii) uses Lemma 10 again, and in (iv) we exploited that $|\,\langle 0|\sqrt{\gamma}\rangle\,| = \sqrt{e^{-\gamma}}$. This yields $\sqrt{1-\lambda} \geq \sqrt{e^{-\gamma}\lambda}$, or $\lambda \leq \frac{1}{1+e^{-\gamma}}$. □

Proof 3. By exploiting Lemma 4 and the Choi matrix of the qubit channel $\mathcal{N}^{(2)}_{\lambda,\gamma}$ reported in (S53), one can easily obtain that $\mathcal{N}^{(2)}_{\lambda,\gamma}$ is anti-degradable if and only if $\lambda \leq \frac{1}{1+e^{-\gamma}}$. Consequently, thanks to Corollary 32, the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable for $\lambda > \frac{1}{1+e^{-\gamma}}$. □

Necessary condition on anti-degradability via qudit restrictions

Let us introduce the following quantity for any $d \in \mathbb{N}$ and $\gamma \geq 0$:

$$\lambda_d(\gamma) := \max\left(\lambda \in [0,1] :\ \mathcal{N}^{(d)}_{\lambda,\gamma} \text{ is anti-degradable}\right)\,. \tag{S57}$$

This quantity is relevant since it allows us to find parameter region where the bosonic loss-dephasing channel is not anti-degradable. Specifically, for $\lambda > \lambda_d(\gamma)$ the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is not anti degradable, as established by Corollary 32. Thanks to the Proof 3 of Theorem 35, it follows that for $d = 2$ we have that $\lambda_2(\gamma) = \frac{1}{1+e^{-\gamma}}$, thereby establishing that $\mathcal{N}_{\lambda,\gamma}$ is not anti degradable for $\lambda > \frac{1}{1+e^{-\gamma}}$. Through an examination of larger values of d, we aim to identify an extended parameter region where the channel is not anti-degradable (see Fig. 3). We begin by proving some useful properties of the quantity $\lambda_d(\gamma)$.

Lemma 36. *For any $\gamma \geq 0$ and $d \in \mathbb{N}, d \geq 2$, the following facts hold:*

- *Fact 1: The qudit restriction of the bosonic loss-dephasing channel $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is anti-degradable if and only if $\lambda \leq \lambda_d(\gamma)$*
- *Fact 2: The quantity $\lambda_d(\gamma)$ is monotonically increasing in γ*
- *Fact 3: For $d = 2$, it precisely holds that $\lambda_2(\gamma) = \frac{1}{1+e^{-\gamma}}$*
- *Fact 4: The quantity $\lambda_d(\gamma)$ is monotonically non-increasing in d*
- *Fact 5: It holds that $\frac{1}{2} \leq \lambda_d(\gamma) \leq \frac{1}{1+e^{-\gamma}}$*
- *Fact 6: When $d = 3$ and $e^{-\gamma} \leq \sqrt{2} - 1$ (or $\gamma \geq 0.881$), it exactly holds that $\lambda_3(\gamma) = \frac{1}{1+e^{-\gamma}}$*

Proof. Fact 1. It suffices to show that for any $\gamma \geq 0$ and $\lambda, \lambda' \in [0,1]$ with $\lambda' < \lambda$, if $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is anti-degradable, then so is $\mathcal{N}^{(d)}_{\lambda',\gamma}$. To show this, we exploit the composition rule

$$\mathcal{E}_{\lambda_1} \circ \mathcal{N}_{\lambda_2,\gamma} = \mathcal{N}_{\lambda_1\lambda_2,\gamma} \qquad \forall\, \lambda_1, \lambda_2 \in [0,1]\,, \tag{S58}$$

as established by Lemma 25, implying that the channel $\mathcal{N}^{(d)}_{\lambda',\gamma}$ can be written as the composition between $\mathcal{N}^{(d)}_{\lambda,\gamma}$ and another channel. Consequently, Lemma 51 concludes the proof.

Fact 2. Analogously to Fact 1, it suffices to show that for any $\lambda \in [0,1]$ and for any $\gamma' \geq \gamma \geq 0$, if $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is anti-degradable, then so is $\mathcal{N}^{(d)}_{\lambda,\gamma'}$. This follows from the composition rule

$$\mathcal{D}_{\gamma_1} \circ \mathcal{N}_{\lambda,\gamma_2} = \mathcal{N}_{\lambda,\gamma_1+\gamma_2} \qquad \forall\, \gamma_1, \gamma_2 \geq 0\,, \tag{S59}$$

as proved in Lemma 25. Furthermore, Lemma 51 concludes the proof.

Fact 3. This has already been proved in the Proof 3 of Theorem 35.

Fact 4. This follows from the observation that for all $d' \geq d$, if $\mathcal{N}^{(d')}_{\lambda,\gamma}$ is anti-degradable, then so is $\mathcal{N}^{(d)}_{\lambda,\gamma}$.

Fact 5. The upper bound $\lambda_d(\gamma) \leq \frac{1}{1+e^{-\gamma}}$ follows from Fact 3 and Fact 4. Moreover, since the pure-loss channel $\mathcal{E}_\lambda$ is anti-degradable if and only if $\lambda \leq \frac{1}{2}$, Fact 4 implies that $\lambda_d(0) \geq \frac{1}{2}$ (more specifically, one can also show that $\lambda_d(0) = \frac{1}{2}$). Consequently, Fact 2 concludes the proof.

Fact 6. This proof relies on the equivalence between anti-degradability of a channel and two-extendibility of its Choi state, as established in Lemma 50. Let λ and γ be such that $\lambda = \frac{1}{1+e^{-\gamma}}$ and $e^{-\gamma} \leq \sqrt{2}-1$, implying that $\lambda \geq \frac{1}{\sqrt{2}}$. By using Lemma 22, we obtain the Choi state of $\mathcal{N}^{(3)}_{\lambda,\gamma}$ as follows:

$$\mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}(|\Phi_3\rangle\!\langle\Phi_3|) = \frac{1}{3}\sum_{m=0}^{2}\sum_{n=0}^{2}\sum_{\ell=0}^{\min(m,n)} e^{-\frac{\gamma}{2}(m-n)^2}\sqrt{\binom{m}{\ell}\binom{n}{\ell}}\,\lambda^{\frac{m+n}{2}-\ell}(1-\lambda)^l\, |m\rangle\!\langle n|_A \otimes |m-\ell\rangle\!\langle n-\ell|_B\,,$$

where Φ_3 is the maximally entangled state of Schmidt rank 3. We define a two-extension $\tilde{\rho}_{AB_1B_2}$ of the Choi state by the following conditions. First, $\tilde{\rho}_{AB_1B_2}$ satisfies the following $B_1 \leftrightarrow B_2$ symmetry for all $i_1, i_2, i_3, j_1, j_2, j_3 \in \{0,1,2\}$:

$$\begin{aligned} \langle j_1|_A \langle j_2|_{B_1} \langle j_3|_{B_2}\, \tilde{\rho}_{AB_1B_2}\, |i_1\rangle_A |i_2\rangle_{B_1} |i_3\rangle_{B_2} &= \langle j_1|_A \langle j_3|_{B_1} \langle j_2|_{B_2}\, \tilde{\rho}_{AB_1B_2}\, |i_1\rangle_A |i_2\rangle_{B_1} |i_3\rangle_{B_2} \\ \langle j_1|_A \langle j_2|_{B_1} \langle j_3|_{B_2}\, \tilde{\rho}_{AB_1B_2}\, |i_1\rangle_A |i_2\rangle_{B_1} |i_3\rangle_{B_2} &= \langle j_1|_A \langle j_2|_{B_1} \langle j_3|_{B_2}\, \tilde{\rho}_{AB_1B_2}\, |i_1\rangle_A |i_3\rangle_{B_1} |i_2\rangle_{B_2}\ . \end{aligned} \tag{S60}$$

Furthermore, if $i_1 < \max(i_2, i_3)$ or $j_1 < \max(j_2, j_3)$, or if $i_1 > i_2+i_3$ or $j_1 > j_2+j_3$, then $\langle j_1|_A \langle j_2|_{B_1} \langle j_3|_{B_2}\, \tilde{\rho}_{AB_1B_2}\, |i_1\rangle_A |i_2\rangle_{B_1} |i_3\rangle_{B_2} = 0$. We can thus define $\tilde{\rho}_{AB_1B_2}$ by writing only the matrix elements with respect the set $\{|i_1\rangle_A |i_2\rangle_{B_1} |i_3\rangle_{B_2}\}$ with $2 \geq i_1 \geq i_2 \geq i_3 \geq 0$ such that $i_2 + i_3 \geq i_1$. Hence, in order to fully define $\tilde{\rho}_{AB_1B_2}$, it suffices to write the matrix elements of $\tilde{\rho}_{AB_1B_2}$ with respect to the set $\{\ |0\rangle_A |0\rangle_{B_1} |0\rangle_{B_2}, |1\rangle_A |0\rangle_{B_1} |0\rangle_{B_2}, |1\rangle_A |1\rangle_{B_1} |1\rangle_{B_2}, |2\rangle_A |1\rangle_{B_1} |1\rangle_{B_2}\ , |2\rangle_A |2\rangle_{B_1} |0\rangle_{B_2}, |2\rangle_A |2\rangle_{B_1} |1\rangle_{B_2}\ , |2\rangle_A |2\rangle_{B_1} |2\rangle_{B_2}\ \}$. This gives rise to the following 7×7 matrix:

$$\begin{array}{c|ccccccc}
 & 0_A0_{B_1}0_{B_2} & 1_A1_{B_1}0_{B_2} & 1_A1_{B_1}1_{B_2} & 2_A1_{B_1}1_{B_2} & 2_A2_{B_1}0_{B_2} & 2_A2_{B_1}1_{B_2} & 2_A2_{B_1}2_{B_2} \\
\hline
0_A0_{B_1}0_{B_2} & 1 & \sqrt{1-\lambda} & 0 & \sqrt{2}(1-\lambda) & \frac{(1-\lambda)^2}{\lambda} & 0 & 0 \\
1_A1_{B_1}0_{B_2} & \sqrt{1-\lambda} & 1-\lambda & 0 & \sqrt{2(1-\lambda)^3} & \sqrt{\frac{(1-\lambda)^5}{\lambda^2}} & 0 & 0 \\
1_A1_{B_1}1_{B_2} & 0 & 0 & 2\lambda-1 & 0 & 0 & \frac{2\lambda-1}{\lambda}\sqrt{1-\lambda} & 0 \\
2_A1_{B_1}1_{B_2} & \sqrt{2}(1-\lambda) & \sqrt{2(1-\lambda)^3} & 0 & 2(1-\lambda)^2 & \sqrt{2}\frac{(1-\lambda)^3}{\lambda} & 0 & 0 \\
2_A2_{B_1}0_{B_2} & \frac{(1-\lambda)^2}{\lambda} & \sqrt{\frac{(1-\lambda)^5}{\lambda^2}} & 0 & \sqrt{2}\frac{(1-\lambda)^3}{\lambda} & (1-\lambda)^2 & 0 & 0 \\
2_A2_{B_1}1_{B_2} & 0 & 0 & \frac{2\lambda-1}{\lambda}\sqrt{1-\lambda} & 0 & 0 & 2(1-\lambda)(2\lambda-1) & 0 \\
2_A2_{B_1}2_{B_2} & 0 & 0 & 0 & 0 & 0 & 0 & (2\lambda-1)^2
\end{array}$$

One can show by direct calculation that this matrix is positive semi-definite if and only $\lambda \geq \frac{1}{\sqrt{2}}$. Note that the matrix is positive semi-definite if and only if $\tilde{\rho}_{AB_1B_2}$ is positive semi-definite. The latter follows from the following two simple facts: (i) A $n \times n$ symmetric matrix with a duplicate column is positive semi-definite if and only if the

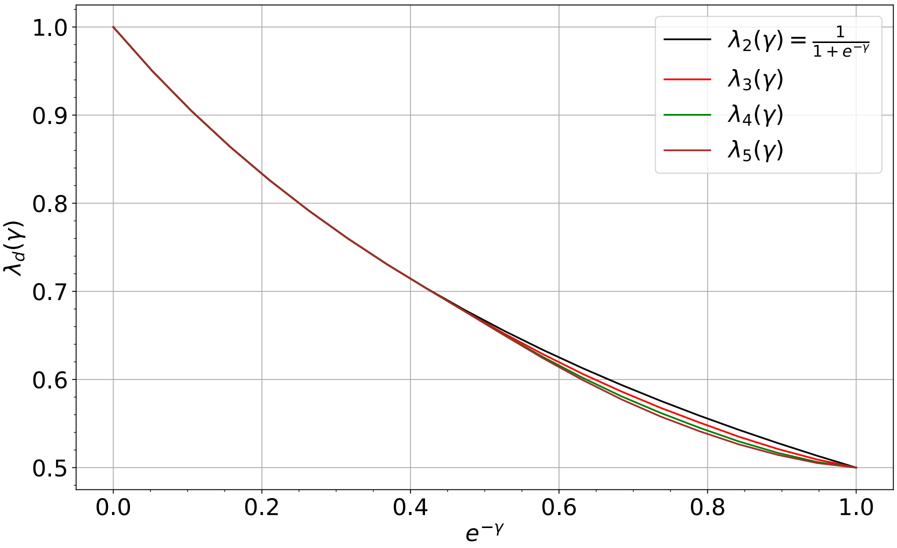

FIG. 3. Each curve indicates necessary and sufficient conditions where the qu*d*it restriction $\mathcal{N}^{(d)}_{\lambda,\gamma}$ of the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable. In the region above the curve $\lambda_5(\gamma)$, the bosonic loss-dephasing channel is never anti-degradable.

$(n-1)\times(n-1)$ matrix obtained by deleting one of the two equal column and the corresponding row is positive semi-definite, and (ii) A $n\times n$ symmetric matrix with a zero column is positive semi-definite if and only if the $(n-1)\times(n-1)$ matrix obtained by deleting such a column and the corresponding row is positive semi-definite. One can also verify $\mathrm{Tr}_{B_1}\,\tilde{\rho}_{AB_1B_2} = \mathrm{Tr}_{B_2}\,\tilde{\rho}_{AB_1B_2}$, and they are equal to the Choi state of the qutrit restriction with $\lambda = \frac{1}{1+e^{-\gamma}}$. We therefore conclude that the curve $\lambda = \frac{1}{1+e^{-\gamma}}$ provides a necessary and sufficient condition for the anti-degradability of the qutrit channel $\mathcal{N}^{(3)}_{\lambda,\gamma}$ when $\lambda \geq \frac{1}{\sqrt{2}}$, or equivalently when $e^{-\gamma} \leq \sqrt{2}-1$. □

To numerically compute the quantity $\lambda_d(\gamma)$ given in (S57), we utilise the equivalence between anti-degradability of a channel and two-extendibility of its Choi state [6]. Specifically, for small values of d, we can determine necessary and sufficient conditions for the anti-degradability of $\mathcal{N}^{(d)}_{\lambda,\gamma}$ by numerically solving the following *semi-definite program*:

$$\begin{aligned} &\min_{\rho_{AB_1B_2}} 1 \\ \text{s.t. } &\rho_{AB_1B_2} \geq 0\,, \\ &\mathrm{Tr}[\rho_{AB_1B_2}] = 1, \\ &\mathrm{Tr}_{B_2}[\rho_{AB_1B_2}] = \mathrm{id}_A \otimes \mathcal{N}^{(d)}_{\lambda,\gamma}(|\Phi_d\rangle\langle\Phi_d|_{AA'})\,, \\ &\mathrm{Tr}_{B_1}[\rho_{AB_1B_2}] = \mathrm{id}_A \otimes \mathcal{N}^{(d)}_{\lambda,\gamma}(|\Phi_d\rangle\langle\Phi_d|_{AA'})\,. \end{aligned} \tag{S61}$$

where $|\Phi_d\rangle$ is the maximally entangled state of schmidt rank d. The channel $\mathcal{N}^{(d)}_{\lambda,\gamma}$ is anti-degradable if and only if the semi-definite program admits a feasible solution. We compute the quantity $\lambda_d(\gamma)$ defined in (S57) by numerically solving the semi-definite program. The results are plotted with respect to $e^{-\gamma}$ for various values of d in Fig. 3, showcasing the dependence of $\lambda_d(\gamma)$ on γ for small values of d. Our numerical analysis reveals that when γ is sufficiently large, i.e. $e^{-\gamma} \lesssim 0.41$ or $\gamma \gtrsim 0.89$, the value of $\lambda_d(\gamma)$ consistently equals $\frac{1}{1+e^{-\gamma}}$ for all examined values of d. In particular, this seems to suggest that within this range of the dephasing parameter, $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable if and only if $\lambda \leq \frac{1}{1+e^{-\gamma}}$. Based on this numerical exploration, we propose the following conjecture:

Conjecture 37. *If γ is sufficiently large ($\gamma \gtrsim 0.89$), then the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is anti-degradable if and only if $\lambda \leq \frac{1}{1+e^{-\gamma}}$.*

Notably, from Fig. 3 we observe that if λ and γ satisfy $\lambda = \frac{1}{1+e^{-\gamma}}$ with $e^{-\gamma} \gtrsim 0.41$ (or $\gamma \lesssim 0.89$), then $\mathcal{N}_{\lambda,\gamma}$ is not anti-degradable.

III. COHERENCE PRESERVATION OF THE BOSONIC LOSS-DEPHASING CHANNEL

In this section we use the notation introduced in Section I H.

Theorem 38. *Let $\gamma \geq 0$ and $\lambda \in (0,1]$. For any energy constraint $N_s > 0$, the energy-constrained two-way quantum and secret-key capacities of the bosonic loss-dephasing channel are strictly positive, $K(\mathcal{N}_{\lambda,\gamma}, N_s) \geq Q_2(\mathcal{N}_{\lambda,\gamma}, N_s) > 0$.*

Proof. We begin by assuming $N_s \in (0,1)$ and defining the two-mode state

$$|\Psi_{N_s}\rangle_{AA'} := \sqrt{1-N_s}\,|00\rangle_{AA'} + \sqrt{N_s}\,|11\rangle_{AA'}\ , \tag{S62}$$

where the mean photon number of A' system is equal to N_s. By exploiting Lemma 22, one can observe that the state

$$\rho_{AB} := \mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}(|\Psi_{N_s}\rangle\!\langle\Psi_{N_s}|_{AA'}) \tag{S63}$$

is effectively a two-qubit state and its matrix with respect to the computational basis $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$ is given by:

$$\rho_{AB} = \begin{pmatrix} 1-N_s & 0 & 0 & \sqrt{(1-N_s)N_s e^{-\gamma}\lambda} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & (1-\lambda)N_s & 0 \\ \sqrt{(1-N_s)N_s e^{-\gamma}\lambda} & 0 & 0 & \lambda N_s \end{pmatrix}.$$

If we perform partial transpose with respect to the system B, we find the matrix

$$(\rho_{AB})^{\intercal_B} = \begin{pmatrix} 1-N_s & 0 & 0 & 0 \\ 0 & 0 & \sqrt{(1-N_s)N_s e^{-\gamma}\lambda} & 0 \\ 0 & \sqrt{(1-N_s)N_s e^{-\gamma}\lambda} & (1-\lambda)N_s & 0 \\ 0 & 0 & 0 & \lambda N_s \end{pmatrix},$$

whose eigenvalues are not all positive, i.e. the state ρ_{AB} is not PPT [28]. By exploiting the fact that any two-qubit state is distillable if and only if it is not PPT [28], it follows that $E_d\left(\mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}(|\Psi_{N_s}\rangle\!\langle\Psi_{N_s}|_{AA'})\right) > 0$, where E_d is the distillable entanglement. On the other hand, from Lemma 26 we have that

$$K(\mathcal{N}_{\lambda,\gamma}, N_s) \geq Q_2(\mathcal{N}_{\lambda,\gamma}, N_s) \geq E_d\big(\mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}(|\Psi_{N_s}\rangle\!\langle\Psi_{N_s}|_{AA'})\big)\ . \tag{S64}$$

This concludes the proof for $N_s \in (0,1)$. Since the energy-constrained capacities are monotonically non-decreasing in the energy constraint N_s, the proof follows for any $N_s > 0$. □

Since the state $\mathrm{id}_A \otimes \mathcal{N}_{\lambda,\gamma}(|\Psi_{N_s}\rangle\!\langle\Psi_{N_s}|_{AA'})$ in (S63) is always entangled, it follows that the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is never entanglement breaking [2]. We state this formally in the following theorem.

Theorem 39. *For all $\gamma \geq 0$ and all $\lambda \in (0,1]$, the bosonic loss-dephasing channel $\mathcal{N}_{\lambda,\gamma}$ is not entanglement breaking.*

In the following subsection we will find an explicit strictly positive lower bound on the two-way capacities of the bosonic loss-dephasing channel.

A. Multi-rail multi-photon encoding

Let $\Pi(N,k)$ be the set of partitions of N objects into k (possibly empty) parts. It is well known that $|\Pi(N,k)| = \binom{N+k-1}{k-1} = \binom{N+k-1}{N}$. Clearly, we can think of each $p \in \Pi(N,k)$ as a vector in $\mathbb{N}_+^k$, also denoted by p, with the constraint that $\sum_{\ell=1}^{k} p_\ell = N$. For each $p \in \Pi(N,k)$, define the associate k-mode Fock state as

$$\left|\psi_p\right\rangle := |p_1\rangle \dots |p_k\rangle\ . \tag{S65}$$

Note that for $p, q \in \Pi(N,k)$, we have that $\langle \psi_p | \psi_q \rangle = \delta_{p,q}$. Let us call

$$P_{N,k} := \sum_{p\in\Pi(N,k)} \psi_p \tag{S66}$$

the projector onto the k-mode subspace of total photon number N. Note that the bosonic dephasing channel satisfies that

$$\mathcal{D}_\gamma^{\otimes k}\left(|\psi_p\rangle\!\langle\psi_q|\right) = e^{-\frac{\gamma}{2}\sum_\ell (p_\ell - q_\ell)^2} |\psi_p\rangle\!\langle\psi_q| = e^{-\frac{\gamma}{2}\|p-q\|^2} |\psi_p\rangle\!\langle\psi_q| = (K_{N,k,\gamma})_{pq} |\psi_p\rangle\!\langle\psi_q| \,, \tag{S67}$$

where $K_{N,k,\gamma}$ is the $\binom{N+k-1}{N} \times \binom{N+k-1}{N}$ matrix with entries

$$(K_{N,k,\gamma})_{pq} := e^{-\frac{\gamma}{2}\|p-q\|^2}. \tag{S68}$$

For any $\binom{N+k-1}{N}$-dimensional state σ, let us denote as $\overline{\sigma}$ the following isometrically equivalent state

$$\overline{\sigma} := \sum_{p,q\in\Pi(N,k)} \sigma_{pq} |\psi_p\rangle\!\langle\psi_q| \,. \tag{S69}$$

The state $\overline{\sigma}$, which is termed as the *rail encoding* of σ, is supported on the subspace of k modes with total photon number equal to N. Now, let ρ be a $\binom{N+k-1}{N}$-dimensional state and let us calculate the output of $\mathcal{D}_\gamma^{\otimes k}$ when the input is $\overline{\rho}$:

$$\mathcal{D}_\gamma^{\otimes k}(\overline{\rho}) = \sum_{p,q\in\Pi(N,k)} \rho_{pq}(K_{N,k,\gamma})_{pq} |\psi_p\rangle\!\langle\psi_q| = \overline{K_{N,k,\gamma} \circ \rho} = \overline{\Theta_{N,k,\gamma}(\rho)} \,, \tag{S70}$$

where the operation $\circ$ denotes the element-wise product between matrices and where we have introduced the following Hadamard channel:

$$\Theta_{N,k,\gamma}(X) := K_{N,k,\gamma} \circ X \,, \tag{S71}$$

Since $\mathcal{D}_\gamma^{\otimes k}$ is a (completely) positive map, this in particular shows that $K_{N,k,\gamma} \geq 0$. (This latter statement can also be proved directly with techniques similar to that in the proof of [29, Lemma 15].) In practice, the k-fold application of the bosonic dephasing channel on the k-mode N-photon code space behaves as a new Hadamard channel $\Theta_{N,k,\gamma}$ with associated matrix $K_{N,k,\gamma}$.

Lower bound on the two-way capacity of the bosonic loss-dephasing channel

Since under the action of $\mathcal{N}_{\lambda,\gamma}$ photons can only be lost and never added, and each photon has a probability λ of being transmitted, the probability that an N-photon state will retain N photons at the output of the channel is exactly λ^N. *If that happens*, then the state in the code space is effectively left untouched by the loss and only dephased under the action of the Hadamard channel $\Theta_{N,k,\gamma}$.

More formally, from the Kraus representation

$$\mathcal{E}_\lambda(X) = \sum_{n=0}^{\infty} \frac{1}{n!}(1-\lambda)^n \lambda^{\frac{a^\dagger a}{2}} a^n X (a^\dagger)^n \lambda^{\frac{a^\dagger a}{2}} \tag{S72}$$

it is easy to deduce the handy identity

$$\mathcal{E}_\lambda^{\otimes k}(\overline{\rho}) = \lambda^N \overline{\rho} + \left(1 - \lambda^N\right) \delta_{N,k,\lambda} \,, \tag{S73}$$

valid for all $\binom{N+k-1}{N}$-dimensional states ρ, with the notation of (S69). Here, $\delta_{N,k,\lambda}$ is a suitable k-mode state supported on the subspace of total photon number at most $N-1$, and thus $\overline{\rho}\delta_{N,k,\lambda} = \delta_{N,k,\lambda}\overline{\rho} = 0$. In turn, the above identity implies that

$$\mathcal{N}_{\lambda,\gamma}^{\otimes k}(\overline{\rho}) = \lambda^N\, \overline{K_{N,k,\gamma} \circ \rho} + \left(1 - \lambda^N\right) \delta'_{N,k,\lambda,\gamma} = \lambda^N\, \overline{\Theta_{N,k,\gamma}(\rho)} + \left(1 - \lambda^N\right) \delta'_{N,k,\lambda,\gamma} \,, \tag{S74}$$

where once again $\delta'_{N,k,\lambda,\gamma}$ is a suitable k-mode state supported on the subspace of total photon number at most $N-1$.

Therefore, we can use the channel $\mathcal{N}_{\lambda,\gamma}^{\otimes k}$ to simulate $\Theta_{N,k,\gamma}$ *probabilistically*, with probability λ^N. The simulation works as follows:

(i) The input state ρ is encoded in the k-mode N-photon subspace according to the mapping $\rho \mapsto \overline{\rho}$.

(ii) The k-mode state $\overline{\rho}$ is sent across $\mathcal{N}_{\lambda,\gamma}^{\otimes k}$, via k uses of the bosonic loss-dephasing channel.

(iii) The total photon number is measured at the output. If N photons are found then the simulation is successful, otherwise the protocol is aborted.

A wealth of operational resource inequalities can be deduced from the above considerations. Here we limit ourselves to the observation that the two-way quantum capacity must satisfy

$$Q_2(\mathcal{N}_{\lambda,\gamma}) \overset{\text{(i)}}{\geq} \frac{\lambda^N}{k}\, Q_2(\Theta_{N,k,\gamma})\,. \tag{S75}$$

Consequently, it holds that

$$\begin{aligned} Q_2(\mathcal{N}_{\lambda,\gamma}) &\geq \frac{\lambda^N}{k}\, Q_2(\Theta_{N,k,\gamma}) \\ &\overset{\text{(i)}}{\geq} \frac{\lambda^N}{k}\, I_{\text{coh}}\left(\text{id}\otimes\Theta_{N,k,\gamma}(|\Psi\rangle\!\langle\Psi|)\right) \\ &\overset{\text{(iii)}}{=} \frac{\lambda^N}{k}\left[\log_2\binom{N+k-1}{N} - S\left(\binom{N+k-1}{N}^{-1} K_{N,k,\gamma}\right)\right]. \end{aligned} \tag{S76}$$

Here, in (ii), we used the fact that the two-way quantum capacity of a channel can be lower bounded in terms of the coherent information [2, 4] and we introduced the two-qu$d$it maximally entangled state $|\Psi\rangle$ of dimension $d = \binom{N+k-1}{N}$. In (iii), we used the definition of coherent information $I_{\text{coh}}(\rho_{AB}) := S(\rho_B) - S(\rho_{AB})$, with $S(\cdot)$ being the von Neumann entropy, and the fact that

$$\begin{aligned} \text{id}\otimes\Theta_{N,k,\gamma}(|\Psi\rangle\!\langle\Psi|) &= \frac{1}{\binom{N+k-1}{N}} \sum_{p,q\in\Pi(N,k)} |p\rangle\!\langle q| \otimes \Theta_{N,k,\gamma}(|p\rangle\!\langle q|) \\ &= \frac{1}{\binom{N+k-1}{N}} \sum_{p,q\in\Pi(N,k)} (K_{N,k,\gamma})_{pq}\, |p\rangle\!\langle q| \otimes |p\rangle\!\langle q|\ , \end{aligned} \tag{S77}$$

which implies that the spectrum of $\text{id}\otimes\Theta_{N,k,\gamma}(|\Psi\rangle\!\langle\Psi|)$ coincides with the spectrum of the matrix $\binom{N+k-1}{N}^{-1} K_{N,k,\gamma}$. Consequently, we have that

$$Q_2(\mathcal{N}_{\lambda,\gamma}) \geq \max_{N,k\in\mathbb{N}_+} \frac{\lambda^N}{k}\left[\log_2\binom{N+k-1}{N} - S\left(\binom{N+k-1}{N}^{-1} K_{N,k,\gamma}\right)\right]. \tag{S78}$$

One can obtain a lower bound on the energy-constrained two-way quantum capacity $Q_2(\mathcal{N}_{\lambda,\gamma}, N_s)$ by restricting the optimisation to the values of N and k such that $\frac{N}{k} \leq N_s$. Indeed, note that the rail-encoded state $\bar{\rho}$ satisfies the energy constraint as its mean photon number per mode is $\frac{N}{k}$. In formula, we have that

$$Q_2(\mathcal{N}_{\lambda,\gamma}, N_s) \geq \max_{N,k\in\mathbb{N}_+:\ \frac{N}{k}\leq N_s} \frac{\lambda^N}{k}\left[\log_2\binom{N+k-1}{N} - S\left(\binom{N+k-1}{N}^{-1} K_{N,k,\gamma}\right)\right]. \tag{S79}$$

Note that $\log_2\binom{N+k-1}{N} - S\left(\binom{N+k-1}{N}^{-1} K_{N,k,\gamma}\right)$ is always positive because $\binom{N+k-1}{N}^{-1} K_{N,k,\gamma}$ is a $\binom{N+k-1}{N}$-dimensional, non-maximally mixed, state and thus its von Neumann entropy is strictly smaller than by $\log_2\binom{N+k-1}{N}$. Consequently, we have the following theorem.

Theorem 40. *Let $\gamma \geq 0$ and $\lambda \in (0,1]$. For any energy constraint $N_s > 0$, the energy-constrained two-way quantum and secret-key capacities of the bosonic loss-dephasing channel are lower bounded by*

$$K(\mathcal{N}_{\lambda,\gamma}, N_s) \geq Q_2(\mathcal{N}_{\lambda,\gamma}, N_s) \geq \max_{\substack{N,k\in\mathbb{N}_+ \\ \frac{N}{k}\leq N_s}} \frac{\lambda^N}{k}\left[\log_2\binom{N+k-1}{N} - S\left(\rho_{N,k,\gamma}\right)\right] > 0\,. \tag{S80}$$

Here, $S(\cdot)$ is the von Neumann entropy, $\rho_{N,k,\gamma}$ is a $\binom{N+k-1}{N}$-dimensional state defined by

$$\rho_{N,k,\gamma} := \binom{N+k-1}{N}^{-1} \sum_{p,q\in\Pi(N,k)} e^{-\frac{\gamma}{2}\|p-q\|_2^2} |p\rangle\!\langle q| \, , \tag{S81}$$

where $\Pi(N,k) := \left\{p \in \mathbb{N}^k : \sum_{i=1}^k p_i = N\right\}$ represents the set of partitions of a set of N elements into k parts, and the vectors $\{|p\rangle\}_{p\in\Pi(N,k)}$ are orthonormal. In particular,

$$K(\mathcal{N}_{\lambda,\gamma}, N_s) \geq Q_2(\mathcal{N}_{\lambda,\gamma}, N_s) > \max_{N,k\in\mathbb{N}_+} \frac{\lambda^N}{k}\left[\log_2\binom{N+k-1}{N} - S\left(\rho_{N,k,\gamma}\right)\right] > 0\, . \tag{S82}$$

IV. APPENDIX

A. Hadamard maps

Given an infinite matrix $A = (a_{mn})_{m,n\in\mathbb{N}}, a_{mn} \in \mathbb{C}$, we can introduce a superoperator H, recognised as the *Hadamard map*, whose action is defined as $H(|m\rangle\!\langle n|) = a_{n,m}\, |m\rangle\!\langle n|$ for all $n, m \in \mathbb{N}$. We are interested in establishing requirements for an infinite matrix A to ensure that the associated Hadamard map H is a quantum channel. We begin with some preliminaries. Let $\ell^2(\mathbb{N})$ be the space of square-summable complex-valued sequences defined as

$$\ell^2(\mathbb{N}) := \left\{ x := \{x_n\}_{n\in\mathbb{N}}, x_n \in \mathbb{C} : \|x\| := \sqrt{\sum_{n=0}^{\infty} |x_n|^2} < \infty \right\}\, . \tag{S83}$$

An infinite matrix $A := (a_{mn})_{m,n\in\mathbb{N}}, a_{mn} \in \mathbb{C}$ defines a linear operator on $\ell^2(\mathbb{N})$. The operator norm of A is defined as follows:

$$\|A\|_\infty := \sup_{\substack{x\in\ell^2(\mathbb{N})\\ \|x\|=1}} \|Ax\| = \sup_{\substack{\{x_n\}_{n\in\mathbb{N}}, x_n\in\mathbb{C}\\ \sum_{n=0}^\infty |x_n|^2=1}} \sqrt{\sum_{m=0}^{\infty}\left|\sum_{n=0}^{\infty} a_{mn}x_n\right|^2}\, .$$

A is said to be bounded if $\|A\|_\infty < \infty$. The following lemma, referred to as *Schur test*, gives a sufficent condition for an infinite matrix to be bounded (e.g. [30, Page 24, Problem 45]).

Lemma 41. *Let $A := (a_{mn})_{m,n\in\mathbb{N}}, a_{mn} \in \mathbb{C}$, be an infinite matrix. Suppose that there exist $\{p_n\}_{n\in\mathbb{N}}, p_n \in \mathbb{R}_{>0}$ and $\{q_m\}_{m\in\mathbb{N}}, q_m \in \mathbb{R}_{>0}$, and $\beta > 0$, and $\gamma > 0$ such that*

$$\sum_{m=0}^{\infty} |a_{mn}|p_m \leq \beta q_n \quad \text{and} \quad \sum_{n=0}^{\infty} |a_{mn}|q_n \leq \gamma p_m\, , \quad \forall\, m, n \in \mathbb{N}\, .$$

Then the matrix A satisfies $\|A\|_\infty \leq \beta\gamma$. In particular, A is bounded.

By choosing $p_n = q_n = 1$ and $\gamma = \beta = \sup_{n\in\mathbb{N}} \sum_{m=0}^\infty |a_{mn}|$, we obtain the following corollary:

Corollary 42. *Let $A = (a_{mn})_{m,n\in\mathbb{N}}, a_{mn} \in \mathbb{C}$, be an infinite Hermitian matrix. If $\sup_{n\in\mathbb{N}} \sum_{m=0}^\infty |a_{mn}|$ is finite, then A is bounded.*

Lemma 43. *Let $A = (a_{mn})_{m,n\in\mathbb{N}}, a_{mn} \in \mathbb{C}$, be a bounded Hermitian infinite matrix. Then A is positive semi-definite as an operator on $\ell^2(\mathbb{N})$ if and only if $A^{(d)} := (a_{mn})_{m,n=0,1,\ldots,d-1}$ is positive semi-definite for all $d \in \mathbb{N}$, where $A^{(d)}$ is the $d \times d$ top left corner of A.*

Proof. Assume that $A^{(d)}$ is positive semi-definite for all $d \in \mathbb{N}$. Let us pick an arbitrary $x \in \ell^2(\mathbb{N})$. It is known that for any $\varepsilon > 0$, there exists $d \in \mathbb{N}$ and $y^{(d)} := (y_n^{(d)})_{n\in\mathbb{N}}, y_n^{(d)} \in \mathbb{C}$, with $y_n^{(d)} = 0$ for all $n > d$, such that $\|x - y^{(d)}\| < \varepsilon$. Note that

$$\begin{aligned} x^\dagger A x &= \left(x - y^{(d)}\right)^\dagger A\, x + \left(y^{(d)}\right)^\dagger A\,(x - y^{(d)}) + \left(y^{(d)}\right)^\dagger A y^{(d)} \\ &\overset{\text{(i)}}{\geq} -\|x - y^{(d)}\|\, \|A\|_\infty \left(\|x\| + \|y^{(d)}\|\right) + \left(y^{(d)}\right)^\dagger A^{(d)}\, y^{(d)} \\ &\overset{\text{(ii)}}{\geq} -\varepsilon\, \|A\|_\infty\, (2\|x\| + \varepsilon)\ , \end{aligned}$$

where in (i) we applied Cauchy-Schwarz inequality twice and the definition of infinity norm as follows

$$|(x-y^{(d)})^{\dagger}A\,x| \leq \|x-y^{(d)}\|\|A\,x\| \leq \|x-y^{(d)}\|\|A\|_{\infty}\|x\|\,,$$
$$|(y^{(d)})^{\dagger}A\,(x-y^{(d)})| \leq \|y^{(d)}\|\|A\,(x-y^{(d)})\| \leq \|y^{(d)}\|\|A\|_{\infty}\|x-y^{(d)}\|\,,$$

and, in (ii), we exploited triangular inequality to derive

$$\|y^{(d)}\| \leq \|y^{(d)}-x\| + \|x\| \leq \varepsilon + \|x\|\,, \tag{S84}$$

together with the fact that $A^{(d)}$ is positive semi-definite. Hence, since $\varepsilon > 0$ is arbitrary, we conclude that $x^{\dagger}Ax \geq 0$, meaning that A is positive semi-definite as an operator on $\ell^2(\mathbb{N})$. □

A square matrix is said to be diagonally dominant if

$$\sum_{m\neq n} |a_{mn}| \leq |a_{nn}|, \quad \forall n.$$

In words, a square matrix is said to be diagonally dominant if for every row of the matrix, the absolute value of the diagonal entry in a row is larger than or equal to the sum of the absolute values of all the other (non-diagonal) entries in that row. Note that for Hermitian matrices one can exchange row with column in this definition. We proceed to state a sufficient condition for a matrix A to be positive semi-definite as an operator on $\ell^2(\mathbb{N})$. While the following sufficient condition is usually stated for finite matrices, it can be generalised to infinite matrices as per Lemma 43.

Lemma 44. *[31, Chapter 6] For any $d \in \mathbb{N}$, let $A = (a_{mn})_{m,n=0,1,\ldots,d-1}, a_{mn} \in \mathbb{C}$, be a $d \times d$ Hermitian matrix with $a_{nn} \in \mathbb{R}_{\geq 0}$ for all $n \in \{0,\ldots,d-1\}$. A is positive semi-definite if it is diagonally dominant.*

Lemma 45. *Let $A = (a_{mn})_{m,n\in\mathbb{N}}, a_{mn} \in \mathbb{C}$ be an infinite Hermitian matrix with $a_{nn} \in \mathbb{R}_{\geq 0}, \forall n \in \mathbb{N}$. Assume that $\sup_{n\in\mathbb{N}} a_{nn}$ is finite and that A is diagonally dominant. Then A is bounded and positive semi-definite when seen as an operator on $\ell^2(\mathbb{N})$.*

Proof. Since

$$\sup_{n\in\mathbb{N}} \sum_{m=0}^{\infty} |a_{mn}| \leq 2 \sup_{n\in\mathbb{N}} a_{n,n} < \infty\,,$$

Corollary 42 implies that A is bounded. The fact that A is positive semi-definite as an operator on $\ell^2(\mathbb{N})$ follows from Lemma 44 together with Lemma 43. □

We now present a lemma from the literature that establishes necessary and sufficient conditions for an infinite matrix A to ensure that the associated Hadamard map H is a quantum channel. We then use it to derive an explicit sufficient condition for an infinite matrix A to give rise to a cptp Hadamard map.

Lemma 46. *[18, Lemma S4] Let $A := (a_{mn})_{m,n\in\mathbb{N}}, a_{mn} \in \mathbb{C}$ be a bounded infinite matrix. The following requirements establish the necessary and sufficient conditions for the associated Hadamard map H to qualify as a quantum channel:*

(i) $a_{nn} = 1$, $\forall n \in \mathbb{N}$;

(ii) A is positive semi-definite as on operator on $\ell^2(\mathbb{N})$.

As a consequence of Lemma 46 and Lemma 45, we obtain:

Lemma 47. *Let $A := (a_{mn})_{m,n\in\mathbb{N}}$ be an infinite Hermitian matrix that is diagonally dominant with $a_{n,n} = 1$ for all $n \in \mathbb{N}$. In this case, its associated Hadamard map H is a quantum channel.*

B. Miscellaneous Lemmas

Lemma 48. *Let $\mathcal{H}_A$ and $\mathcal{H}_B$ be two Hilbert spaces and let $\mathcal{N} : \mathcal{T}(\mathcal{H}_A) \to \mathcal{T}(\mathcal{H}_B)$ be a quantum channel. For all normalised states $|\psi_1\rangle, |\psi_2\rangle \in \mathcal{H}_A$ and $|\phi_1\rangle, |\phi_2\rangle \in \mathcal{H}_B$ it holds that*

$$\left|\langle\phi_1|\mathcal{N}(|\psi_1\rangle\!\langle\psi_2|)\,|\phi_2\rangle\right| \leq 1\,. \tag{S85}$$

Proof. It holds that

$$\begin{aligned} \left|\langle\phi_1\right|\mathcal{N}(|\psi_1\rangle\!\langle\psi_2|)\left|\phi_2\rangle\right| &\overset{\text{(i)}}{\le} \|\mathcal{N}(|\psi_1\rangle\!\langle\psi_2|)\|_\infty \\ &\overset{\text{(ii)}}{\le} \|\mathcal{N}(|\psi_1\rangle\!\langle\psi_2|)\|_1 \\ &\overset{\text{(iii)}}{\le} \|\,|\psi_1\rangle\!\langle\psi_2|\,\|_1 \\ &= 1\,. \end{aligned} \tag{S86}$$

Here, in (i), we exploited one of the definition of the operator norm in (S2). In (ii), we exploited that the trace norm is always an upper bound on the operator norm. Finally, in (iii), we leveraged the monotonicity of the trace norm under quantum channels [1]. □

Lemma 49 [10, 11]. *Let $\mathcal{H}_A, \mathcal{H}_{A'}$ be isomorphic Hilbert spaces, possibly infinite dimensional. Let $|\psi\rangle_{A'A}$ be a pure state that satisfies $\mathrm{Tr}_{A'}\left[|\psi\rangle\!\langle\psi|_{AA'}\right] > 0$. The generalised Choi–Jamiołkowski matrix defines an isomorphism between the set of quantum channels from $\mathcal{H}_{A'}$ to $\mathcal{H}_B$ and the set of bipartite states $\sigma_{AB} \in \mathcal{P}(\mathcal{H}_{AB})$ such that $\mathrm{Tr}_B\,\sigma_{AB} = \mathrm{Tr}_{A'}\left[|\psi\rangle\!\langle\psi|_{AA'}\right]$. Specifically, for any quantum channel $\mathcal{N}_{A'\to B} : \mathcal{T}(\mathcal{H}_{A'}) \to \mathcal{T}(\mathcal{H}_B)$, it holds that*

$$\mathcal{N}_{A'\to B}(|e_i\rangle\!\langle e_j|) = \frac{1}{\sqrt{\lambda_i\lambda_j}}\,\mathrm{Tr}_A\left[\left(|e_j\rangle\!\langle e_i|_A \otimes \mathbb{1}_B\right)\sigma_{AB}\right], \quad \forall\, i,j \in \mathbb{N}, \tag{S87}$$

where $(|e_i\rangle)_{i\in\mathbb{N}}$ and $(\lambda_i)_{i\in\mathbb{N}}$ form a spectral decomposition of $\mathrm{Tr}_{A'}\left[|\psi\rangle\!\langle\psi|_{AA'}\right]$, i.e. $\mathrm{Tr}_{A'}\left[|\psi\rangle\!\langle\psi|_{AA'}\right] = \sum_i \lambda_i\,|e_i\rangle\!\langle e_i|_A$, and where the state $\sigma_{AB} := \mathrm{id}_A \otimes \mathcal{N}_{A'\to B}(|\psi\rangle\!\langle\psi|_{AA'})$ is called the generalised Choi state of $\mathcal{N}$. Eq. S87 is enough to specify the channel $\mathcal{N}_{A'\to B}$ completely, as the linear span of the operators $\left(|e_i\rangle\!\langle e_j|\right)_{i,j\in\mathbb{N}}$ (i.e. the set of finite-rank operators) is dense in $\mathcal{T}(\mathcal{H}_{A'})$.

Lemma 50 [6]. *Let $\mathcal{H}_A, \mathcal{H}_{A'}, \mathcal{H}_B$ be isomorphic Hilbert spaces, possibly infinite dimensional. Let $\mathcal{N}_{A'\to B} : \mathcal{T}(\mathcal{H}_{A'}) \to \mathcal{T}(\mathcal{H}_B)$ be a quantum channel. Let $|\psi\rangle_{A'A} \in \mathcal{H}_A \otimes \mathcal{H}_{A'}$ be a pure state such that the reduced state $\mathrm{Tr}_{A'}[|\psi\rangle\!\langle\psi|_{AA'}]$ is positive definite. Then, $\mathcal{N}_{A'\to B}$ is anti-degradable if and only if the state $\mathrm{id}_A \otimes \mathcal{N}_{A'\to B}(|\psi\rangle\!\langle\psi|_{AA'})$ is two-extendible on B, meaning that there exists a state $\rho_{AB_1B_2} \in \mathcal{P}(\mathcal{H}_A \otimes \mathcal{H}_{B_1} \otimes \mathcal{H}_{B_2})$ such that*

$$\begin{aligned} \mathrm{Tr}_{B_2}\left[\rho_{AB_1B_2}\right] &= \mathrm{id}_A \otimes \mathcal{N}_{A'\to B_1}(|\psi\rangle\!\langle\psi|_{AA'})\,, \\ \mathrm{Tr}_{B_1}\left[\rho_{AB_1B_2}\right] &= \mathrm{id}_A \otimes \mathcal{N}_{A'\to B_2}(|\psi\rangle\!\langle\psi|_{AA'}), \end{aligned} \tag{S88}$$

where $\mathcal{H}_{B_1}$ and $\mathcal{H}_{B_2}$ are Hilbert spaces that are isomorphic to $\mathcal{H}_B$.

Proof. Let $U_{A'E\to BE}$ be a Stinespring dilation of the channel $\mathcal{N}_{A'\to B}$. Further assume that $\mathcal{N}_{A'\to B}$ is anti-degradable. By definition, there exists a quantum channel $\mathcal{A}_{E\to B}$ such that $\mathcal{A}_{E\to B} \circ \mathcal{N}^{\mathrm{c}}_{A'\to B} = \mathcal{N}_{A'\to B}$. Let us consider the tripartite state $\rho_{AB_1B_2}$, with B_1, B_2 being copies of B, defined as

$$\rho_{AB_1B_2} = \mathrm{id}_A \otimes \mathrm{id}_{B_1} \otimes \mathcal{A}_{E\to B_2}\left(U_{A'E\to B_1E}\left(\,|\psi\rangle\!\langle\psi|_{AA'} \otimes |0\rangle\!\langle 0|_E\,\right)U^\dagger_{A'E\to B_1E}\right)\,. \tag{S89}$$

It holds that

$$\begin{aligned} \mathrm{Tr}_{B_2}\left[\rho_{AB_1B_2}\right] &= \mathrm{Tr}_{B_2}\left[\mathrm{id}_A \otimes \mathrm{id}_{B_1} \otimes \mathcal{A}_{E\to B_2}\left(U_{A'E\to B_1E}\left(\,|\psi\rangle\!\langle\psi|_{AA'} \otimes |0\rangle\!\langle 0|_E\,\right)U^\dagger_{A'E\to B_1E}\right)\right] \\ &= \mathrm{id}_A \otimes \mathrm{Tr}_E\left[U_{A'E\to B_1E}\left(\,|\psi\rangle\!\langle\psi|_{AA'} \otimes |0\rangle\!\langle 0|_E\,\right)U^\dagger_{A'E\to B_1E}\right] \\ &= \mathrm{id}_A \otimes \mathcal{N}_{A'\to B_1}\left(|\psi\rangle\!\langle\psi|_{AA'}\right)\,, \end{aligned}$$

and

$$\begin{aligned} \mathrm{Tr}_{B_1}\left[\rho_{AB_1B_2}\right] &= \mathrm{Tr}_{B_1}\left[\mathrm{id}_A \otimes \mathrm{id}_{B_1} \otimes \mathcal{A}_{E\to B_2}\left(U_{A'E\to B_1E}\left(\,|\psi\rangle\!\langle\psi|_{AA'} \otimes |0\rangle\!\langle 0|_E\,\right)U^\dagger_{A'E\to B_1E}\right)\right] \\ &= \mathrm{id}_A \otimes \mathcal{A}_{E\to B_2}\left(\mathrm{Tr}_{B_1}\left[U_{A'E\to B_1E}\left(\,|\psi\rangle\!\langle\psi|_{AA'} \otimes |0\rangle\!\langle 0|_E\,\right)U^\dagger_{A'E\to B_1E}\right]\right) \\ &= \mathrm{id}_A \otimes \mathcal{A}_{E\to B_2} \circ \mathcal{N}^{\mathrm{c}}_{A'\to B_2}\left(|\psi\rangle\!\langle\psi|_{AA'}\right) \\ &= \mathrm{id}_A \otimes \mathcal{N}_{A'\to B_2}\left(|\psi\rangle\!\langle\psi|_{AA'}\right)\,. \end{aligned}$$

Now, let us establish the converse. Assume that there exists $\rho_{AB_1B_2}$ which satisfies (S88). Let $|\Psi\rangle_{AB_1B_2P} \in \mathcal{H}_A \otimes \mathcal{H}_{B_1} \otimes \mathcal{H}_{B_2} \otimes \mathcal{H}_P$ be a purification of $\rho_{AB_1B_2}$, with $\mathcal{H}_P$ being the purifying Hilbert space. Note that both $|\Psi\rangle_{AB_1B_2P}$ and $U_{A'E\to B_1E}\left(|\psi\rangle_{AA'} \otimes |0\rangle_E\right)$ are purifications of $\mathrm{id}_A \otimes \mathcal{N}_{A'\to B_1}\left(|\psi\rangle\langle\psi|_{AA'}\right)$, with $\mathcal{H}_{B_2} \otimes \mathcal{H}_P$ and $\mathcal{H}_E$ being their purifying Hilbert spaces, respectively. It follows that [1] there exists an isometry $V_{E\to B_2P} : \mathcal{H}_E \to \mathcal{H}_{B_2} \otimes \mathcal{H}_P$ such that $V_{E\to B_2P}\, U_{A'E\to B_1E}\left(|\psi\rangle_{AA'} \otimes |0\rangle_E\right) = |\Psi\rangle_{AB_1B_2P}$. Hence, the quantum channel $\mathcal{A}_{E\to B_2} : \mathcal{T}(\mathcal{H}_E) \to \mathcal{T}(\mathcal{H}_{B_2})$, defined by $\mathcal{A}_{E\to B_2}(\cdot) = \mathrm{Tr}_P\left[V_{E\to B_2P}(\cdot)V^\dagger_{E\to B_2P}\right]$, satisfies that

$$\begin{aligned}\mathrm{id}_A \otimes \mathcal{A}_{E\to B_2} \circ \mathcal{N}^{\mathrm{c}}_{A'\to B_2}(|\psi\rangle\langle\psi|_{AA'}) &= \mathrm{id}_A \otimes \mathcal{A}_{E\to B_2}\left(\mathrm{Tr}_{B_1}\left[U_{A'E\to B_1E}(|\psi\rangle\langle\psi|_{AA'} \otimes |0\rangle\langle 0|_E)U^\dagger_{A'E\to B_1E}\right]\right)\\ &= \mathrm{Tr}_{B_1P}\left[|\Psi\rangle\langle\Psi|_{AB_1B_2P}\right]\\ &= \mathrm{Tr}_{B_1}\left[\rho_{AB_1B_2}\right]\\ &= \mathrm{id}_A \otimes \mathcal{N}_{A'\to B_2}\left(|\psi\rangle\langle\psi|_{AA'}\right)\,.\end{aligned}$$

Consequently, since the pure state $|\psi\rangle_{A'A}$ satisfies $\mathrm{Tr}_{A'}\left[|\psi\rangle\langle\psi|_{AA'}\right] > 0$, Lemma 49 implies that $\mathcal{A}_{E\to B_2} \circ \mathcal{N}^{\mathrm{c}}_{A'\to B_2} = \mathcal{N}_{A'\to B_2}$, meaning that $\mathcal{N}_{A'\to B_2}$ is anti-degradable. □

Lemma 51. *Let $\mathcal{N}, \mathcal{M} : \mathcal{T}(\mathcal{H}_S) \to \mathcal{T}(\mathcal{H}_S)$ be quantum channels. If either $\mathcal{M}$ or $\mathcal{N}$ is anti-degradable, then the composition $\mathcal{M} \circ \mathcal{N}$ is anti-degradable. Specifically, let E_1 and E_2 be the Stinespring environments of $\mathcal{N}$ and $\mathcal{M}$, respectively. If $\mathcal{N}$ is anti-degradable with anti-degrading map $\mathcal{A}_{E_1\to S}$, then $(\mathcal{M} \circ \mathcal{A}_{E_1\to S}) \otimes \mathrm{Tr}_{E_2}$ is an anti-degrading map of $\mathcal{M} \circ \mathcal{N}$. Analogously, if $\mathcal{M}$ is anti-degradable with anti-degrading map $\mathcal{A}_{E_2\to S}$, then $\mathrm{Tr}_{E_1} \otimes \mathcal{A}_{E_2\to S}$ is an anti-degrading map of $\mathcal{M} \circ \mathcal{N}$.*

Proof. Let $V^{S\to SE_1}$ and $W^{S\to SE_2}$ be Stinespring isometries associated with $\mathcal{N}$ and $\mathcal{M}$, respectively. By considering the following complementary channel of $\mathcal{M} \circ \mathcal{N}$,

$$(\mathcal{M} \circ \mathcal{N})^{\mathrm{c}}(\rho) = \mathrm{Tr}_S\left[W^{S\to SE_2}V^{S\to SE_1}\,\rho\,\left(V^{S\to SE_1}\right)^\dagger\left(W^{S\to SE_2}\right)^\dagger\right], \qquad \forall\,\rho \in \mathcal{T}(\mathcal{H}_S)\,,$$

one can easily check that if $\mathcal{N}$ is anti-degradable with anti-degrading map $\mathcal{A}_{E_1\to S}$, then

$$[(\mathcal{M} \circ \mathcal{A}_{E_1\to S}) \otimes \mathrm{Tr}_{E_2}] \circ (\mathcal{M} \circ \mathcal{N})^{\mathrm{c}} = \mathcal{M} \circ \mathcal{N}\,. \tag{S90}$$

Analogously, one can easily verify that if $\mathcal{M}$ is anti-degradable with anti-degrading map $\mathcal{A}_{E_2\to S}$, then

$$[\mathrm{Tr}_{E_1} \otimes \mathcal{A}_{E_2\to S}] \circ (\mathcal{M} \circ \mathcal{N})^{\mathrm{c}} = \mathcal{M} \circ \mathcal{N}\,. \tag{S91}$$

□

V. GENERALISATION OF OUR METHODS TO GENERAL BOSONIC DEPHASING CHANNELS

In Theorem 27 we introduced a method to analyse anti-degradability of the bosonic loss-dephasing channel. In this section, we show that this method can be applied also to analyse the anti-degradability of the composition between a *general* bosonic dephasing channel and the pure-loss channel channel.

Given a probability distribution $p(\cdot)$ over $\mathbb{R}$, the associated *general bosonic dephasing channel* is given by

$$\mathcal{D}^{(p)}(X) := \int_{-\infty}^{\infty} \mathrm{d}\phi\, p(\phi)\, e^{i\phi\hat{a}^\dagger\hat{a}}\, X\, e^{-i\phi\hat{a}^\dagger\hat{a}}\,. \tag{S92}$$

If $p(\phi)$ is the Gaussian distribution $p(\phi) := \frac{1}{\sqrt{2\pi\gamma}}e^{-\frac{\phi^2}{2\gamma}}$, the general bosonic dephasing channel $\mathcal{D}^{(p)}$ exactly coincides with the bosonic dephasing channel $\mathcal{D}_\gamma$ analysed in this work. The action of $\mathcal{D}^{(p)}$ on operators of the form $|n\rangle\langle m|$ is given by

$$\mathcal{D}^{(p)}(|n\rangle\langle m|) = \tilde{p}(n-m)\,|n\rangle\langle m|\,, \tag{S93}$$

where $\tilde{p}$ is the Fourier transform of the probability distribution p, i.e.

$$\tilde{p}(k) := \int_{-\infty}^{\infty} \mathrm{d}\phi\, p(\phi)\, e^{ik\phi}\,. \tag{S94}$$

Let $\mathcal{N}_\lambda^{(p)}$ be the composition between such a general bosonic dephasing channel $\mathcal{D}^{(p)}$ and the pure-loss channel, i.e.

$$\mathcal{N}_\lambda^{(p)} := \mathcal{D}^{(p)} \circ \mathcal{E}_\lambda = \mathcal{E}_\lambda \circ \mathcal{D}^{(p)} \,. \tag{S95}$$

We can apply the exact same method that we have introduced in the proof of Thereom 27 in order to analyse the anti-degradability of $\mathcal{N}_\lambda^{(p)}$. The key observation is that in the proof of Theorem 27 we did not use the explicit expression of the channel $\mathcal{D}^{(p)}$ before stating (S37). This simple observation allows us to generalise our results to arbitrary bosonic dephasing channels, as stated in the following theorem.

Theorem 52 (Sufficient condition on the anti-degradability of the composition between a general bosonic dephasing channel and pure-loss channel)**.** *Let $\lambda \in [0,1)$ and let $p(\cdot)$ be a probability distribution over $\mathbb{R}$. Let $A = (a_{mn})_{m,n\in\mathbb{N}}$ be the infinite matrix whose components are defined by*

$$a_{mn} := \frac{\tilde{\phi}(n-m)}{\sum_{j=0}^{\min(n,m)} \sqrt{\mathcal{B}_j\left(n, \frac{2\lambda-1}{\lambda}\right)\, \mathcal{B}_j\left(m, \frac{2\lambda-1}{\lambda}\right)}}\,, \qquad \forall\, n,m \in \mathbb{N}\,. \tag{S96}$$

The channel $\mathcal{N}_\lambda^{(p)}$ is anti-degradable as long as either $\lambda \in [0, \frac{1}{2}]$ or the infinite matrix A is positive semi-definite.

Bombs and prizes, and the communication power of a single noisy qubit

Abstract. A fundamental property of quantum information is that a single qubit, taken in isolation, can carry at most 1 bit. The situation is different if the sender and receiver share entangled particles: in this case, the rate at which classical information can be transmitted through a qubit channel, quantified by its entanglement-assisted capacity, can generally exceed 1 bit. But what if the entanglement-assisted capacity is not more than 1 bit, as it happens for an important class of qubit channels known as entanglement-breaking? Can a noisy entanglement-breaking qubit channel be replaced by a noisy bit channel for the purposes of classical communication? Here we answer the question in the negative. We introduce a game where a player helps another player to find a prize hidden in one of four possible boxes, while avoiding a bomb hidden in one of the remaining three boxes. In this game, the two players cannot be sure to avoid the bomb if they communicate through a noisy bit channel. In contrast, they can avoid the bomb with certainty and find the prize with 1/3 probability if they communicate through an entanglement-breaking qubit channel, known as the universal `NOT` channel. The features of the quantum strategy can be simulated through the transmission of a bit, but this simulation requires the transmission to be a noiseless bit and to be assisted by shared randomness: without shared randomness, even the noiseless transmission of a three-level classical system cannot match the winning probability of the quantum strategy.

Keywords: Classical communication, Entanglement breaking channel, Shared Randomness

Introduction.- A celebrated result by Holevo [1] implies that a d-dimensional quantum system, taken in isolation, can carry at most $\log d$ bits of classical information, where log denotes the base-2 logarithm. This statement was later generalized by Frenkel and Weiner [2], who showed that the set of conditional probability distributions achievable by a sender and a receiver through the transmission of a d-dimensional quantum system coincides with the set of conditional probability distributions achievable through the transmission of a d-dimensional classical system, possibly assisted by correlated random bits shared by the sender and the receiver before the start of the communication protocol. This result implies that, for every possible classical task, the transmission of a d-dimensional quantum system can be replaced by the transmission of a d-dimensional classical system assisted by classical shared randomness.

The situation is different when the sender and receiver pre-share entanglement. In this case, the rate at which bits can be reliably transmitted through a quantum communication channel is quantified by its entanglement-assisted classical capacity [3]. For qubit channels, the entanglement-assisted capacity can generally exceed one bit, as shown by the dense coding protocol [4]. In this case, the transmission of a two-dimensional quantum system is clearly superior to the transmission of a two-dimensional classical system. But what if the entanglement-assisted capacity is not more than one bit? The prototype of qubit channels with entanglement-assisted capacity no more than 1 bit is the class of *entanglement-breaking* channels [5, 6, 7]. In general, the transmission of a d-dimensional quantum system through an entanglement-breaking channel can yield at most $\log d$ bits of classical communication [7]. Hence, a natural question is whether, for the purposes of classical communication, the transmission of a two-dimensional quantum system through a noisy entanglement-breaking channel can be replaced by the transmission of a two-dimensional classical system through a noisy classical channel.

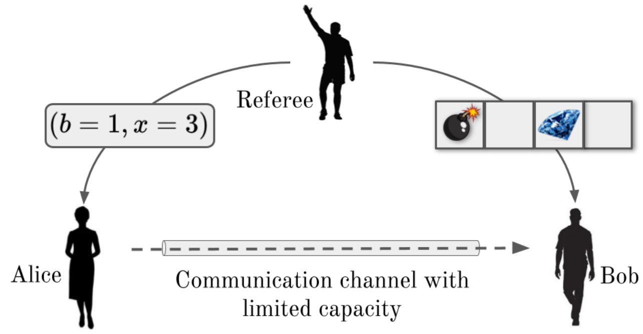

Figure 1: **The bomb and prize game.** A referee puts a prize in one of four possible boxes, labelled as $\{1, 2, 3, 4\}$, and a bomb in one of the three remaining boxes. The referee communicates to Alice the label b of the box containing the bomb and the label x of the box containing the prize. Then, the referee closes the boxes and sends them over to Bob, asking him to open one box. Bob wins if the finds the prize, under the constraint that the bomb is avoided with certainty. In this task, he is assisted by Alice, who communicates classical messages to him through a channel with limited capacity.

Here we answer the above question in the negative: we provide a purely classical communication task that we put in the form of a game where a noisy entanglement-breaking qubit channel is more valuable than any noisy bit channel, even with the assistance of arbitrary amounts of shared randomness between the sender and receiver. In stark contrast, we show that the entanglement-assisted transmission of a qubit through a noisy entanglement-breaking channel allows the task to be accomplished with a finite probability of success. Finally, we analyze the additional classical resources required to achieve the communication task.

The bomb and prize game.– We now provide the precise mathematical formulation of the bomb and prize game illustrated in Figure 1. The location of the bomb and prize is described by a pair (b, x), where $b \in \{1, 2, 3, 4\}$ specifies the position of the bomb and $x \in \{1, 2, 3, 4\} \setminus \{b\}$ specifies the position of the prize. The overall strategy adopted by Alice and Bob can be described by a conditional probability distribution $p(y|b, x)$, where $y \in \{1, 2, 3, 4\}$ is the box opened by Bob. For a given configuration (b, x), the probability of winning the game is $p(x|b, x)$. In the following, we will consider the worst case winning probability

$$p_{\text{worst}}^{\text{prize}} := \min_{b,x} p(x|b, x)\,, \tag{1}$$

under the constraint that the bomb is avoided, corresponding to the condition

$$p_{\text{worst}}^{\text{bomb}} = 0 \quad \text{with} \quad p_{\text{worst}}^{\text{bomb}} := \max_{b,x} p(b|b, x)\,. \tag{2}$$

We now show two key results about classical strategies: *(i)* the bomb-avoiding condition (2) cannot be satisfied by any bit channel with nonmaximal capacity, and *(ii)* if the Alice and Bob do not share randomness, then the winning probability (1) subject to the bomb-avoiding condition (2) is zero even if a noiseless bit channel (or even a noiseless trit channel) is available.

Result *(i)* is established by the following theorem:

Theorem 1 *For every classical strategy using a single-bit channel of capacity $C < 1$ and an arbitrary amount of shared randomness, the worst-case probability of opening the box containing the bomb is lower bounded as*

$$p_{\text{worst}}^{\text{bomb}} \geq \frac{[1 - C]^{\ln 4}}{8}\,. \tag{3}$$

The proof of the theorem is provided in the technical version.

Result *(ii)* is established by the following theorem:

Theorem 2 *In the absence of shared randomness between Alice and Bob, the worst-case winning probability (1) subject to the bomb-avoiding condition (2) is zero for every classical strategy using the transmission of a classical system of dimension $d \leq 3$.*

The detailed proof of the theorem is in the technical version.

It is worth noting that the above theorem provides the best possible result in terms of dimensionality of the transmitted classical system: indeed, if Alice could transmit a 4-dimensional system through a noiseless channel, then she could communicate to Bob the exact location of the prize, thereby trivializing the game.

The quantum strategy. We now show that the transmission of a single qubit through a noisy entanglement-breaking channel allows Bob to avoid the bomb with certainty and to find the prize with a guaranteed probability of 1/3. The quantum strategy uses an entanglement-breaking channel known as the *(approximate) universal* `NOT` *channel* [8] (see also [9] for an extension to $d \geq 2$.) The universal `NOT` channel, hereafter denoted by `UNOT`, acts on an input density matrix ρ as follows:

$$\texttt{UNOT}(\rho) = \frac{2}{3}\,\text{Tr}[\rho]\,I - \frac{1}{3}\,\rho\,. \tag{4}$$

Experimental realizations of this transformation have been demonstrated with photons [10, 11]. The `UNOT` channel is unitarily equivalent to the optimal universal transpose [12, 13], which also has been implemented experimentally [14, 15, 16, 17].

The universal `NOT` channel can be equivalently realized as a uniform mixture of three Bloch sphere rotations about the three Cartesian axes; specifically, one has $\texttt{UNOT}(\rho) = \frac{1}{3}(X\rho X + Y\rho Y + Z\rho Z)$, where, $\{X, Y, Z\}$ are the spin-1/2 Pauli operators along x, y and z directions respectively. Since `UNOT` is a Pauli channel, its entanglement-assisted capacity can be computed via a closed-form expression [3, 18], which yields the value $C_{\text{E}}(\texttt{UNOT}) = 2 - \log 3 \approx 0.415$. Hence, the universal `NOT` channel satisfies the constraint of the bomb game: even with the assistance of quantum correlations, it does not allow Alice to transmit more than one bit per channel use.

On the other hand, the entanglement-assisted transmission of a qubit through the `UNOT` channel can be used to avoid the bomb with certainty and to win the game with a guaranteed probability of 1/3. The protocol that achieves this feature is a "universal `NOT` version" of the dense coding protocol [4].

Protocol 1 (`UNOT` dense coding) *Before the start of the protocol, Alice and Bob share two qubits A and B in the entangled state $|\Phi^+\rangle_{AB} = (|0\rangle_A \otimes |0\rangle_B + |1\rangle_A \otimes |1\rangle_B)/\sqrt{2}$. Then, they perform the following operations:*

1. *Alice applies one of the unitary gates $I, X, Y,$ or Z depending on whether the bomb is in box $1, 2, 3,$ or 4, respectively.*

2. *Alice sends qubit A to Bob through the universal* `NOT` *channel.*

3. *Bob measures both qubits A and B in the Bell basis, that is, the orthonormal basis consisting of states $|\Phi_1\rangle := |\Phi^+\rangle$, $|\Phi_2\rangle := (X \otimes I)|\Phi^+\rangle$, $|\Phi_3\rangle := (Y \otimes I)|\Phi^+\rangle$, and $|\Phi_4\rangle := (Z \otimes I)|\Phi^+\rangle$. If the measurement outcome is y, Bob will open the y-th box.*

Checking that the above protocol allows Bob to avoid the bomb is relatively straightforward. If the bomb is in position $b \in \{1,2,3,4\}$, then qubits A and B are in the state $|\Phi_b\rangle$. When qubit A is sent through the UNOT channel, the final state of qubits AB is

$$(\mathtt{UNOT} \otimes \mathcal{I}_B)(|\Phi_b\rangle\langle\Phi_b|) = \frac{1}{3}\, I \otimes I - \frac{1}{3}\,|\Phi_b\rangle\langle\Phi_b| \\ = \frac{1}{3}\sum_{y\neq b} |\Phi_y\rangle\langle\Phi_y| \,. \qquad (5)$$

Hence, when Bob measures the two qubits in the Bell basis, he will obtain an outcome y that is guaranteed to satisfy the condition $y \neq b$. Thanks to this fact, Bob avoids the bomb with certainty. Since the value of y is uniformly random in the set $\{1,2,3,4\} \setminus \{b\}$, Bob is guaranteed to find the prize with probability $p^{\rm prize}_{\rm worst} = 1/3$.

Comparing this result with Theorem 1, we can conclude that the entanglement-assisted transmission of a qubit through the UNOT channel is more valuable than the transmission of a bit through a noisy channel, even in the presence of shared randomness. Note also that the net effect of Protocol 1 is to reproduce the transmission of a *four-dimensional* classical system through the noisy channel specified by the conditional probability distribution

$$p_{\mathtt{NOT}}(y|b) = \begin{cases} 0 & \text{if } y = b \\ \frac{1}{3} & \text{if } y \neq b\,. \end{cases} \qquad (6)$$

This channel, which we call *classical 4-dimensional* NOT *channel*, has capacity $C = 2 - \log_2 3$-bits, exactly equal to the entanglement-assisted capacity of the universal NOT channel. A corollary of Theorem 1 is that the classical 4-dimensional NOT channel cannot be simulated by any noisy bit channel.

The shared randomness requirement. Theorem 2 implies that, in the absence of shared randomness, even the noiseless transmission of a trit cannot match the transmission of a qubit through the UNOT channel. It is then natural to ask how much shared randomness is needed to reproduce the features of the quantum strategy. In the following, we answer this question.

Consider a variant of the bomb and prize game where the referee communicates to Alice only the position of the bomb, without communicating the position of the prize. A general strategy for this variant of the game is described by the conditional probability distribution $p(y|b)$ that Bob opens box y when the bomb is in position b. In this case, the worst-case winning probability is $p^{\rm prize}_{\rm worst} := \min_b \min_{y\neq b} p(y|b)$ and the worst-case probability of opening the bomb is $p^{\rm bomb}_{\rm worst} : \max_b p(b|b)$. With these settings, the maximum of $p^{\rm prize}_{\rm worst}$ over all strategies $p(y|b)$ satisfying the bomb-avoiding condition $p^{\rm bomb}_{\rm worst} = 0$ is 1/3. This maximum winning probability is achieved by one and only one strategy, corresponding to the classical NOT channel $p_{\mathtt{NOT}}(y|b)$ in Eq. (6).

We now show that every classical strategy that simulates the channel $p_{\mathtt{NOT}}(y|b)$ using a noiseless bit channel must be assisted by $\log 3$ bits of shared randomenss. Moreover, this amount of shared randomness is sufficient:

Theorem 3 *The classical 4-dimensional* NOT *channel (6) can be simulated through the transmission of a single bit if and only if the sender and receiver share* $\log 3$ *bits of randomness.*

The proof is provided in the technical version. Note that the amount of shared randomness required by the simulation is more than 1 bit: while the 4-dimensional NOT channel can be simulated with two entangled qubits and a noisy, entanglement-breaking qubit channel, it cannot be simulated with two correlated bits and a noiseless bit channel.

Simulation of the universal NOT *channel.* Quite remarkably, a bit of noiseless classical communication plus $\log 3$ bits of classical shared randomness is also sufficient to simulate the UNOT channel. To this purpose, Alice and Bob can use the following protocol:

Protocol 2 (Simulation of the universal NOT channel) *Before the beginning of the protocol, Alice and Bob share two perfectly correlated trits, with uniformly distributed values.*

1. *If the value of the trit is* $i \in \{1,2,3\}$, *Alice measures the input qubit in the orthonormal basis* $\mathsf{B}_i = \{|\psi^{(i)}_0\rangle, |\psi^{(i)}_1\rangle\}$ *corresponding to the eigenstates of the Pauli matrix* σ_i, *with* $\sigma_1 := X$, $\sigma_2 := Y$, *and* $\sigma_3 := Z$,

2. *Alice uses the classical bit channel to communicate the outcome of her measurement to Bob,*

3. *Upon receiving the measurement outcome* $j \in \{0,1\}$, *Bob prepares the output qubit in the basis state* $|\psi^{(i)}_{(j+1) \bmod 2}\rangle$, *depending on the outcome* j *and on the trit value* i.

On average, Protocol 2 yields the UNOT channel, as shown in the technical version. This result can be further generalized, showing that every entanglement-breaking qubit channel can be simulated by using a noiseless classical bit channel assisted by shared randomness (see the technical version). An interesting open question is whether the result further generalizes to higher dimensions.

Conclusions.- We have shown that the transmission of a qubit through a noisy entanglement-breaking channel cannot, in general, be reproduced by the transmission of a bit through a noisy channel, even if the sender and receiver share arbitrary amounts of randomness. Moreover, we have shown that even if a bit (or a trit) channel with maximal capacity is available, reproducing the transmission of a qubit requires shared randomness. The advantage of the transmission of a noisy qubit can be demonstrated experimentally on a photonic platform.

Appendix A: Proof of Theorem 1

The single-bit channel $\mathcal{N}$ available to Alice and Bob can be represented by a conditional probability distribution $p_{\rm chan}(j|i)$, $i,j\in\{0,1\}$, specifying the probability that Bob receives a bit in the state j when Alice sent a bit in the state i.

The bit channel $\mathcal{N}$ has unit capacity if and only if j is an invertible function of i, that is, if and only if $p_{\rm chan}(j|i)=\delta_{j,i}$ or $p_{\rm chan}(j|i)=\delta_{j,i\oplus 1}$, where $\oplus$ denotes addition modulo 2. Hence, the hypothesis that $\mathcal{N}$ has non-unit capacity implies that there exists at least one value j such that $p_{\rm chan}(j|0)>0$ and $p_{\rm chan}(j|1)>0$. We call such an j an "ambiguous output" and denote its minimum probability of the ambiguous output as

$$p_{\rm min}(j):=\min_i p_{\rm chan}(j|i). \tag{A1}$$

Taking the worst case over all ambiguous outputs, we obtain the ambiguous probability

$$p_? := \max_j p_{\rm min}(j)\,. \tag{A2}$$

In the following, we will denote by j_* the value such that $p_{\rm min}(j_*)=p_?$. Since the channel $\mathcal{N}$ has non-unit capacity, the ambiguous probability is nonzero: $p_?>0$.

Let us start by analyzing the setting where Alice and Bob do not share any correlated random bit. In this case, Alice's and Bob's strategy is completely described by an encoding channel $\mathcal{E}$, used by Alice to encode the position of the bomb into the input of channel $\mathcal{C}$, and a decoding channel $\mathcal{D}$, used by Bob to convert the output of channel $\mathcal{C}$ into the decision as to which box Bob should open. The two channels are represented by probability distributions $p_{\rm enc}(i|m)$ and $p_{\rm dec}(n|j)$, with $m,n\in\{1,2,3,4\}$. Hence, the probability that Bob opens box n when the bomb is in box m is

$$\begin{aligned} p_{\rm in/out}(n|m) &:= \sum_{i,j} p_{\rm dec}(n|j)\, p_{\rm chan}(j|i)\, p_{\rm enc}(i|m) \\ &= \sum_j p_{\rm dec}(n|j)\,\mathsf{Prob}(j|m)\,, \end{aligned} \tag{A3}$$

having defined $\mathsf{Prob}(j|m):=\sum_i p_{\rm chan}(j|i)\,p_{\rm enc}(i|m)$.

Now, notice that the ambiguous output j_* has probability lower bounded as $\mathsf{Prob}(j_*|m)\geq p_?$, independently of m. Denoting by $p_{\rm worst}:=\max_n p_{\rm in/out}(n|n)$ the worst-case probability that Bob opens a box containing the bomb, we then have the bound

$$\begin{aligned} p_{\rm worst} &\geq p_{\rm in/out}(n|n) \\ &\geq p_{\rm dec}(n|j_*)\,\mathsf{Prob}(j_*|n) \\ &\geq p_{\rm dec}(n|j_*)\,p_?\,, \qquad \forall n\in\{1,2,3,4\}\,. \end{aligned} \tag{A4}$$

In particular, let $n_{\rm max}$ be the most likely output of Bob's decoder when the output of the transmission channel is j_*, namely $p_{\rm dec}(n_{\rm max}|j_*)\geq p_{\rm dec}(n|j_*)$ for every $n\in\{1,2,3,4\}$. With this definition, we have $p_{\rm dec}(n_{\rm max}|j_*)\geq 1/4$, and the above bound becomes

$$p_{\rm worst}\geq \frac{p_?}{4}\,. \tag{A5}$$

Since the non-unit capacity condition implies $p_?>0$, the probability of opening the box with the bomb is nonzero.

Bound (A5) holds even if Alice and Bob share randomness. If Alice and Bob pick encoding and decoding operations $\mathcal{E}_k$ and $\mathcal{D}_k$ with probability λ_k, then the overall input-output distribution takes the form $p_{\rm in/out}(n|m)=\sum_k \lambda_k\, p^{(k)}_{\rm in/out}(n|m)$, where $p^{(k)}_{\rm in/out}(n|m)$ is the input-output distribution for fixed encoding and decoding operations $\mathcal{E}_k$ and $\mathcal{D}_k$. The worst case probability is then lower bounded as

$$\begin{aligned} p_{\rm worst} &\geq \sum_k \lambda_k\, p^{(k)}_{\rm in/out}(n|n) \\ &\geq \sum_k \lambda_k\, p^{(k)}_{\rm dec}(n|j_*)\,\mathsf{Prob}^{(k)}(j_*|n) \\ &\geq \sum_k \lambda_k\, p^{(k)}_{\rm dec}(n|j_*)\,p_? \\ &= p_{\rm dec}(n|j_*)\,p_?\,, \qquad \forall n\in\{1,2,3,4\}\,, \end{aligned} \tag{A6}$$

having defined $p_{\rm dec}(n|j):=\sum_k \lambda_k\, p^{(k)}_{\rm dec}(n|j)$ to be the average probability that Bob opens box n upon receiving the bit value j. Defining $n_{\rm max}$ to be the value of n that maximizes $p_{\rm dec}(n|j_*)$, we then have the inequality $p_{\rm dec}(n|j_*)\geq 1/4$, which plugged into Eq. (A6) yields Eq. (A5).

To conclude, we provide a lower bound to the r.h.s. of Eq. (A5) in terms of the channel capacity. To this purpose, note that the capacity of channel $\mathcal{N}$ is an upper bound to the capacity of the binary symmetric channel $\mathcal{N}_{\rm sym}=(\mathcal{N}+\mathcal{N}')/2$, where $\mathcal{N}'$ is the channel obtained by pre- and post- composing channel $\mathcal{N}$ with a bit flip (explicitly, channel $\mathcal{N}'$ corresponds to the probability distribution $p'_{\rm chan}(j|i)=p_{\rm chan}(j\oplus 1|i\oplus 1)$). Explicitly, the capacity of the binary symmetric channel $\mathcal{N}_{\rm sym}$ is [1]

$$C(\mathcal{N}_{\rm sym})=1-H(p_{\rm sym})\,, \tag{A7}$$

where $H(p)=-p\log p-(1-p)\log(1-p)$ is the binary entropy, and

$$p_{\rm sym}:=\min\left\{\frac{p(0|0)+p(1|1)}{2},\frac{p(0|1)+p(1|0)}{2}\right\}, \tag{A8}$$

Since the binary entropy satisfies the bound $H(p)\leq[4p(1-p)]^{1/\ln 4}$ [2], we obtain the bound

$$\begin{aligned} 4\,p_{\rm sym}\,(1-p_{\rm sym}) &\geq [1-C(\mathcal{N}_{\rm sym})]^{\ln 4} \\ &\geq [1-C(\mathcal{N})]^{\ln 4}\,, \end{aligned} \tag{A9}$$

which in turn implies the bound

$$p_{\mathrm{sym}} \geq \frac{1-\sqrt{1-[1-C(\mathcal{N})]^{\ln 4}}}{2} \geq \frac{[1-C(\mathcal{N})]^{\ln 4}}{2}. \qquad \text{(A10)}$$

Finally, note that the definition of p_{sym} implies $p_{\mathrm{sym}} \leq p_?$. Hence, Eqs. (A5) and (A10) imply $p_{\mathrm{worst}} \geq p_?/4 \geq p_{\mathrm{sym}}/4 \geq [1-C(\mathcal{N})]^{\ln 4}/8$. ■

Appendix B: Proof of Theorem 2

The most general classical strategy using a classical bit channel and no shared randomness consists of an encoding operation, described by the conditional probability $p_{\mathrm{enc}}(s|b,x)$ that Alice communicates the bit value s if the initial configuration of the boxes is (b,x), and a decoding operation, described by the conditional probability $p_{\mathrm{dec}}(y|s)$ that Bob opens box y upon receiving the bit value s. Without loss of generality, we assume that the communication channel from Alice to Bob is the identity channel, since any other bit channel can be reproduced by appending an additional noisy operation to Bob's decoding. Now, for every $s \in \{0,1,2\}$ we define the sets $\widetilde{\mathsf{A}}_s := \{(b,x) \mid p_{\mathrm{enc}}(s|b,x) \neq 0\}$, $\mathsf{A}_s := \{b \mid \exists x : (b,x) \in \widetilde{\mathsf{A}}_s\}$, and $\mathsf{B}_s := \{y \mid p_{\mathrm{dec}}(y|s) \neq 0\}$. Since Bob opens at least one box with non-zero probability, the set B_s is nonempty for every $s \in \{0,1,2\}$. The constraint that the bomb is avoided with certainty implies the condition $B_0 \cap B_1 \cap B_2 = \emptyset$: indeed, if the intersection were nonempty, there would be a box that has nonzero probability to be opened no matter what value is communicated by Alice, and meaning that there is no way to avoid the bomb with certainty if the bomb is placed into that box.

If the union $B_0 \cup B_1 \cup B_2$ is not the full set $\{1,2,3,4\}$, then there exist a box that has zero probability to be opened, no matter what message Alice sends. Clearly, putting the prize in that box brings the winning probability down to zero. In the following we will assume that $B_0 \cup B_1 \cup B_2 = \{1,2,3,4\}$. Now, there are two possible cases: (1) there exist two indices s and t such that the intersection $B_s \cap B_t$ has cardinality at least 2, (2) the intersection $B_s \cap B_t$ has cardinality at most 1 for every $s,t \in \{0,1,2\}$. Let us consider case (1) first, assuming $s=0$ and $t=1$ without loss of generality. Let y_0 and y_1 be the boxes in the intersection $B_0 \cap B_1$. The condition $B_0 \cap B_1 \cap B_2 = \emptyset$ then implies that neither y_0 nor y_1 is contained in B_2. Hence, placing the bomb in box y_0 forces Alice to communicate the message $s=2$, and placing the prize in box y_1 implies that Bob has zero probability of finding the prize.

Let us now consider the case (2). Since the intersection between any two of the sets B_0, B_1, and B_2 has cardinality at most 1, the set $B := (B_0 \cap B_1) \cup (B_1 \cap B_2) \cup (B_0 \cap B_2)$ has cardinality at most 3. Hence, there exists at least one element y_0 that is not in B. Since $B_0 \cup B_1 \cup B_2 = \{1,2,3,4\}$, the element y_0 should be in one of the three sets B_0, B_1, and B_2. Without loss of generality, let us assume $y_0 \in B_0$. To conclude, we separate two cases: (2a) $|B_0| \geq 2$ and (2b) $|B_0| = 1$. In case (2a), B_0 contains at least another index y_1 in addition to y_0. Hence, putting the bomb in y_1 guarantees that Alice will not communicate the message $s=0$, and putting the prize in y_0 guarantees that Bob has zero probability of finding the prize. In case (2b), the condition $B_0 \cup B_1 \cup B_2 = \{1,2,3,4\}$ implies $B_1 \cup B_2 = \{1,2,3,4,\} \setminus \{y_0\}$. Hence, at least one of the two sets has cardinality 2. Without loss of generality, let us assume that B_2 has cardinality 2. Since the intersection $B_1 \cap B_2$ has cardinality at most 1, B_2 must contain at least one element y_2 that is not contained in B_1, plus another element y_1. Putting the bomb in y_1 guarantees that Alice does not send the message $s=2$, and putting the prize in y_2 guarantees that Bob has zero probability of finding the prize. ■

Appendix C: Proof of Theorem 3

Here we introduce a compact notation of *strategy matrices* for the strategies that can be implemented by limited classical communication. They are characterized by the input-output statistics that the strategy $\mathcal{S}$ induces. Therefore, formally,

Definition 1. *A strategy $\mathcal{S}$ is a 4×4 matrix containing the entire set of input(b)-output(y) conditional probabilities $\{p(y|b)\}$ such that $\mathcal{S}^{by} = p(y|b)$.*

In our work, we will be interested in the scenario when Alice is allowed to communicate a classical two-level system $x \in \{0,1\}$ to Bob, which finally partitioned the full set of output indices $\{1,2,3,4\}$ in two disjoint subsets B_x, $x \in \{0,1\}$. With the condition $B_0 \cup B_1 = \{1,2,3,4\}$ and $B_0 \cap B_1 = \emptyset$, only two possibilities arise: $|B_x| = 1$, $|B_{x\oplus 1}| = 3$ and $|B_x| = |B_{x\oplus 1}| = 2$.

The *first* possibility encapsulates ${}^4C_1 = 4$ differently partitioned subsets each corresponding to a strategy with two independent probability parameters (p,q). As an example, consider a particular partition where $B_0 = \{1\}$ and $B_1 = \{2,3,4\}$, i.e., for $x=0$ communication from Alice, Bob always outputs 1, and for $x=1$, he outputs $\{2,3,4\}$ with the probabilities $(p,q,1-p-q)$ respectively. Then these four strategy matrices which we will henceforth call $1:3$ strategies can be represented as:

$$\mathcal{S}_{(1,1)} := \begin{pmatrix} 0 & p & q & (1-p-q) \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}, \mathcal{S}_{(1,2)} := \begin{pmatrix} 0 & 1 & 0 & 0 \\ p & 0 & q & (1-p-q) \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}$$

,

$$\mathcal{S}_{(1,3)} := \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ p & q & 0 & (1-p-q) \\ 0 & 0 & 1 & 0 \end{pmatrix} \text{ and } \mathcal{S}_{(1,4)} := \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \\ p & q & (1-p-q) & 0 \end{pmatrix}$$

On the other hand, for the strategy matrices belonging to the *second* class, there are 3 different set partitioning each with the two-parameter probabilities (p, q) denoting three distinct strategies. However, here when Alice communicates $x = 0$ $(x = 1)$, Bob any one index randomly from B_0 (B_1) following a probability distribution $\{p, 1-p\}$ $(\{q, 1-q\})$. Hence under this partitioning possibility, we obtain the following three strategy matrices which from now on will be referred to as $2:2$ strategies:

$$\mathcal{S}_{(2,1)} := \begin{pmatrix} 0 & p & (1-p) & 0 \\ q & 0 & 0 & (1-q) \\ q & 0 & 0 & (1-q) \\ 0 & p & (1-p) & 0 \end{pmatrix}, \mathcal{S}_{(2,2)} := \begin{pmatrix} 0 & p & 0 & (1-p) \\ q & 0 & (1-q) & 0 \\ 0 & p & 0 & (1-p) \\ q & 0 & (1-q) & 0 \end{pmatrix} \text{ and } \mathcal{S}_{(2,3)} := \begin{pmatrix} 0 & 0 & p & (1-p) \\ 0 & 0 & p & (1-p) \\ q & (1-q) & 0 & 0 \\ q & (1-q) & 0 & 0 \end{pmatrix}.$$

In all these strategy matrices $S_{(i,j)}$, $i = 1$ and $i = 2$ correspond respectively the $1:3$ and $2:2$ partitioning and j denotes the particular set partition for the corresponding group $i \in \{1, 2\}$.

A general strategy receives assistance from a shared classically correlated system. The role of any shared correlation (randomness) is to mix these deterministic strategies. Therefore any strategy using shared randomness takes the form

$$\mathcal{S} = \sum_{i=1}^{d} P_i \, \mathcal{S}_{(x_i, y_i)}(p_i, q_i), \text{ where } \sum_i P_i = 1. \quad \text{(C1)}$$

Here d is the local dimension of the shared classically correlated state. Also, d denotes the maximal number of strategies $\mathcal{S}_{(x,y)}$ that can be mixed.

With all these preliminaries we will now move to the question of simulating the classical 4-dimensional `NOT` channel with two-level classical communication and SR. Let us begin with the characterization of the classical 4-dimensional `NOT` gate in terms of a strategy matrix.

Proposition 1. *In the strategy matrix notation, the 4-dimensional* `NOT` *gate takes the form* $\mathcal{S}^* := \frac{1}{3}\begin{pmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 0 \end{pmatrix}$.

Proof. The proof directly follows from the action of 4-dimensional `NOT` gate, as in Eq. (**??**) of the main manuscript. ■

Evidently, the strategy matrix $\mathcal{S}^*$ cannot be obtained from any particular $\mathcal{S}_{(x,y)}$. Then the objective is to find the min d (as in Eq. (C1)), such that we can have $\mathcal{S} = \mathcal{S}^*$ by optimally choosing the free parameters x_i, y_i, p_i, q_i, and P_i. Our analysis reveals that the minimal dimension of the local subsystem of the classically correlated state to implement the 4-dimensional `NOT` strategy is three $(d = 3)$, a trit. Furthermore, we show that one requires two perfectly correlated trits, i.e., $\log 3$ bits of shared randomness to implement the 4-dimensional `NOT` strategy. We prove this to be a necessary and sufficient condition. This rules out the possibility of using the shared randomness of two classically correlated two-level systems to implement $\mathcal{S}^*$. We give a detailed description of our findings subsequently.

Sharing two $d = 3$ dimensional classical systems implies that the strategies that can be generated are obtained from mixing at most three deterministic strategies listed before into $1:3$ and $2:2$ classes. From Eq. (C1) the most general strategies in this case take the form $\mathcal{S} = \alpha\mathcal{S}_{(x_1,y_1)}(p_1, q_1) + \beta\mathcal{S}_{(x_2,y_2)}(p_2, q_2) + \gamma\mathcal{S}_{(x_3,y_3)}(p_3, q_3)$, where $\alpha + \beta + \gamma = 1$.

Lemma 1. *Mixing three strategies from class* $1:3$ *cannot generate* $\mathcal{S}^*$.

Proof. Let us consider any three strategy matrices $\mathcal{S}_{(1,y_i)}$, $y_i \in \{1,2,3,4\}$ chosen from the $1:3$ classes, such that $\mathcal{S} = \sum_{i=1}^{3} P_i \mathcal{S}_{(1,y_i)}(p_i,q_i)$. A closer inspection reveals that for any three such strategies, there is one row $\bar{y} = \{1,2,3,4\} \setminus \{y_1,y_2,y_3\}$, where two of the non-diagonal elements are zero. This immediately tells that $\mathcal{S}$ can not be identified as $\mathcal{S}^*$. ■

Lemma 2. *Mixing any strategy from class* $1:3$ *with any two strategies from the* $2:2$ *class cannot generate* $\mathcal{S}^*$.

Proof. There are $\binom{3}{2} \times 4 = 12$ ways one can choose such a mixture of strategies. However, all such mixtures are mathematically equivalent. This is because mixing any two class $2:2$ strategies can make all the non-diagonal elements of the effective strategy matrix non-zero. Mixing any class $1:3$ strategy on top of this yields identical equations for generating the optimal strategy matrix $\mathcal{S}^*$. So without loss of generality we mix $\mathcal{S}_{(2,1)}$, $\mathcal{S}_{(2,2)}$, and $\mathcal{S}_{(1,1)}$ and demand the generation of $\mathcal{S}^*$. We have

$$S = \alpha\mathcal{S}_{(2,1)}(p_1,q_1) + \beta\mathcal{S}_{(2,2)}(p_2,q_2) + \gamma\mathcal{S}_{(1,1)}(p_3,q_3), \tag{C2}$$

where we have $\alpha+\beta+\gamma = 1$, and p_is and q_is denote the local randomness parameters. We want to solve for $S = \mathcal{S}^*$, which translates to $S^{ij} = \frac{1-\delta_{ij}}{3}$, where ij denotes the ij^{th} matrix element. Here there are only 8 unknowns but 12 equations making it an overdetermined system. For there to be a consistent solution, we must have

$$S^{01} - S^{21} - S^{31} = -\frac{1}{3} \implies \gamma p_3 = -\frac{1}{3}. \tag{C3}$$

Since $\gamma \geq 0$, for a consistent solution, we need $p_3 < 0$. Being a probability $p_3 \geq 0$ and hence a consistent solution for $S = \mathcal{S}^*$ cannot exist. ■

Lemma 3. $\log 3$ *bits of shared randomness is necessary to generate the optimal strategy matrix* $\mathcal{S}^*$.

Proof. The possible candidates are obtained by mixing three strategies from class $2:2$, and mixing two class $1:3$ strategies with a class $2:2$ strategy.
Case 1. Here we consider mixing three strategies from class $2:2$. When they are mixed with probabilities α, β, and γ we have

$$S = \alpha\mathcal{S}_{(2,1)}(p_1,q_1) + \beta\mathcal{S}_{(2,2)}(p_2,q_2) + \gamma\mathcal{S}_{(2,3)}(p_3,q_3), \tag{C4}$$

where p_i, q_i denote the local randomness that Bob employs for the $(2,i)^{\text{th}}$ strategy. Of course the mixing probabilities sum to unity, $\alpha+\beta+\gamma = 1$. We want to solve for $S = \mathcal{S}^*$. This is equivalent to the condition $S^{ij} = \frac{1-\delta_{ij}}{3}$, where ij in superscript denotes the ij^{th} matrix element. The number of non-trivial relations, as pointed out before, is 12, but the number of unknowns is 8 making it an overdetermined system. For a consistent solution to exist we must have

$$S^{01} + S^{10} + S^{23} + S^{32} = \frac{4}{3} \implies \alpha + \beta = \frac{2}{3},$$
$$S^{12} + S^{21} + S^{03} + S^{30} = \frac{4}{3} \implies \beta + \gamma = \frac{2}{3},$$
$$S^{02} + S^{20} + S^{13} + S^{31} = \frac{4}{3} \implies \alpha + \gamma = \frac{2}{3}.$$

The above equations imply that for a consistent solution to exist we must have $\alpha = \beta = \gamma = \frac{1}{3}$. It corresponds to an initial shared randomness of $\log 3$ bits.
Case 2.
Now we will consider the scenario where two of the 1:3 strategies is combined with one of the 2:2 class strategy. Note that, due to the symmetric structure of each of the individual strategy classes we can choose any two of the $1:3$ class, however, depending upon this choice not all the strategies from $2:2$ classes are equivalent. Let us first consider the following convex combination of strategies:

$$S = \alpha\mathcal{S}_{(1,1)}(p_1,q_1) + \beta\mathcal{S}_{(1,2)}(p_2,q_2) + \gamma\mathcal{S}_{(2,1)}(p_3,q_3),$$

where, $\{p_k, q_k | k \in \{1,2\}\}$ and p_3, q_3 are the local randomness for $(1,k)^{\text{th}}$ and $(2,1)^{\text{th}}$ strategies respectively and α,β,γ denote the same as in Eq. (C4). Using the notation S^{ij} to denote the ij^{th} element of the matrix S and identifying S with $\mathcal{S}^*$, we obtain the following equations:

$$S^{21} = \beta = \frac{1}{3},$$
$$S^{30} = \alpha = \frac{1}{3},$$

which readily implies $\gamma = \frac{1}{3}$. On the other hand, if they choose $\mathcal{S}_{(2,2)}$ instead of $\mathcal{S}_{(2,1)}$, then the similar analysis will again lead to the condition $\alpha = \beta = \gamma = \frac{1}{3}$. However, for choice of $\mathcal{S}_{(2,3)}$ as the $2:2$ class element, both the third and fourth rows will contain zeros other than the input position b. Hence such a strategy will never work to obtain $\mathcal{S}^*$. With a similar analysis, one may argue that for every pair of $1:3$ class strategies, there exists one $2:2$ strategy, combining which lead to a failure in the worst case scenario. In particular, $\mathcal{S}_{(2,1)}$ should be avoided whenever the pair $\{\mathcal{S}_{(1,1)}, \mathcal{S}_{(1,4)}\}$ or, $\{\mathcal{S}_{(1,2)}, \mathcal{S}_{(1,3)}\}$ is chosen and so on. ■

1. Sufficiency of a classical bit and $\log 3$-bit SR to simulate 4-dimensional `NOT` channel

In the following, we will give a strategy to utilize $\log 3$-bits of SR, along with the communication of a two-level classical system to simulate 4-dimensional `NOT` gate. To begin with Alice and Bob have two perfectly correlated trits: the probability p_i that Alice's and Bob's trits are in the state $i \in \{1,2,3\}$ is $1/3$ for every i. Alice can communicate one bit $x_{i,b} \in \{0,1\}$ to Bob which depends on i and the input $b \in \{1,2,3,4\}$. Precisely, $x_{i,b} = 0$ whenever the input variable b to Alice is in the sector $B_{i,0} = \{1, 1+i\} \subset \{1,2,3,4\}$ and $x_{i,b} = 1$ for $b \in B_{i,1} = \{1,2,3,4\} \setminus B_{i,0}$. Finally depending upon i and $x_{i,b}$, Bob produces an output $y \in \{1,2,3,4\}$ with the following probability distribution.

$$\begin{aligned} p\Big(y = B^{1(2)}_{i,x_{i,b}} | i, x_{i,b}\Big) &= \frac{1}{2}, \\ p\Big(y = B^{1(2)}_{i,x_{i,b}\oplus 1} | i, x_{i,b}\Big) &= 0, \end{aligned} \tag{C5}$$

where $B^{1(2)}_{i,k}$ are the respective elements of the set $B_{i,k}$, i.e., $B_{i,k} = \{B^1_{i,k}, B^2_{i,k}\}$.

We are interested in the input-output statistics $p(y|b)$ that the above strategy produces. Formally, we can write

$$p(y|b) = \sum_{i=1}^{3} p_i p(y|i, x_{i,b}) = \frac{1}{3}\sum_{i=1}^{3} p(y|i, x_{i,b}). \tag{C6}$$

Now two distinct cases arise. When $y \neq b$, then there exists a unique $i^* \in \{1,2,3\}$, s.t. $\{y, b\} = B_{i^*,0}$ or $B_{i^*,1}$. Then from (C5), it right away implies $p(y|i^*, x_{i^*,b}) = 0$. Again from Eq. (C5), for all $i \in \{1,2,3\} \setminus i^*$, we have $p(y|i, x_{i,b}) = \frac{1}{2}$. Combining the above findings with (C6), we get

$$p(y \neq b|b) = \frac{1}{3}\sum_{i \neq i^*} p(y|i, x_{i,b}) + \frac{1}{3} p(y|i^*, x_{i^*,b}) = \frac{1}{3}. \tag{C7}$$

For $y = b$, (C5) immediately forces $p(y = b|i, x_{i,b}) = 0$ for all i. Substituting this in (C6) we get $p(y = b|b) = 0$. This along with (C7) demonstrate the simulation of the classical NOT channel (**??**). ■

Appendix D: Simulation of universal NOT channel

We will now prove that the Protocol. 2 in the main manuscript exactly simulates the universal qubit NOT channel.

Note that, Protocol. 2 simulates a qubit channel from $L(\mathcal{H}_A) \to L(\mathcal{H}_B)$ which takes the form

$$\mathcal{N}_{A\to B}(\rho_A) = \sum_{i=1}^{3}\sum_{j=-1}^{1} p_i \langle\psi^{(i)}_j|\,\rho_A\,|\psi^{(i)}_j\rangle\,|\psi^{(i)}_{-j}\rangle\langle\psi^{(i)}_{-j}|_B,$$

where, $|\psi^{(i)}_j\rangle$, $j \in \{\pm 1\}$ are the respective eigenstates of the Pauli matrices σ_i, $i \in \{1,2,3\}$ and $0 \le p_i \le 1$ are the probabilities at which Alice performs the corresponding Pauli measurement. In the following we will drop the subscripts A and B for simplicity. Now, if Alice and Bob share a classically correlated trit system randomly sampled over $\{1,2,3\}$, then for an arbitrary two-level quantum state $\rho = \frac{1}{2}(\mathbb{I} + \vec{n}.\vec{\sigma})$, we obtain

$$\begin{aligned} \mathcal{N}(\rho) &= \frac{1}{3}\sum_{i=1}^{3}\Big(\frac{1 \pm n_i}{2}\Big)|\psi^{(i)}_{\mp 1}\rangle\langle\psi^{(i)}_{\mp 1}| \\ &= \frac{1}{3}\sum_{i=1}^{3}\Big(\frac{1 \pm n_i}{2}\Big)\frac{1}{2}(\mathbb{I} \mp \sigma_i) \\ &= \frac{1}{2}(\mathbb{I} - \frac{1}{3}\vec{n}.\vec{\sigma}) \\ &= \frac{1}{3}\sum_{i=1}^{3}\sigma_i \rho \sigma_i. \end{aligned}$$

Appendix E: Simulation of entanglement-breaking qubit channels

An entanglement-breaking channel Φ_{CQ} is called classical-quantum (CQ) if its action on arbitrary state $\rho \in L(\mathcal{H})$ can be expressed as $\Phi_{CQ}(\rho) = \sum_k R_k \langle\psi_k|\rho|\psi_k\rangle$, where R_ks are arbitrary density matrices and $\{|\psi_k\rangle\}$ constitutes an orthonormal basis. Being a special case, a qubit CQ map $\Phi^{\texttt{qubit}}_{CQ}$ assumes a particularly simple form

$$\Phi^{\texttt{qubit}}_{CQ}(\rho) = R_0\langle\psi|\rho|\psi\rangle + R_1\langle\psi^\perp|\rho|\psi^\perp\rangle. \tag{E1}$$

for all possible $\rho \in L(\mathbb{C}^2)$, where $\mathbb{C}^2$ is the two dimensional complex Hilbert space.

It is known that every extreme point of the set of entanglement-breaking qubit maps is an extreme CQ map $\mathcal{E}^j_{CQ}$. Therefore, the set of entanglement-breaking qubit maps is the convex hull of extreme qubit CQ maps [3, 4]. Hence, every entanglement-breaking qubit map $\Phi^{\texttt{qubit}}$ can be written as

$$\Phi^{\texttt{qubit}}(\rho) = \sum_j p_j \mathcal{E}^j_{CQ}(\rho), \quad \text{with} \quad \sum_j p_j = 1. \tag{E2}$$

Since $\mathcal{E}^j_{CQ}$ is an extreme CQ map, we have $\mathcal{E}^j_{CQ}(\rho) = R^j_0\langle\psi_j|\rho|\psi_j\rangle + R^j_1\langle\psi^\perp_j|\rho|\psi^\perp_j\rangle$, with $R^j_{0(1)} = |\phi^j_{0(1)}\rangle\langle\phi^j_{0(1)}|$ being pure states. Now, two distant parties, one (say Alice) in possession of an arbitrary state ρ, and the other (say Bob) responsible for simulating $\Phi^{\texttt{qubit}}(\rho)$ employ the following protocol.

Protocol 1 (Simulation of a qubit entanglement-breaking channel). *Before the protocol begins, Alice and Bob share a classically correlated random variable k distributed with the same probabilities as in Eq.* (E2).

1. *If the value of the random variable is j, which they obtain with probability p_j, Alice measures the state ρ in her possession in the basis $\{|\psi_j\rangle, |\psi^\perp_j\rangle\}$.*

2. *Alice then communicates a bit* $\{0 \mapsto |\psi_j\rangle, 1 \mapsto |\psi_j^\perp\rangle\}$ *conveying the measurement outcome to Bob.*

3. *Bob prepares* R_0^j *or* R_1^j *when the communicated bit is* 0 *or* 1 *respectively.*

The net effect of the protocol is to simulate every $\mathcal{E}_{CQ}^j$ with a probability p_j, and on average, generates the same map as in Eq. (E2). Therefore, Protocol. 1 demonstrates that every entanglement-breaking qubit channel can be simulated by using a perfect classical bit channel assisted by shared randomness.

Abstract. Coherent control over the configurations of quantum devices in a network scenario offer promising advantages in quantum information processing. So far such advantages were assuming the control system is uncorrelated with the communicated data. Here, we explore the power of quantum correlation between them, showing two communication tasks that can be accomplished by the information-erasing channels if and only if the sender shares prior entanglement with a third party controlling the network configuration. While the first task considers a-bit of classical communication keeping secret to the controller, the second task is to establish entanglement among a number of distant receivers.

Keywords: Coherent control of path, Indefinite causal order

1 Introduction

A remarkable feature for quantum particles is their ability to undergo multiple evolutions simultaneously, in a coherent superposition [1, 2, 3]. The application of such an interfering evolution to filter out the noise in a quantum channel was first pointed out in [4] and thereafter, recently studied from various information theoretic perspectives both theoretically [5, 6, 7, 8] and experimentally [9, 10]. In a quantum network, such a superposition of multiple evolutions, i.e., the quantum channels, is modelled in presence of a control system, which routes the target system through a particular path.

Alternatively, such a network model, equipped with the control system, also provides an interesting toy model to investigate a new causal structure that could potentially arise in a quantum theory of gravity [11, 12]. A concrete example of such a new causal structure is quantum SWITCH [13, 14], which connects two quantum channels in an order determined by the quantumness of the control and gives rise to causal nonseparability [15, 16]. Over the past decade, quantum SWITCH is found to offer information processing advantages in various tasks [17, 18, 19, 20, 7, 21, 22, 23, 24, 25, 26, 27, 28] and also stimulated several experimental investigations [29, 30, 31, 32, 33, 34].

Previous studies of all coherently controlled networks, including quantum SWITCH, are explored the benefits of quantum superposition by assuming the controller initially uncorrelated with the target system. It is possible, however, to consider a more general situation, in which the control and the target share prior correlations. In this situation, the data processed by the network becomes correlated with its evolution, potentially giving rise to new phenomena that could not be observed in the traditional setting.

Here, we explore the power of quantum correlations between control and target, showing that they enable two communication tasks that are impossible with an uncorrelated control, or even with a classically correlated one. Both the tasks involve an assistance of the controller, who also shares a prior quantum correlation with the sender. The controller, for instance, can be considered as a communication company responsible for the connection between the sender and the receiver, or in general, any third party who has access on the outcomes of the measurement performed on the control system.

Our first task considers perfect communication of the classical information via completely information-erasing channels and also without leaking any information to the controller. The second task is to establish bipartite, or more generally, multipartite entangled network between sender and a number of spatially separated receivers via the same completely information-erasing channels. We show that both the tasks can be accomplished perfectly if and only if the sender and the controller initially shares a maximally entangled state.

2 Basic Framework

The general quantum evolutions are referred as quantum channels acting on the set of quantum states. Mathematically, the action of any quantum channel (say $\mathcal{E}$) on a quantum system (ρ) can be identified with a non-unique set of operators ($\{E_i\}$), namely the Kraus operators, summed up to the identity operator on the system Hilbert space.

Quantum SWITCH, in its simplest form, considers two such quantum channels $\mathcal{E}$ and $\mathcal{F}$ acting on a single target system in a controlled-order fashion and gives rise to a combined channel $\mathcal{S}(\mathcal{E},\mathcal{F})$ acting jointly on the target-control pair. In particular, the target effectively passes through two different quantum channels $\mathcal{E}\circ\mathcal{F}$ or $\mathcal{F}\circ\mathcal{E}$ depending upon whether the control system is in $|0\rangle$ or $|1\rangle$ state. In the present context $\mathcal{E}$ and $\mathcal{F}$ are regarded as completely information erasing *qubit* channels, which we will denote as $\mathcal{E}_0$ and $\mathcal{E}_1$ respectively. Here, $\mathcal{E}_\psi$ represents a channel which produces a fixed quantum state $|\psi\rangle$ independent of the input system. The Kraus opera-

*g.tamal91@gmail.com

†sapsoy@gmail.com

‡giulio@cs.hku.hk

tors for the combined SWITCH channel $\mathcal{S}(\mathcal{E}_0,\mathcal{E}_1)$ can be found in the main manuscript [35], where we have also considered the SWITCH action of d-different completely information erasing *qudit* channels $\{\mathcal{E}_0,\mathcal{E}_1,\cdots,\mathcal{E}_{d-1}\}$.

The control over the choice of the same quantum channels $\mathcal{E}_0$ and $\mathcal{E}_1$ can be described in a similar manner. Here, the target system will pass through the channel $\mathcal{E}_0$ or, $\mathcal{E}_1$, whenever the control is in the state $|0\rangle$ or, $|1\rangle$ respectively. We will denote the combined channel action on the target-control quantum system for the controlled choice configuration as $\mathcal{T}(\mathcal{E}_0,\mathcal{E}_1)$ and the corresponding Kraus operators can be found in our main manuscript [35].

It is important to mention that while the controlled-order configuration (quantum SWITCH) $\mathcal{S}(\mathcal{E}_0,\mathcal{E}_1)$ depends only on the channels, the Kraus operators of controlled-choice configuration $\mathcal{T}(\mathcal{E}_0,\mathcal{E}_1)$ involves a couple of complex parameters, generally referred as vacuum amplitudes from the experimental perspectives [6, 36]. Physically, these externally tunable parameters carry the information of the trivial path, i.e., the path which is *not* used in a particular instance of choice.

In our main manuscript [35], it is shown in detail that for a particular choice of these external parameters, the effective action of $\mathcal{T}(\mathcal{E}_0,\mathcal{E}_1)$ exactly matches with that of the $\mathcal{S}(\mathcal{E}_0,\mathcal{E}_1)$, even when more numbers of orthogonal completely information erasing channels $\{\mathcal{E}_0,\mathcal{E}_1,\cdots,\mathcal{E}_{d-1}\}$ are considered. This, in turn, helps us to continue our analysis only with the controlled-order configuration of these channels, which at the same time holds true for the controlled-choice configuration.

3 Private Classical Communication

Consider a scenario where the sender Alice would like to communicate a bit of classical information to a distant receiver Bob. Unfortunately, they do not have access to clean classical channel, instead connected via a pair of completely information erasing set-reset channels: one of them ($\mathcal{E}_0$) produces the bit "0" and the other ($\mathcal{E}_1$) produces "1" irrespective of any input they fed into the line. However, there is a third party Charlie who has access to a controlling quibt which can rout the sent bit through these channels in any arbitrary order. Still there is no way to establish perfect classical communication between Alice and Bob, keeping Charlie completely ignorant, by probing the channels in a definite causal order. Interestingly, the SWITCH action $\mathcal{S}(\mathcal{E}_0,\mathcal{E}_1)$ has a decoherence free subspace spanned $|0\rangle\otimes|0\rangle$ and $|1\rangle\otimes|1\rangle$ (see our main manuscript [35] for detailed analysis), which contains both states $|\Phi^{\pm}\rangle := \frac{1}{\sqrt{2}}(|0\rangle\otimes|0\rangle \pm |1\rangle\otimes|1\rangle)$. Therefore, if Alice initially shares a maximally entangled state $|\Phi^{+}\rangle$ with Charlie, then she can encode the classical bit $x\in\{0,1\}$ on her qubit by applying nothing or, a σ_x rotation respectively. In either case, the state will be transferred intact after the SWITCH action and Charlie will remain ignorant about the message x since it is impossible distinguish between $|\Phi^{\pm}\rangle$ just by performing measurement on the control qubit. Then Charlie can perform a σ_x measurement on his qubit and communicate the information classically to Bob. Finally, performing again a σ_x measurement on his qubit Bob can decode the bit x perfectly: $x=0$ when Bob's outcome is same with that of Charlie and $x=1$ otherwise (see Fig. 1).It can be shown that the initial maximal entanglement between Alice and Charlie is necessary for the perfect accomplishment of the task. This, along with its d-dimensional generalization, leads us to the following theorem, proof of which is presented in our main manuscript [35].

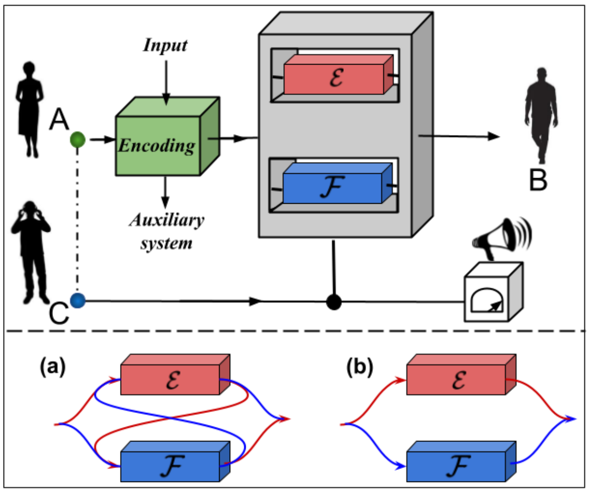

Figure 1: Communication with the assistance of correlations with a control system. Sender A communicates to receiver B through two noisy channels with the assistance of a third party, C, who controls the configuration of the two channels. We focus on the case where the configuration is either the order of the noisy channels (a), or the choice of which channel is used (b). The controller and the sender initially share an entangled state (dotted line on the top left). Then, the sender encodes some input data, by performing local operations on her part of the entangled state. The output of these operations is a signal that is sent through the network, and possibly some auxiliary systems that the sender will keep in her laboratory. After transmission, the controller assists the receiver by providing him classical information extracted from the control system.

Theorem 1 *A classical dit can be communicated, with no leakage to the controller, through d orthogonal information-erasing channels in d coherently controlled configurations if and only if the control and target are initially in a d-dimensional maximally entangled state.*

Theorem 1 also highlights a fundamental difference between protocols using control over the configurations of channel configuration and protocols using the noisy channels in a fixed configuration, while allowing control over operations performed before and after each noisy channel [37]. Such a protocol allow Alice to communication the classical information through the control, in a way which is completely independent of the noisy channels [38]. However, it generally leaks information to Charlie, violating the privacy requirement of the present task (see [35] for detailed analysis).

4 Establishment of Multipartite Entanglement

Our second task is to establish entanglement between the sender (Alice) and an N numbers of spatially separated receivers (Bobs), all of whom are connected via completely information erasing channels to Alice. While the general scenario with an arbitrary N is discussed in our main manuscript [35], here we will consider only $N = 2$ case. Note that, being completely information erasing, such channels acting on one part of a multipartite quantum state, destroy any form of initial correlations the state possessed and hence obviously entanglement-breaking too. This suggests that it is impossible to establish entanglement between sender and receivers via these channels, even in any possible definite causal orderings. However, if Alice is allowed to share a maximally entangled state $|\Phi^+\rangle$ with Charlie, using two ancillary qubit $|0\rangle \otimes |0\rangle$ and applying C-NOT gate on each of them she can prepare a four-partite GHZ state $\frac{1}{\sqrt{2}}(|0\rangle^{\otimes 4} + |1\rangle^{\otimes 4})$. Then keeping the first qubit with her, Alice can send other two qubits via individual SWITCH channels. Interestingly, it transfers the GHZ state unaffected at the receivers end (see our manuscript [35]), which could also be understood intuitively, by recalling the fact that every individual SWITCH line admits a decoherence free subspace. However, the crucial point here is that using a single control qubit and two different transmission lines of completely information erasing channels $\mathcal{E}_0$ and $\mathcal{E}_1$ it is possible to preserve the subspace spanned by $|0\rangle \otimes |0\rangle \otimes |0\rangle$ and $|1\rangle \otimes |1\rangle \otimes |1\rangle$. Finally, by performing the Fourier measurement on the control qubit, Charlie can communicate the outcome to any of the receivers (say Bob$_1$) and accordingly Bob$_1$ can apply a local unitary to establish a tripartite GHZ state among Alice, Bob$_2$ and himself. In particular, Bob$_1$ will do nothing or apply a σ_x rotation if Charlie communicates + or −, respectively (see Fig 2).

Also, in this case we have proved the necessity of maximal entanglement between target and control system for GHZ distribution [35]. This result and its d-dimensional generalization is contained in the following theorem.

Theorem 2 *Coherent control on the configuration of d orthogonal information-erasing channels enables perfect establishment of d-dimensional GHZ states between the sender and N spatially separated receivers if and only if the sender and controller initially share a d-dimensional maximally entangled state.*

Besides of its various information theoretic applications [39, 40, 41], a distributed GHZ-state can be used to achieve a task, namely Random Receiver Quantum Communication (RRQC) [23], where the goal is to transfer the quantum information to one of many receivers, however, whose identity will only be disclosed after the communication. Strikingly, initial target-control entanglement allows us to accomplish RRQC with completely information erasing channels, while in lack of such entanglement the task can only be achieved with channels which preserve classical information [23].

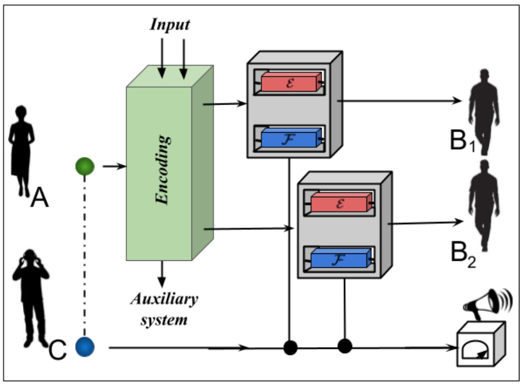

Figure 2: Distribution of entanglement to $N = 2$ spatially separated parties through coherently controlled information-erasing channels. The task can be perfectly achieved with the assistance of shared entanglement between the qubit at the sender's end, and a qubit used to control the configuration of channels between the sender and each receiver.

5 Conclusion

In this work we initiated the exploration of quantum networks whose configuration is entangled with the state of a control system. We focused on applications to quantum communication, identifying two tasks that can be perfectly achieved if and only if the sender and the controller initially share maximal entanglement.

Both the tasks highlights the power of initial target-control quantum correlation in compared to their uncorrelated or even classically correlated configurations. Moreover, the first task points out that the coherent controlled configurations of noisy channels are fundamentally different from those of other protocols where the encoded information bypassed via the controller, avoiding the actual noises. The coherently controlled configurations in our work involves both the coherently controlled order as well as the coherently controlled choice configuration of the completely information erasing channels.

While in this work we focused on quantum communication, we believe that protocols using quantum correlations with the configuration of quantum networks will have significant implications also in other quantum technology, likely including quantum metrology, thermodynamics, and computation. Such protocols are potentially within reach with existing photonic setups, and would mark a new step in the development of a quantum technology of coherent control over the configurations of quantum networks.

Abstract. We introduce the task of shadow process simulation, where the goal is to reproduce the expectation values of arbitrary quantum observables at the output of a target physical process. When the sender and receiver share no-signaling resources, we show that the performance of shadow process simulation exceeds that of conventional process simulation protocols in scenarios including communication, noise simulation, and data compression. Remarkably, shadow simulation provides increased accuracy without any increase in the sampling cost. Overall, shadow simulation provides a unified framework for a variety of quantum protocols, including probabilistic error cancellation and circuit knitting in quantum computing.

Keywords: Quantum Shannon Theory, Quantum Channel Simulation, Quantum Communication

1 Introduction

Quantum channel simulation [1, 2, 3, 4, 5, 6, 7] is a fundamental primitive in quantum Shannon theory. It serves as an abstraction of many practical tasks in quantum computing and quantum information processing, including quantum communication and quantum error correction. The aim of quantum channel simulation is to reproduce the output states of a target channel using an available channel $\mathcal{N}$.

However, in many practical scenarios, what we are interested in is shadow information, *i.e.*, the information about the expectation values of all possible observables. Shadow information unravels many physical properties of a quantum system, and its importance has motivated the invention of protocols such as shadow tomography [8] and classical shadow [9]. In this work, we ask the question that what if we only want to transmit the shadow information through quantum channels? Would it be an easier task than transmitting the quantum state itself?

To answer this question, we introduce a new quantum information processing task called *shadow process simulation*, where the goal is to reproduce the expectation values of all possible observables at the output of a target quantum channel. Shadow process simulation can be regarded as a generalization of quantum channel simulation. This generalization is useful for quantum information processing in the near term, where classical post-processing of expectation values can be used to simulate larger quantum memories [10, 11, 12, 13], probe properties of quantum systems [14, 9, 15], mitigate errors [16, 17, 18, 19, 20, 21], and simulate unphysical operations [22, 23, 24].

We start the investigation under a framework where the two parties involved in this task are allowed to perform local operations assisted by shared classical randomness. In particular, within this framework we establish the following:

- We prove that shared randomness together with post-processing can simulate arbitrary no-signaling resources, providing a complete characterization of randomness-assisted shadow simulation codes.
- We find in several applications that shadow simulation overcomes the limits of conventional channel simulation at the price of an increase in the number of samples needed to accurately estimate the expectation values.
- We also find scenarios where shadow simulation achieves lower error than conventional channel simulation without any sampling overhead, demonstrating a strict advantage of shadow simulation.

Our work challenges a common interpretation of quantum states. While the quantum state is often regarded as an encoding of the expectation values of arbitrary observables, we show that transferring an encoding of all expectation values is a much less demanding task than transmitting the quantum state. In this respect, the quantum state appears to be more than just a catalogue of expectation values.

2 Framework of shadow process simulation

Conventional channel simulation aims to simulate the action of a target channel $\mathcal{M}$ by using an available channel $\mathcal{N}$. To accomplish this simulation, Alice and Bob perform local encoding and decoding channels $\mathcal{E}$ and $\mathcal{D}$, respectively, thus obtaining the new channel $\mathcal{D}\circ\mathcal{N}\circ\mathcal{E} = \mathcal{M}$. In shadow simulation, because the final result is the expectation value of some observable, which is obtained by multiple rounds of measurement, Alice and Bob can sample their local operations $\mathcal{E}$ and $\mathcal{D}$ from sets of channels $\{\mathcal{E}_j\}$ and $\{\mathcal{D}_j\}$ in each round as in Figure 1. We allow

[*] This submission is based on arXiv:2401.14934.

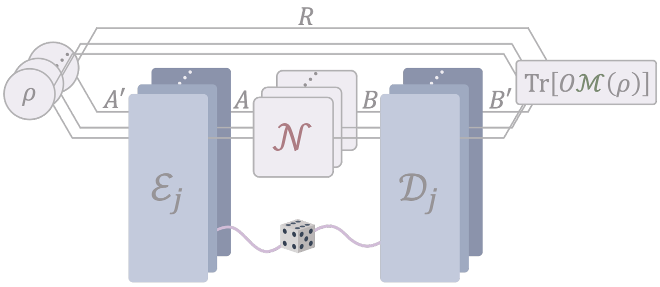

Figure 1: Alice and Bob are connected through a quantum channel $\mathcal{N}$. The task is to enable Bob to estimate the expectation value $\mathrm{Tr}[O\mathcal{M}(\rho)]$ of an arbitrary observable O on the output state $\mathcal{M}(\rho)$ produced by a target channel $\mathcal{M}$ when acting on an arbitrary input state ρ of a reference system R and a system A' in Alice's laboratory.

them to share classical randomness so that they can coordinate their local operations. After the output has been measured, Bob can post-process the measurement statistics, taking arbitrary linear combinations of the outcome probabilities. In this way, Alice and Bob can simulate any linear map of the form

$$\widetilde{\mathcal{S}}(\mathcal{N}) = \sum_j \lambda_j \mathcal{D}_j \circ \mathcal{N} \circ \mathcal{E}_j. \tag{1}$$

The linear map $\widetilde{\mathcal{S}}$ is an example of a supermap [25], that is, a map acting on the vector space spanned by quantum operations. Due to the possible presence of negative coefficients in the set $\{\lambda_j\}$, $\widetilde{\mathcal{S}}$ generally does not transform quantum channels into quantum channels. Instead, it transforms Hermitian-preserving maps into Hermitian-preserving maps, and we call such a supermap a *virtual supermap*.

A virtual supermap $\widetilde{\mathcal{S}}$ of the form (1) represents a *randomness-assisted shadow simulation code*, corresponding to a virtual bipartite process $\widehat{\mathcal{S}} := \sum_j \lambda_j \mathcal{E}_j \otimes \mathcal{D}_j$. It is rather straightforward to see that this virtual process is *no-signaling*, meaning that no information is exchanged between Alice and Bob. The converse is less straightforward but turns out to be true:

Theorem 1 *A virtual supermap $\widetilde{\mathcal{S}}$ is a randomness-assisted shadow simulation code if and only if the corresponding virtual process $\widehat{\mathcal{S}}$ is no-signaling.*

Theorem 1 provides a complete characterization of the randomness-assisted shadow simulation codes and allows us to directly study shadow process simulation with *no-signaling shadow simulation codes*, which are linear combinations of quantum no-signaling codes. Sampling over different quantum codes generally leads to a sampling overhead, meaning that more rounds of data collection are needed to estimate the desired expectation values [22, 23, 24]. We define the *sampling cost* of the code $\widetilde{\mathcal{S}}$ as

$$c_{\mathrm{smp}}\left(\widetilde{\mathcal{S}}\right) := \inf\left\{p_+ + p_- \,\middle|\, \widehat{\mathcal{S}} = p_+\widehat{\mathcal{S}}^+ - p_-\widehat{\mathcal{S}}^-,\ p_\pm \in \mathbb{R}^+,\right.$$
$$\left.\widehat{\mathcal{S}}^\pm \in \mathrm{CPTP} \cap \mathrm{NS}\right\}, \tag{2}$$

where CPTP and NS denote the set of completely positive, trace-preserving maps and the set of no-signaling virtual processes, respectively, and $\mathbb{R}^+$ is the set of non-negative real numbers. Note that every conventional channel simulation protocol has $c_{\mathrm{smp}}\left(\widetilde{\mathcal{S}}\right) = 1$, since the map $\widehat{\mathcal{S}}$ is a no-signaling channel. The sampling cost c_{smp} characterizes the range of post-processed measurement outcomes, and a wider range requires more rounds of measurement to accurately estimate the expectation value.

3 Surpassing the limits of quantum channel simulation

We illustrate the power of shadow simulation in three applications. The first application we consider is communication, which can be viewed as the simulation of an identity channel acting on a given number of qubits. The key quantity to study in communication is capacity, which measures the highest dimension of an identity channel that one can simulate. Here, we define the one-shot γ-cost shadow capacity assisted by no-signaling resources as

$$Q^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{N}) := \sup_{d,\widehat{\mathcal{S}}\in\mathrm{NS}} \left\{\log_2 d \,\middle|\, \widetilde{\mathcal{S}}(\mathcal{N}) = \mathrm{id}_d,\ c_{\mathrm{smp}}\left(\widetilde{\mathcal{S}}\right) \le \gamma\right\}, \tag{3}$$

where the dimension d is optimized over positive integers. In the technical version, we provide an explicit semidefinite programming expression for the shadow capacity for every given γ. This expression extends the previously known expression for the one-shot quantum capacity assisted by no-signaling resources [4, 26], which can be retrieved in the special case $\gamma = 1$. For $\gamma > 1$, we show that the one-shot shadow capacity is generally larger than the one-shot quantum capacity. A concrete example is provided below:

Theorem 2 *Let $\mathcal{N}_{\mathrm{depo},p}(\rho) = p\rho + (1-p)\mathbb{1}_2/2$ be a single-qubit depolarizing channel, where $p \in [0,1]$ is a probability and $\mathbb{1}_2$ is the identity operator on $\mathbb{C}^2$. For $\gamma \ge 1$, the one-shot zero-error shadow capacity assisted by no-signaling resources is*

$$Q^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p}) = \log_2 \left\lfloor \sqrt{2p\gamma + p + 1} \right\rfloor. \tag{4}$$

Theorem 2 shows that a qubit depolarizing channel can be used to transmit the expectation values of all observables on a quantum system of arbitrarily high dimension, at the price of an increased sampling cost, provided that the channel is not completely depolarizing ($p \neq 0$). This fact is interesting because, for $p \le 1/3$, the depolarizing channel is entanglement-breaking [27] and therefore it cannot reliably transmit quantum states, even if infinitely many copies of it are available.

In the technical version, we also show similar results in the dual task to communication, that is, the simulation of a target noisy channel using a noiseless one. In this case, the key quantity is the simulation cost, defined as

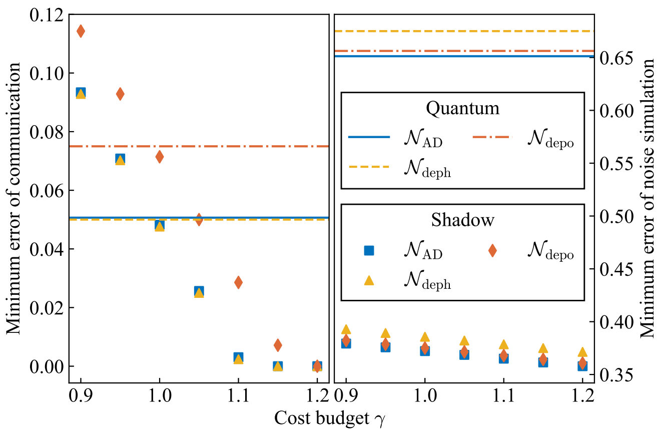

Figure 2: Compared with that of conventional quantum channel simulation (horizontal lines), the minimum error in the shadow simulation case is smaller with the same or even lower cost budget.

the number of noiseless qubits that must be sent from the sender to a receiver. The shadow simulation cost generalizes the quantum simulation cost studied in the conventional scenario [4, 7] and can generally be reduced by increasing the sampling cost.

Besides communication and noisy channel simulation, shadow simulation also allows simulating high-dimensional noiseless channels using low-dimensional ones. This shadow simulation can also be viewed as a form of quantum compression, where the goal is to store the expectation values of all possible observables. Alternatively, one can view this shadow simulation as the simulation of a high-dimensional quantum measurement using a low-dimensional one. In the following theorem, we provide an exact characterization of the minimum sampling cost required for this shadow compression task.

Theorem 3 *Given identity channels* id_d *and* $\mathrm{id}_{d'}$ *with* $d' \geq d \geq 2$, *the minimum sampling cost of an exact shadow simulation of* $\mathrm{id}_{d'}$ *using* id_d *and no-signaling resources is* $2{d'}^2/d^2 - 1$.

This theorem implies that one can perfectly shadow-simulate the transmission of an arbitrarily large number of qubits, and thus any quantum channel, using only a single-qubit identity channel, a task that cannot be achieved in conventional channel simulation. Furthermore, it also implies that every channel with non-zero shadow capacity $Q^{(1)}_{\gamma,\text{NS}}$ for some γ can shadow-simulate every other channel, generalizing the result of Theorem 2 for single-qubit depolarizing channels.

4 Achieving lower error without sampling overhead

In the zero-error scenario, we have seen that the shadow capacity and shadow simulation cost coincide with the conventional capacity and simulation cost for $\gamma = 1$. In stark contrast, we now show that in the approximate scenario, shadow simulation can achieve lower error than conventional channel simulation even if $\gamma = 1$.

In this scenario, our goal is to convert channel $\mathcal{N}$ into an approximation of channel $\mathcal{M}$. We define the minimum error achievable with sampling cost bounded by γ based on the diamond distance:

$$\varepsilon^*_{\gamma,\text{NS}}(\mathcal{N},\mathcal{M}) := \inf_{\widetilde{\mathcal{S}}\in\text{NS}} \left\{ \frac{1}{2}\left\| \widetilde{\mathcal{S}}(\mathcal{N}) - \mathcal{M} \right\|_{\diamond} \;\middle|\; c_{\text{smp}}\left(\widetilde{\mathcal{S}}\right) \leq \gamma \right\}. \tag{5}$$

We use the diamond distance because, as we show in the technical version, it captures the worst case error of measuring observables. Figure 2 presents the minimum errors in both shadow communication and noisy channel simulation at different cost budgets ranging from 0.9 to 1.2 for some commonly used quantum channels. Surprisingly, shadow simulation codes achieve smaller errors at the same or even lower levels of sampling cost compared with quantum simulation codes. This implies that classical post-processing can enhance the transmission of expectation values even if no sampling overhead is involved.

5 Conclusions

In this work, we introduced the task of shadow simulation of quantum channels, showing that transmitting and processing expectation values of arbitrary observables is generally a less demanding task than transmitting and processing quantum states. Besides their foundational interest, our results are relevant to practical applications to NISQ quantum technologies. Our work provides new efficient methods for measuring observables with noisy quantum devices, and new communication protocols for transmitting multiple complementary pieces of information, opening up a systematic way to study new quantum protocols that sample over different transformations of quantum processes.

We introduce the task of shadow process simulation, where the goal is to reproduce the expectation values of arbitrary quantum observables at the output of a target physical process. When the sender and receiver share no-signaling resources, we show that the performance of shadow process simulation exceeds that of conventional process simulation protocols in a variety of scenarios including communication, noise simulation, and data compression. Remarkably, shadow simulation provides increased accuracy without any increase in the sampling cost. Overall, shadow simulation provides a unified framework for a variety of quantum protocols, including probabilistic error cancellation and circuit knitting in quantum computing.

Introduction.— "What is a quantum state?" is one of the central questions in the foundations of quantum mechanics. A minimal interpretation is that a quantum state is a compact way to represent all expectation values of the possible observable quantities associated to a given system. This interpretation may suggest that transmitting a quantum state from a place to another is equivalent to transferring information about the expectation values of arbitrary observables. In this paper, we show that this equivalence does not hold when the sender and receiver share random bits: in this case, transferring information about all possible expectation values is a much less demanding task than transferring the quantum state. Some instances of this phenomenon can be derived from results on error mitigation [1–3], while other more radical instances emerge from a new task that we name *shadow simulation of quantum processes.*

The settings of shadow simulation are illustrated in Figure 1, and we only consider finite-dimensional quantum systems. A sender, Alice, has access to a quantum communication channel $\mathcal{N}$ that transfers quantum states to a receiver, Bob. Initially, Alice has a quantum system A', which may be entangled with a reference system R and together in an arbitrary state ρ possibly unknown to her. Bob has a device that measures an arbitrary observable O, possibly unknown to him. The goal of shadow simulation is to enable Bob to estimate the expectation value $\mathrm{Tr}[O\mathcal{M}(\rho)]$ for a target quantum channel $\mathcal{M}$. To achieve this goal, Alice and Bob perform pre- and post-processing operations $\mathcal{E}_j$ and $\mathcal{D}_j$, coordinating their actions using shared random bits. To estimate the expectation value $\mathrm{Tr}[O\mathcal{M}(\rho)]$, Bob will perform measurements at the output of the channel $\mathcal{N}$ and perform classical post-processing on the measurement outcomes. The protocol is successful if Bob's estimate deviates from the true value $\mathrm{Tr}[O\mathcal{M}(\rho)]$ by less than a given error tolerance ϵ, for every possible state ρ and for every possible observable O.

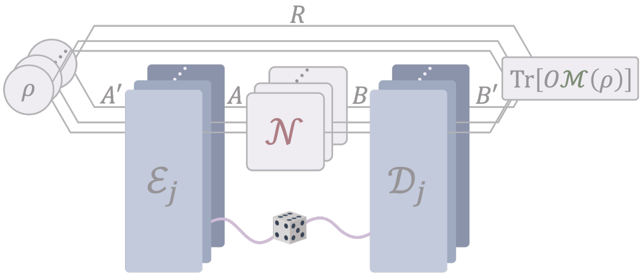

FIG. 1. **Shadow simulation of quantum channels.** A sender (Alice) and a receiver (Bob) are connected through a quantum channel $\mathcal{N}$. The task is to enable Bob to estimate the expectation value $\mathrm{Tr}[O\mathcal{M}(\rho)]$ of an arbitrary observable O on the output state $\mathcal{M}(\rho)$ produced by a target channel $\mathcal{M}$ when acting on an arbitrary input state ρ of a reference system R and a system A' in Alice's laboratory. To achieve this task, Alice and Bob can coordinate their operations $\mathcal{E}_j$ and $\mathcal{D}_j$ by sharing random bits.

Shadow simulation can be viewed as a generalization of the task of quantum channel simulation [4–10]. The crucial difference is that shadow simulation does not aim at reproducing the output states of a target channel, but only their "shadow information" [11, 12], *i.e.*, the information about the expectation values of all possible observables. This generalization is useful for quantum information processing in the noisy intermediate-scale quantum (NISQ) era [13], where classical post-processing of expectation values can be used to simulate larger quantum memories [14–17], probe properties of quantum systems [18–20], mitigate errors [1, 2, 21–24], and simulate unphysical operations [25–27].

Remarkably, we find that shadow simulation is not constrained by the limits of conventional channel simulation. For example, we show that one can perfectly shadow-simulate the transmission of an arbitrarily large number of qubits using only a single-qubit channel, a task that cannot be achieved in conventional channel simulation. In this example, the transmission of a larger number of qubits is simulated at the price of an increase of the number of samples needed to accurately estimate the expectation values. Quite surprisingly, we also find scenarios where shadow simulation achieves lower error than conventional channel simulation without any overhead in sampling cost, provided that Alice and Bob have access to no-signaling quantum resources. Overall, our results reveal that shared classical randomness and classical post-processing are valuable resources for quantum communication and other quantum technologies.

Framework: virtual supermaps. — In conventional quantum channel simulation, the aim is to simulate the action of a target channel $\mathcal{M}$ (with input A' and output B') by using an available channel $\mathcal{N}$ (with input A and output B). To convert channel $\mathcal{N}$ into an approximation of channel $\mathcal{M}$, Alice and Bob perform encoding and decoding channels $\mathcal{E}$ and $\mathcal{D}$ in their local laboratories, respectively, thus obtaining the new channel $\mathcal{D} \circ \mathcal{N} \circ \mathcal{E}$. In shadow simulation, instead, Bob can sample his decoding operation $\mathcal{D}$ from a set of channels $\{\mathcal{D}_j\}$ and, after the output has been measured, he can post-process the measurement statistics, taking arbitrary linear combinations of the outcome probabilities. In this way, Bob can effectively implement a linear map of the form $\widetilde{\mathcal{D}}= \sum_j \lambda_j \mathcal{D}_j$, where $\{\lambda_j\}$ are arbitrary real numbers [1, 18, 25, 28]. Note that in general $\widetilde{\mathcal{D}}$ is not a valid quantum channel (completely positive, trace-preserving map), but rather a virtual channel, described by a Hermitian-preserving and trace-scaling map [11, 29–32].

More generally, Bob may share classical randomness with Alice, and coordinate his local operations with hers, as in Figure 1. Hence, Bob's post-processing gives rise to linear maps of the form

$$\widetilde{\mathcal{S}}(\mathcal{N}) = \sum_j \lambda_j \mathcal{D}_j \circ \mathcal{N} \circ \mathcal{E}_j . \tag{1}$$

The linear map $\widetilde{\mathcal{S}}$ is an example of a supermap [33–35], that is, a map acting on the vector space spanned by quantum operations. Unlike most supermaps considered so far, however, $\widetilde{\mathcal{S}}$ generally does not transform quantum channels into quantum channels due to the possible presence of negative coefficients in the set $\{\lambda_j\}$. Instead, $\widetilde{\mathcal{S}}$ transforms Hermitian-preserving maps into Hermitian-preserving maps, and trace-scaling maps into trace-scaling maps with possibly different scaling factors. We call the supermaps with these two properties *virtual supermaps.*

Any virtual supermap $\widetilde{\mathcal{S}}$ is into one-to-one correspondence with a virtual bipartite processes $\widehat{\mathcal{S}}$ transforming operators on system $A'B$ into operators on system AB'. The correspondence can be made explicit by decomposing the action of the virtual supermap $\widetilde{\mathcal{S}}$ as $\widetilde{\mathcal{S}}(\mathcal{N}) = \sum_k \mathcal{B}_k \circ \mathcal{N} \circ \mathcal{A}_k$, where $\mathcal{A}_k$ and $\mathcal{B}_k$ are suitable linear maps, and by defining $\widehat{\mathcal{S}} := \sum_k \mathcal{A}_k \otimes \mathcal{B}_k$.

A virtual supermap $\widetilde{\mathcal{S}}$ of the special form (1) will be called a *(randomness-assisted) shadow simulation code.* For a shadow simulation code $\widetilde{\mathcal{S}}$, the corresponding virtual bipartite process is $\widehat{\mathcal{S}} := \sum_j \lambda_j \mathcal{E}_j \otimes \mathcal{D}_j$. It is rather straightforward to see that this virtual process is *no-signaling*, meaning that for every pair of operators $\rho_{A'}$ and ρ_B acting on A' and B, respectively, the operator $\mathsf{Tr}_{B'}[\widehat{\mathcal{S}}(\rho_{A'} \otimes \rho_B)]$ is independent of ρ_B, and the operator $\mathsf{Tr}_A[\widehat{\mathcal{S}}(\rho_{A'} \otimes \rho_B)]$ is independent of $\rho_{A'}$. The converse is less straightforward but turns out to be true, yielding a complete characterization of the randomness-assisted shadow simulation codes:

Theorem 1 *A virtual supermap $\widetilde{\mathcal{S}}$ is a randomness-assisted shadow simulation code if and only if the corresponding virtual process $\widehat{\mathcal{S}}$ is no-signaling.*

The proof is provided in Appendix A. An important consequence of Theorem 1 is that shared randomness and classical post-processing can be used to simulate arbitrary no-signaling resources. Explicitly, a no-signaling resource is represented by a quantum no-signaling channel $\widehat{\mathcal{S}}$ [36, 37] with input $A'B$ and output AB'. Using the no-signaling channel $\widehat{\mathcal{S}}$, Alice and Bob can implement the corresponding supermap $\widetilde{\mathcal{S}}$, which can be implemented using only shared randomness and classical post-processing, as guaranteed by Theorem 1. The same conclusion applies to protocols using local operations and shared entanglement, which is a special case of no-signaling resources.

No-signaling assisted shadow simulation.— Quantum no-signaling resources have been extensively studied in quantum Shannon theory [7, 10, 38]. We now extend their study to the task of shadow simulation. While in channel simulation Alice and Bob have the assistance of a fixed no-signaling channel, in shadow simulation they can more generally sample over a set of no-signaling channels $\{\widehat{\mathcal{S}}_j\}$. Using classical post-processing, they can reproduce the virtual supermap $\widetilde{\mathcal{S}} := \sum_j \lambda_j \widetilde{\mathcal{S}}_j$. We call this supermap a *no-signaling shadow simulation code.*

The randomization over different settings generally comes at the price of an increased sampling cost, meaning that more rounds of data collection are needed to estimate the desired expectation values [25–27]. To quantify this price, we define the *sampling cost* of the code $\widetilde{\mathcal{S}}$ as

$$c_{\text{smp}}\left(\widetilde{\mathcal{S}}\right) := \inf\Big\{p_+ + p_- \;\Big|\; \widehat{\mathcal{S}} = p_+ \widehat{\mathcal{S}}^+ - p_- \widehat{\mathcal{S}}^-, \\ p_\pm \in \mathbb{R}^+,\; \widehat{\mathcal{S}}^\pm \in \text{CPTP} \cap \text{NS}\Big\},$$

where CPTP and NS denote the set of completely positive, trace-preserving maps and the set of no-signaling virtual processes, respectively, and $\mathbb{R}^+$ is the set of non-negative real numbers. Note that every conventional channel simulation protocol has $c_{\rm smp}\left(\widetilde{\mathcal{S}}\right) = 1$, since the map $\widehat{\mathcal{S}}$ is a no-signaling channel. The sampling cost $c_{\rm smp}$ characterizes the range of post-processed measurement outcomes. Intuitively, a wider range requires more rounds of measurement to accurately estimate the expectation value. In Appendix A, we rigorously justify the definition of sampling cost using Hoeffding's inequality [39], which confirms this intuition.

To quantify the simulation error, we adopt the diamond-norm distance $\|\widetilde{\mathcal{S}}(\mathcal{N}) - \mathcal{M}\|_\diamond/2 =: p_{\rm err}(\widetilde{\mathcal{S}};\mathcal{N},\mathcal{M})$ [40], which is the same as the worst case error of measuring observables as we show in Appendix A. This error measure applies to conventional and shadow simulation, with the only difference that in the conventional scenario the no-signaling bipartite map $\widehat{\mathcal{S}}$ is completely positive and trace-preserving, while in the shadow simulation scenario $\widehat{\mathcal{S}}$ can be any Hermitian-preserving and trace-scaling map.

The optimal quantum limits to the task of shadow simulation can be quantified by two parameters. One is the minimum error achievable with sampling cost bounded by γ:

$$\varepsilon^*_{\gamma,\rm NS}(\mathcal{N},\mathcal{M}) := \inf_{\widehat{\mathcal{S}}\in \rm NS} \left\{ p_{\rm err}\left(\widetilde{\mathcal{S}};\mathcal{N},\mathcal{M}\right) \;\middle|\; c_{\rm smp}\left(\widetilde{\mathcal{S}}\right) \leq \gamma \right\}.$$

The other is the minimum sampling cost needed to guarantee that the error is below a given error tolerance ε:

$$\gamma^*_{\varepsilon,\rm NS}\left(\mathcal{N},\mathcal{M}\right) := \inf_{\widehat{\mathcal{S}}\in \rm NS} \left\{ c_{\rm smp}\left(\widetilde{\mathcal{S}}\right) \;\middle|\; p_{\rm err}\left(\widetilde{\mathcal{S}};\mathcal{N},\mathcal{M}\right) \leq \varepsilon \right\}.$$

Both quantities can be computed efficiently by semidefinite programs (SDPs) given in Appendix B. In the following, we illustrate the power of shadow simulation in three applications.

Shadow communication.— Quantum communication can be viewed as a special case of channel simulation: the simulation of an identity channel acting on a given number of qubits. Here we consider the zero-error scenario [7, 41–43], corresponding to an exact simulation of the identity channel. We define a zero-error shadow communication code $\widetilde{\mathcal{S}}$ as a supermap satisfying the condition $p_{\rm err}\left(\widetilde{\mathcal{S}};\mathcal{N},{\rm id}_d\right) = 0$, where ${\rm id}_d$ denotes the identity channel on a d-dimensional quantum system. Then, we define the one-shot zero-error shadow capacity assisted by no-signaling resources as

$$Q^{(1)}_{\gamma,\rm NS}(\mathcal{N}) := \sup_{d,\widehat{\mathcal{S}}\in \rm NS} \left\{ \log_2 d \;\middle|\; \widetilde{\mathcal{S}}(\mathcal{N}) = {\rm id}_d,\; c_{\rm smp}\left(\widetilde{\mathcal{S}}\right) \leq \gamma \right\}, \tag{2}$$

where the dimension d is optimized over positive integers. Here the term "one-shot" refers to the fact that the communication protocol only involves quantum operations on the inputs and outputs of a *single* use of channel $\mathcal{N}$. Note that $\widetilde{\mathcal{S}}$ is not a physical operations but a virtual one implemented as the average action across multiple rounds, where each round involves a single use of $\mathcal{N}$.

In Appendix C, we provide an explicit SDP expression for the shadow capacity for every given γ. This expression extends the previously known expression for the one-shot zero-error quantum capacity assisted by no-signaling resources [7, 44], which can be retrieved in the special case $\gamma = 1$.

For $\gamma > 1$, we show that the zero-error shadow capacity is generally larger than the zero-error quantum capacity. A concrete example is provided by the following theorem:

Theorem 2 *Let $\mathcal{N}_{{\rm depo},p}(\rho) = p\rho + (1-p)\mathbb{1}_2/2$ be a single-qubit depolarizing channel, where $p \in [0,1]$ is a probability and $\mathbb{1}_2$ is the identity operator on $\mathbb{C}^2$. For $\gamma \geq 1$, the one-shot zero-error shadow capacity assisted by no-signaling resources is*

$$Q^{(1)}_{\gamma,\rm NS}(\mathcal{N}_{{\rm depo},p}) = \log_2 \left\lfloor \sqrt{2p\gamma + p + 1} \right\rfloor. \tag{3}$$

Eq. (3) shows that the shadow capacity can become arbitrarily large as γ grows, provided that the channel is not completely depolarizing ($p \neq 0$). In other words, a qubit depolarizing channel can be used to transmit the expectation values of all observables on a quantum system of arbitrarily high dimension, at the price of an increased sampling cost.

It is useful to compare the above finding with the existing results about error mitigation. Error mitigation protocols, such as those in Refs. [25, 45], can be used to transmit arbitrary expectation values *on a single-qubit state* through repeated uses of a single-qubit depolarizing channel. This fact is interesting because, for $p \leq 1/3$, the depolarizing channel is entanglement-breaking [46] and therefore it cannot reliably transmit quantum states, even if infinitely many copies of it are available. Theorem 2 takes this observation to a much stronger level: not only can a qubit depolarizing channel transmit all expectation values for a single qubit, but also it can transmit the expectation values on arbitrarily high-dimensional quantum systems.

Now, recall that Theorem 1 guarantees that every no-signaling code can be simulated with local operations and shared classical randomness, generally at the expense of a larger sampling cost. Combining this fact with Theorem 2, we obtain that randomness-assisted shadow simulation codes can have arbitrarily large capacity for sufficiently large values of the sampling cost. The same argument applies to shadow simulation codes assisted by shared entanglement. Remarkably, these phenomena are not limited to the depolarizing channel, but apply in general to every quantum channel achieving at least one non-zero value of the zero-error no-signaling assisted shadow

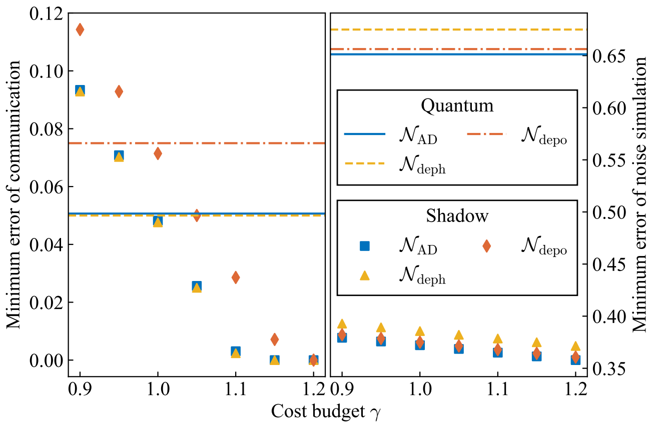

FIG. 2. Minimum error of shadow simulation of common channels under different budgets for sampling cost. The channels we consider here are the amplitude damping channel, the dephasing channel, and the depolarizing channel at a low noise level ($p = 0.9$). For communication (left), single-qubit versions of these channels are studied, and the goal is to simulate a qubit identity channel id_2. For noise simulation (right), we consider simulating two-qubit versions of the noisy channels via id_2, where by a two-qubit amplitude damping channel we mean two single-qubit amplitude damping channels acting independently on two qubits. Compared with that of conventional quantum channel simulation (horizontal lines), the minimum error in the shadow case is smaller with the same or even lower cost budget.

capacity (2). The proof of this fact will be provided at the end of the next section.

Shadow simulation via noiseless channels.— The dual task to communication is the simulation of a target noisy channel using a noiseless channel. In this case, the key quantity is the simulation cost, defined as the number of noiseless qubits that must be sent from the sender to a receiver. In the context of zero-error shadow simulation assisted by no-signaling resources, we define the one-shot shadow simulation cost of channel $\mathcal{M}$ as

$$S^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{M}) := \inf_{d,\widetilde{\mathcal{S}}\in\mathrm{NS}} \left\{ \log_2 d \;\middle|\; \widetilde{\mathcal{S}}(\mathrm{id}_d) = \mathcal{M},\ c_{\mathrm{smp}}\left(\widetilde{\mathcal{S}}\right) \leq \gamma \right\},$$

where the dimension d is optimized over positive integers. This quantity generalizes the one-shot zero-error simulation cost studied in the conventional quantum channel simulation scenario [7, 10]. In Appendix D, we provide an SDP for the zero-error shadow simulation cost, and we show that the simulation cost can generally be reduced by increasing the sampling cost.

Besides simulating noisy channels, shadow simulation also allows simulating high-dimensional noiseless channels using low-dimensional ones. This shadow simulation can also be viewed as a form of quantum compression, where the goal is to store the expectation values of all possible observables. Alternatively, one can view this shadow simulation as the simulation of a high-dimensional quantum measurement using a low-dimensional one. Differing from previous works that aimed at the simulation of the full measurement statistics [47], however, shadow simulation focuses on the expectation values.

The minimum sampling cost for simulating a higher-dimensional identity channel is provided by the following theorem:

Theorem 3 *Given identity channels* id_d *and* $\mathrm{id}_{d'}$ *with* $d' \geq d \geq 2$, *the minimum sampling cost of an exact shadow simulation of* $\mathrm{id}_{d'}$ *using* id_d *and no-signaling resources is*

$$\gamma^*_{0,\mathrm{NS}}\left(\mathrm{id}_d, \mathrm{id}_{d'}\right) = 2\left(\frac{d'}{d}\right)^2 - 1. \tag{4}$$

Theorem 3 has two important implications. First, it implies that the shadow simulation cost of every quantum channel can be lowered to 1 by allowing a sufficiently large sampling overhead. Indeed, let $\mathcal{M}$ be a quantum channel with one-shot zero-error quantum simulation cost $S^{(1)}_{\mathrm{NS}}(\mathcal{M}) = \log_2 d'$, meaning that $\mathcal{M}$ can be simulated using $\mathrm{id}_{d'}$ through a quantum no-signaling code. In turn, Eq. (4) implies that $\mathrm{id}_{d'}$ can be shadow-simulated using a qubit identity channel, with a sampling cost $(d'^2-2)/2$. Composing the two simulations, one then gets a shadow simulation of $\mathcal{M}$ from id_2 with sampling cost $(d'^2-2)/2$.

Second, Theorem 3 implies that every channel $\mathcal{N}$ with non-zero shadow capacity $Q^{(1)}_{\gamma,\mathrm{NS}}$ for some γ can shadow-simulate every other channel $\mathcal{M}$. In particular, it can simulate an identity channel on arbitrarily many qubits. This observation generalizes the result of Theorem 2 for single-qubit depolarizing channels.

Achieving lower error without sampling overhead.— In the zero-error scenario, we have seen that the shadow capacity and shadow simulation cost coincide with the conventional capacity and simulation cost for $\gamma = 1$. In stark contrast, we now show that in the approximate scenario, shadow simulation can achieve lower error than conventional channel simulation even if $\gamma = 1$, that is, without incurring a sampling overhead. As examples, we consider three common quantum channels: the single-qubit amplitude damping channel $\mathcal{N}_{\mathrm{AD}}$ with two Kraus operators $|0\rangle\langle 0| + \sqrt{p}|1\rangle\langle 1|$ and $\sqrt{1-p}|0\rangle\langle 1|$, the dephasing channel $\mathcal{N}_{\mathrm{deph}}(\cdot) = p(\cdot) + (1-p)\mathrm{diag}(\cdot)$, and the depolarizing channel $\mathcal{N}_{\mathrm{depo}}(\cdot) = p(\cdot) + (1-p)\mathsf{Tr}[\cdot]\mathbb{1}_d/d$. For each channel, the parameter $p \in [0,1]$ indicates the level of the noise. For the depolarizing channel, the parameter d represents the dimension of the system on which they act, and $\mathbb{1}_d$ is the d-dimensional identity operator.

Figure 2 shows the minimum errors in both shadow communication and noisy channel simulation at different cost budgets ranging from 0.9 to 1.2. Surprisingly, shadow simulation codes achieve a smaller error at the same or even a lower level of cost compared with quantum simulation codes, whose sampling cost is 1. The difference is more evident in the plot of noise simulation, where the minimum error of quantum codes is almost the twice of the shadow simulation codes. This implies that classical post-processing can enhance the transmission of expectation values even if no sampling overhead is involved. The underlying reason can be attributed to the existence of a virtual channel simulable by a unit-cost shadow simulation code that is closer to the target channel than all quantum channels simulable by quantum simulation codes.

Conclusions.— In this paper, we introduced the task of shadow simulation of quantum channels, showing that transmitting and processing expectation values of arbitrary observables is generally a less demanding task than transmitting and processing quantum states. Besides their foundational interest, our results are relevant to practical applications to NISQ quantum technologies, as they provide more efficient schemes for measuring observables at the output of noisy quantum devices. An interesting direction of future research is to explore scenarios where only a given set of physically relevant observables is concerned [12, 19]. Our results also open up a systematic way to study new quantum protocols that sample over different transformations of quantum processes, known as quantum supermaps [33–35].

Appendix A: Shadow Simulation Codes

A quantum simulation code $(\mathcal{E}_{A'\to A}, \mathcal{D}_{B\to B'})$ can be written as a quantum supermap [33], which sends a quantum channel $\mathcal{N}_{A\to B}$ to another quantum channel $\mathcal{M}_{A'\to B'}$. Each quantum supermap is associated with a bipartite quantum operation that is no-signaling from Bob to Alice, *i.e.*, no transmission of information from Bob to Alice. In the setting of shadow simulation of quantum channels, simulation codes are not restricted to quantum supermaps. A shadow simulation code allows classical post-processing so that its encoding and decoding parts do not have to be quantum channels. For example, one can consider the encoding operation $\widetilde{\mathcal{E}}_{A'\to A} := \sum_j \lambda_j \mathcal{E}_{j,A'\to A}$ and the decoding operation $\widetilde{\mathcal{D}}_{B\to B'} := \sum_k \mu_k \mathcal{D}_{k,B\to B'}$ with real coefficients λ_j, μ_k and quantum channels $\mathcal{E}_{j,A'\to A}, \mathcal{D}_{k,B\to B'}$. The expectation value with respect to the state transmitted through a quantum channel $\mathcal{N}_{A\to B}$ using this shadow simulation code $\left(\widetilde{\mathcal{E}}_{A'\to A}, \widetilde{\mathcal{D}}_{B\to B'}\right)$ can be decomposed as

$$\mathrm{Tr}\left[\widetilde{\mathcal{D}}_{B\to B'} \circ \mathcal{N}_{A\to B} \circ \widetilde{\mathcal{E}}_{A'\to A}(\rho_{RA'}) O_{RB'}\right] = \sum_{j,k} \lambda_j \mu_k \mathrm{Tr}\left[\mathcal{D}_{k,B\to B'} \circ \mathcal{N}_{A\to B} \circ \mathcal{E}_{j,A'\to A}(\rho_{RA'}) O_{RB'}\right]. \tag{A1}$$

Hence, although we cannot directly implement $\widetilde{\mathcal{E}}_{A'\to A}$ and $\widetilde{\mathcal{D}}_{B\to B'}$, we can simulate their effect by sending copies of the state using quantum simulation codes sampled from $\{(\mathcal{E}_{j,A'\to A}, \mathcal{D}_{k,B\to B'})\}$ for multiple rounds and then post-processing the measurement results from all rounds.

Though the encoding operation $\widetilde{\mathcal{E}}$ and the decoding operation $\widetilde{\mathcal{D}}$ are seemingly independent, it is important to note that both maps are implemented with classical post-processing, which only happens at Bob's side after Bob completes the measurement. Therefore, Bob needs information on Alice's sampled operation in each round to guide the post-processing. Hence, we consider simulation codes where Alice and Bob have pre-shared randomness, and such codes are realized by the following steps:

1. Alice randomly samples one encoding channel $\mathcal{E}_{\alpha,A'\to A}$ from the set of channels $\{\mathcal{E}_{j,A'\to A}\}$ with a probability distribution $\Pr(\mathcal{E}_{j,A'\to A}) = |\lambda_j|/\gamma$, where $\gamma = \sum_j |\lambda_j|$, and applies the sampled channel to state $\rho_{RA'}$.

2. Alice then sends the post-encoding state $\mathcal{E}_{\alpha,A'\to A}(\rho_{RA'})$ into the noisy channel $\mathcal{N}_{A\to B}$.

3. Upon receiving the state $\mathcal{N}_{A\to B} \circ \mathcal{E}_{\alpha,A'\to A}(\rho_{RA'})$ coming out of the noisy channel, Bob applies the decoding channel $\mathcal{D}_{\alpha,B\to B'}$ to the received state, where the value α is known to Bob due to the classical randomness shared between him and Alice.

4. Bob measures the decoded state $\mathcal{D}_{\alpha,B\to B'} \circ \mathcal{N}_{A\to B} \circ \mathcal{E}_{\alpha,A'\to A}(\rho_{RA'})$ with an observable $O_{RB'}$, which gives a measurement outcome o.

5. Repeat the above steps for M times, and denote the index α and the measurement outcome o in the m-th round by α_m and o_m, respectively. Then, compute $\xi := \frac{\gamma}{M}\sum_{m=1}^{M}\operatorname{sgn}(\lambda_{\alpha_m})o_m$ as the communicated expectation value, where sgn is the sign function.

This protocol offers an unbiased estimator ξ for the desired expectation value $\mathsf{Tr}\left[\left(\widetilde{\mathcal{S}}\left(\mathcal{N}\right)\right)(\rho)O\right]$, where $\widetilde{\mathcal{S}}$ is a virtual supermap representing a randomness-assisted shadow simulation code whose action on $\mathcal{N}_{A\to B}$ is

$$\widetilde{\mathcal{S}}(\mathcal{N})_{A'\to B'} = \sum_j \lambda_j \mathcal{D}_{j,B\to B'} \circ \mathcal{N}_{A\to B} \circ \mathcal{E}_{j,A'\to A}. \tag{A2}$$

This can be seen by checking the expectation value of ξ:

$$\begin{aligned}
\mathbb{E}\left[\xi\right] &= \frac{\gamma}{M}\sum_{m=1}^{M}\mathbb{E}\left[\operatorname{sgn}(\lambda_{\alpha_m})o_m\right] && \text{(A3)}\\
&= \frac{\gamma}{M}\sum_{m=1}^{M}\sum_j \frac{|\lambda_j|}{\gamma}\operatorname{sgn}(\lambda_j)\mathsf{Tr}\left[\mathcal{D}_j\circ\mathcal{N}\circ\mathcal{E}_j(\rho)O\right] && \text{(A4)}\\
&= \frac{1}{M}\sum_{m=1}^{M}\sum_j \lambda_j\mathsf{Tr}\left[\mathcal{D}_j\circ\mathcal{N}\circ\mathcal{E}_j(\rho)O\right] && \text{(A5)}\\
&= \mathsf{Tr}\left[\sum_j \lambda_j\mathcal{D}_j\circ\mathcal{N}\circ\mathcal{E}_j(\rho)O\right] && \text{(A6)}\\
&= \mathsf{Tr}\left[\left(\widetilde{\mathcal{S}}(\mathcal{N})\right)(\rho)O\right]. && \text{(A7)}
\end{aligned}$$

Each supermap is associated with a bipartite map, and for a randomness-assisted shadow simulation code in Eq. (A2), its corresponding bipartite map is

$$\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_j \lambda_j \mathcal{E}_{j,A'\to A}\otimes\mathcal{D}_{j,B\to B'}. \tag{A8}$$

It is clear that every randomness-assisted shadow simulation code is associated with a Hermitian-preserving bipartite map. This is because the Choi operator of the associated bipartite map is Hermitian, and a map is Hermitian-preserving if and only if its Choi operator is Hermitian. In the following, we show that bipartite maps associated with randomness-assisted shadow simulation codes, besides being Hermitian-preserving, are also no-signaling. For a bipartite map $\widehat{\mathcal{S}}_{A'B\to AB'}$, being no-signaling from Bob to Alice means that the output state at A is independent of the input state at B, *i.e.*, $\mathsf{Tr}_{B'}\circ\widehat{\mathcal{S}}_{A'B\to AB'} = \widehat{\mathcal{S}}_{A'\to A}\circ\mathsf{Tr}_B$, where $\widehat{\mathcal{S}}_{A'\to A}$ is the local effective operation of the map $\widehat{\mathcal{S}}_{A'B\to AB'}$ from A to A'. By the Choi-Jamiołkowski isomorphism [48, 49], we can uniquely represent $\widehat{\mathcal{S}}_{A'B\to AB'}$ using its Choi operator $J^{\widehat{\mathcal{S}}}_{A'BAB'} := \mathrm{id}_{A'B}\otimes\widehat{\mathcal{S}}_{\bar{A}'\bar{B}\to AB'}(|\Gamma\rangle\langle\Gamma|_{A'B\bar{A}'\bar{B}})$, where $|\Gamma\rangle_{A'B\bar{A}'\bar{B}} := \sum_{j=0}^{d_{A'B}-1}|j\rangle_{A'B}|j\rangle_{\bar{A}'\bar{B}}$ is the unnormalized maximally entangled state, $d_{A'B}$ is the dimension of the system $A'B$, and the Hilbert space associated with the system $\bar{A}'\bar{B}$ is isomorphic to that of $A'B$. In terms of the map's Choi operator, no-signaling from Bob to Alice means $\mathsf{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right] = J^{\widehat{\mathcal{S}}}_{A'A}\otimes\mathbb{1}_B$, where $J^{\widehat{\mathcal{S}}}_{A'A} := \mathsf{Tr}_{BB'}[J^{\widehat{\mathcal{S}}}_{A'BAB'}]/d_B$.

Theorem 1 shows that randomness-assisted shadow simulation codes are equivalent to Hermitian-preserving no-signaling bipartite maps, which is both no-signaling from Bob to Alice and no-signaling from Alice to Bob.

Theorem 1 *A virtual supermap $\widetilde{\mathcal{S}}$ is a randomness-assisted shadow simulation code if and only if the corresponding virtual process $\widehat{\mathcal{S}}$ is no-signaling.*

Proof For the "only if" part, let $\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_j \lambda_j\mathcal{M}^{(j)}_{A'\to A}\otimes\mathcal{N}^{(j)}_{B\to B'}$ denote a bipartite map associated with an arbitrary randomness-assisted code, where $\mathcal{M}^{(j)}_{A'\to A}$ and $\mathcal{N}^{(j)}_{B\to B'}$ are quantum channels. It is clear that the Choi operator $J^{\widehat{\mathcal{S}}}_{A'BAB'} = \sum_j \lambda_j J^{\mathcal{M}^{(j)}}_{A'A}\otimes J^{\mathcal{N}^{(j)}}_{BB'}$ is Hermitian, indicating that $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving. Furthermore, as $\mathcal{M}^{(j)}_{A'\to A}$ and $\mathcal{N}^{(j)}_{B\to B'}$ are trace-preserving, *i.e.*, $\mathsf{Tr}_A\left[J^{\mathcal{M}^{(j)}}_{A'A}\right] = \mathbb{1}_{A'}$ and $\mathsf{Tr}_{B'}\left[J^{\mathcal{N}^{(j)}}_{BB'}\right] = \mathbb{1}_B$, we have

$$\mathsf{Tr}_A\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right] = \sum_j \lambda_j\mathsf{Tr}_A\left[J^{\mathcal{M}^{(j)}}_{A'A}\right]\otimes J^{\mathcal{N}^{(j)}}_{BB'} = \mathbb{1}_{A'}\otimes\sum_j \lambda_j J^{\mathcal{N}^{(j)}}_{BB'} \tag{A9}$$

and

$$\mathsf{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right]=\sum_j \lambda_j J^{\mathcal{M}^{(j)}}_{A'A}\otimes \mathsf{Tr}_{B'}\left[J^{\mathcal{N}^{(j)}}_{BB'}\right]=\sum_j \lambda_j J^{\mathcal{M}^{(j)}}_{A'A}\otimes \mathbb{1}_B, \tag{A10}$$

which imply that $\widehat{\mathcal{S}}_{A'B\to AB'}$ is no-signaling.

For the “if” part, we first assume that $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving and no-signaling. By Theorem 14 in Ref. [50], its Choi operator can be decomposed as

$$J^{\widehat{\mathcal{S}}}_{A'BAB'}=\sum_j \lambda_j M^{(j)}_{A'A}\otimes N^{(j)}_{BB'}, \tag{A11}$$

where, for each j, λ_j is a real number, and $M^{(j)}_{A'A}$ and $N^{(j)}_{BB'}$ are Hermitian operators such that $\mathsf{Tr}_A\left[M^{(j)}_{A'A}\right]$ and $\mathsf{Tr}_{B'}\left[N^{(j)}_{BB'}\right]$ are proportional to the identity operators $\mathbb{1}_{A'}$ and $\mathbb{1}_B$, respectively. In other words, we can treat $M^{(j)}_{A'A}$ and $N^{(j)}_{BB'}$ as Choi operators for some Hermitian-preserving and trace-scaling (HPTS) maps $\widetilde{\mathcal{M}}^{(j)}_{A'\to A}$ and $\widetilde{\mathcal{N}}^{(j)}_{B\to B'}$, respectively. Here, trace-scaling means that the map scales the trace of the input operator with a constant factor.

According to Lemma 6 in Ref. [11], every HPTS map can be written as a linear combination of two quantum channels. Thus, we can write $\widehat{\mathcal{S}}_{A'B\to AB'}$ as

$$\begin{aligned}\widehat{\mathcal{S}}_{A'B\to AB'}&=\sum_j \lambda_j\widetilde{\mathcal{M}}^{(j)}_{A'\to A}\otimes\widetilde{\mathcal{N}}^{(j)}_{B\to B'} &\text{(A12)}\\ &=\sum_j \lambda_j\left(m_1\mathcal{M}^{(j,1)}_{A'\to A}+m_2\mathcal{M}^{(j,2)}_{A'\to A}\right)\otimes\left(n_1\mathcal{N}^{(j,1)}_{B\to B'}+n_2\mathcal{N}^{(j,2)}_{B\to B'}\right) &\text{(A13)}\\ &=\sum_j\sum_{k=1}^{2}\sum_{l=1}^{2}\lambda_j m_k n_l\mathcal{M}^{(j,k)}_{A'\to A}\otimes\mathcal{N}^{(j,l)}_{B\to B'}, &\text{(A14)}\end{aligned}$$

which represents a randomness-assisted shadow simulation code. ■

Alternative to pre-shared classical randomness, forward classical communication from Alice to Bob also allows Bob to acquire information on Alice’s local operation in each round. A shadow simulation protocol with the assistance of forward classical communication is represented by a bipartite linear map

$$\widehat{\mathcal{S}}_{A'B\to AB'}=\sum_j \lambda_j\mathcal{M}^{(j)}_{A'\to A}\otimes\mathcal{N}^{(j)}_{B\to B'}, \tag{A15}$$

where $\left\{\mathcal{M}^{(j)}_{A'\to A}\right\}_j$ is a quantum instrument, $\left\{\mathcal{N}^{(j)}_{B\to B'}\right\}_j$ is a collection of quantum channels, and each λ_j is a real coefficient. In the following proposition, we show that not only $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving and one-way no-signaling, but any one-way no-signaling Hermitian-preserving bipartite map represents a forward-classical-assisted shadow simulation code. For completeness, we also consider shadow simulation codes assisted by two-way classical communication, where both $\left\{\mathcal{M}^{(j)}_{A'\to A}\right\}_j$ and $\left\{\mathcal{N}^{(j)}_{B\to B'}\right\}_j$ are quantum instruments. Such codes are equivalent to the set of all bipartite Hermitian-preserving maps.

Theorem 4 *Consider a bipartite linear map $\widehat{\mathcal{S}}_{A'B\to AB'}$. It is Hermitian-preserving if and only if it corresponds to a shadow simulation code assisted by two-way classical communication. It is Hermitian-preserving and B-to-A no-signaling if and only if it corresponds to a forward-classical-assisted shadow simulation code.*

This theorem tells us that shadow simulation codes with one-way classical communication are powerful enough to simulate arbitrary quantum channels and even beyond. An intuitive explanation is that Alice can measure the initial state ρ with an informationally complete POVM and communicate the measurement outcomes to Bob so that Bob is able to reconstruct the expectation value of every observable on ρ transformed by any channel. Now, we prove this theorem by proving the following two lemmas.

Lemma 5 *A bipartite linear map $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving and B-to-A no-signaling if and only if it corresponds to a forward-classical-assisted shadow simulation code.*

Proof The "if" direction is straightforward. Let $\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_j \lambda_j \mathcal{M}^{(j)}_{A'\to A} \otimes \mathcal{N}^{(j)}_{B\to B'}$ represent a forward-classical-assisted shadow simulation code, where each $\left\{\mathcal{M}^{(j)}_{A'\to A}\right\}_j$ is a quantum instrument, and each $\mathcal{N}^{(j)}_{B\to B'}$ is a quantum channel. Then, the Choi operator of $\widehat{\mathcal{S}}_{A'B\to AB'}$ is

$$J^{\widehat{\mathcal{S}}}_{A'BAB'} = \sum_j \lambda_j J^{\mathcal{M}^{(j)}}_{A'A} \otimes J^{\mathcal{N}^{(j)}}_{BB'} . \tag{A16}$$

Clearly, $J^{\widehat{\mathcal{S}}}_{A'BAB'}$ is a Hermitian operator, indicating that $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving. In addition, $\widehat{\mathcal{S}}_{A'B\to AB'}$ is no-signaling from Bob to Alice as

$$\mathsf{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right] = \sum_j \lambda_j J^{\mathcal{M}^{(j)}}_{A'A} \otimes \mathsf{Tr}_{B'}\left[J^{\mathcal{N}^{(j)}}_{BB'}\right] = \sum_j \lambda_j J^{\mathcal{M}^{(j)}}_{A'A} \otimes \mathbb{1}_B \tag{A17}$$

due to $\mathcal{N}$ being trace-preserving.

For the "only if" direction, part of the proof is adapted from the proof of Theorem 14 in Ref. [50]. Let $\widehat{\mathcal{S}}_{A'B\to AB'}$ be a Hermitian-preserving supermap and $\left\{M^{(1)}_{A'A}, \ldots, M^{(D)}_{A'A}\right\}$ be a basis for the Hermitian operator space Herm$\,(A'A)$ on the system $A'A$, where D is the dimension of this space. Then, there exists a unique set of Hermitian operators $\left\{N^{(1)}_{BB'}, \ldots, N^{(D)}_{BB'}\right\} \subseteq$ Herm$\,(BB')$ such that $J^{\widehat{\mathcal{S}}}_{A'BAB'} = \sum_{j=1}^D M^{(j)}_{A'A} \otimes N^{(j)}_{BB'}$. For each j, let $H^{(j)}_{A'A}$ be a Hermitian operator such that $\mathsf{Tr}\left[H^{(j)}_{A'A} M^{(k)}_{A'A}\right] \neq 0$ if and only if $j = k$. Denoting the mapping $M_{A'A} \mapsto \mathsf{Tr}\left[H^{(j)}_{A'A} M^{(k)}_{A'A}\right]$ by $h^{(j)}(M_{A'A})$, we have

$$\left(h^{(j)} \otimes \mathrm{id}_{BB'}\right)\left(J^{\widehat{\mathcal{S}}}_{A'BAB'}\right) = \sum_{k=1}^D h^{(j)}\left(M^{(k)}_{A'A}\right) \otimes N^{(k)}_{BB'} = h^{(j)}\left(M^{(j)}_{A'A}\right) N^{(j)}_{BB'} . \tag{A18}$$

Because $\widehat{\mathcal{S}}_{A'B\to AB'}$ is no-signaling from Bob to Alice, we have $\mathsf{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right] = J^{\widehat{\mathcal{S}}}_{A'A} \otimes \mathbb{1}_B$. Then,

$$\left(h^{(j)} \otimes \mathrm{id}_{BB'}\right) \mathsf{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right] = h^{(j)}\left(J^{\widehat{\mathcal{S}}}_{A'A}\right) \otimes \mathbb{1}_B = h^{(j)}\left(M^{(j)}_{A'A}\right) \mathsf{Tr}_{B'}\left[N^{(j)}_{BB'}\right] , \tag{A19}$$

where the second equality holds because the order of applying $\left(h^{(j)} \otimes \mathrm{id}_{BB'}\right)$ and $\mathsf{Tr}_{B'}$ does not affect the result as they act on different subspaces.

It follows from Eq. (A19) that, for each j, $\mathsf{Tr}_{B'}\left[N^{(j)}_{BB'}\right]$ is proportional to the identity operator $\mathbb{1}_B$, and thus it serves as a Choi operator of an HPTS map, which we denote by $\widetilde{\mathcal{N}}^{(j)}_{B\to B'}$. According to Lemma 6 in Ref. [11], each $\widetilde{\mathcal{N}}^{(j)}_{B\to B'}$ can be written as a linear combination of two quantum channels, *i.e.*,

$$\widetilde{\mathcal{N}}^{(j)}_{B\to B'} = n_{j,1} \mathcal{N}^{(j,1)}_{B\to B'} + n_{j,2} \mathcal{N}^{(j,2)}_{B\to B'} , \tag{A20}$$

where $n_{j,1}$ and $n_{j,2}$ are real numbers and $\mathcal{N}^{(j,1)}_{B\to B'}$ and $\mathcal{N}^{(j,2)}_{B\to B'}$ are quantum channels.

For each Hermitian operator $M^{(j)}_{A'A}$, we can write it as the difference of two positive semidefinite operators, say, $m_{j,1} M^{(j,1)}_{A'A} - m_{j,2} M^{(j,2)}_{A'A}$, where $m_{j,1} M^{(j,1)}_{A'A}$ and $m_{j,2} M^{(j,2)}_{A'A}$ are positive semidefinite and $m_{j,1}$ and $m_{j,2}$ are positive real numbers so that $\mathsf{Tr}_A\left[M^{(j,1)}_{A'A}\right] \leq \mathbb{1}_{A'}$ and $\mathsf{Tr}_A\left[M^{(j,2)}_{A'A}\right] \leq \mathbb{1}_{A'}$. In other words, both $M^{(j,1)}_{A'A}$ and $M^{(j,2)}_{A'A}$ are Choi operators of some completely positive and trace-non-increasing (CPTN) maps, say $\mathcal{M}^{(j,1)}_{A'\to A}$ and $\mathcal{M}^{(j,2)}_{A'\to A}$, respectively. Moreover, the scalars $m_{j,1}$ and $m_{j,2}$ should be chosen so that $\sum_{j=1}^D \sum_{k=1}^2 \mathsf{Tr}_A\left[M^{(j,k)}_{A'A}\right] \leq \mathbb{1}_{A'}/2$. We will see the reason of this requirement later.

Combining the decomposition of every $M^{(j)}_{A'A}$ and every $N^{(j)}_{BB'}$, we have

$$\mathcal{S}_{A'B\to AB'} = \sum_{j=1}^{D} \left(m_{j,1}\mathcal{M}^{(j,1)}_{A'\to A} - m_{j,2}\mathcal{M}^{(j,2)}_{A'\to A} \right) \otimes \left(n_{j,1}\mathcal{N}^{(j,1)}_{B\to B'} + n_{j,2}\mathcal{N}^{(j,2)}_{B\to B'} \right) \tag{A21}$$

$$= \sum_{j=1}^{D} \Big(m_{j,1}n_{j,1}\mathcal{M}^{(j,1)}_{A'\to A} \otimes \mathcal{N}^{(j,1)}_{B\to B'} + m_{j,1}n_{j,2}\mathcal{M}^{(j,1)}_{A'\to A} \otimes \mathcal{N}^{(j,2)}_{B\to B'}$$

$$- m_{j,2}n_{j,1}\mathcal{M}^{(j,2)}_{A'\to A} \otimes \mathcal{N}^{(j,1)}_{B\to B'} - m_{j,2}n_{j,2}\mathcal{M}^{(j,2)}_{A'\to A} \otimes \mathcal{N}^{(j,2)}_{B\to B'} \Big) \tag{A22}$$

$$= \sum_{j=1}^{4D} \lambda_j \mathcal{M}^{(j)}_{A'\to A} \otimes \mathcal{N}^{(j)}_{B\to B'} \tag{A23}$$

with appropriate relabeling, where each $\lambda_j \in \{m_{j,1}n_{j,1}, m_{j,1}n_{j,2}, -m_{j,2}n_{j,1}, -m_{j,2}n_{j,2}\}_j$ is a real number, each $\mathcal{M}^{(j)}_{A'\to A} \in \left\{\mathcal{M}^{(j,1)}_{A'\to A}, \mathcal{M}^{(j,2)}_{A'\to A}\right\}_j$ is a CPTN map, and each $\mathcal{N}^{(j)}_{B\to B'} \in \left\{\mathcal{N}^{(j,1)}_{B\to B'}, \mathcal{N}^{(j,2)}_{B\to B'}\right\}_j$ is a quantum channel. Note that

$$\sum_{j=1}^{4D} \mathsf{Tr}_A \left[J^{\mathcal{M}^{(j)}}_{A'A} \right] = 2 \sum_{j=1}^{D} \sum_{k=1}^{2} \mathsf{Tr}_A \left[J^{\mathcal{M}^{(j,k)}}_{A'A} \right] \le \mathbb{1}_{A'} \tag{A24}$$

due to our choice of scalars $\{m_{j,1}, m_{j,2}\}_j$. Let $\mathcal{M}'_{A'\to A}$ be a CPTN map such that $\sum_{j=1}^{4D} \mathsf{Tr}_A \left[J^{\mathcal{M}^{(j)}}_{A'A}\right] + 2\mathsf{Tr}_A \left[J^{\mathcal{M}'}_{A'A}\right] = \mathbb{1}_{A'}$. Then, $\left\{\mathcal{M}^{(1)}, \ldots, \mathcal{M}^{(4D)}, \mathcal{M}', \mathcal{M}'\right\}$ is a quantum instrument and

$$\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_{j=1}^{4D} \lambda_j \mathcal{M}^{(j)}_{A'\to A} \otimes \mathcal{N}^{(j)}_{B\to B'} + \mathcal{M}'_{A'\to A} \otimes \mathcal{N}'_{B\to B'} - \mathcal{M}'_{A'\to A} \otimes \mathcal{N}'_{B\to B'} \tag{A25}$$

for any quantum channel $\mathcal{N}'_{B\to B'}$. Therefore, any bipartite linear map $\mathcal{S}_{A'B\to AB'}$ that is Hermitian-preserving and B-to-A no-signaling represents a forward-classical-assisted shadow simulation code. ■

Lemma 6 *A bipartite linear map $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving if and only if it corresponds to a shadow simulation code assisted by two-way classical communication.*

Proof The "if" part can be directly verified by checking that the Choi operator of a bipartite map $\sum_j \lambda_j \mathcal{M}^{(j)}_{A'\to A} \otimes \mathcal{N}^{(j)}_{B\to B'}$ is Hermitian, where both $\left\{\mathcal{M}^{(j)}_{A'\to A}\right\}_j$ and $\left\{\mathcal{N}^{(j)}_{B\to B'}\right\}_j$ are quantum instruments.

For the "only if" part, we follow the proof of Lemma 5 to write the Choi operator of a bipartite Hermitian-preserving map $\widehat{\mathcal{S}}_{A'B\to AB'}$ as $J^{\widehat{\mathcal{S}}}_{A'BAB'} = \sum_{j=1}^{D} M^{(j)}_{A'A} \otimes N^{(j)}_{BB'}$, where $M^{(j)}_{A'A}$ and $N^{(j)}_{BB'}$ are Hermitian operators. Each $M^{(j)}_{A'A}$ or $N^{(j)}_{BB'}$ can be written as the difference of two positive semidefinite operators. We write each $M^{(j)}_{A'A}$ as $m_{j,+}M^{(j,+)}_{A'A} - m_{j,-}M^{(j,-)}_{A'A}$ and each $N^{(j)}_{BB'}$ as $n_{j,+}N^{(j,+)}_{BB'} - n_{j,-}N^{(j,-)}_{BB'}$, where $m_{j,\pm}M^{(j,1)}_{A'A}, n_{j,2}N^{(j,\pm)}_{BB'}$ are positive semidefinite and $m_{j,\pm}, n_{j,\pm}$ are positive real numbers that will be fixed later. The Choi operator $J^{\widehat{\mathcal{S}}}_{A'BAB'}$ now can be written as

$$J^{\widehat{\mathcal{S}}}_{A'BAB'} = \sum_{j=1}^{D} \left(m_{j,+}M^{(j,+)}_{A'A} - m_{j,-}M^{(j,-)}_{A'A} \right) \otimes \left(n_{j,+}N^{(j,+)}_{BB'} - n_{j,-}N^{(j,-)}_{BB'} \right) \tag{A26}$$

$$= \sum_{j=1}^{D} \sum_{k\in\{+,-\}} \sum_{l\in\{+,-\}} (-1)^{1-\delta_{k,l}} m_{j,k}n_{j,l} M^{(j,k)}_{A'A} \otimes N^{(j,l)}_{BB'}, \tag{A27}$$

where $\delta_{k,l} = 1$ if $k = l$ and $\delta_{k,l} = 0$ otherwise. Because $M^{(j,\pm)}_{A'A}$ and $N^{(j,\pm)}_{BB'}$ are positive semidefinite operators, they can be treated as Choi operators of completely positive maps, say, $\mathcal{M}^{(j,\pm)}_{A'\to A}$ and $\mathcal{N}^{(j,\pm)}_{B\to B'}$. Then, we can write $\widehat{\mathcal{S}}_{A'B\to AB'}$

as

$$\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_{j=1}^{D}\sum_{k\in\{+,-\}}\sum_{l\in\{+,-\}} (-1)^{1-\delta_{k,l}} m_{j,k}n_{j,l}\mathcal{M}^{(j,k)}_{A'\to A}\otimes\mathcal{N}^{(j,l)}_{B\to B'} \tag{A28}$$

$$= \sum_{j=1}^{4D}\lambda_j \mathcal{M}^{(j)}_{A'\to A}\otimes \mathcal{N}^{(j)}_{B\to B'} \tag{A29}$$

with appropriate relabeling, where each $\lambda_j \in \left\{(-1)^{1-\delta_{k,l}} m_{j,k}n_{j,l}\right\}_{j,k,l}$ is a real number, each $\mathcal{M}^{(j)}_{A'\to A} \in \left\{\mathcal{M}^{(j,\pm)}_{A'\to A}\right\}_j$ or $\mathcal{N}^{(j)}_{B\to B'} \in \left\{\mathcal{N}^{(j,\pm)}_{B\to B'}\right\}_j$ is a CPTN map. We can fix the values of the coefficients $m_{j,\pm}$ and $n_{j,\pm}$ to be large enough so that both $\sum_{j=1}^{4D}\mathcal{M}^{(j)}_{A'\to A}$ and $\sum_{j=1}^{4D}\mathcal{N}^{(j)}_{B\to B'}$ are trace-non-increasing. Let $\mathcal{M}'_{A'\to A}$ and $\mathcal{N}'_{B\to B'}$ be CPTN maps such that $\sum_{j=1}^{4D}\mathcal{M}^{(j)}_{A'\to A} + 2\mathcal{M}'_{A'\to A}$ and $\sum_{j=1}^{4D}\mathcal{N}^{(j)}_{B\to B'} + 2\mathcal{N}'_{B\to B'}$ are CPTP. That is, $\left\{\mathcal{M}^{(1)},\dots,\mathcal{M}^{(4D)},\mathcal{M}',\mathcal{M}'\right\}$ and $\left\{\mathcal{N}^{(1)},\dots,\mathcal{N}^{(4D)},\mathcal{N}',\mathcal{N}'\right\}$ are quantum instruments. Because we can write

$$\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_{j=1}^{4D}\lambda_j \mathcal{M}^{(j)}_{A'\to A}\otimes \mathcal{N}^{(j)}_{B\to B'} + \mathcal{M}'_{A'\to A}\otimes\mathcal{N}'_{B\to B'} - \mathcal{M}'_{A'\to A}\otimes\mathcal{N}'_{B\to B'}, \tag{A30}$$

it follows that $\widehat{\mathcal{S}}_{A'B\to AB'}$ corresponds to a shadow simulation code assisted by two-way classical communication. Hence the proof. ■

From now on, we focus on no-signaling shadow simulation codes. We consider implementing such codes by sampling quantum no-signaling codes. This is possible due to the following proposition.

Proposition 7 *A bipartite linear map is Hermitian-preserving and no-signaling if and only if it is a linear combination of bipartite linear maps that correspond to quantum no-signaling codes.*

Proof For the “if” direction, let $\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_j \mathcal{S}^{(j)}_{A'B\to AB'}$ be a linear combination of bipartite linear maps that correspond to quantum no-signaling codes. The map $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving because $J^{\widehat{\mathcal{S}}}_{A'BAB'}$, the Choi operator of $\widehat{\mathcal{S}}_{A'B\to AB'}$, is Hermitian. Also, $\widehat{\mathcal{S}}_{A'B\to AB'}$ is no-signaling from B to A, because

$$\mathsf{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right] = \sum_j \lambda_j \mathsf{Tr}_{B'}\left[J^{\mathcal{S}^{(j)}}_{A'BAB'}\right] = \sum_j \lambda_j J^{\mathcal{S}^{(j)}}_{A'A}\otimes \mathbb{1}_B = J^{\widehat{\mathcal{S}}}_{A'A}\otimes \mathbb{1}_B, \tag{A31}$$

where the second inequality follows from each $\mathcal{S}^{(j)}_{A'B\to AB'}$ being no-signaling. Similarly, $\widehat{\mathcal{S}}_{A'B\to AB'}$ is no-signaling from A to B as

$$\mathsf{Tr}_{A}\left[J^{\widehat{\mathcal{S}}}_{A'BAB'}\right] = \sum_j \lambda_j \mathsf{Tr}_{A}\left[J^{\mathcal{S}^{(j)}}_{A'BAB'}\right] = \sum_j \lambda_j J^{\mathcal{S}^{(j)}}_{BB'}\otimes \mathbb{1}_{A'} = J^{\widehat{\mathcal{S}}}_{BB'}\otimes \mathbb{1}_{A'}. \tag{A32}$$

Therefore, the map $\widehat{\mathcal{S}}_{A'B\to AB'}$ is Hermitian-preserving and no-signaling.

For the “only if” part, let $\widetilde{\mathcal{S}}_{A'B\to AB'}$ be a Hermitian-preserving and no-signaling bipartite linear map. According to Theorem 1, $\widehat{\mathcal{S}}_{A'B\to AB'}$ can be decomposed as $\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_j \lambda_j \mathcal{M}^{(j)}_{A'\to A}\otimes\mathcal{N}^{(j)}_{B\to B'}$ for some quantum channels $\mathcal{M}^{(j)}_{A'\to A}$ and $\mathcal{N}^{(j)}_{B\to B'}$. Note that each $\mathcal{S}^{(j)}_{A'B\to AB'} \coloneqq \mathcal{M}^{(j)}_{A'\to A}\otimes\mathcal{N}^{(j)}_{B\to B'}$ is a bipartite linear map corresponding to a quantum no-signaling code. Therefore, $\widehat{\mathcal{S}}_{A'B\to AB'} = \sum_j \lambda_j \mathcal{S}^{(j)}_{A'B\to AB'}$ is indeed a linear combination of bipartite linear maps corresponding to quantum no-signaling codes. ■

By decomposing it into a few quantum no-signaling codes, we can implement any no-signaling shadow simulation code by sampling quantum no-signaling codes in a way similar to the protocol given earlier in this section for realizing randomness-assisted shadow simulation codes. The implementation of a no-signaling shadow simulation code incurs a cost quantifying how many sampling rounds are required. Such a cost can be derived from Hoeffding's inequality. Let $\widetilde{\mathcal{S}} = \sum_j \lambda_j \mathcal{S}_j$ be a no-signaling shadow simulation code decomposed into a linear combination of quantum no-signaling codes $\{\mathcal{S}_j\}$ so that

$$\mathsf{Tr}\left[\left(\widetilde{\mathcal{S}}\left(\mathcal{N}\right)\right)(\rho)O\right] = \sum_j \lambda_j \mathsf{Tr}\left[\left(\mathcal{S}_j\left(\mathcal{N}\right)\right)(\rho)O\right] \tag{A33}$$

for any quantum state ρ and any observable O. We assume that the observable is bounded as $\|O\|_\infty \leq 1$ so that each measurement outcome belongs to the interval $[-1,1]$. For post-processing, we multiply each measurement outcome by a factor of magnitude $\gamma := \sum_j |\lambda_j|$, and the average of all the post-processed outcomes serves as an unbiased estimator ξ for $\mathsf{Tr}\left[\left(\widetilde{\mathcal{S}}\left(\mathcal{N}\right)\right)(\rho)O\right]$. According to Hoeffding's inequality [39], the probability that the estimator has an error larger than or equal to ϵ is bounded as

$$\Pr\left(\left|\xi - \mathbb{E}\left[\xi\right]\right| \geq \epsilon\right) \leq 2\exp\left(-\frac{M\epsilon^2}{2\gamma^2}\right), \tag{A34}$$

where M is the number of sampling rounds. Hence, we can conclude that

$$M \geq \frac{2\gamma^2 \log\frac{2}{\delta}}{\epsilon^2} \tag{A35}$$

rounds are enough for the final estimation to have an error smaller than ϵ with a probability no less than $1-\delta$.

The number of rounds M is proportional to γ^2, where γ is the sum of the absolute values of the coefficients in the decomposition of $\widetilde{\mathcal{S}}$. Considering that a no-signaling shadow simulation code $\widetilde{\mathcal{S}}$ can have many different decompositions, we define its sampling cost as the smallest possible γ achieved by any feasible decomposition:

$$c_{\text{smp}}\left(\widetilde{\mathcal{S}}\right) := \inf\left\{\sum_j |\lambda_j| \;\middle|\; \widehat{\mathcal{S}} = \sum_j \lambda_j \widehat{\mathcal{S}}_j,\ \lambda_j \in \mathbb{R},\ \widehat{\mathcal{S}}_j \in \text{CPTP} \cap \text{NS}\right\}. \tag{A36}$$

Note that all the quantum no-signaling channels in the decomposition whose corresponding coefficients have the same sign can be grouped into one single quantum no-signaling channel without changing the cost. Hence, it is sufficient to consider all combinations in the form of $\widehat{\mathcal{S}} = p_+\widehat{\mathcal{S}}^+ - p_-\widehat{\mathcal{S}}^-$, where $p_\pm$ are non-negative coefficients and $\widehat{\mathcal{S}}^\pm$ are quantum no-signaling channels:

$$c_{\text{smp}}\left(\widetilde{\mathcal{S}}\right) = \inf\left\{p_+ + p_- \;\middle|\; \widehat{\mathcal{S}} = p_+\widehat{\mathcal{S}}^+ - p_-\widehat{\mathcal{S}}^-,\ p_\pm \in \mathbb{R}^+, \widehat{\mathcal{S}}_j \in \text{CPTP} \cap \text{NS}\right\}. \tag{A37}$$

Note that every conventional channel simulation protocol has a sampling cost of 1, while a shadow simulation protocol can have a sampling cost either larger or smaller than 1, in addition to being equal to 1.

Besides sampling cost, simulation error is an important indicator on the performance of a simulation code. In the main text, we use diamond distance between the simulated map $\widetilde{\mathcal{M}} := \widetilde{\mathcal{S}}(\mathcal{N})$ and the target channel $\mathcal{M}$ to measure this error. Here, we justify our choice.

As the target of our task is to estimate the expectation value, the most direct measure of the error is

$$\left|\mathsf{Tr}\left[O_{RB'}\widetilde{\mathcal{M}}_{A'\to B'}(\rho_{RA'})\right] - \mathsf{Tr}\left[O_{RB'}\mathcal{M}_{A'\to B'}(\rho_{RA'})\right]\right| \tag{A38}$$

for some given observable $O_{RB'}$ and quantum state $\rho_{RA'}$, where R is some reference system inaccessible to Alice. Because one simulation code should work for every quantum state and every observable, we consider the worst case error, which maximizes the error over all quantum states and observables. Without loss of generality, we consider only observables with $\|O\|_\infty \leq 1$ since every other observable is such an observable multiplied by a scalar:

$$\sup_{\rho_{RA'},\ O_{RB'}:\|O\|_\infty \leq 1} \left|\mathsf{Tr}[O\widetilde{\mathcal{M}}(\rho)] - \mathsf{Tr}[O\mathcal{M}(\rho)]\right|. \tag{A39}$$

Observe that the worst case error is upper-bounded by diamond norm because for any observable O and state ρ, we have

$$\begin{aligned}
\left|\mathsf{Tr}[O\widetilde{\mathcal{M}}(\rho)] - \mathsf{Tr}[O\mathcal{M}(\rho)]\right| &\leq \left|\mathsf{Tr}[O^+(\widetilde{\mathcal{M}}(\rho) - \mathcal{M}(\rho))]\right| + \left|\mathsf{Tr}[O^-(\widetilde{\mathcal{M}}(\rho) - \mathcal{M}(\rho))]\right| && \text{(A40)}\\
&\leq \frac{1}{2}\left\|\widetilde{\mathcal{M}}(\rho) - \mathcal{M}(\rho)\right\|_1 + \frac{1}{2}\left\|\widetilde{\mathcal{M}}(\rho) - \mathcal{M}(\rho)\right\|_1 && \text{(A41)}\\
&= \left\|\widetilde{\mathcal{M}}(\rho) - \mathcal{M}(\rho)\right\|_1 && \text{(A42)}\\
&\leq \left\|\widetilde{\mathcal{M}} - \mathcal{M}\right\|_\diamond, && \text{(A43)}
\end{aligned}$$

where O^+ and O^- are positive semidefinite operators representing the positive and negative parts of O, respectively. Furthermore, this upper bound is tight in the sense that there always exists an observable O and a quantum state ρ that saturate this bound. Specifically, let ρ^* be a quantum state such that $\left\|\widetilde{\mathcal{M}}(\rho^*) - \mathcal{M}(\rho^*)\right\|_1 = \left\|\widetilde{\mathcal{M}} - \mathcal{M}\right\|_\diamond$ and $O^* \geq 0$ be an observable such that $\left|\mathsf{Tr}\left[O\left(\widetilde{\mathcal{M}}(\rho^*) - \mathcal{M}(\rho^*)\right)\right]\right| = \frac{1}{2}\left\|\widetilde{\mathcal{M}}(\rho^*) - \mathcal{M}(\rho^*)\right\|$. Such state ρ^* and observable O^* always exist, and they saturate the upper bound, that is

$$\sup_{\rho,\ O:\|O\|_\infty\leq 1}\left|\mathsf{Tr}\left[O\widetilde{\mathcal{M}}(\rho)\right] - \mathsf{Tr}\left[O\mathcal{M}(\rho)\right]\right| = \left|\mathsf{Tr}\left[O^*\widetilde{\mathcal{M}}(\rho^*)\right] - \mathsf{Tr}\left[O^*\mathcal{M}(\rho^*)\right]\right| \tag{A44}$$

$$= \left\|\widetilde{\mathcal{M}} - \mathcal{M}\right\|_\diamond. \tag{A45}$$

Therefore, diamond distance is indeed the worst case error of estimating expectation values.

Appendix B: General SDPs for Minimum Error and Minimum Sampling Cost

We show that the minimum sampling cost and the minimum error of shadow simulation assisted by no-signaling codes can be formulated as SDPs. The minimum sampling cost can be formulated as

$$\gamma^*_{\varepsilon,\mathrm{NS}}(\mathcal{N},\mathcal{M}) = \inf p_+ + p_- \tag{B1a}$$

$$\text{s.t. } \widehat{\mathcal{S}} = p_+\widehat{\mathcal{S}}^+ - p_-\widehat{\mathcal{S}}^-, \tag{B1b}$$

$$\frac{1}{2}\left\|\mathcal{M}_{A'\to B'} - \widetilde{\mathcal{S}}\left(\mathcal{N}_{A\to B}\right)\right\|_\diamond \leq \varepsilon, \tag{B1c}$$

$$\widehat{\mathcal{S}}^\pm \in \mathrm{CPTP}\cap\mathrm{NS}. \tag{B1d}$$

This optimization problem can be modified to one for $\varepsilon^*_{\gamma,\mathrm{NS}}\left(\mathcal{N},\mathcal{M}\right)$ by changing the optimization objective to ε and adding the constraint $p_+ + p_- \leq \gamma$. For a pair of quantum channels, *i.e.*, CPTP maps, the diamond distance between them can be efficiently computed via a simple SDP [51]. For shadow simulation, however, the map $\widetilde{\mathcal{S}}\left(\mathcal{N}\right)$ is HPTS, which is more general than CPTP. Here, we show how to adapt the SDP for the diamond distance between two quantum channels to compute the diamond distance between any two HPTS maps.

Let $\widetilde{\mathcal{N}}_{A\to B} = p_+\mathcal{N}^+_{A\to B} - p_-\mathcal{N}^-_{A\to B}$ and $\widetilde{\mathcal{M}}_{A\to B} = q_+\mathcal{M}^+_{A\to B} - q_-\mathcal{M}^-_{A\to B}$ be two HPTS maps, where $p_\pm$ and $q_\pm$ are non-negative real numbers, and $\mathcal{N}^\pm_{A\to B}$ and $\mathcal{M}^\pm_{A\to B}$ are quantum channels. By the definition of the diamond norm, the diamond distance between these two maps is

$$\frac{1}{2}\left\|\widetilde{\mathcal{N}}_{A\to B} - \widetilde{\mathcal{M}}_{A\to B}\right\|_\diamond = \sup_{\psi_{RA}}\frac{1}{2}\left\|\widetilde{\mathcal{N}}_{A\to B}(\psi_{RA}) - \widetilde{\mathcal{M}}_{A\to B}(\psi_{RA})\right\|_1 \tag{B2}$$

$$= \sup_{\psi_{RA}}\left\{\sup_{M:0\leq M\leq \mathbb{1}}\mathsf{Tr}\left[M\left(\widetilde{\mathcal{N}}_{A\to B}(\psi_{RA}) - \widetilde{\mathcal{M}}_{A\to B}(\psi_{RA})\right)\right]\right.$$

$$\left. - \frac{1}{2}\mathsf{Tr}\left[\widetilde{\mathcal{N}}_{A\to B}(\psi_{RA}) - \widetilde{\mathcal{M}}_{A\to B}(\psi_{RA})\right]\right\}, \tag{B3}$$

where ψ_{RA} is a pure state with $d_R = d_A$, and the second equality follows from the Helstrom-Holevo theorem (see, for example, Theorem 3.13 in Ref. [52]). Defining $p \coloneqq p_+ - p_-$ and $q \coloneqq q_+ - q_-$, we have

$$\frac{1}{2}\left\|\widetilde{\mathcal{N}}_{A\to B} - \widetilde{\mathcal{M}}_{A\to B}\right\|_\diamond = \sup_{\substack{\psi_{RA}\\ M:0\leq M\leq\mathbb{1}}}\mathsf{Tr}\left[M\left(\widetilde{\mathcal{N}}_{A\to B}(\psi_{RA}) - \widetilde{\mathcal{M}}_{A\to B}(\psi_{RA})\right)\right] - \frac{p-q}{2}. \tag{B4}$$

Following the proof from Sec. 3.C.2 in Ref. [52], it is easy to show that the first term on the right hand side of the above equation can be computed using the standard SDP for the diamond distance between two quantum channels. Hence, the diamond distance between two HPTS maps can be calculated as the result obtained from the SDP for two quantum channels minus the normalized difference between the trace scalars of the two maps, *i.e.*,

$$\frac{1}{2}\left\|\widetilde{\mathcal{N}}_{A\to B} - \widetilde{\mathcal{M}}_{A\to B}\right\|_\diamond = \inf_{Z_{AB}\geq 0}\left\{\mu - \frac{p-q}{2}\ \middle|\ Z_{AB} \geq J^{\widetilde{\mathcal{N}}}_{AB} - J^{\widetilde{\mathcal{M}}}_{AB},\ \mathsf{Tr}_B[Z_{AB}] \leq \mu\mathbb{1}_A\right\}, \tag{B5}$$

where $J^{\widetilde{\mathcal{N}}}_{AB}$ and $J^{\widetilde{\mathcal{M}}}_{AB}$ are the Choi operators of $\widetilde{\mathcal{N}}_{A\to B}$ and $\widetilde{\mathcal{M}}_{A\to B}$, respectively. Then, the minimum error $\varepsilon^*_{\gamma,\mathrm{NS}}\left(\mathcal{N},\mathcal{M}\right)$ and minimum sampling cost $\gamma^*_{\varepsilon,\mathrm{NS}}$ can be written as SDPs in terms of the relevant maps' Choi operators.

Proposition 8 *Consider two quantum channels $\mathcal{N}_{A\to B}$ and $\mathcal{M}_{A'\to B'}$ whose Choi operators are $J^{\mathcal{N}}_{AB}$ and $J^{\mathcal{M}}_{A'B'}$, respectively. The minimum error of shadow simulation from $\mathcal{N}$ to $\mathcal{M}$ under no-signaling codes with a cost budget γ is given by the following SDP:*

$$\varepsilon^*_{\gamma,\mathrm{NS}}(\mathcal{N},\mathcal{M}) = \inf \varepsilon \tag{B6a}$$

$$\text{s.t. } J^{\widetilde{\mathcal{M}}}_{A'B'} = \operatorname{Tr}_{AB}\Big[\Big(\big(J^{\mathcal{N}}_{AB}\big)^T \otimes \mathbb{1}_{A'B'}\Big)\Big(J^{\widehat{\mathcal{S}}^+}_{A'BAB'} - J^{\widehat{\mathcal{S}}^-}_{A'BAB'}\Big)\Big], \tag{B6b}$$

$$Z_{A'B'} \geq 0,\ Z_{A'B'} \geq J^{\mathcal{M}}_{A'B'} - J^{\widetilde{\mathcal{M}}}_{A'B'},\ \operatorname{Tr}_{B'}[Z_{A'B'}] \leq \frac{2\varepsilon + 1 - p_+ + p_-}{2}\mathbb{1}_{A'}, \tag{B6c}$$

$$J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'} \geq 0,\ \operatorname{Tr}_{AB'}\left[J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}\right] = p_\pm \mathbb{1}_{A'B},\ p_+ + p_- \leq \gamma, \tag{B6d}$$

$$\operatorname{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}\right] = \frac{1}{d_B}\operatorname{Tr}_{BB'}\left[J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}\right] \otimes \mathbb{1}_B, \tag{B6e}$$

$$\operatorname{Tr}_{A}\left[J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}\right] = \frac{1}{d_{A'}}\operatorname{Tr}_{A'A}\left[J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}\right] \otimes \mathbb{1}_{A'}. \tag{B6f}$$

Similarly, the minimum sampling cost $\gamma^*_{\varepsilon,\mathrm{NS}}(\mathcal{N},\mathcal{M})$ under an error tolerance ε is given by changing the optimization objective of the above SDP to $p_+ + p_-$ and removing the condition $p_+ + p_- \leq \gamma$.

Appendix C: Shadow Communication

In this section, we derive the SDP for $Q^{(1)}_{\gamma,\mathrm{NS}}$, the one-shot zero-error γ-cost shadow capacity assisted by no-signaling codes, given in Theorem 11. To achieve this, we first need to derive SDPs for some other quantities, which are of interest on their own.

First, we tailor the general SDPs of minimum error and minimum sampling cost for the shadow communication task. The original SDPs are given in Proposition 8. The target channel $\mathcal{M}_{A'\to B'}$ becomes id_d, where $d = d_{A'} = d_{B'}$ is the dimension of the target noiseless channel.

Lemma 9 *Given a fixed dimension $d = d_{A'} = d_{B'}$ and an error tolerance ε, the minimum error of shadow simulation from $\mathcal{N}_{A\to B}$ to id_d under no-signaling codes with a cost budget γ is given by the following SDP:*

$$\varepsilon^*_{\gamma,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d) = \inf \varepsilon \tag{C1a}$$

$$\text{s.t. } J^{\widetilde{\mathcal{M}}}_{A'B'} = \operatorname{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T\left(T^+_{AB} - T^-_{AB}\right)\right]\frac{d^2\Phi_{A'B'} - \mathbb{1}_{A'B'}}{d\,(d^2-1)} + \operatorname{Tr}\left[V^+_A - V^-_A\right]\frac{\mathbb{1}_{A'B'} - \Phi_{A'B'}}{d\,(d^2-1)}, \tag{C1b}$$

$$Z_{A'B'} \geq 0,\ Z_{A'B'} \geq J^{\mathrm{id}_d}_{A'B'} - J^{\widetilde{\mathcal{M}}}_{A'B'},\ \operatorname{Tr}_{B'}[Z_{A'B'}] \leq \frac{1}{2}\left(2\varepsilon + 1 - \frac{\operatorname{Tr}\left[V^+_A - V^-_A\right]}{d^2}\right)\mathbb{1}_{A'}, \tag{C1c}$$

$$0 \leq T^\pm_{AB} \leq V^\pm_A \otimes \mathbb{1}_B,\ \operatorname{Tr}_A\left[T^\pm_{AB}\right] = \frac{\operatorname{Tr}\left[V^\pm_A\right]}{d^2}\mathbb{1}_B,\ \frac{\operatorname{Tr}\left[V^+_A + V^-_A\right]}{d^2} \leq \gamma. \tag{C1d}$$

Similarly, the minimum sampling cost $\gamma^*_{\varepsilon,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d)$ with an error tolerance ε is given by changing the optimization objective of the above SDP to $\operatorname{Tr}\left[V^+_A + V^-_A\right]/d^2$ and removing the condition $\operatorname{Tr}\left[V^+_A + V^-_A\right]/d^2 \leq \gamma$.

Proof When the target identity channel has dimension d, and we denote it by id_d, the minimum error and the minimum sampling cost of shadow communication over the channel $\mathcal{N}$ are $\varepsilon^*_{\gamma,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d)$ and $\gamma^*_{\varepsilon,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d)$, respectively, where ε and γ are the error tolerance and cost budget. Below, we exploit the symmetry of optimal solutions under twirling to obtain simplified SDPs for both quantities.

Consider the SDP for minimum error in Proposition 8 with the target channel being id_d first. Note that if $J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}$ are optimal, then for any d-dimensional unitary U, the Choi operators

$$\bar{J}^{\widehat{\mathcal{S}}^\pm}_{A'BAB'} \coloneqq (U_{A'} \otimes \overline{U}_{B'})J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}(U_{A'} \otimes \overline{U}_{B'})^\dagger \tag{C2}$$

are also optimal, where $\overline{U}$ denotes the complex conjugate of U. The optimality of $\bar{J}^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}$ can be checked by verifying that they satisfy all the conditions in the original SDP while keeping the value of ε unchanged. Due to the linearity of the constraints, any convex combination of optimal Choi operators is still optimal. Hence, we now redefine

$$\bar{J}^{\widehat{\mathcal{S}}^\pm}_{A'BAB'} \coloneqq \int dU (U_{A'} \otimes \overline{U}_{B'})J^{\widehat{\mathcal{S}}^\pm}_{A'BAB'}(U_{A'} \otimes \overline{U}_{B'})^\dagger, \tag{C3}$$

where the integral is taken over the Haar measure on the unitary group. This new pair of Choi operators are also optimal. It was shown in Ref. [53] that the twirling operation $\mathcal{T}_{A'B'} : X_{A'B'} \mapsto \int dU (U_{A'} \otimes \overline{U}_{B'}) X_{A'B'} (U_{A'} \otimes \overline{U}_{B'})^\dagger$ has the following action:

$$\mathcal{T}_{A'B'}(X_{A'B'}) = \mathsf{Tr}[X_{A'B'}\Phi_{A'B'}]\Phi_{A'B'} + \frac{\mathsf{Tr}[X_{A'B'}(\mathbb{1}_{A'B'} - \Phi_{A'B'})]}{d^2-1}(\mathbb{1}_{A'B'} - \Phi_{A'B'}), \tag{C4}$$

where $\Phi_{A'B'} = |\Phi\rangle\langle\Phi|_{A'B'}$ is the maximally entangled state with $|\Phi\rangle_{A'B'} \coloneqq \frac{1}{\sqrt{d}}\sum_{j=0}^{d-1}|j\rangle_{A'}|j\rangle_{B'}$. Thus,

$$\bar{J}^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'} = \Phi_{A'B'} \otimes \mathsf{Tr}_{A'B'}\left[J^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'}\Phi_{A'B'}\right] + (\mathbb{1}_{A'B'} - \Phi_{A'B'}) \otimes \frac{\mathsf{Tr}_{A'B'}\left[J^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'}(\mathbb{1}_{A'B'} - \Phi_{A'B'})\right]}{d^2-1}. \tag{C5}$$

Without any constraints, $\mathsf{Tr}_{A'B'}\left[J^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'}\Phi_{A'B'}\right]$ and $\mathsf{Tr}_{A'B'}\left[J^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'}(\mathbb{1}_{A'B'} - \Phi_{A'B'})\right] / \left(d^2-1\right)$ can be any linear operators. We denote them by $T^{\pm}_{AB}$ and $W^{\pm}_{AB}$, respectively, so that

$$\bar{J}^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'} = \Phi_{A'B'} \otimes T^{\pm}_{AB} + (\mathbb{1}_{A'B'} - \Phi_{A'B'}) \otimes W^{\pm}_{AB}. \tag{C6}$$

We now express SDP (B6) in terms of $T^{\pm}_{AB}$ and $W^{\pm}_{AB}$. The Choi operator of the simulated map $\widetilde{\mathcal{M}}$ in Eq. (B6b) can be written as

$$J^{\widetilde{\mathcal{M}}}_{A'B'} = \mathsf{Tr}\left[(J^{\mathcal{N}}_{AB})^T(T^{+}_{AB} - T^{-}_{AB})\right]\Phi_{A'B'} + \mathsf{Tr}\left[(J^{\mathcal{N}}_{AB})^T(W^{+}_{AB} - W^{-}_{AB})\right](\mathbb{1}_{A'B'} - \Phi_{A'B'}). \tag{C7}$$

The first inequality in condition (B6d) becomes $T^{\pm}_{AB} \geq 0$ and $W^{\pm}_{AB} \geq 0$, and the equality in condition (B6d) can be written as

$$\frac{\mathbb{1}_{A'}}{d} \otimes \mathsf{Tr}_A\left[T^{\pm}_{AB} + (d^2-1)W^{\pm}_{AB}\right] = p_{\pm}\mathbb{1}_{A'B}, \tag{C8}$$

which is equivalent to the requirement that

$$\mathsf{Tr}_A\left[T^{\pm}_{AB} + (d^2-1)W^{\pm}_{AB}\right] = dp_{\pm}\mathbb{1}_{B}. \tag{C9}$$

For the B-to-A no-signaling condition (B6e), its left-hand side can be written as

$$\mathsf{Tr}_{B'}\left[J^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'}\right] = \frac{\mathbb{1}_{A'}}{d} \otimes \left(T^{\pm}_{AB} + \left(d^2-1\right)W^{\pm}_{AB}\right), \tag{C10}$$

and its right-hand side can be written as

$$\frac{1}{d_B}\mathsf{Tr}_{BB'}\left[J^{\widehat{\mathcal{S}}^{\pm}}_{A'BAB'}\right] \otimes \mathbb{1}_B = \frac{\mathbb{1}_{A'}}{d} \otimes \mathsf{Tr}_B\left[T^{\pm}_{AB} + \left(d^2-1\right)W^{\pm}_{AB}\right] \otimes \frac{\mathbb{1}_B}{d_B}. \tag{C11}$$

Hence, the condition (B6e) is equivalent to

$$T^{\pm}_{AB} + \left(d^2-1\right)W^{\pm}_{AB} = \mathsf{Tr}_B\left[T^{\pm}_{AB} + \left(d^2-1\right)W^{\pm}_{AB}\right] \otimes \frac{\mathbb{1}_B}{d_B}. \tag{C12}$$

Similarly, the right-hand side of the A-to-B no-signaling condition (B6f) can be simplified as

$$\frac{\mathbb{1}_{A'B'}}{d^2} \otimes \mathsf{Tr}_A\left[T^{\pm}_{AB} + \left(d^2-1\right)W^{\pm}_{AB}\right] = \frac{p_{\pm}\mathbb{1}_{A'BB'}}{d} \tag{C13}$$

due to Eq. (C9). Hence, the condition (B6f) is equivalent to

$$\Phi_{A'B'} \otimes \mathsf{Tr}_A\left[T^{\pm}_{AB}\right] + (\mathbb{1}_{A'B'} - \Phi_{A'B'}) \otimes \mathsf{Tr}_A\left[W^{\pm}_{AB}\right] = \frac{p_{\pm}\mathbb{1}_{A'BB'}}{d}. \tag{C14}$$

Note that the equation above holds if and only if $\mathsf{Tr}_A\left[T^{\pm}_{AB}\right] = \mathsf{Tr}_A\left[W^{\pm}_{AB}\right] = \frac{p_{\pm}\mathbb{1}_B}{d}$, which implies Eq. (C9).

Now the original SDP has been simplified to

$$\varepsilon^*_{\gamma,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d) = \inf \varepsilon \tag{C15a}$$

$$\text{s.t. } J^{\widetilde{\mathcal{M}}}_{A'B'} = \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T\left(T^+_{AB}-T^-_{AB}\right)\right]\Phi_{A'B'} + \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T\left(W^+_{AB}-W^-_{AB}\right)\right]\left(\mathbb{1}_{A'B'}-\Phi_{A'B'}\right), \tag{C15b}$$

$$Z_{A'B'} \geq 0,\ Z_{A'B'} \geq J^{\mathrm{id}_d}_{A'B'} - J^{\widetilde{\mathcal{M}}}_{A'B'},\ \mathrm{Tr}_{B'}[Z_{A'B'}] \leq \frac{2\varepsilon+1-p_++p_-}{2}\mathbb{1}_{A'}, \tag{C15c}$$

$$T^\pm_{AB} \geq 0,\ W^\pm_{AB} \geq 0,\ \mathrm{Tr}_A\left[T^\pm_{AB}\right] = \mathrm{Tr}_A\left[W^\pm_{AB}\right] = \frac{p_\pm \mathbb{1}_B}{d},\ p_+ + p_- \leq \gamma, \tag{C15d}$$

$$T^\pm_{AB} + \left(d^2-1\right)W^\pm_{AB} = \mathrm{Tr}_B\left[T^\pm_{AB} + \left(d^2-1\right)W^\pm_{AB}\right] \otimes \frac{\mathbb{1}_B}{d_B}. \tag{C15e}$$

Denoting $V^\pm_A \coloneqq d\mathrm{Tr}_B\left[T^\pm_{AB} + \left(d^2-1\right)W^\pm_{AB}\right]/d_B$, by condition (C15e), we can write the variables $W^\pm_{AB}$ in terms of $V^\pm_A$ and $T^\pm_{AB}$ as

$$\left(d^2-1\right)dW^\pm_{AB} = V^\pm_A \otimes \mathbb{1}_B - dT^\pm_{AB}. \tag{C16}$$

Then, other conditions involving $W^\pm_{AB}$ can also be written as conditions on $V^\pm_A$ and $T^\pm_{AB}$. The condition $W^\pm_{AB} \geq 0$ becomes $V^\pm_A \otimes \mathbb{1}_B \geq dT^\pm_{AB}$. The condition $\mathrm{Tr}_A\left[W^\pm_{AB}\right] = \frac{p_\pm \mathbb{1}_B}{d}$ becomes

$$d\mathrm{Tr}_A\left[W^\pm_{AB}\right] = \frac{\mathrm{Tr}\left[V^\pm_A\right]\mathbb{1}_B - p_\pm \mathbb{1}_B}{d^2-1} = p_\pm \mathbb{1}_B, \tag{C17}$$

which is equivalent to requiring $\mathrm{Tr}\left[V^\pm_A\right] = d^2 p_\pm$. Finally, the Choi operator of the simulated map $\widetilde{\mathcal{M}}$ can be written as

$$J^{\widetilde{\mathcal{M}}}_{A'B'} = \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T \Delta T_{AB}\right]\Phi_{A'B'} + \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T\left(\frac{\Delta V_A \otimes \mathbb{1}_B - d\Delta T_{AB}}{d\left(d^2-1\right)}\right)\right]\left(\mathbb{1}_{A'B'}-\Phi_{A'B'}\right) \tag{C18}$$

$$= \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T \Delta T_{AB}\right]\frac{d^2\Phi_{A'B'} - \mathbb{1}_{A'B'}}{d^2-1} + \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{A}\right)^T \Delta V_A\right]\frac{\mathbb{1}_{A'B'} - \Phi_{A'B'}}{d\left(d^2-1\right)}, \tag{C19}$$

where we denote $\Delta T_{AB} \coloneqq T^+_{AB} - T^-_{AB}$, $\Delta V_A \coloneqq V^+_A - V^-_A$, and $J^{\mathcal{N}}_A \coloneqq \mathrm{Tr}_B\left[J^{\mathcal{N}}_{AB}\right]$. Because $\mathcal{N}_{A\to B}$ is a quantum channel, the partial trace of its Choi operator over the output system B equals $\mathbb{1}_A$. Hence,

$$J^{\widetilde{\mathcal{M}}}_{A'B'} = \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T \Delta T_{AB}\right]\frac{d^2\Phi_{A'B'} - \mathbb{1}_{A'B'}}{d^2-1} + \mathrm{Tr}\left[\Delta V_A\right]\frac{\mathbb{1}_{A'B'} - \Phi_{A'B'}}{d\left(d^2-1\right)}. \tag{C20}$$

By further relabeling $dT^\pm_{AB}$ as $T^\pm_{AB}$ and replacing $p_\pm$ with $\mathrm{Tr}\left[V^\pm_A\right]/d^2$ lead to SDP (C1).

Because $p_+ + p_- = \mathrm{Tr}\left[V^+_A + V^-_A\right]/d^2$, by Proposition 8, we know changing the optimization objective of SDP (C1) to $\mathrm{Tr}\left[V^+_A + V^-_A\right]/d^2$ and removing the condition $\mathrm{Tr}\left[V^+_A + V^-_A\right]/d^2 \leq \gamma$ gives us an SDP for $\gamma^*_{\varepsilon,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d)$. ■

Now, we turn to zero-error shadow communication. In this case, the preset error tolerance ε is 0. We can greatly simplify the SDP for $\gamma^*_{\varepsilon,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d)$ using the fact $\varepsilon = 0$.

Lemma 10 *The zero-error minimum sampling cost of shadow communication with* NS *codes is given by the following SDP:*

$$\gamma^*_{0,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d) = \inf \frac{\mathrm{Tr}\left[V^+_A + V^-_A\right]}{d^2} \tag{C21a}$$

$$\text{s.t. } \mathrm{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T\left(T^+_{AB} - T^-_{AB}\right)\right] = \mathrm{Tr}\left[V^+_A - V^-_A\right] = d^2, \tag{C21b}$$

$$0 \leq T^\pm_{AB} \leq V^\pm_A \otimes \mathbb{1}_B,\ \mathrm{Tr}_A\left[T^\pm_{AB}\right] = \frac{\mathrm{Tr}\left[V^\pm_A\right]}{d^2}\mathbb{1}_B. \tag{C21c}$$

Proof Consider the SDP for $\gamma^*_{\varepsilon,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d)$ given in Lemma 9. For $\varepsilon = 0$, we have

$$\mathrm{Tr}_{B'}[Z_{A'B'}] \leq \frac{1}{2}\left(1 - \frac{\mathrm{Tr}\left[\Delta V_A\right]}{d^2}\right)\mathbb{1}_{A'}, \tag{C22}$$

where $\Delta V_A \coloneqq V_A^+ - V_A^-$. On the other hand, taking the partial trace of $J_{A'B'}^{\widetilde{\mathcal{M}}}$ over system B', we get

$$\mathsf{Tr}_{B'}\left[J_{A'B'}^{\widetilde{\mathcal{M}}}\right] = \mathsf{Tr}\left[\left(J_{AB}^{\mathcal{N}}\right)^T \Delta T_{AB}\right] \frac{d\mathbb{1}_{A'} - d\mathbb{1}_{A'}}{d\left(d^2-1\right)} + \mathsf{Tr}\left[\Delta V_A\right] \frac{d\mathbb{1}_{A'} - \mathbb{1}_{A'}/d}{d\left(d^2-1\right)} = \mathsf{Tr}\left[\Delta V_A\right] \frac{\mathbb{1}_{A'}}{d^2}. \tag{C23}$$

Then, it follows that

$$\frac{1}{2}\left(1 - \frac{\mathsf{Tr}\left[\Delta V_A\right]}{d^2}\right)\mathbb{1}_{A'} \geq \mathsf{Tr}_{B'}\left[Z_{A'B'}\right] \geq \mathsf{Tr}_{B'}\left[J_{A'B'}^{\mathrm{id}_d} - J_{A'B'}^{\widetilde{\mathcal{M}}}\right] = \left(1 - \frac{\mathsf{Tr}\left[\Delta V_A\right]}{d^2}\right)\mathbb{1}_{A'}. \tag{C24}$$

For $Z_{A'B'} \geq 0$, we conclude that $Z_{A'B'} = 0$ and $\mathsf{Tr}\left[\Delta V_A\right] = d^2$, implying $J_{A'B'}^{\widetilde{\mathcal{M}}} = J_{A'B'}^{\mathrm{id}}$.

Note that we can also write $J_{A'B'}^{\widetilde{\mathcal{M}}}$ as

$$J_{A'B'}^{\widetilde{\mathcal{M}}} = \mathsf{Tr}\left[\left(J_{AB}^{\mathcal{N}}\right)^T \frac{\Delta T_{AB}}{d}\right]\Phi_{A'B'} + \mathsf{Tr}\left[\left(J_{AB}^{\mathcal{N}}\right)^T\left(\frac{\Delta V_A \otimes \mathbb{1}_B - \Delta T_{AB}}{d\left(d^2-1\right)}\right)\right]\left(\mathbb{1}_{A'B'} - \Phi_{A'B'}\right) \tag{C25}$$

by reorganizing Eq. (C1b) with $\Delta T_{AB} \coloneqq T_{AB}^+ - T_{AB}^-$. Because $J_{A'B'}^{\widetilde{\mathcal{M}}} = J_{A'B'}^{\mathrm{id}} = d\Phi_{A'B'}$, it must be true that

$$\mathsf{Tr}\left[\left(J_{AB}^{\mathcal{N}}\right)^T \Delta T_{AB}\right] = \mathsf{Tr}\left[\Delta V_A\right] = d^2. \tag{C26}$$

Hence the proof. ■

From this lemma, we can derive an SDP for the one-shot zero-error γ-cost shadow capacity as follows.

Theorem 11 *The one-shot zero-error γ-cost shadow capacity assisted by no-signaling codes of a quantum channel $\mathcal{N}_{A\to B}$ is given by the following SDP:*

$$Q_{\gamma,\mathrm{NS}}^{(1)}(\mathcal{N}) = \sup\ \log_2\ \left\lfloor\sqrt{\mathsf{Tr}\left[V_A\right]}\right\rfloor \tag{C27a}$$

$$\text{s.t. } \mathsf{Tr}\left[\left(J_{AB}^{\mathcal{N}}\right)^T T_{AB}\right] = \mathsf{Tr}\left[V_A\right],\ \mathsf{Tr}_A\left[T_{AB}\right] = \mathbb{1}_B,\ 0 \leq T_{AB} + R_{AB} \leq \left(V_A + W_A\right)\otimes\mathbb{1}_B, \tag{C27b}$$

$$0 \leq R_{AB} \leq W_A \otimes \mathbb{1}_B,\ \mathsf{Tr}_A\left[R_{AB}\right] = \frac{\gamma-1}{2}\mathbb{1}_B,\ \mathsf{Tr}\left[W_A\right] = \frac{\gamma-1}{2}\mathsf{Tr}\left[V_A\right]. \tag{C27c}$$

Proof The SDP given in Lemma 10 allows us to formulate $Q_{\gamma,\mathrm{NS}}^{(1)}(\mathcal{N})$ as an optimization problem by replacing d^2 with $\mathsf{Tr}\left[V_A^+ - V_A^-\right]$, and the objective of the optimization is to maximize $\log_2\ \left\lfloor\sqrt{\mathsf{Tr}\left[V_A^+ - V_A^-\right]}\right\rfloor$ according to the definition of $Q_{\gamma,\mathrm{NS}}^{(1)}$:

$$Q_{\gamma,\mathrm{NS}}^{(1)}(\mathcal{N}) = \sup\ \log_2\ \left\lfloor\sqrt{\mathsf{Tr}\left[V_A^+ - V_A^-\right]}\right\rfloor \tag{C28a}$$

$$\text{s.t. } \mathsf{Tr}\left[\left(J_{AB}^{\mathcal{N}}\right)^T\left(T_{AB}^+ - T_{AB}^-\right)\right] = \mathsf{Tr}\left[V_A^+ - V_A^-\right],\ \frac{\mathsf{Tr}\left[V_A^+ + V_A^-\right]}{\mathsf{Tr}\left[V_A^+ - V_A^-\right]} \leq \gamma, \tag{C28b}$$

$$0 \leq T_{AB}^{\pm} \leq V_A^{\pm} \otimes \mathbb{1}_B,\ \mathsf{Tr}_A\left[T_{AB}^{\pm}\right] = \frac{\mathsf{Tr}\left[V_A^{\pm}\right]\mathbb{1}_B}{\mathsf{Tr}\left[V_A^+ - V_A^-\right]}, \tag{C28c}$$

where the inequality in condition (C28b) corresponds to the limited cost budget. This is not an SDP, but observe that the equality in condition (C28c) is equivalent to the following two equations:

$$\mathsf{Tr}_A\left[T_{AB}^+ - T_{AB}^-\right] = \mathbb{1}_B \quad \text{and} \quad \mathsf{Tr}_A\left[T_{AB}^+ + T_{AB}^-\right] = \frac{\mathsf{Tr}\left[V_A^+ + V_A^-\right]}{\mathsf{Tr}\left[V_A^+ - V_A^-\right]}\mathbb{1}_B. \tag{C29}$$

In addition, the inequality in condition (C28b) can be restricted to equality without affecting the optimization result because if $\bar{T}_{AB}^{\pm}$ and $\bar{V}_A^{\pm}$ form a set of optimal solution such that $\mathsf{Tr}\left[\bar{V}_A^+ + \bar{V}_A^-\right]/\mathsf{Tr}\left[\bar{V}_A^+ - \bar{V}_A^-\right] = \bar{\gamma} < \gamma$, then $\bar{T}_{AB}^{\prime\pm} \coloneqq \bar{T}_{AB}^{\pm} + (\gamma - \bar{\gamma})\mathbb{1}_{AB}/2d_A$ and $\bar{V}_A^{\prime\pm} \coloneqq \bar{V}_A^{\pm} + (\gamma - \bar{\gamma})\,\mathsf{Tr}\left[\bar{V}_A^+ - \bar{V}_A^-\right]\mathbb{1}_A/2d_A$ also form a set of optimal solution with $\mathsf{Tr}\left[\bar{V}_A^{\prime +} + \bar{V}_A^{\prime -}\right]/\mathsf{Tr}\left[\bar{V}_A^{\prime +} - \bar{V}_A^{\prime -}\right] = \gamma$. Note that for $\bar{T}_{AB}^{\prime\pm}$ and $\bar{V}_A^{\prime\pm}$ to be valid solution, it must be true that $\mathsf{Tr}\left[\bar{V}_A^+ - \bar{V}_A^-\right] \geq 1$ so that $\bar{V}_A^{\prime\pm} \otimes \mathbb{1}_B \geq \bar{T}_{AB}^{\prime\pm}$. This is indeed the case because from the constraint $T_{A'B'}^{\pm} \leq V_A^{\pm} \otimes \mathbb{1}_B$ we have $\mathsf{Tr}_A\left[\bar{T}^+_{AB}+\bar{T}^-_{AB}\right]\leq \mathsf{Tr}\left[\bar{V}^+_A+\bar{V}^-_A\right]\mathbb{1}_B$. For the equality $\mathsf{Tr}_A\left[\bar{T}^+_{AB}+\bar{T}^-_{AB}\right]= \mathsf{Tr}\left[\bar{V}^+_A+\bar{V}^-_A\right]\mathbb{1}_B/\mathsf{Tr}\left[\bar{V}^+_A-\bar{V}^-_A\right]$ to hold, $\mathsf{Tr}\left[\bar{V}^+_A-\bar{V}^-_A\right]$ has to be larger than or equal to 1.

Now we can safely require $\mathsf{Tr}\left[V^+_A+V^-_A\right]=\gamma\mathsf{Tr}\left[V^+_A-V^-_A\right]$ and thus $\mathsf{Tr}_A\left[T^+_{AB}+T^-_{AB}\right]=\gamma\mathbb{1}_B$. Changing the variables to $T_{AB}\coloneqq T^+_{AB}-T^-_{AB}$, $R_{AB}\coloneqq T^-_{AB}$, $V_A\coloneqq V^+_A-V^-_A$, and $W_A\coloneqq V^-_A$ results in the claimed SDP. ■

In the main text, we claimed that $Q^{(1)}_{\gamma,\mathrm{NS}}$ generalizes the no-signaling-assisted one-shot zero-error quantum capacity $Q^{(1)}_{\mathrm{NS}}$ in the sense that $Q^{(1)}_{1,\mathrm{NS}}(\mathcal{N})=Q^{(1)}_{\mathrm{NS}}(\mathcal{N})$ for any quantum channel $\mathcal{N}$. To see this, note that when $\gamma=1$, variables R_{AB} and W_A from SDP (C27) satisfy $\mathsf{Tr}_A\left[R_{AB}\right]=0$ and $\mathsf{Tr}\left[W_A\right]=0$. Because both R_{AB} and W_A are positive semidefinite operators, they can only be 0. Therefore, the original SDP (C27) reduces to

$$\sup\ \log_2\ \left\lfloor\sqrt{\mathsf{Tr}\left[V_A\right]}\right\rfloor \tag{C30a}$$

$$\text{s.t. } \mathsf{Tr}\left[\left(J^{\mathcal{N}}_{AB}\right)^T T_{AB}\right]=\mathsf{Tr}\left[V_A\right],\ \mathsf{Tr}_A\left[T_{AB}\right]=\mathbb{1}_B,\ 0\leq T_{AB}\leq V_A\otimes\mathbb{1}_B, \tag{C30b}$$

which is an SDP for $Q^{(1)}_{\mathrm{NS}}(\mathcal{N})$ [7, 44].

Below, we provide an exact characterization of $Q^{(1)}_{\gamma,\mathrm{NS}}$ for single-qubit depolarizing channels.

Theorem 2 *Let $\mathcal{N}_{\mathrm{depo},p}(\rho)=p\rho+(1-p)\mathbb{1}_2/2$ be a single-qubit depolarizing channel, where $p\in[0,1]$ is a probability and $\mathbb{1}_2$ is the identity operator on $\mathbb{C}^2$. For $\gamma\geq 1$, the one-shot zero-error shadow capacity assisted by no-signaling resources is*

$$Q^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p})=\log_2\left\lfloor\sqrt{2p\gamma+p+1}\right\rfloor. \tag{C31}$$

Proof The Choi operator of the depolarizing channel $\mathcal{N}_{\mathrm{depo},p}$ from qubit system A to qubit system B is

$$J^{\mathcal{N}_{\mathrm{depo},p}}_{AB}=p\Gamma_{AB}+\frac{1-p}{2}\mathbb{1}_{AB}, \tag{C32}$$

where $\Gamma_{AB}\coloneqq|\Gamma\rangle\langle\Gamma|_{AB}$ is the unnormalized maximally entangled state with $|\Gamma\rangle_{AB}\coloneqq\sum_{j=0}^{1}|j\rangle_A|j\rangle_B$. We first consider the case where $p\in(0,1]$. It is straightforward to verify that

$$\bar{T}^+_{AB}\coloneqq\frac{d^2-1+p}{4p}\Gamma_{AB},\quad \bar{T}^-_{AB}\coloneqq\frac{d^2-1-3p}{6p}\mathbb{1}_{AB}-\frac{d^2-1-3p}{12p}\Gamma_{AB}, \tag{C33}$$

$$\bar{V}^+_A\coloneqq\frac{d^2(d^2-1+p)}{8p}\mathbb{1}_A,\quad \bar{V}^-_A\coloneqq\frac{d^2(d^2-1-3p)}{8p}\mathbb{1}_A \tag{C34}$$

form a feasible solution to the SDP for $\gamma^*_{0,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p},\mathrm{id}_d)$ as presented in Lemma 10, implying

$$\gamma^*_{0,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p},\mathrm{id}_d)\leq\frac{\mathsf{Tr}\left[\bar{V}^+_A+\bar{V}^-_A\right]}{d^2}=\frac{d^2-1-p}{2p}. \tag{C35}$$

Using the Lagrange dual function, we can derive that the following problem is the dual problem associated with SDP (C21):

$$\gamma^*_{0,\mathrm{NS}}(\mathcal{N},\mathrm{id}_d)\geq\sup\ \lambda-\mu \tag{C36}$$

$$\text{s.t. } M^\pm_{AB}\geq 0,\ M^\pm_{AB}+d^2\mathbb{1}_A\otimes N^\pm_B\geq\pm\lambda\left(J^{\mathcal{N}}_{AB}\right)^T, \tag{C37}$$

$$\mathsf{Tr}_B\left[M^\pm_{AB}\right]=\left(1-\mathsf{Tr}\left[N^\pm_B\right]\pm\mu\right)\mathbb{1}_A. \tag{C38}$$

Again, it is straightforward to verify that, given $J^{\mathcal{N}}_{AB}=J^{\mathcal{N}_{\mathrm{depo},p}}_{AB}$,

$$\bar{\lambda}\coloneqq\frac{d^2}{2p},\quad \bar{\mu}\coloneqq\frac{1+p}{2p},\quad \bar{N}^+_B\coloneqq\frac{1+3p}{4p}\mathbb{1}_B,\quad \bar{N}^-_B\coloneqq\frac{p-1}{4p}\mathbb{1}_B,\quad M^\pm_{AB}=0 \tag{C39}$$

form a feasible solution to the dual problem, implying

$$\gamma^*_{0,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p},\mathrm{id}_d)\geq\bar{\lambda}-\bar{\mu}=\frac{d^2-1-p}{2p}. \tag{C40}$$

Combining Eqs. (C35) and (C40), we conclude that

$$\gamma^*_{0,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p}, \mathrm{id}_d) = \frac{d^2 - 1 - p}{2p}, \tag{C41}$$

which is the minimum sampling cost required to simulate the d-dimensional identity channel id_d from $\mathcal{N}_{\mathrm{depo},p}$. In other words, for any γ such that

$$\frac{d^2 - 1 - p}{2p} \leq \gamma < \frac{(d+1)^2 - 1 - p}{2p}, \tag{C42}$$

we have $Q^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p}) = \log_2 d$. Solving for the value of d in terms of γ, we obtain $d = \left\lfloor \sqrt{2p\gamma + p + 1} \right\rfloor$, and hence

$$Q^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p}) = \log_2 \left\lfloor \sqrt{2p\gamma + p + 1} \right\rfloor. \tag{C43}$$

When $p = 0$, the Choi operator of the depolarizing channel is simply $\mathbb{1}_{AB}/2$. Taking this into SDP (C27), we see that $\mathsf{Tr}[V_A]$ can only takes a fixed value of 1. Hence, $Q^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p}) = 0$ for $p = 0$ and arbitrary γ, which coincides with the value that $\log_2 \left\lfloor \sqrt{2p\gamma + p + 1} \right\rfloor$ evaluates to. Therefore, $Q^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{N}_{\mathrm{depo},p}) = \log_2 \left\lfloor \sqrt{2p\gamma + p + 1} \right\rfloor$ for any $p \in [0, 1]$. ■

To further showcase the difference between shadow simulation and conventional quantum channel simulation, we in addition consider two other common quantum channels: the single-qubit amplitude damping channel $\mathcal{N}_{\mathrm{AD}}$ with two Kraus operators $|0\rangle\langle 0| + \sqrt{p}|1\rangle\langle 1|$ and $\sqrt{1-p}|0\rangle\langle 1|$ and the single-qubit dephasing channel $\mathcal{N}_{\mathrm{deph}}(\cdot) = p(\cdot) + (1-p)\mathrm{diag}(\cdot)$. For each channel, the parameter $p \in [0, 1]$ indicates the level of noise.

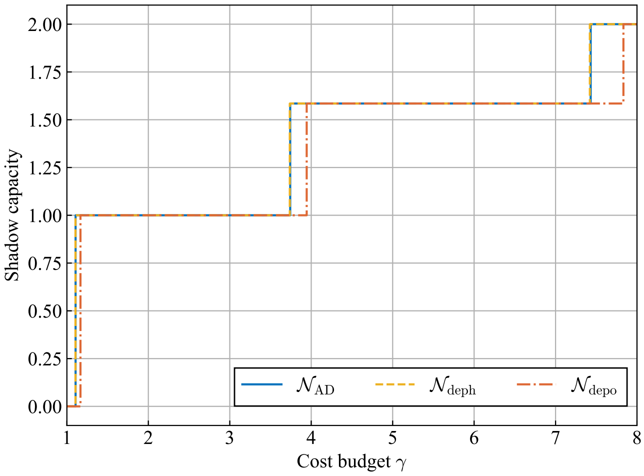

FIG. 3. Comparison between the conventional no-signaling-assisted quantum communication and no-signaling-assisted shadow communication under different cost budgets. Compared with the quantum case, where the one-shot zero-error quantum capacities are 0 for all channels, higher one-shot zero-error shadow capacity is achieved for every channel with increased cost budget.

In Figure 3, we present some numerical results on these channels at a low noise level ($p = 0.9$). For conventional quantum communication with no-signaling codes, all these channels' one-shot zero-error capacities are zero. For shadow communication, on the other hand, the one-shot zero-error capacities of these three channels steadily go up as the budget for sampling cost increases. The stepwise changes in the zero-error capacity show that we can trade in computational resources for better performance in shadow communication, attaining computational power beyond purely quantum protocols.

Appendix D: Shadow Simulation via Noiseless Channels

In this section, we derive the SDP for $S^{(1)}_{\gamma,\mathrm{NS}}$, the one-shot zero-error γ-cost shadow simulation cost assisted by no-signaling codes. Along the way, we derive SDPs for some related quantities, which are of interest on their own.

To begin with, the minimum error and minimum sampling cost of shadow simulation with a noiseless channel can be solved by SDPs in Lemma 12. We omit the proof here as it is very similar to the proof of Lemma 9.

Lemma 12 *For an identity channel* id_d *with dimension* d *and a target quantum channel* $\mathcal{M}_{A'\to B'}$*, the minimum error of the simulation from* id_d *to* $\mathcal{M}_{A'\to B'}$ *assisted by* NS *codes with a cost budget* γ *is given by the following SDP:*

$$\varepsilon^*_{\gamma,\mathrm{NS}}(\mathrm{id}_d,\mathcal{N}) = \inf\ \varepsilon \tag{D1a}$$

$$\text{s.t. } Z_{A'B'} \geq 0,\ Z_{A'B'} \geq J^{\mathcal{M}}_{A'B'} - Y^{+}_{A'B'} + Y^{-}_{A'B'}, \tag{D1b}$$

$$\mathsf{Tr}_{B'}[Z_{A'B'}] \leq \frac{1}{2}\left(2\varepsilon + 1 - \frac{\mathsf{Tr}\left[V^{+}_{B'} - V^{-}_{B'}\right]}{d^2}\right)\mathbb{1}_{A'}, \tag{D1c}$$

$$0 \leq Y^{\pm}_{A'B'} \leq \mathbb{1}_{A'} \otimes V^{\pm}_{B'},\ \mathsf{Tr}_{B'}\left[Y^{\pm}_{A'B'}\right] = \frac{\mathsf{Tr}\left[V^{\pm}_{B'}\right]}{d^2}\mathbb{1}_{A'},\ \frac{\mathsf{Tr}\left[V^{+}_{B'} + V^{-}_{B'}\right]}{d^2} \leq \gamma. \tag{D1d}$$

Similarly, the minimum sampling cost $\gamma^*_{\varepsilon,\mathrm{NS}}(\mathrm{id}_d,\mathcal{M}_{A'\to B'})$ *with an error tolerance* ε *is given by changing the optimization objective of the above SDP to* $\mathsf{Tr}\left[V^{+}_{B'} + V^{-}_{B'}\right]/d^2$ *and removing the condition* $\mathsf{Tr}\left[V^{+}_{B'} + V^{-}_{B'}\right]/d^2 \leq \gamma$*.*

Provided with Lemma 12, we now give an SDP for the zero-error minimum sampling cost of the shadow simulation of a noisy channel via a noiseless one.

Lemma 13 *The zero-error minimum sampling cost of the shadow simulation of a channel* $\mathcal{M}_{A'\to B'}$ *via a* d*-dimensional identity channel* id_d *assisted by* NS *codes is given by the following SDP:*

$$\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d,\mathcal{M}_{A'\to B'}) = \inf\ \frac{\mathsf{Tr}\left[V^{+}_{B'} + V^{-}_{B'}\right]}{d^2} \tag{D2a}$$

$$\text{s.t. } \mathsf{Tr}\left[V^{+}_{B'} - V^{-}_{B'}\right] = d^2,\ \mathsf{Tr}_{B'}\left[R_{A'B'}\right] = \frac{\mathsf{Tr}\left[V^{-}_{B'}\right]}{d^2}\mathbb{1}_{A'}, \tag{D2b}$$

$$J^{\mathcal{M}}_{A'B'} + R_{A'B'} \leq \mathbb{1}_{A'} \otimes V^{+}_{B'},\ 0 \leq R_{A'B'} \leq \mathbb{1}_{A'} \otimes V^{-}_{B'} \tag{D2c}$$

Proof As in the shadow communication setting, the zero-error simulation of the channel $\mathcal{M}$ requires $J^{\mathcal{N}}_{A'B'} = Y^{+}_{A'B'} - Y^{-}_{A'B'}$ and $\mathsf{Tr}\left[V^{+}_{B'} - V^{-}_{B'}\right] = d^2$ (see the proof of Lemma 10). The equalities $\mathsf{Tr}_{B'}\left[Y^{\pm}_{A'B'}\right] = \frac{\mathsf{Tr}[V^{\pm}_{B'}]}{d^2}\mathbb{1}_{A'}$ in condition (D1d) can be equivalently written as

$$\mathsf{Tr}_{B'}\left[Y^{+}_{A'B'} + Y^{-}_{A'B'}\right] = \frac{\mathsf{Tr}\left[V^{+}_{B'} + V^{-}_{B'}\right]}{d^2}\mathbb{1}_{A'} \quad \text{and} \quad \mathsf{Tr}_{B'}\left[Y^{+}_{A'B'} - Y^{-}_{A'B'}\right] = \frac{\mathsf{Tr}\left[V^{+}_{B'} - V^{-}_{B'}\right]}{d^2}\mathbb{1}_{A'}. \tag{D3}$$

Note that the latter equality $\mathsf{Tr}_{B'}\left[Y^{+}_{A'B'} - Y^{-}_{A'B'}\right] = \mathsf{Tr}\left[V^{+}_{B'} - V^{-}_{B'}\right]\mathbb{1}_{A'}/d^2$ can be removed because it is already implied by $J^{\mathcal{N}}_{A'B'} = Y^{+}_{A'B'} - Y^{-}_{A'B'}$ and $\mathsf{Tr}\left[V^{+}_{B'} - V^{-}_{B'}\right] = d^2$ with the observation that $\mathsf{Tr}_{B'}\left[J^{\mathcal{N}}_{A'B'}\right] = \mathbb{1}_{A'}$ for $\mathcal{N}$ being a quantum channel. Hence, we arrive at the following SDP:

$$\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d,\mathcal{M}_{A'\to B'}) = \inf\ \frac{\mathsf{Tr}\left[V^{+}_{B'} + V^{-}_{B'}\right]}{d^2} \tag{D4a}$$

$$\text{s.t. } J^{\mathcal{M}}_{A'B'} = Y^{+}_{A'B'} - Y^{-}_{A'B'},\ \mathsf{Tr}\left[V^{+}_{B'} - V^{-}_{B'}\right] = d^2, \tag{D4b}$$

$$0 \leq Y^{\pm}_{A'B'} \leq \mathbb{1}_{A'} \otimes V^{\pm}_{B'},\ \mathsf{Tr}_{B'}\left[Y^{+}_{A'B'} + Y^{-}_{A'B'}\right] = \frac{\mathsf{Tr}\left[V^{+}_{B'} + V^{-}_{B'}\right]}{d^2}\mathbb{1}_{A'}. \tag{D4c}$$

Denoting $R_{A'B'} := Y^{-}_{A'B'}$, writing $Y^{+}_{A'B'}$ as $J^{\mathcal{M}}_{A'B'} + R_{A'B'}$, and exploiting $\mathsf{Tr}_{B'}\left[J^{\mathcal{M}}_{A'B'}\right] = \mathbb{1}_{A'}$, one can obtain the claimed SDP. ■

From this lemma, we can arrive at the following SDP for the one-shot zero-error γ-cost shadow simulation cost.

Theorem 14 *The one-shot zero-error* γ*-cost simulation cost of a quantum channel* $\mathcal{M}_{A'\to B'}$ *assisted by no-signaling codes is given by the following SDP:*

$$S^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{M}) = \inf\ \log_2\left\lceil\sqrt{\mathsf{Tr}\left[V_{B'}\right]}\right\rceil \tag{D5a}$$

$$\text{s.t. } J^{\mathcal{M}}_{A'B'} + R_{A'B'} \leq \mathbb{1}_{A'} \otimes \frac{\gamma+1}{2}V_{B'},\ 0 \leq R_{A'B'} \leq \mathbb{1}_{A'} \otimes W_{B'}, \tag{D5b}$$

$$\mathsf{Tr}_{B'}\left[R_{A'B'}\right] = \frac{\gamma-1}{2}\mathbb{1}_{A'},\ \mathsf{Tr}\left[W_{B'}\right] = \frac{\gamma-1}{2}\mathsf{Tr}\left[V_{B'}\right]. \tag{D5c}$$

Proof According to the SDP given in Lemma 13, we can write the one-shot simulation cost $S^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{M})$ as an optimization problem by substituting d^2 with $\mathsf{Tr}\left[V^+_{B'} - V^-_{B'}\right]$:

$$S^{(1)}_{\gamma,\mathrm{NS}}(\mathcal{M}) = \inf\ \log_2\ \left\lceil \sqrt{\mathsf{Tr}\left[V^+_{B'} - V^-_{B'}\right]}\right\rceil \tag{D6a}$$

$$\text{s.t. } \mathsf{Tr}_{B'}\left[R_{A'B'}\right] = \frac{\mathsf{Tr}\left[V^-_{B'}\right]}{\mathsf{Tr}\left[V^+_{B'} - V^-_{B'}\right]}\mathbb{1}_{A'},\ \frac{\mathsf{Tr}\left[V^+_{B'} + V^-_{B'}\right]}{\mathsf{Tr}\left[V^+_{B'} - V^-_{B'}\right]} \leq \gamma, \tag{D6b}$$

$$J^{\mathcal{M}}_{A'B'} + R_{A'B'} \leq \mathbb{1}_{A'} \otimes V^+_{B'},\ 0 \leq R_{A'B'} \leq \mathbb{1}_{A'} \otimes V^-_{B'}. \tag{D6c}$$

Note that the inequality in condition (D6b) can be restricted to equality while keeping the optimized value unchanged. This is true because if $R_{A'B'}$ and $\bar{V}^{\pm}_{B'}$ is a set of optimal solution with $\mathsf{Tr}\left[V^+_{B'} + V^-_{B'}\right]/\mathsf{Tr}\left[\bar{V}^+_{B'} - \bar{V}^-_{B'}\right] = \bar{\gamma} < \gamma$, then $R'_{A'B'} := R_{A'B'} + (\gamma - \bar{\gamma})\mathbb{1}_{A'B'}/2d_{B'}$ and $\bar{V}'^{\pm}_{B'} := \bar{V}^{\pm}_{B'} + (\gamma - \bar{\gamma})\mathsf{Tr}\left[\bar{V}^+_{B'} - \bar{V}^-_{B'}\right]\mathbb{1}_{B'}/2d_{B'}$ also form a set of optimal solution such that $\mathsf{Tr}\left[\bar{V}'^+_{B'} + \bar{V}'^-_{B'}\right]/\mathsf{Tr}\left[\bar{V}'^+_{B'} - \bar{V}'^-_{B'}\right] = \gamma$. Note that for $\bar{R}'^{\pm}_{A'B'}$ and $\bar{V}'^{\pm}_{B'}$ to be valid solution, it must be true that $\mathsf{Tr}\left[\bar{V}^+_{B'} - \bar{V}^-_{B'}\right] \geq 1$ so that $\mathbb{1}_{A'} \otimes \bar{V}'^-_{B'} \geq \bar{R}'_{A'B'}$. This is indeed the case because from the constraint $R_{A'B'} \leq \mathbb{1}_{A'} \otimes V^-_{B'}$ we have $\mathsf{Tr}_{B'}\left[\bar{R}_{A'B'}\right] \leq \mathsf{Tr}\left[\bar{V}^-_{B'}\right]\mathbb{1}_{A'}$. For the equality $\mathsf{Tr}_{B'}\left[\bar{R}_{A'B'}\right] = \mathsf{Tr}\left[\bar{V}^-_{B'}\right]\mathbb{1}_{A'}/\mathsf{Tr}\left[\bar{V}^+_{B'} - \bar{V}^-_{B'}\right]$ to hold, $\mathsf{Tr}\left[\bar{V}^+_{B'} - \bar{V}^-_{B'}\right]$ has to be larger than or equal to 1.

By changing the inequality in condition (D6b) to $\mathsf{Tr}\left[V^+_{B'} + V^-_{B'}\right]/\mathsf{Tr}\left[V^+_{B'} - V^-_{B'}\right] = \gamma$, it follows that $\mathsf{Tr}[V^-_{B'}] = (\gamma - 1)\mathsf{Tr}[V^+_{B'}]/(\gamma + 1)$ and thus $\mathsf{Tr}_{B'}\left[R_{A'B'}\right] = (\gamma - 1)\mathbb{1}_{A'}/2$. Changing the variables to $V_{B'} := 2V^+_{B'}/(\gamma + 1)$ and $W_{B'} := V^-_{B'}$ gives the claimed SDP. ■

Similar to the one-shot zero-error shadow capacity, the SDP above implies that $S(1)_{\gamma,\mathrm{NS}}$ is a generalization of the no-signaling-assisted one-shot zero-error quantum simulation cost $S(1)_{\mathrm{NS}}$ as it reduces to the SDP for the latter [7, 10] when $\gamma = 1$. To showcase the difference between $S(1)_{\gamma,\mathrm{NS}}$ and $S(1)_{\mathrm{NS}}$, we consider the two-qubit amplitude damping channel $\mathcal{N}_{\mathrm{AD}}$, the two-qubit dephasing channel $\mathcal{N}_{\mathrm{deph}}$, and the two-qubit depolarizing channel $\mathcal{N}_{\mathrm{depo}}(\cdot) = p(\rho) + (1 - p)\mathbb{1}_4/4$, where $\mathbb{1}_4$ denotes the four-dimensional identity operator, the parameter $p \in [0, 1]$ indicates the level of noise, and by a two-qubit amplitude damping channel we mean two single-qubit amplitude damping channels with the same noise parameter acting independently on two qubits.

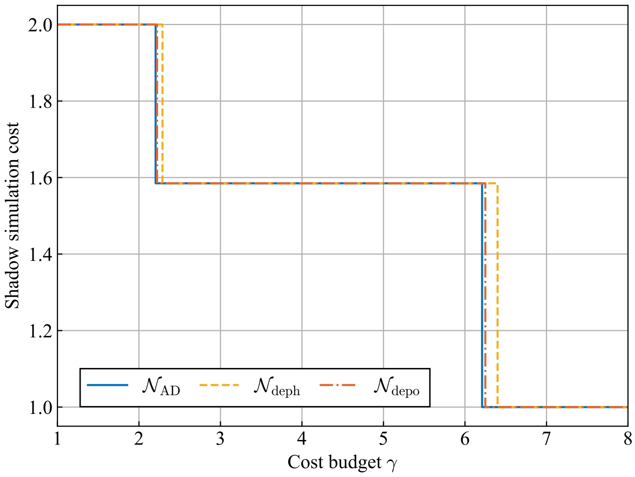

FIG. 4. Comparison between the conventional no-signaling-assisted one-shot zero-error quantum simulation cost $S^{(1)}_{\mathrm{NS}}$ and no-signaling-assisted one-shot zero-error shadow simulation cost $S^{(1)}_{\gamma,\mathrm{NS}}$ under different cost budgets γ. Compared with the quantum case, where the simulation cost is 2 for all channels, lower simulation cost is achieved for each channel with increased cost budget.

As in the task of shadow communication, we present numerical results on these channels at a low noise level ($p = 0.9$) in Figure 4. The zero-error simulation costs of these channels decrease from 2 (quantum simulation cost) to 1 with increased cost budget. Again, the stepwise changes in the zero-error simulation cost show that we can attain computational power beyond purely quantum protocols by trading in more computational resources.

In the main text, we presented the minimum sampling cost of simulating a high-dimensional identity channel with a low-dimensional one. Now, we prove this result.

Theorem 3 *Given identity channels* id_d *and* $\mathrm{id}_{d'}$ *with* $d' \geq d \geq 2$, *the minimum sampling cost of an exact shadow simulation of* $\mathrm{id}_{d'}$ *using* id_d *and no-signaling resources is*

$$\gamma^*_{0,\mathrm{NS}}\left(\mathrm{id}_d, \mathrm{id}_{d'}\right) = 2\left(\frac{d'}{d}\right)^2 - 1. \tag{D7}$$

Proof The Choi operators of the noiseless channel id_d from system A to system B and the noiseless channel $\mathrm{id}_{d'}$ from system A' to system B' are $J^{\mathrm{id}_d}_{AB} = \Gamma_{AB}$ and $J^{\mathrm{id}_{d'}}_{A'B'} = \Gamma_{A'B'}$, respectively. It is straightforward to verify that

$$\bar{V}^+_{B'} = d'\mathbb{1}_{B'}, \quad \bar{V}^-_{B'} = \frac{d'^2 - d^2}{d'}\mathbb{1}_{B'}, \quad \bar{R}_{A'B'} = \frac{d'(d'^2 - d^2)}{(d'^2-1)d^2}\mathbb{1}_{A'B'} - \frac{d'^2 - d^2}{(d'^2-1)d^2}\Gamma_{A'B'} \tag{D8}$$

form a feasible solution to the SDP for $\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d, \mathrm{id}'_d)$ as given in Lemma 13, implying

$$\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d, \mathrm{id}'_d) \leq \frac{1}{d^2}\mathsf{Tr}\left[\bar{V}^+_{B'} + \bar{V}^-_{B'}\right] = \frac{2d'^2}{d^2} - 1. \tag{D9}$$

Using the Lagrange dual function, we can derive that the following problem is the dual problem associated with SDP (D2):

$$\begin{aligned}\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d, \mathcal{M}_{A'\to B'}) \geq \sup\ & \mathsf{Tr}\left[M_{A'B'}J^{\mathcal{M}}_{A'B'}\right] - \lambda & \text{(D10a)}\\ \text{s.t. } & M_{A'B'} \geq 0,\ N_{A'B'} \geq 0,\ M_{A'B'} + N_{A'B'} + K_{A'} \otimes \mathbb{1}_{B'} \geq 0, & \text{(D10b)}\\ & d^2\mathsf{Tr}_{A'}\left[M_{A'B'}\right] = (1+\lambda)\mathbb{1}_{B'},\ d^2\mathsf{Tr}_{A'}\left[N_{A'B'}\right] = (1 - \lambda - \mathsf{Tr}\left[K_{A'}\right])\mathbb{1}_{B'}. & \text{(D10c)}\end{aligned}$$

It is straightforward to verify that

$$\bar{\lambda} = 1, \quad \bar{M}_{A'B'} = \frac{2}{d^2}\Gamma_{A'B'}, \quad \bar{N}_{A'B'} = 0, \quad \bar{K}_{A'} = 0. \tag{D11}$$

form a feasible solution to the dual problem for $\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d, \mathrm{id}_{d'})$, implying

$$\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d, \mathrm{id}_{d'}) \geq \mathsf{Tr}\left[\bar{M}_{A'B'}J^{\mathrm{id}_{d'}}_{A'B'}\right] - \bar{\lambda} = \frac{2d'^2}{d^2} - 1. \tag{D12}$$

Combining Eqs. (D9) and (D12), we conclude that

$$\gamma^*_{0,\mathrm{NS}}(\mathrm{id}_d, \mathrm{id}'_d) = \frac{2d'^2}{d^2} - 1, \tag{D13}$$

which completes the proof. ■

Device-independent quantum key distribution with arbitrarily small nonlocality (extended abstract)

Abstract. [Phys. Rev. Lett. **127**, 050503 (2021)] showed some correlations cannot be used for standard device-independent quantum key distribution (DIQKD), despite being nonlocal. This leads to the question of whether there is a fundamental minimum amount of nonlocality needed for DIQKD. Here we show no such bound exists: arbitrarily good key can be certified using correlations with arbitrarily small nonlocality. Somewhat surprisingly we also show that it is possible to simultaneously certify both perfect key and maximal randomness with a single set of correlations; the inequalities studied provide a direction for improving experimental robustness for DIQKD and DI randomness expansion.

Keywords: DIQKD, self-testing, nonlocality

1 Motivation

Distributing a secret key between two separated parties enables private communication over long distances. Given access to classical resources, security can only be established by making computational assumptions on an adversary, which are difficult to ensure given the advent of quantum computing. In contrast, sharing quantum resources, such as entanglement, enables secure key distribution against an arbitrarily powerful quantum adversary [1, 2, 3].

Despite the theoretical promises of quantum key distribution (QKD), its implementation security is typically dependent on well characterized devices. Any mismatch between the physical device and this characterization can open security loopholes (see e.g., [4]). Device-independent (DI) QKD aims to circumvent this problem, deriving security from the input-output behaviour of devices and without relying on their internal workings [2, 5, 6, 7, 8, 9, 10]. Any observation of nonlocality, that is, input-output statistics incompatible with any classical physical model, is a certificate of quantum behaviour within the device, and can be used to derive security. In a sense, DI protocols certify the underlying quantum mechanism used by the device (or enough about it to conclude that the device can carry out the task).

A natural question to ask is, how nonlocal does a device behaviour need to be to permit DIQKD? Nonlocality is clearly necessary, but when is it sufficient, if at all? Recently, the work of Farkas *et al.* [11] showed that not all nonlocal behaviours can be used for DIQKD under a standard class of protocols. Nevertheless, this left open whether a fundamental bound on the minimum amount of nonlocality needed to perform DIQKD exists.

In the related task of randomness expansion [12, 13, 14, 15, 16, 17], we recently showed that no such bound exists [18] — in fact, perfect randomness expansion is possible with arbitrarily small nonlocality. The main contribution of our submission is to prove an analogous result for DIQKD. In the 2-input 2-output scenario, we show that for an arbitrarily small violation of the Clauser-Horne-Shimony-Holt (CHSH) inequality, there exist extremal quantum behaviours achieving that violation, which generate arbitrarily close to 1 secure key bit per entangled state. Moreover, for any CHSH value between the local bound of 2 and 5/2, there also exist quantum behaviours optimal for key generation. We also generalize the constructions from [18] which achieve the maximum of 2 random bits per entangled state. Finally, we introduce quantum behaviours that generate arbitrarily good key from one pair of measurement settings, and maximum global randomness from another, whilst exhibiting CHSH values between 2 and $1+\sqrt{2}$. To our knowledge, this is the first example of a quantum behaviour with this property in the literature.

2 Methods and results

We consider a spot checking DIQKD protocol with two inputs and two outputs per party, labeled X, Y, A, B (all binary), and an adversary E. The figure of merit is the asymptotic key-rate given by the Devetak-Winter formula [19], $H(A|X=0,E) - H(A|B,X=Y=0)$, minimized over all quantum states and measurements compatible with some observed statistics, where H is the conditional von Neumann entropy. Key-rates of non-asymptotic protocols can also be obtained via techniques like the entropy accumulation theorem [20, 10]. To derive our result, we design Bell expressions whose maximum violation is uniquely achieved by a strategy tailored to key generation. More precisely, the maximum value of our Bell-expressions allow us to self-test [21, 22, 23, 24, 25] the optimal state and measurements, which in turn imply that $H(A|X=0,E)=1$. Furthermore, our Bell expressions also self-test a key generation measurement

*lewis.wooltorton@york.ac.uk
†peter.brown@telecom-paris.fr
‡roger.colbeck@york.ac.uk

for Bob, from which we obtain a minimal error correction cost, i.e., $H(A|B, X = Y = 0) \approx 0$. Note that we do not require a third measurement for Bob, as is the case for many DIQKD protocols (see [26, Section 4.4] for an example using the CHSH inequality). In this Bell scenario, the nonlocality of a behaviour is quantified by its CHSH violation, I_{CHSH}, and we obtain our main result by self-testing behaviours that simultaneously lie close to the local boundary, and generate near perfect key.

The family of Bell expressions we study first appeared in [27, 28], and we provide an alternative self-testing proof using Jordan's lemma [29]. Our proof structure is modular, self-contained, and applicable generally to the 2-input 2-output scenario. The Bell expressions take the form:

$$\begin{aligned}\langle B_{\theta,\phi,\omega}\rangle = &\cos(\theta+\phi)\cos(\theta+\omega)\,\big\langle A_0\big(\cos\omega\, B_0 - \cos\phi\, B_1\big)\big\rangle\\ &+\cos\phi\cos\omega\,\big\langle A_1\big(-\cos(\theta+\omega)\, B_0 + \cos(\theta+\phi)\, B_1\big)\big\rangle,\end{aligned} \tag{1}$$

for any angles (θ, ϕ, ω) satisfying

$$\cos(\theta+\phi)\cos(\phi)\cos(\theta+\omega)\cos(\omega) < 0. \tag{2}$$

For such angles, the quantum bound is given by $\sin(\theta)\sin(\omega-\phi)\sin(\theta+\omega+\phi)$ and is uniquely achieved up to local isometries by the two-qubit strategy:

$$\begin{aligned}|\Phi_0\rangle &= \frac{|00\rangle + |11\rangle}{\sqrt{2}}\\ A_0 &= \sigma_Z,\ A_1 = \cos(\theta)\,\sigma_Z + \sin(\theta)\,\sigma_X\\ B_0 &= \sin(\phi)\,\sigma_Z + \cos(\phi),\\ B_1 &= \sin(\omega)\,\sigma_Z + \cos(\omega)\,\sigma_X,\end{aligned} \tag{3}$$

where σ_Z and σ_X are the Pauli operators.

By carefully choosing one or more of the parameters (θ, ϕ, ω) such that Eq. (2) holds, we can tune the self-tested measurements of both devices to perform well at a given task. More precisely, we obtain three sub-families of Eq. (1) tailored for randomness generation, key generation, and both, which are saturated by behaviours exhibiting an arbitrarily small CHSH violation. These are summarized below:

(i) A two-parameter family of Bell expressions that certifies 2 bits of global DI randomness, conditioned on the input choice $X = 0, Y = 1$, that is $\inf H(AB|X = 0, Y = 1, E) = 2$. The range of achievable CHSH violations are displayed in Fig. 1, and cover the interval $(2, 3\sqrt{3}/2]$, recovering the result of [18] as a special case.

(ii) A two-parameter family of Bell expressions tailored for maximal key generation, conditioned on the input choice $X = Y = 0$, that is $\inf H(A|X = 0, E) - H(A|B, X = Y = 0) = 1 - \epsilon$ for any $\epsilon > 0$. CHSH violations in the interval $(2, 5/2]$ are achieved, which is our main result: near perfect DIQKD is compatible with arbitrarily small nonlocality. The full range of achievable CHSH values are displayed in Fig. 2.

(iii) A one-parameter family of Bell expressions that certify near optimal key from one pair of measurement settings, and maximum global randomness from another; that is, $\inf H(A|X = 0, E) - H(A|B, X = Y = 0) = 1 - \epsilon$, $\epsilon > 0$, and $\inf H(AB|X = 0, Y = 1, E) = 2$. The interval of CHSH values $(2, 1 + \sqrt{2}]$ is achieved, and can be seen by the dashed black lines in Fig. 2; we see both near perfect key and perfect randomness can be certified from a single quantum behaviour lying arbitrarily close to the local boundary.

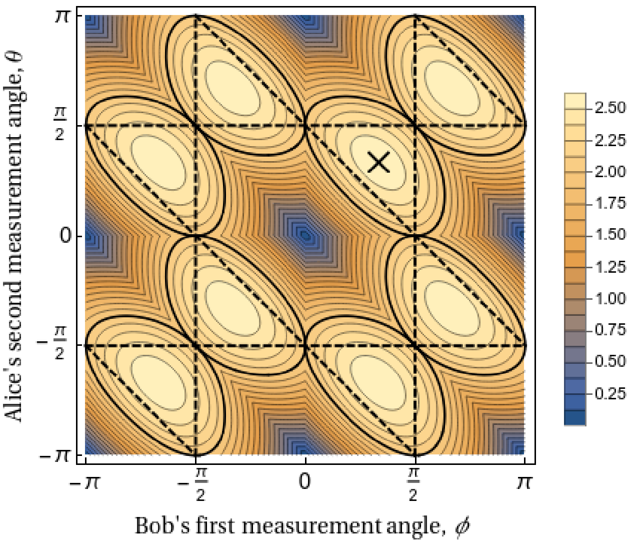

Figure 1: Contour plot of nonlocality, measured using the maximum of the 8 CHSH-type inequalities, for the strategies in Eq. (3) with $\omega = \pi$. The points inside the dashed triangles, excluding the boundary, can be used for perfect DIRE with a single linear Bell inequality: they satisfy Eq. (2) and have a value in $(2, 3\sqrt{3}/2]$ for one of the CHSH-type inequalities, with the maximum of I_{CHSH} indicated with the black cross at $\theta = \phi = \pi/3$. Approaching $\phi = -\pi/2$ or $\phi = \pi/2$ inside the corresponding region also allows arbitrarily good DIQKD. The black contours indicate $I_{\text{CHSH}} = 2$ for at least one CHSH-type inequality.

3 Impact

Our results prove that there is no fundamental bound on the minimum nonlocality needed to enable DIQKD. The underlying reason for this is that there exist extremal quantum behaviours that lie near the boundary of the local set which can be self-tested with a single Bell expression, and consist of a measurement pair with near perfectly correlated outcomes. In addition, such behaviours can have another measurement combination with perfectly un-correlated outcomes, giving rise to a stronger statement concerning maximal key and randomness with arbitrarily small nonlocality. This progresses our understanding of fundamental limits in DI cryptography, and answers a question left open by Farkas *et al.* [11] who, in contrast, showed there exist behaviours in the interior

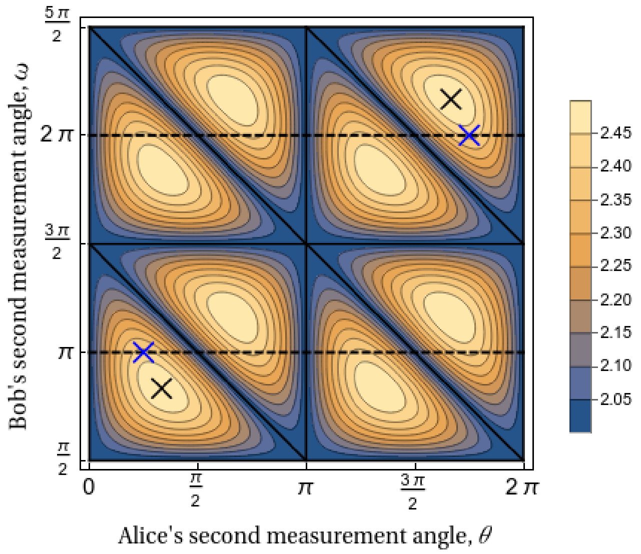

Figure 2: Contour plot of nonlocality, measured using the maximum of the 8 CHSH-type inequalities of the strategies in Eq. (3), at the limit $\phi = \pi/2$. The contours with CHSH values equal to 2 are the black triangular lines, and are the limit points of correlations that achieve arbitrarily perfect DIQKD with a single linear Bell inequality. The black dashed lines show where perfect DIRE can also be achieved, with the blue crosses denoting the maximum value of $I_{\text{CHSH}} = 1 + \sqrt{2}$ at $\theta = \pi/4, \omega = \pi$ and $\theta = 7\pi/4, \omega = 2\pi$. The black crosses denote the global maximum of $I_{\text{CHSH}} = 5/2$ at $\theta = \pi/3, \omega = 5\pi/6$ and $\theta = 5\pi/3, \omega = 13\pi/6$.

of the quantum set, which are nonlocal, yet cannot be used for DIQKD under standard protocols. As we have now shown, this fact does not imply the existence of a fundamental bound.

In addition, we highlighted the versatility of the Bell expressions used, and given the additional degrees of freedom, it would be interesting to understand their practical benefit. For example, an experimentalist could optimize the Bell expression for their setup, possibly yielding larger rates in a DI task such as randomness expansion or key distribution. We also introduced a spot-checking DIQKD protocol which remains in the two-input two-output scenario, rather than adding a third measurement for Bob as is typically done when using the CHSH inequality. This simpler setup removes the need for additional alignment tests, which might make the protocol more efficient with finite numbers of rounds.

Finally, to the best of our knowledge, we have given the first example of behaviours which exhibit near-perfect key and perfect randomness from different measurement combinations. It would be interesting if this could find an application in a novel DI protocol. For example, perfect global randomness implies a single bit of blind randomness per party, per round. One might hope to distill this randomness alongside a DIQKD protocol, replenishing the randomness consumed during key exchange.

For the full technical manuscript, please see arXiv:2309.09650. During the writing up of this work we became aware of a related work [30] that also shows the possibility of key distribution with arbitrarily small nonlocality using an alternative approach.

Abstract. Differential-phase-shift (DPS) quantum key distribution (QKD) is one of the major QKD protocols, and it is implementable with a simple experimental setup using a train of coherent pulses and a passive measurement unit composed of a basic optical interferometer. Thanks to this simplicity, its field demonstration was conducted in the Tokyo QKD network, and there are high expectations for future practical use. However, the experimental simplicity would imply that the number of available experimental parameters is small, and thus its information-theoretic security proof becomes challenging. In fact, all previous security proofs needed assumptions on eavesdropper's attacks or assumptions that compromise the simplicity of the DPS protocol. In this work, we provide an information-theoretic security proof of the DPS protocol in the finite-key regime while maintaining the inherent experimental simplicity of this protocol. As a result of our security proof, we reveal that a 3 Mbit unconditionally secure key can be distributed over 77 km in 8.3 hours, assuming typical experimental setups. This result demonstrates the feasibility of the DPS protocol for generating secret keys over long distances in realistic experimental setups and contributes to realizing truly secure communication. The full details of this work can be found in [1].

Keywords: quantum cryptography, finite-key security proof, concentration inequality

1 Introduction

Quantum key distribution (QKD) realizes information-theoretically secure communication between two distant parties (Alice and Bob) against any eavesdropper (Eve) [2, 3]. Among QKD protocols, the differential-phase-shift (DPS) protocol [4] is a promising one, which can be implemented with an experimentally simple setup using a train of coherent pulses and a passive measurement unit composed of a Mach-Zehnder interferometer (see Fig. 1). Due to its simplicity, experimental demonstrations were conducted in [5, 6, 7], and also its field demonstration was executed in the Tokyo QKD network [8]. Although the DPS protocol has an advantage of simple implementation, establishing its security proof is a challenging problem. This is because, in general, the security proof of QKD becomes more complex as the experimental setup is simplified. To make the security proof of the DPS protocol easier, previous works restricted Eve's attacks on the quantum channel [9, 10, 11] or made assumptions that compromise the simplicity of the experiment, such as employing a single-photon source [12] or a phase randomized coherent source [13, 14].

In our previous work [15], we established the information-theoretic security proof of the DPS protocol while maintaining the inherent simplicity of this protocol. Unfortunately, this security proof is only valid in the asymptotic regime, where the length of the sifted key is assumed to be infinite. To implement the DPS protocol in the real world, it is indispensable to reveal its key-generation efficiency with a finite key length.

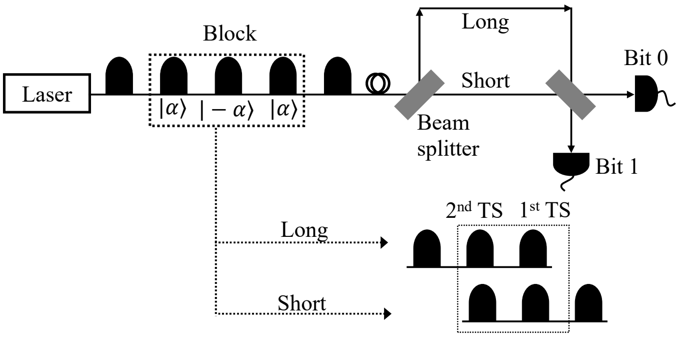

Figure 1: Schematics of our DPS protocol. Alice sends blocks of three pulses to Bob, and he receives them with the one-bit delay Mach-Zehnder interferometer and detectors. A detection event occurs if Bob obtains one photon in total among the 1st and 2nd time slots (TSs).

Here, we solve this problem by providing the finite-key security proof of the DPS protocol [1]. In the finite-key analysis, it is crucial to evaluate statistical deviation terms of concentration inequalities in deriving an upper bound on the amount of privacy amplification N_{PA}. In so doing, it is important to employ a concentration inequality that results in a small deviation with a smaller number of trials; otherwise the speed of convergence to the asymptotic key rate becomes slow, leading to a poor performance. For this, Azuma's inequality [16] is a well-known concentration inequality used in various security proofs [17]-[21]. However, we reveal that the analysis with Azuma's inequality results in a substantially low key rate under a realistic experimental setup. To overcome this problem, we exploit Kato's inequality [22, 23] and show that the key rate is drastically improved. Specifically, our numerical simulation shows that its achievable distance becomes more than four times longer than the one based on the analysis using Azuma's inequality with typical experimental setups. Also, assuming the number of emitted pulses that can be realized within practical experimental times, we find that the rate does not significantly degrade from the asymptotic limit (see Fig. 2).

2 Main result

We first describe our DPS protocol followed by stating our main result, Theorem 1. In the following protocol description (see Fig. 1), we assume that Alice emits weak coherent states $|\alpha\rangle$ of intensity $\mu := \alpha^2 \ll 1$ with modulating the phase either 0 or π perfectly. However, this demanding assumption is not mandatory; as long as Alice emits independent and identically distributed states, she can securely employ them in the DPS protocol, even without knowledge of the emitted states [24, 1]. This is another advantage of the DPS protocol, which is important for the implementation security of QKD [3].

(P1) Alice and Bob respectively repeat the following procedures for N rounds.

  (a) Alice generates uniformly random three bits $b_1b_2b_3 \in \{0,1\}^3$ and sends three coherent states (we call three coherent states *block*)

$$\bigotimes_{i=1}^{3} |(-1)^{b_i}\alpha\rangle_{B_i} \qquad (1)$$

  to Bob via a quantum channel.

  (b) Bob forwards the incoming three pulses into the Mach-Zehnder interferometer followed by photon detection by single-photon detectors. We call the round *detected* if Bob detects one photon in total among the 1st and 2nd time slots. The detection event at the jth time slot determines the raw key bit $d \in \{0,1\}$ depending on which of the two detectors clicks.

(P2) Bob takes note of a set of detected rounds $\mathcal{D} \subseteq \{1,...,N\}$ with length $N_{\mathrm{det}} := |\mathcal{D}|$, a set of time slots $\boldsymbol{j} := (j_i)_{i\in\mathcal{D}}$, and a raw key $\boldsymbol{d} := (d_i)_{i\in\mathcal{D}}$. Here, j_i and d_i are j and d of the ith detected round, respectively. Bob associates each detected round with a code or sample round with probability t or $1-t$, respectively ($0 < t < 1$). He defines the code set $\mathcal{D}_{\mathrm{code}}$ with length $N_{\mathrm{code}} := |\mathcal{D}_{\mathrm{code}}|$, the sample one $\mathcal{D}_{\mathrm{sample}} := \mathcal{D} \setminus \mathcal{D}_{\mathrm{code}}$ with length $N_{\mathrm{sample}} := |\mathcal{D}_{\mathrm{sample}}|$, his sifted key $\kappa_B := (d_i)_{i\in\mathcal{D}_{\mathrm{code}}}$ and the sample bit sequence $\kappa_B^{\mathrm{sample}} := (d_i)_{i\in\mathcal{D}_{\mathrm{sample}}}$.

(P3) Bob announces $\mathcal{D}_{\mathrm{code}}$, $\mathcal{D}_{\mathrm{sample}}$, $\boldsymbol{j}$ and $\kappa_B^{\mathrm{sample}}$ to Alice through an authenticated public channel.

(P4) Alice calculates her sifted key $\kappa_A := (b_{j_i} \oplus b_{j_i+1})_{i\in\mathcal{D}_{\mathrm{code}}}$ and sample bit sequence $\kappa_A^{\mathrm{sample}} := (b_{j_i} \oplus b_{j_i+1})_{i\in\mathcal{D}_{\mathrm{sample}}}$.

(P5) (Bit error correction) Using a pre-shared secret key of length N_{EC}, Bob corrects the bit errors in his sifted key κ_B and obtains the reconciled key κ_B^{rec}. By consuming a pre-shared secret key of length ζ', Alice and Bob verify the correctness of their reconciled keys by comparing the output (ζ'-bit) of a randomly chosen universal$_2$ hash function H_{EC}.

(P6) (Privacy amplification) Alice and Bob conduct privacy amplification by shortening their reconciled keys by N_{PA} bits and respectively share the final keys k_A and k_B of length $N_{\mathrm{fin}} = N_{\mathrm{code}} - N_{\mathrm{PA}}$.

We define the bit error rate in the sample rounds by

$$e_{\mathrm{bit}} := \mathrm{wt}(\kappa_A^{\mathrm{sample}} \oplus \kappa_B^{\mathrm{sample}})/N_{\mathrm{sample}}.$$

Here, wt$(\cdot)$ denotes the Hamming weight. The net length of the final key, namely, the increased length of the secret key is $\ell = N_{\mathrm{code}} - N_{\mathrm{PA}} - N_{\mathrm{EC}} - \zeta'$.

Below, we state the result of our security proof revealing the amount of privacy amplification $N_{\mathrm{PA}} = N_{\mathrm{code}} h\left(\frac{M_{\mathrm{ph}}^{\mathrm{U}}}{N_{\mathrm{code}}}\right)$ against any Eve's attack, based on the phase-error correction approach [28] (see details in Sec. 3). Importantly, the upper bound on the number of phase errors $M_{\mathrm{ph}}^{\mathrm{U}}$ in Eq. (3) is expressed as a function of the experimental parameters obtained in the above protocol; once the protocol is completed, this amount can be determined. We adopt the standard composable security framework [25, 26], where the imperfection of the final keys k_A and k_B is measured by the trace distance between the actual and ideal states of Alice, Bob and Eve, which is upper-bounded by the security parameter ϵ_{sec}.

Theorem 1 *For any ζ, $\zeta' > 0$ and $0 < \epsilon_1, \epsilon_2 < 1$, the above DPS protocol generates the secret key of length*

$$\ell = N_{\mathrm{code}} - N_{\mathrm{code}} h\left(M_{\mathrm{ph}}^{\mathrm{U}}/N_{\mathrm{code}}\right) - N_{\mathrm{EC}} - \zeta', \qquad (2)$$

$$M_{\mathrm{ph}}^{\mathrm{U}} := \frac{(3+\sqrt{5})te_{\mathrm{bit}}N_{\mathrm{sample}}}{1-t} + tq_2N + \Gamma_2 + (3+\sqrt{5})\times \prod_{n=1,3} \sqrt{tq_nN + \Gamma_n + \Delta_n(n,\epsilon_1)} + t\Delta_1(D^2,\epsilon_1) \qquad (3)$$

with $\epsilon_{\mathrm{sec}} = 2^{-\zeta'} + \sqrt{2}\sqrt{3(\epsilon_1+\epsilon_2) + 2^{-\zeta}}$. *Here,* $\Delta_1(x,y) := \sqrt{-2xN_{\mathrm{det}}\ln y}$,

$$D := \max\left\{(4+\sqrt{5}-t)/(1-t), 1/t + 4 + \sqrt{5}\right\},$$

$$\Gamma_n := \left[\sqrt{(\ln\epsilon_2)^2 - 8tq_nN\ln\epsilon_2} - \ln\epsilon_2\right]/2,$$

$h(x)$ is the binary entropy function, $\Delta_3(n,\epsilon)$ is the deviation term of Kato's inequality [22] (see Eq. (42) [1]), and q_n denotes the probability of emitting n or more photons in each emitted block, namely, $q_n = \sum_{\nu=n}^{\infty} e^{-3\mu}(3\mu)^\nu/\nu!$ for $n = 1, 2, 3$.

As a result of the security proof, in Fig. 2, we present our simulation results of the key rate $R = \ell/3N$ with ℓ given in Eq. (2) as a function of the channel transmission η including the detection efficiency. We optimize R over the mean photon number μ of the emitted pulse and the probability t of choosing the code round in step (P2) for each value of η. We assume the number of detected rounds as $N_{\mathrm{det}} = 2N\eta\mu e^{-2\eta\mu}$, $N_{\mathrm{code}} = tN_{\mathrm{det}}$, $N_{\mathrm{sample}} = (1-t)N_{\mathrm{det}}$, and the practical cost of error correction being $N_{\mathrm{EC}} = 1.16N_{\mathrm{code}}h(e_{\mathrm{bit}})$ with 1.16 [27] is an error

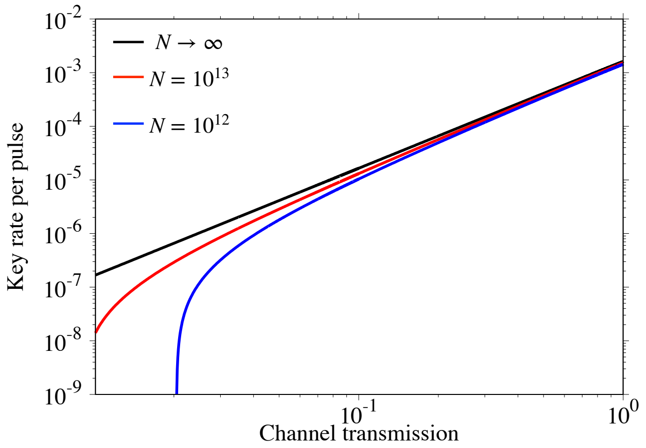

Figure 2: Secret key rate $R = \ell/3N$ of our DPS protocol per an emitted pulse as a function of the overall channel transmission η. From top to bottom, we plot the key rates for $N = \infty, 10^{13}, 10^{12}$ under the 1% bit error rate and a typical security parameter $\epsilon_{\rm sec} \fallingdotseq 10^{-8.1}$.

correction inefficiency. Also, we set $\zeta' = 28$, $\zeta = 58$, and $\epsilon_1 = \epsilon_2 = 2^{-58}/6$, which results in $\epsilon_{\rm sec} \fallingdotseq 10^{-8.1}$. From the result with $N = 10^{13}$ in Fig. 2, if we assume the overall channel transmission as $\eta = 0.5 \times 10^{-\frac{0.2l}{10}}$ with l denoting the distance between Alice and Bob and laser diodes operating at 1 GHz repetition rate, by running our protocol for 8.3 hours, we can generate a 3 Mbit secret key for a channel length of 77 km under 1% bit error rate. The results suggest the feasibility of long-distance QKD with realistic time and experimental setups.

3 Proof idea of Theorem 1

In the proof of Theorem 1, we consider the entanglement-based scenario, which gives the same statistics of the final keys k_A and k_B as in the actual protocol. In this scenario, instead of Alice preparing the state in Eq. (1), she prepares the following entangled state

$$\bigotimes_{i=1}^{3} \left(|0\rangle_{A_i}|\alpha\rangle_{B_i} + |1\rangle_{A_i}|-\alpha\rangle_{B_i}\right)/\sqrt{2}$$

and sends only systems $B_1B_2B_3$ to Bob. Bob's setup is the same as in Fig. 1. When the detection event occurs at the 1st time slot, Alice obtains her shifted key by applying the CNOT gate to qubits A_1 and A_2 and measuring the target qubit A_2 in the Z-basis $\{|0\rangle, |1\rangle\}$. Our proof adopts the complementarity proof technique [28], and its goal is to determine the number of phase errors $M_{\rm ph}$. A phase error is an event where Alice fails to predict the measurement outcome $x_{A_2} \in \{0,1\}$ if qubit A_2 were measured in the complementary X-basis instead of the Z-basis. This prediction is a task of guessing which of the first or second emitted pulse contained a photon. Since the result of this X-measurement cannot be obtained directly from the actual protocol, we need to estimate the number of failures in predicting this outcome from the actually observed quantities. For this prediction, measurements that do not disturb x_{A_2} can be performed. Hence, to enhance the accuracy of her prediction, Alice measures qubit A_1 in the X-basis and obtains the parity information $x_{A_1} \oplus x_{A_2}$. Furthermore, Bob performs a measurement to know which pulse contains a photon by removing the second beam splitter and informs Alice of this information $t_{\rm Bob}$ (see Fig. 3). Using the information $x_{A_1} \oplus x_{A_2}$ and $t_{\rm Bob}$, Alice predicts x_{A_2}. Let Y_i be the binary random variable representing the presence of a phase error in the ith detection event and $M_{\rm ph} = \sum_{i=1}^{N_{\rm det}} Y_i$ be the number of phase errors. Here, due to Eve's attack on the quantum channel, these random variables Y_i are correlated with each other, and therefore, to relate $M_{\rm ph}$ to the actually observed quantities in the protocol, it is necessary to use a concentration inequality applicable to correlated stochastic processes.

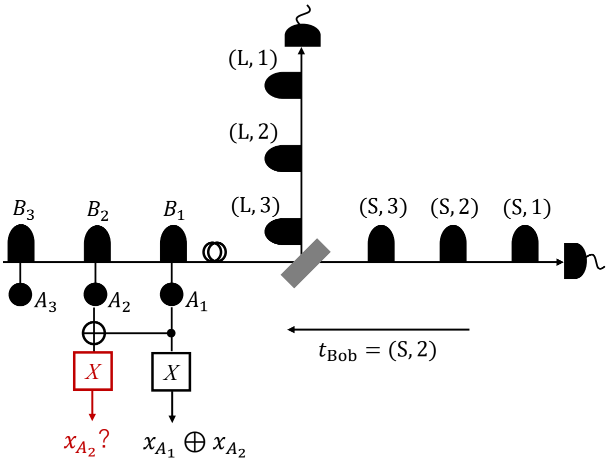

Figure 3: Alice's complementary task of predicting the outcome $x_{A_2} \in \{0,1\}$ if qubit A_2 were measured in the X-basis. A phase error occurs if she fails in the prediction.

In the case of correlated stochastic processes, Azuma's inequality is a well-known concentration inequality to relate a random variable and its expectation [17]-[21]. In Eq. (3), $tq_3N + \Gamma_3 + \Delta_3(3, \epsilon_1)$ is the upper bound on the random variable X_3 representing the number of times Alice emits three photons in a block and Bob obtains a detection event. In the proof of Theorem 1, X_3 appears as the result of evaluation of its expectation $E[X_3]$. We reveal that applying Azuma's inequality to this evaluation results in a significant decrease in the key rate due to the large deviation term $|X_3 - E[X_3]|$ compared to X_3 (see Fig. 5 in [1]). This is because the event of emitting three photons, whose probability is $q_3 \sim \mu^3$, hardly occurs in the protocol using weak coherent states with intensity $\mu \ll 1$. On the other hand, Kato's inequality can incorporate the knowledge of the rarity of the events into the concentration inequality (more precisely, our estimation of X_3 can be reflected in the inequality), thereby reducing the deviation term. This is the reason why we apply Kato's inequality to upper-bound $E[X_3]$ with X_3.

Abstract. We propose a continuous-variable quantum key distribution (CV QKD) protocol with time-bin encoding and present a complete security analysis using discrete-variable (DV) methods. The new protocol is secure under the most general attacks and does not require any pilot reference, a costly requirement for common CV QKD. We unify the security analysis of CV QKD under standard DV approaches through the discrete photon-number tagging of the continuous optical fields. Moreover, by applying the DV technique of decoy states to the parameter estimation, our CV QKD protocol yields short-distance key-rate performance comparable to the state-of-the-art Bennett-Brassard-1984 implementation.

Keywords: quantum communication, quantum key distribution, coherent detection, quantum optics

1 Introduction

Continuous-variable quantum key distribution (CV QKD) [1–3] using optical coherent detectors is practically favorable due to its low implementation cost, flexibility of wavelength division multiplexing [4–6], and compatibility with standard coherent communication technologies [7]. However, the security analysis and parameter estimation of CV QKD are complicated due to the infinite-dimensional latent Hilbert space [8]. Also, the transmission of strong reference pulses undermines the security and complicates the experiments [9–14].

In this work, we tackle these two problems by presenting a time-bin-encoding CV protocol with a simple phase-error-based security analysis valid against general coherent attacks [15–17]. With the key encoded into the relative intensity between two optical modes, the need for global references is removed. Furthermore, phase randomization can be introduced to decouple the security analysis of different photon-number components. We can hence tag the photon number for each round, effectively estimate the associated privacy using a carefully designed coherent-detection method, and independently extract encryption keys from each component [18, 19]. Simulations manifest that the protocol using multi-photon components increases the key rate by two orders of magnitude compared to the one using only the single-photon component. Meanwhile, the protocol with four-intensity decoy analysis [20, 21] is sufficient to yield tight parameter estimation with a short-distance key rate comparable to the best Bennett-Brassard-1984 (BB84) implementation.

2 Protocol and security analysis outline

The protocol implementation is given in Fig. 1. Raw keys are obtained when both Alice and Bob choose the Z-basis, Alice chooses light intensity $\mu_a = \mu$, and Bob obtains a non-abort key bit $k_b \neq \emptyset$. The Z-bases are mainly used for key encoding and decoding, and the X-bases are used for parameter estimation. Here, we briefly explain the ideas behind the protocol design.

2.1 Time-bin BB84-like key encoding/decoding (Z-bases)

1. Source states:

(1) Alice's raw key k_a is encoded in the relative intensity between two time-bin modes (0 versus μ_a in two modes);
(2) Joint phase randomization block-diagonalizes the two-mode state on the total photon-number basis (random phase parameter φ_a over two modes).

2. Detection:

(1) Bob's raw key k_b is decoded from light intensity measurement (difference between quadrature absolute values $|q_1|$ and $|q_2|$);
(2) A threshold value τ in quadrature measurement is set to tackle shot noise in homodyne detection (an abort result $k_b = \emptyset$ is allowed);
(3) LO phase randomization block-diagonalizes the POVM elements on the total photon-number basis (random phase parameter φ_b over two LOs).

The key encoding and decoding resembles the time-bin-encoding BB84 protocol with coherent states [22], with the difference that single-photon detectors are replaced with homodyne detectors. As the key is encoded in the relative intensity, the protocol avoids the necessity of a pilot reference pulse.

For security analysis, we set up an equivalent virtual protocol (Fig. 2). On the source side, we set up an equivalent entanglement-based key encoding. On the detection side, we set up an equivalent squashing channel that generates the raw key with the same acceptance ($k_b \neq \emptyset$) probability. Alice's and Bob's raw keys k_a and k_b can be seen as Z-basis measurement results on qubit systems A' and B', respectively. This allows a discrete-variable-type complementarity-based security analysis [17]: Should Alice and Bob instead measure the qubit systems on the complementary X-basis, the probability they obtain different results, or the phase-error rate, e^X, could be used to upper-bound the privacy amplification cost.

Figure 1: Experimental setup. Alice's state preparation and Bob's detection and processing are listed in the tables. IM: intensity modulation; PM: phase modulation; ATTN: attenuation; LO: local oscillator.

After phase randomization (blue boxes), photon-number measurements M_{n_a} and M_{n_b} can be inserted without changing the key statistics. We can hence tag the emitted and received pulses according to the photon-number space, allowing the Gottesman-Lütkenhaus-Lo-Preskill (GLLP) framework [18] for analyzing the key privacy contained in each photon-number subspace.

2.2 Reverse reconciliation

Alice reconciles her raw keys with respect to Bob's. Therefore, the rounds Bob receives a vacuum state become secure. This is a common practice in usual CV QKD and in accordance with the observation in Ref. [23]. Based on the above design, we have the following result.

Theorem 1 (Asymptotic limit) *For the time-bin CV QKD protocol in Fig. 1 with reverse reconciliation, the distillable secure key rate r is lower bounded by r_{rev},*

$$r \geq r_{\text{rev}} = Q_{*,0} + \sum_{m=1}^{\infty} Q_{m,m}[1 - h(e^X_{m,m})] - fQ^Z h(e^Z), \tag{1}$$

$Q_{m,n}$ (gain): probability of sending an m-photon state and accepting an n-photon state; $e^X_{m,m}$: phase-error rate in the rounds where m photons are sent and m photons are accepted; $Q_{*,0}$: gain of the rounds where Bob accepts a vacuum state; Q^Z: Z-basis gain; e^Z: bit-error rate; f: efficiency of information reconciliation.

We discard the rounds where the total photon number decreases after state transmission, as Eve can apply a photon-number-splitting attack. In addition, we do not account for the terms where the total photon number increases, considering the practical lossy channels.

2.3 Parameter estimation (X-bases)

The phase-error probabilities and gains are defined by particular Fock-basis states. For instance, the single-photon phase-error rate is defined via the probability that Alice transmits $\left|\Psi_1^{\pm}\right\rangle = (|01\rangle \pm |10\rangle)/\sqrt{2}$ while Bob measures $\left|\Psi_1^{\mp}\right\rangle$, and the two-photon phase-error rate is defined via the probability that Alice transmits $\left|\Psi_2^{\pm}\right\rangle = (|02\rangle \pm |20\rangle)/\sqrt{2}$ while Bob measures $\left|\Psi_2^{\mp}\right\rangle$ or $|11\rangle$. To estimate these values, we construct unbiased estimators with the available coherent states and homodyne detection settings.

1. **Source:** To construct the state for desired statistics, we utilize coherent states from both bases,

$$\begin{aligned}&\Pr_\mu(m)\left|\Psi_m^{\pm}\right\rangle\left\langle\Psi_m^{\pm}\right| \\ =&\hat{P}_m\left(\hat{\rho}_\mu^Z \pm \frac{2^{m-2}}{m}\sum_{k=0}^{m-1}\hat{\rho}_\mu^{\frac{2\pi k}{m}} \mp \frac{2^{m-2}}{m}\sum_{k=0}^{m-1}\hat{\rho}_\mu^{\frac{2\pi k}{m}+\delta}\right)\hat{P}_m,\end{aligned} \tag{2}$$

where $\Pr_\mu(m)$ gives the Poisson distribution, $\hat{P}_m$ is the m-photon projector, $\hat{\rho}_\mu^Z$ is the Z-basis state, $\hat{\rho}_\mu^{\varphi_a}$ are the X-basis states with relative phase $\varphi_a^1 - \varphi_a^2 = \varphi_a$, and $\delta = \pi$ for odd m and $\pi/2$ for even m. The yields for each term can be estimated via the decoy-state method [20, 21].

2. **Detection:** We apply homodyne tomography to evaluate the photon-number operators [24–29]. Unbiased estimators can be obtained via weighted integrals over observed statistics, $p(q_1, q_2|\varphi_b^1, \varphi_b^2)$, the joint probability of quadrature measurement results on the two modes conditioned on LO phases φ_b^1 and φ_b^2.

2.4 Finite-size analysis against coherent attacks

The discrete-variable-type analysis allows the use of mature techniques like martingale theory [30–32] for finite-size parameter estimation under coherent attacks. Details can be found in the attached technical version.

3 Performance

We simulate the asymptotic key rate of our protocol with a thermal noise channel and a unit-efficiency homodyne detector. Note an inefficient detector with thermal electronic noise can be equated to a fiber section with transmittance equal to the detector efficiency, and the electronic noise absorbed into the channel excess noise. The fiber attenuation is 0.2 dB/km.

3.1 Utility of multi-photon components

The rounds where Alice sends m photons and Bob receives m photons can assure secure keys. Fig. 3a plots the asymptotic key rate of the i-photon protocol [utilizing at most $m = i$ photon components in Eq. (1)] with optimized setting parameters. Fig. 3b plots the key-rate contribution of each photon component at different distances. The m-photon contribution of the i-photon protocol is defined as $Q_{m,m}/(Q_{*,0} + \sum_{m=1}^{i} Q_{m,m})$ and the vacuum contribution is $Q_{*,0}/(Q_{*,0} + \sum_{m=1}^{i} Q_{m,m})$.

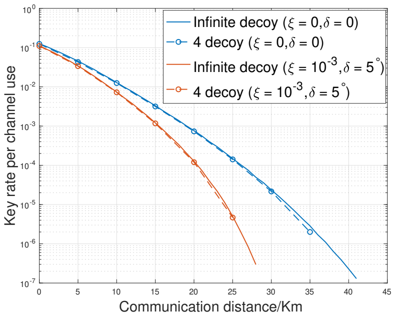

Figure 4: Two-photon protocol performances.

3.2 DV-comparable short-distance key rate

The key rate improves as we make use of the multi-photon components, most remarkable between the one and two-photon protocols. If we consider the protocol with infinite photon-number components, the 0-km key rate is around 0.31 bit/channel, and the BB84 protocol with currently the best single-photon detector of 80% efficiency [36, 37] has 0-km key rate 0.29 bit/channel, based on the model from Ref. [38]. Our key rate matches the best BB84 key rate with practically favorable devices.

3.3 Robustness

Fig. 4 illustrates the practical performances of the two-photon time-bin CV QKD protocol. We consider the issues of (1) the excess noise in transmission and detection, (2) the mode reference misalignment, where the two optical modes generating the time-bin qubit differ by δ in the reference phases intrinsically, and (3) a finite decoy level. Compared to the noiseless case (blue curves), the key rate decays mildly in the practical setup (red curves), considering reasonable parameters of excess noise $\xi = 10^{-3}$ and misalignment $\delta = 5°$. Moreover, an optimized 4-level decoy estimation is almost exact for both the noiseless and the practical setups (optimization using linear programming with a cutoff photon number 10 [39, 40]).

4 Comparison with relevant protocols

To sum up, we compare our protocol and analysis with relevant ones (Table 1). Our protocol has the advantage of removing the need of a reference pilot pulse, robust implementation with practically favorable devices, and reasonable performance in metropolitan distances. Moreover, we provide a complete analytical security analysis valid against coherent attacks in the finite-size regime.

Continuous-variable quantum key distribution (CV QKD) using optical coherent detectors is practically favorable due to its low implementation cost, flexibility of wavelength division multiplexing, and compatibility with standard coherent communication technologies. However, the security analysis and parameter estimation of CV QKD are complicated due to the infinite-dimensional latent Hilbert space. Also, the transmission of strong reference pulses undermines the security and complicates the experiments. In this work, we tackle these two problems by presenting a time-bin-encoding CV protocol with a simple phase-error-based security analysis valid under general coherent attacks. With the key encoded into the relative intensity between two optical modes, the need for global references is removed. Furthermore, phase randomization can be introduced to decouple the security analysis of different photon-number components. We can hence tag the photon number for each round, effectively estimate the associated privacy using a carefully designed coherent-detection method, and independently extract encryption keys from each component. Simulations manifest that the protocol using multi-photon components increases the key rate by two orders of magnitude compared to the one using only the single-photon component. Meanwhile, the protocol with four-intensity decoy analysis is sufficient to yield tight parameter estimation with a short-distance key-rate performance comparable to the best Bennett-Brassard-1984 implementation.

I. INTRODUCTION

Quantum key distribution (QKD) allows the generation of random secure keys between distant communication parties, of which the security is guaranteed by quantum physical laws. Apart from its theoretical advances, QKD is also one of the few quantum information processing technologies that can be robustly deployed in the fields, where photonic systems are considered the most suitable carriers of QKD operation. In general, two types of QKD protocols exist based on the detection methods: discrete-variable (DV) QKD [1, 2] uses the single-photon detector or photon-number-resolving detector to generate discrete detection information, while continuous-variable (CV) QKD [3–5] applies optical homodyne or heterodyne detection to generate continuous measurement information.

CV QKD has its advantages over DV QKD in short distances, mainly attributing to the distinct features of the coherent detectors used. The homodyne and heterodyne detectors are compatible with the standard classical communication and can be operated at much milder conditions than single-photon detectors. The spatial-temporal filtering of the local oscillators (LO) allows dense wavelength-division multiplexing with intense classical channels [6–8], and the high quantum efficiency and operation rate give CV QKD high key rates in metropolitan distances [9–11]. Moreover, the feasibility of on-chip implementations of the coherent detectors [12] promises large-scale integrated quantum networks. CV QKD is therefore considered highly practical and promising.

However, there exist two major limitations to the reliability of CV QKD. First, the transmission of the strong local oscillators is usually necessary to set up the phase reference between the communication parties, yet this complicates the implementation in the multiplexing separation and the relative phase shift calibration with the signals [13]. The LO transmission also opens up security loopholes where the eavesdropper Eve can affect the estimation of the signal variance by manipulating the LO intensity [14, 15], input time [16] and wavelength [17]. The “local” local oscillator scheme [13, 18] is a valid solution, yet it still requires the transmission of pilot pulses and compensation in the classical post-processing layer, which increase the experimental complexity. Second, the security of CV QKD in the finite-data regime under coherent attacks is still incomplete. In fact, for the traditional entanglement-distillation approach [19], the finite-size coherent attack security is only tackled for Gaussian-modulated CV QKD [20], which is, however, impractical since continuous modulation is never possible in reality.

Recently, several remarkable works on CV QKD have

[*] peizeng@uchicago.edu

been proposed, aiming at closing its security loopholes. In Ref. [5, 21], Matsuura et al. proposed a DV-like security analysis for the binary phase shift keying CV QKD. Their analysis covers finite size and coherent attack intrinsically since it follows the phase-error complementarity approach [22], yet their protocol still assumes the transmission of local oscillators. Qi [23] and Primaatmaja et al. [24] respectively proposed CV QKD protocols with two-mode encoding, generating dual-rail qubits that do not require global references. Their security analyses, however, do not cover the finite-data regime and coherent attacks. In fact, Qi's analysis requires repeated measurements and is only valid for individual attacks, and Primaatmaja et al.'s analysis is based on Devetak-Winter formula [19] and is only valid for collective attacks. Hence, the gap in CV QKD between theory and practice is still a challenging problem to be tackled.

In this work, we close this gap by proposing a new time-bin-encoding CV QKD protocol that enjoys both simple security proof and practical implementation. We remove the necessity of LO transmission by the two-mode encoding, hence closing the security loophole while simplifying the experimental setups. We follow the phase-error complementarity approach [22, 25, 26] so that the security naturally covers the general coherent-attack case. What is more, the intensity-based encoding allows phase randomization to be applied, where we can group the received signals based on the transmitted photon numbers and restore the tagging-based security analysis [27, 28] and the decoy-state method [29, 30]. Instead of generating secure key bits from all raw key bits, we can thus take advantage of the photon-number tags and distill key bits from the rounds with low phase-error rate. Our tagging-based security analysis builds a direct connection between CV QKD and the normal Bennett-Brassard-1984 (BB84) protocol: we clearly show how the multi-photon components in the CV QKD protocol contribute to a higher key rate in short distances. Compared with a similar protocol in Ref. [24] with numerical optimization under collective attacks, our protocol generates higher key rates with simpler parameter estimation using four decoy levels under coherent attacks.

We will start with the protocol description of the time-bin-encoding CV QKD in Sec. II. We present its security analysis based on phase error correction [22, 25, 26] in Sec. III, identifying an equivalent protocol squashing the optical modes into qubits with identical key mapping statistics [5, 27, 31] in Sec. III A. We exploit the block-diagonal structures of both the source and the receiver in Sec. III B, thus invoking the photon-number tagging technique [27, 28] standard in DV QKD in this CV protocol. In Sec. III C, we calculate the parameters in the key-rate formula with quantities on optical modes. The estimation of these quantities will be explained in Sec. IV with homodyne tomography [32] and decoy method [29, 30]. We finally simulate the performances of the time-bin CV QKD under realistic fiber-channel setups in Sec. V.

II. PROTOCOL DESCRIPTION

We present the proposed time-bin-encoding CV QKD protocol in Table I and depict its schematic diagram in Fig. 1. The two communication parties, Alice and Bob, employ the time-bin degree of freedom to encode keys. They use Z-basis for key generation and X-basis for parameter estimation. At the moment, we do not present the details of the X-basis parameter settings. We will specify the choices of the random phase factors, $\varphi_a^1, \varphi_a^2, \varphi_b^1$ and φ_b^2, and the light intensity, $\mu_a \in \{\mu, \nu_1, \nu_2, 0\}$, in Sec. IV.

Here, we briefly explain the idea behind the protocol design. The source states of our scheme resemble the ones in the time-bin-encoding BB84 protocol with coherent states [1], where the light intensities of the consecutive pulses naturally encode the key-bit information. As the key information is encoded in the relative intensity between the two modes, Alice does not need to send a pilot phase reference as in common CV QKD.

In our scheme, Bob decodes the key bit information, namely the Z-basis information, by measuring the light intensity of the pulses using the homodyne detectors. For instance, when Bob observes q_1 to be close to 0 and q_2 to be far away from 0, he may naturally guess that the original state sent by Alice corresponds to $k_a = 0$. However, unlike the key decoding with photon-number detectors, the result of measuring a coherent state's quadrature is subjected to a Gaussian distribution rather than a fixed value. The inherent shot noise of the homodyne detection introduces an intrinsic error in distinguishing a vacuum state from a pulse with a non-zero intensity [33]. To suppress the bit error, we introduce a threshold value, τ, in key decoding. The pulse intensity will be considered non-zero only when the quadrature magnitude is larger than τ. So a bit 0 will be decoded if $|q_1| < \tau$ and $|q_2| > \tau$ and bit 1 if $|q_1| > \tau$ and $|q_2| < \tau$. The choice of τ should be optimized with respect to the channel transmittance and pulse intensity. As we will show in Sec. VI, although this key mapping scheme can be further optimized, the performance of the simple key mapping scheme is already near-optimal.

The X-basis is designed to estimate the information leakage of different photon-number components of the Z-basis. Thanks to the phase randomization for both the sources and the detectors, the Z-basis states are block-diagonal on the total photon-number basis on the two optical modes after emitted from the source and before being measured by the homodyne detectors. As we will clarify in Sec. III, we can equivalently introduce total photon-number measurements at these two locations. As a result, Eve's eavesdropping strategy is effectively "twirled" to a photonic channel that only acts on the states incoherently with respect to the total photon numbers. One can thus virtually tag the emitted and received pulses according to the photon-number space, allowing the Gottesman-Lütkenhaus-Lo-Preskill (GLLP) framework [27] for analyzing the key privacy contained

TABLE I: Phase-randomized time-bin-encoding CV QKD

1. On Alice's side (source):
   - *Z-basis*:
     (a) Randomly select a key bit $k_a \in \{0, 1\}$, a phase factor $\varphi_a \in [0, 2\pi)$, and a light intensity $\mu_a \in \{\mu, \nu_1, \nu_2, 0\}$.
     (b) Prepare a coherent state of $|0\rangle_{A1} |\sqrt{\mu_a} e^{i\varphi_a}\rangle_{A2}$ for $k_a = 0$ or $|\sqrt{\mu_a} e^{i\varphi_a}\rangle_{A1} |0\rangle_{A2}$ for $k_a = 1$.
   - *X-basis*:
     (a) Randomly select two phase factors φ_a^1 and φ_a^2 and a light intensity $\mu_a \in \{\mu, \nu_1, \nu_2, 0\}$.
     (b) Prepare a coherent state of $|\sqrt{\mu_a/2} e^{i\varphi_a^1}\rangle |\sqrt{\mu_a/2} e^{i\varphi_a^2}\rangle$.
2. Alice sends the state through an authenticated channel to Bob.
3. On Bob's side (detection):
   - *Z-basis*:
     (a) Randomly select a phase factor $\varphi_b \in [0, 2\pi)$.
     (b) Use homodyne detectors both with LO phases φ_b to measure the modes and obtain quadratures q_1 and q_2.
     (c) Decode the key bit as 0 if $|q_1| < \tau \wedge |q_2| > \tau$, 1 if $|q_1| > \tau \wedge |q_2| < \tau$, and $\emptyset$ otherwise.
   - *X-basis*:
     (a) Randomly select two phases φ_b^1 and φ_b^2 independently.
     (b) Use homodyne detectors with LO phases φ_b^1 and φ_b^2 to measure the modes and obtain quadratures q_1 and q_2.
     (c) Use φ_1, φ_2 and q_1, q_2 for phase-error estimation (see Sec. IV).
4. Alice and Bob perform basis sifting, where they obtain raw keys in the rounds they both choose Z-basis with light intensity $\mu_a = \mu$ and $k_b \neq \emptyset$.
5. Based on parameter estimation, Alice and Bob perform information reconciliation and privacy amplification to obtain final keys.

FIG. 1: Schematic diagram of the experimental setup. The setups of Alice and Bob are shaded in green and blue, respectively. Alice prepares two-mode phase-randomized states according to the basis choice and raw key value in key generation rounds, as shown in the table. In this work, we consider a time-bin encoding, where one obtains two modes via time delay. The state modulation consists of intensity modulation (IM), phase modulation (PM), and necessary attenuation (ATTN). Upon receiving the state, Bob measures each mode with homodyne detectors. He uses a synchronized clock to distinguish adjacent modes and applies phase modulation (PM) to the local oscillator (LO).

in each photon-number subspace. In particular, dealing with photon-number spaces effectively brings our security analysis to the DV regime. In Sec. III, we shall construct observables to estimate the m-photon component phase-error rates $e^X_{m,m}$ for privacy estimation. Intuitively, the phase-error rates $e^X_{m,m}$ provide upper bounds on the key information leakage to the eavesdropper, Eve.

To estimate the m-photon component phase-error rates, $e^X_{m,m}$, ideally, we need a source emitting the photon-number cat states, $(|0\rangle|m\rangle \pm |m\rangle|0\rangle)/\sqrt{2}$, and photon-number-resolving measurements that distinguish the cat states. While this is not directly implementable, we can use only coherent states and homodyne measurements to establish unbiased estimators of $e^X_{m,m}$, as shown in Table II. On the source side, we employ a generalized decoy-state method to estimate the behaviors of photon-number-cat states using coherent states with various intensities [29, 30], which shall be discussed in Sec. IV B. On the detection side, ideally, we also want to measure the photon-number-cat states to obtain unbiased estimation of the phase-error rates, $e^X_{m,m}$. While this is not directly measurable in practice, we employ the homodyne tomography technique and estimate the photon-number-cat state measurement via quadrature measurement results [34–39], which shall be discussed in Sec. IV A.

We briefly remark on the performance of homodyne detection. In key decoding, one may consider the homodyne detection as ill-performed single-photon detectors that introduce an inevitable bit-error rate. On the other hand, homodyne detection allows for more efficient parameter estimation than single-photon detection. As we shall discuss later, the set of all quadrature operators spans the underlying mode, thus allowing one to express any linear operator in terms of the quadrature operators. Therefore, with proper transformation of the quadrature measurement results, homodyne detection allows one to obtain an unbiased estimation of linear operator expectations. This is the reason for accurately estimating phase-error rates with repeated homodyne measurements, including those of the multi-photon components. In comparison, as the single-photon detection is not information-complete, estimation of multi-photon observables requires more complex setups such as sequential beam splitting [40], and one can only obtain upper and lower bounds rather than an unbiased estimation.

III. SECURITY ANALYSIS

We analyze the security of our phase-randomized time-bin-encoding CV QKD protocol along the complementarity approach [22, 26, 27]. As outlined in Fig. 2, we shall set up a series of equivalent protocols of the realistic implementation that do not change the statistics of any observer, with which we define the phase-error observable and estimate the key privacy. In Sec. III A, we shall prove that raw key generation can be effectively regarded as qubit measurements on a pair of entangled qubits, which allows us to borrow the mature complementarity-based security analysis in the DV regime. In brief, on the source side, we transform the preparation of key states to an entanglement-based protocol [25, 26], where a qubit measurement controls the key-encoding process, as shown in Fig. 2(b). On the detection side, we prove that the homodyne measurement can be squashed into an effective qubit measurement, as shown in Fig. 2(c). Moreover, in Sec. III B, we shall rigorously prove that phase randomization twirls the photonic modes into diagonal states on the Fock basis and explain how to apply the tagging idea of the GLLP framework [27, 28]. We also show how to estimate the phase-error rates for different photon-number components from Fock-basis observables in Sec. III C. Later in Sec. IV, we show that the estimation can be realized in the realistic implementation with coherent states and homodyne detection.

To focus on the essence of security analysis, we present the result in a single-round analysis in this section, where one can interpret it as the quantum Shannon limit under collective attacks. Nevertheless, the complementarity-based security analysis is inherently adapted to the most general case, namely the coherent attack, where the statistics over the rounds may not be independent and identically distributed (i.i.d.) [41]. We will discuss the parameter estimation with non-i.i.d. finite statistics in Sec. IV C.

A. Entanglement-based squashing protocol

Here, we show the equivalence of the time-bin CV QKD protocol to a qubit-based entanglement distribution protocol, where the protocols generate the same transmitted quantum states and measurement statistics. The latter protocol enables us to simplify the security analysis and estimate the information leakage from phase-error rates.

We first focus on the key-generation rounds in the protocol where both users choose the Z-basis, of which the whole procedure is depicted in Fig. 2(a). In the realistic implementation, Alice prepares phase-randomized coherent states,

$$\int_0^{2\pi} \frac{d\varphi_a}{2\pi} \left|\Psi(k_a)_{\varphi_a}\right\rangle_{A_1A_2} \left\langle\Psi(k_a)_{\varphi_a}\right|, \tag{1}$$

where

$$\left|\Psi(k_a)_{\varphi_a}\right\rangle_{A_1A_2} = \begin{cases} |0\rangle_{A_1}\left|\sqrt{\mu}e^{i\varphi_a}\right\rangle_{A_2}, & \text{if } k_a = 0, \\ \left|\sqrt{\mu}e^{i\varphi_a}\right\rangle_{A_1}|0\rangle_{A_2}, & \text{if } k_a = 1. \end{cases} \tag{2}$$

We denote the optical modes sent to Bob as A_1 and A_2, which are CV systems. Throughout this paper, we treat the phase of optical modes, φ_a, as fully randomized over $[0, 2\pi)$. Finite phase randomization, $\varphi_a \in \{2j\pi/D\}_{j\in[D]}$, suffices for a practical implementation, where its difference from the full phase randomization is negligible when D is sufficiently large [42]. This is also the case in later

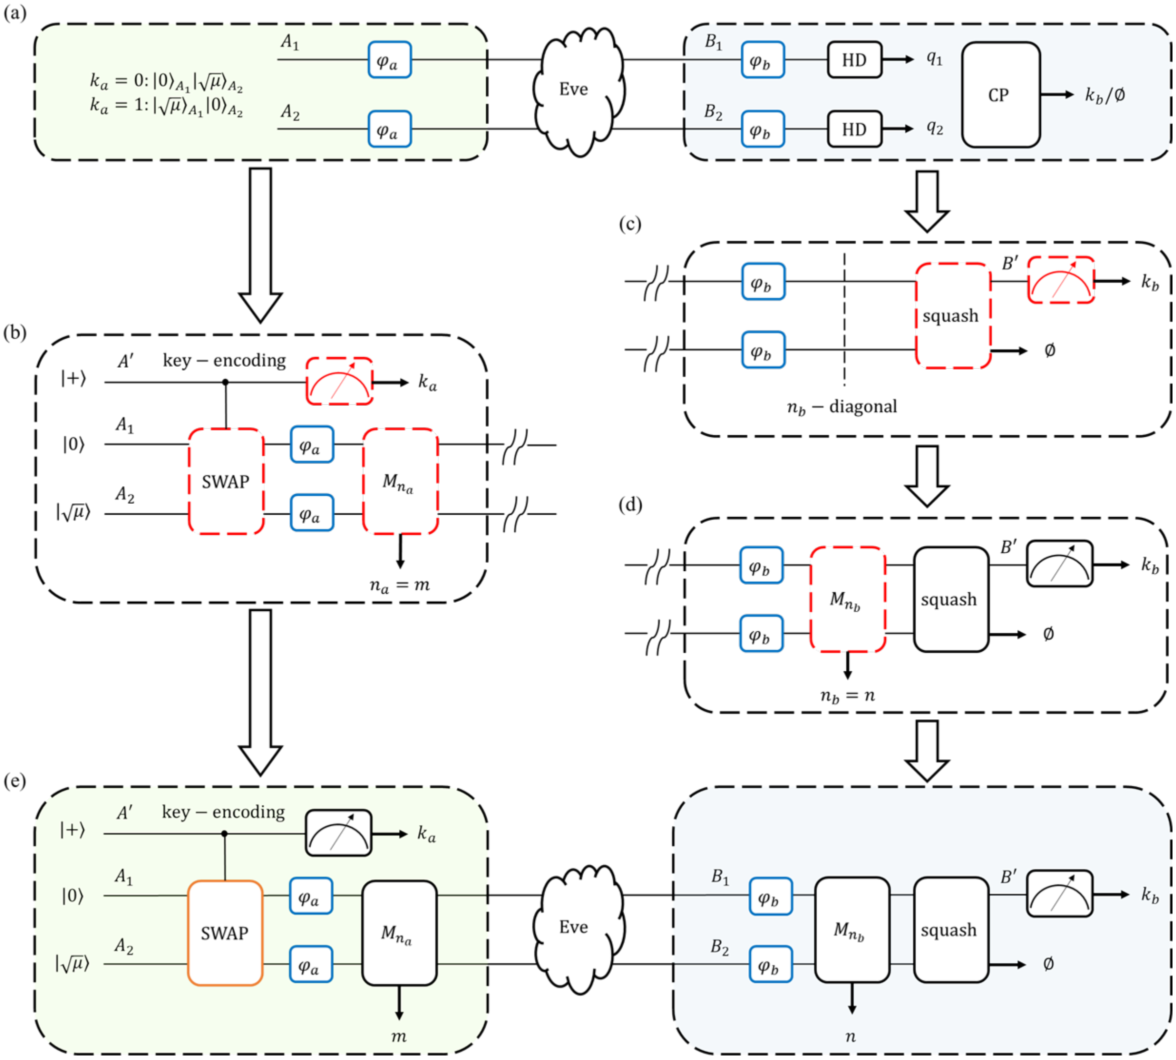

FIG. 2: Equivalent quantum circuits in key generation rounds. Reductions in each step are plotted with red dashed boxes. (a) The realistic implementation. The operations on Alice's and Bob's sides are shaded in green and blue, respectively. Alice prepares weak coherent states on two modes, which depend on the basis choice and the raw key value. On Bob's side, Bob measures the two modes with homodyne detectors (HD) and obtains quadratures q_1 and q_2. Afterward, Bob performs classical post-processing (CP) on the data and obtains a raw key k_b probabilistically, where the key decoding may fail due to the key mapping threshold, denoted as $\emptyset$. The blue rounded boxes represent phase randomization processes in state preparation or for the LOs in homodyne detection. (b) Equivalent entanglement-based state preparation. Key encoding can be interpreted as a qubit control operation on two modes where the control qubit measurement gives Alice's raw key k_a. The joint state on the two modes is diagonal on the Fock basis after phase randomization. One can insert a photon-number measurement, $\hat{M}_{n_a}$, and read out the total photon number, m, without changing the state. (c) Equivalent key-decoding measurement. The joint state of the two modes becomes diagonal on the Fock basis due to detector phase randomization. In key decoding, the modes are first squashed into a qubit probabilistically, where the failure gives the abort signal $\emptyset$. Upon successful squashing into a qubit, the computational-basis measurement gives the raw key bit. (d) Due to detector phase randomization, one can insert a photon-number measurement, $\hat{M}_{n_b}$, and read out the total photon number, n, without changing the state. (e) Equivalent circuit for security analysis. After the above reductions, the key generation measurements can be equivalently defined on a pair of (sub-normalized) qubit states.

TABLE II: State preparation and detection settings in the ideal implementation and the realistic implementation. For brevity, we omit the subscripts of modes and express the detection with the measurement operators. In key generation rounds, Bob applies phase-randomized homodyne detection for key-decoding. The expression of measurement operator $\hat{\Pi}(q_1, q_2)$ is given in Eq. (9), where q_1 and q_2 represent the quadratures of the two modes. The operator is block-diagonal on the total photon-number basis. For parameter estimation, ideally, Alice sends photon-number-cat states, and Bob performs a corresponding projective measurement. In the realistic setting, Alice can only prepare phase-randomized weak coherent states, and Bob can only perform phase-randomized homodyne measurements. The homodyne measurement operator, $\hat{Q}_{\varphi_1} \otimes \hat{Q}_{\varphi_2}$, is given in Eq. (6). Afterward, Bob estimates the photon-number-cat state measurement expectations via homodyne tomography methods, as shown in Eq. (28).

discussions on the detector phase randomization. Alice's key-state preparation can be effectively seen as an entanglement-based protocol [25, 26]. Given the phase value, φ_a, Alice first prepares the following entangled state,

$$\begin{aligned} |\Psi_{\varphi_a}\rangle_{A'A_1A_2} =& \frac{1}{\sqrt{2}}\big(|0\rangle_{A'} |\Psi(k_a = 0)_{\varphi_a}\rangle_{A_1A_2} \\ &+ |1\rangle_{A'} |\Psi(k_a = 1)_{\varphi_a}\rangle_{A_1A_2} \big), \end{aligned} \tag{3}$$

where system A' is a qubit system that superposes the two possible key states. The entangled state can be prepared by the quantum circuit in Fig. 2(b). Up to phase randomization, systems A' and A_1A_2 are initialized in $|+\rangle$ and $|0\rangle|\sqrt{\mu}\rangle$, and a control-swap operation is then applied from the qubit system to the optical modes. Alice obtains raw key bit k_a by measuring system A' on the computational basis, and the optical modes are prepared into the corresponding key state, $|\Psi(k_a)_{\varphi_a}\rangle$. The complementary observable of Alice's key-generation measurement can thus be defined over qubit system A', which measures the complementary basis of $\{|+\rangle, |-\rangle\} := \{(|0\rangle \pm |1\rangle)/\sqrt{2}\}$.

At the detection side in Fig. 2(a), Bob receives two optical modes B_1 and B_2, takes homodyne measurements, and maps the quadratures to a raw key or an abort signal. This process can be described by a trace-non-preserving completely positive map,

$$\begin{aligned} \mathcal{F}_{\text{rand}}^{B_1B_2\to B'}(\hat{\rho}_{B_1B_2}) = \int_0^{2\pi} \frac{d\varphi_b}{2\pi} \int_{\mathbf{R_0}} dq_1 dq_2 \\ \hat{K}^{(q_1,q_2,\varphi_b)} \hat{\rho}_{B_1B_2} \hat{K}^{(q_1,q_2,\varphi_b)\dagger}, \end{aligned} \tag{4}$$

where

$$\begin{aligned} \hat{K}^{(q_1,q_2,\varphi_b)} :=& |0\rangle_{B'} \langle q_1(\varphi_b), q_2(\varphi_b)|_{B_1,B_2} \\ &+ |1\rangle_{B'} \langle q_2(\varphi_b), q_1(\varphi_b)|_{B_1,B_2}, \end{aligned} \tag{5}$$

$|q(\varphi)\rangle$ is the rotated position eigenstate of quadrature observable

$$\hat{Q}_{\varphi} = \hat{a}e^{-i\varphi} + \hat{a}^{\dagger}e^{i\varphi}, \tag{6}$$

with $\hat{a}$ and $\hat{a}^{\dagger}$ denoting the annihilation and creation operators, respectively, and $\mathbf{R_0} \in \mathbb{R}^2$ records the region that decodes the real-valued tuple, (q_1, q_2), as $k_b = 0$. Note that in our protocol, $\mathbf{R_0} = \{|q_1| < \tau\} \times \{|q_2| > \tau\}$, and the region decodes the quadratures to $k_b = 1$ under the mapping $(q_1, q_2) \mapsto (q_2, q_1)$, which we denote as $\mathbf{R_1} = \{|q_1| > \tau\} \times \{|q_2| < \tau\}$. The LOs of homodyne measurements are synchronically randomized, as denoted by φ_b in Eq. (4). As the key-decoding region does not cover the entire parameter space, $\mathcal{F}_{\text{rand}}^{B_1B_2\to B'}$ is hence not trace-preserving, where $\text{Tr}[\mathcal{F}_{\text{rand}}^{B_1B_2\to B'}(\hat{\rho}_{B_1B_2})]$ gives the probability of obtaining raw key bit $k_b \in \{0, 1\}$. Bob's raw key can be equivalently seen as obtained by measuring the squashed sub-normalized qubit on the computational basis, and the probabilities are given by

$$\begin{aligned} &\Pr(k_b = 0) = \langle 0| \mathcal{F}_{\text{rand}}^{B_1B_2\to B'}(\hat{\rho}_{B_1B_2}) |0\rangle \\ =& \int_0^{2\pi} \frac{d\varphi_b}{2\pi} \int_{\mathbf{R_0}} dq_1 dq_2 \langle q_1(\varphi_b), q_2(\varphi_b)| \hat{\rho}_{B_1B_2} |q_1(\varphi_b), q_2(\varphi_b)\rangle, \\ &\Pr(k_b = 1) = \langle 1| \mathcal{F}_{\text{rand}}^{B_1B_2\to B'}(\hat{\rho}_{B_1B_2}) |1\rangle \\ =& \int_0^{2\pi} \frac{d\varphi_b}{2\pi} \int_{\mathbf{R_1}} dq_1 dq_2 \langle q_1(\varphi_b), q_2(\varphi_b)| \hat{\rho}_{B_1B_2} |q_1(\varphi_b), q_2(\varphi_b)\rangle. \end{aligned} \tag{7}$$

Similar to the treatment to A', we can define the complementary observable of Bob's key generation measurement on qubit system B'.

B. Photon-number tagging of the source and receiver

In the last section, we have shown that raw keys can be equivalently seen as generated from qubit measurements on A' and B'. Should Alice and Bob instead measure the qubit system on the complementary bases, the probability they obtain different results, or the phase-error rate, e^X, could be used to upper-bound the average privacy amplification cost per round as $h(e^X)$, where $h(p) = -p\log p - (1-p)\log(1-p)$ is the binary entropy function. Nevertheless, the actual privacy leakage may be less than the direct calculation. Note that the above privacy leakage estimation is averaged over the overall quantum state transmitted from Alice to Bob. The contribution to the privacy leakage of different components in quantum signals can differ. For instance, Eve can apply the photon-number-splitting (PNS) attack in the rounds in which Alice transmits two photons and Bob receives only a single photon [43, 44]; hence no privacy should be expected, rendering the phase-error probability to be 1/2 in these rounds. If Alice and Bob can distinguish such rounds from the others, they can simply discard them in privacy amplification. The GLLP framework makes the above statement rigorous [27, 28]. Suppose Alice and Bob can categorize the transmitted quantum signals into different groups, or tags, and evaluate phase-error probabilities separately. The privacy amplification cost can be evaluated by $\sum_i Q_i h(e_i^X)$, where Q_i is the probability that a signal in the i'th group is transmitted and detected, namely the gain, and e_i^X is the phase-error probability of the group. Due to the concavity of the entropy function, this estimation is no larger than $h(\sum_i Q_i e_i^X)$.

In DV QKD, the tagging idea has been well practiced. In the coherent-state-based BB84 protocol, phase randomization on the source side diagonalizes the quantum signals on the Fock basis [29, 30], and an ideal single-photon detector naturally distinguishes the single photon components from other detected Fock components, allowing Alice and Bob to tag the quantum states with respect to the photon number [45]. Similarly, we now prove that the photon-number tag can also be applied to the phase-randomized CV QKD protocol in Table I. On the source side, the phase randomization diagonalizes the state on the joint Fock basis,

$$\begin{aligned}\hat{\rho}^Z &= \int_0^{2\pi} \frac{d\varphi_a}{2\pi} \quad \frac{1}{2} \left|0\right\rangle_{A_1} \left\langle 0\right| \otimes \left|\sqrt{\mu}e^{i\varphi_a}\right\rangle_{A_2} \left\langle \sqrt{\mu}e^{i\varphi_a}\right| \\ &\quad + \frac{1}{2} \left|\sqrt{\mu}e^{i\varphi_a}\right\rangle_{A_1} \left\langle \sqrt{\mu}e^{i\varphi_a}\right| \otimes \left|0\right\rangle_{A_2} \left\langle 0\right| \\ &= \sum_{m=0}^{\infty} \Pr(m) \frac{1}{2} \left(\left|0m\right\rangle_{A_1A_2} \left\langle 0m\right| + \left|m0\right\rangle_{A_1A_2} \left\langle m0\right|\right),\end{aligned} \tag{8}$$

where $\Pr(m) = e^{-\mu}\mu^m/m!$ is the Poisson distribution. Consequently, one can virtually insert a photon-number measurement after phase randomization to measure the total photon number on the two modes without changing the state, as shown in Fig. 2(b). On the detection side, when Bob takes the Z-basis measurement, the phase-randomized homodyne detector POVM elements can be expanded on the Fock basis [24],

$$\begin{aligned}&\hat{\Pi}(q_1, q_2) \\ &= \int_0^{2\pi} \frac{d\varphi_b}{2\pi} \left|q_1(\varphi_b)\right\rangle_{B_1} \left\langle q_1(\varphi_b)\right| \otimes \left|q_2(\varphi_b)\right\rangle_{B_2} \left\langle q_2(\varphi_b)\right| \\ &= \sum_{n=0}^{\infty} \sum_{k_0=0}^{n} \sum_{l_0=0}^{n} \psi_{k_0}(q_1)\psi_{l_0}(q_1)\psi_{n-k_0}(q_2)\psi_{n-l_0}(q_2) \\ &\qquad \left|k_0, n-k_0\right\rangle_{B_1B_2} \left\langle l_0, n-l_0\right|,\end{aligned} \tag{9}$$

where

$$\psi_n(q_j) = \frac{1}{\sqrt{2^n n! \sqrt{2\pi}}} H_n(q_j/\sqrt{2}) e^{-q_j^2/4} \tag{10}$$

is the coordinate representation of Fock state $|n\rangle$, with H_n being the n-th Hermite polynomial. Therefore, one can virtually insert another photon-number measurement after phase randomization before the squashing channel Eq. (4) on the detection side to measure the total photon number of the received state, as shown in Fig. 2(d).

Based on the above results, we depict a virtual quantum circuit of the protocol when both Alice and Bob chooses the Z-basis in Fig. 2(e). We denote the photon-number measurement results on the source side and the detection side as m and n, respectively. Alice and Bob can thus distill secrete keys separately based on the photon-number tag of (m, n). A lower bound on the key rate can then be given by [27, 28]

$$r \geq \sum_{m=0}^{\infty} Q_{m,m}[1 - h(e_{m,m}^X)] - fQ^Z h(e^Z), \tag{11}$$

where $Q_{m,m}$ and $e_{m,m}^X$ denote the gain and the phase-error rate in the rounds where m photons are sent and m photons are accepted, Q^Z is the Z-basis gain, e^Z is the bit-error rate, and f is the efficiency of information reconciliation. Note not to confuse the gains with quadrature observables. In addition, since Bob's key decoding succeeds probabilistically where he only accepts quadratures above the threshold, we use the term "accepting" to represent receiving a certain state and passing the post-selection. All the gains and error rates in the key-rate formula are restricted to the rounds with light intensity $\mu_a = \mu$. We discard the rounds where the total photon number decreases after state transmission, as the photons that are lost may come from Eve's interception, with which Eve can apply a PNS attack. The corresponding phase-error probability is 1/2; hence these rounds do not contribute to key generation. In addition, as the transmission channel is naturally lossy in a usual setting, we do not account for the terms where the total photon number increases.

Note that the key-rate formula in Eq. (11) assumes forward reconciliation, where Bob reconciles his raw keys to Alice's, k_a, and then the users perform privacy amplification. The rounds where Alice sends a non-vacuum state while Bob receives a vacuum state are hence insecure, since the information carriers are lost through the channel. Instead, if reverse reconciliation is used, where Alice reconciles her raw keys to Bob's, the rounds where Bob receives a vacuum state become secure. One can interpret Bob's raw keys in these rounds as generated from local random numbers, and no information is known *a priori* in transmission. This is a common practice in usual CV QKD and in accordance with the observation in Ref. [23]. The fact that the vacuum component can also contribute to key rate formula is first observed in Ref. [46]. We present as Theorem 1 the key-rate lower bound with reverse reconciliation as the main key-rate formula to be used throughout this paper.

Theorem 1. *For the time-bin CV QKD protocol in Table I with reverse reconciliation, in the asymptotic limit of an infinite data size, the distillable secure key rate r is lower bounded by r_{rev},*

$$r \geq r_{\text{rev}} = Q_{*,0} + \sum_{m=1}^{\infty} Q_{m,m}[1 - h(e^X_{m,m})] - fQ^Z h(e^Z), \tag{12}$$

where $Q_{m,m}$ and $e^X_{m,m}$ denote the gain and the phase-error rate in the rounds where m photons are sent and m photons are accepted, Q^Z is the Z-basis gain, e^Z is the bit-error rate, and f is the efficiency of information reconciliation. $Q_{*,0}$ represents the gain of the rounds where Bob accepts a vacuum state for whatever state sent by Alice.

C. Phase-error probability calculation

We now evaluate the key-rate formula in Eq. (12) with Fock-basis observables [5]. The bit-error rate e^Z can be directly measured, as the Z-measurement statistics in the entanglement-based squashing model are the same as the realistic statistics. To evaluate the gains and phase-error probabilities, we first determine the state before the phase-error measurement under each photon-number tag. Define $\hat{P}_m$ as the projector onto the m-photon state on modes A_1 and A_2. When sending m photons, the source in Fig. 2(b) collapses to

$$\hat{P}_m^{A_1A_2} \hat{\rho}_{A'A_1A_2} \hat{P}_m^{A_1A_2} = \Pr(m) \left|\Psi_m\right\rangle_{A'A_1A_2} \left\langle\Psi_m\right|, \tag{13}$$

where

$$\begin{aligned} \left|\Psi_m\right\rangle_{A'A_1A_2} &= \frac{1}{\sqrt{2}}(\left|0\right\rangle_{A'} \left|0m\right\rangle_{A_1A_2} + \left|1\right\rangle_{A'} \left|m0\right\rangle_{A_1A_2}), \\ \Pr(m) &= \frac{e^{-\mu}\mu^m}{m!}. \end{aligned} \tag{14}$$

Upon transmitting the m-photon state, $\left|\Psi_m\right\rangle_{A'A_1A_2}$, the n-photon state is selected on the detection side after the squashing channel,

$$\mathcal{F}_{\text{rand}}^{B_1B_2\to B'} \left\{ \hat{P}_n^{B_1B_2} \mathcal{N}_E^{A_1A_2\to B_1B_2} \left[\Pr(m) \left|\Psi_m\right\rangle_{A'A_1A_2} \left\langle\Psi_m\right| \right] \hat{P}_n^{B_1B_2} \right\} = Q_{m,n} \hat{\rho}^{(m,n)}_{A'B'}, \tag{15}$$

where $\mathcal{N}_E^{A_1A_2\to B_1B_2}$ represents Eve's channel, and $Q_{m,n}$ denotes the probability of sending an m-photon state and accepting an n-photon state, namely the gain for the states tagged by the photon-number tuple, (m,n). Note the probability that Bob aborts the signal is reflected in $Q_{m,n}$. The normalized state, $\hat{\rho}^{(m,n)}_{A'B'}$, is a bipartite qubit, with which we evaluate the phase-error probability,

$$e^X_{m,n} = \mathrm{Tr}\left[\hat{\rho}^{(m,n)}_{A'B'} \left(\left|+-\right\rangle_{A'B'} \left\langle+-\right| + \left|-+\right\rangle_{A'B'} \left\langle-+\right| \right) \right]. \tag{16}$$

With respect to the complementary-basis measurement result on the qubit A', $+$ or $-$, the state on modes A_1 and A_2 collapses to

$$\left|\Psi_m^{\pm}\right\rangle_{A_1A_2} = \frac{1}{\sqrt{2}}(\left|0m\right\rangle \pm \left|m0\right\rangle)_{A_1A_2} \tag{17}$$

with equal probabilities. For the state on Bob's systems B_1 and B_2 under tag (m,n), $\hat{\rho}^{(m,n)}_{B_1B_2}$, the statistics of the complementary measurement are given by

$$\begin{aligned} {}_{B'}\left\langle\pm\right| \mathcal{F}_{\text{rand}}^{B_1B_2\to B'}[\hat{\rho}^{(m,n)}_{B_1B_2}] \left|\pm\right\rangle_{B'} &= \mathrm{Tr}\left[\hat{\rho}^{(m,n)}_{B_1B_2} \hat{M}_{\pm} \right] \\ &= \mathrm{Tr}\left[\hat{\rho}^{(m,n)}_{B_1B_2} \hat{P}_n \hat{M}_{\pm} \hat{P}_n \right], \end{aligned} \tag{18}$$

where

$$\begin{aligned} \hat{M}_{\pm} = \frac{1}{2} \int_{\mathbf{R_0}} dq_1 dq_2 \int_0^{2\pi} \frac{d\varphi_b}{2\pi} \big[&\left|q_1(\varphi_b), q_2(\varphi_b)\right\rangle \pm \\ &\left|q_2(\varphi_b), q_1(\varphi_b)\right\rangle \big] \left[\left\langle q_1(\varphi_b), q_2(\varphi_b)\right| \pm \left\langle q_2(\varphi_b), q_1(\varphi_b)\right| \right]. \end{aligned} \tag{19}$$

In the last equation in Eq. (18), we utilize the fact that $\hat{\rho}^{(m,n)}_{B_1B_2}$ acts on the n-photon space of system B_1B_2. Combining the above results, we can express the phase-error rate for each tag with observables on optical modes:

Proposition 1. *The phase-error rate $e^X_{m,n}$ of the rounds where m photons are sent and n photons are accepted can be calculated by:*

$$\frac{Q_{m,n}e^X_{m,n}}{\Pr(m)} = \frac{1}{2}\mathrm{Tr}[\mathcal{N}_E^{A_1A_2\to B_1B_2}(|\Psi_m^+\rangle_{A_1A_2}\langle\Psi_m^+|)\hat{P}_n\hat{M}_-\hat{P}_n + \mathcal{N}_E^{A_1A_2\to B_1B_2}(|\Psi_m^-\rangle_{A_1A_2}\langle\Psi_m^-|)\hat{P}_n\hat{M}_+\hat{P}_n], \tag{20}$$

where $Q_{m,n}$ denotes the probability of sending an m-photon state and accepting an n-photon state, and $\Pr(m)$ is the probability of the source emitting m photons. $\mathcal{N}_E$ denotes Eve's channel on the two optical modes and $\hat{P}_n$ denotes the projector onto the n-photon subspace. $|\Psi_m^\pm\rangle$ and $\hat{M}_\pm$ defined in Eq. (17) and (19) respectively.

We can write $\hat{P}_n\hat{M}_{+(-)}\hat{P}_n$ on the Fock basis using Eq. (9), expressing the phase-error rate as quantities on optical modes. Here, we list the final results for a protocol that utilizes up to the two-photon components. The detailed calculation is placed in Appendix A.

- For the single-photon component,

$$\begin{aligned}\frac{Q_{1,1}e^X_{1,1}}{\Pr(1)} = \frac{c_1}{2}\Big\{&\mathrm{Tr}\left[\mathcal{N}_E^{A_1A_2\to B_1B_2}(|\Psi_1^+\rangle_{A_1A_2}\langle\Psi_1^+|)\frac{1}{2}(|01\rangle_{B_1B_2} - |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} - \langle 10|_{B_1B_2})\right] \\ &+\mathrm{Tr}\left[\mathcal{N}_E^{A_1A_2\to B_1B_2}(|\Psi_1^-\rangle_{A_1A_2}\langle\Psi_1^-|)\frac{1}{2}(|01\rangle_{B_1B_2} + |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} + \langle 10|_{B_1B_2})\right]\Big\},\end{aligned} \tag{21}$$

where

$$c_1 = \int_{\mathbf{R_0}} dq_1dq_2[\psi_0^2(q_1)\psi_1^2(q_2) + \psi_0^2(q_2)\psi_1^2(q_1)], \tag{22}$$

and gain $Q_{1,1}$ is given by

$$\frac{Q_{1,1}}{\Pr(1)} = c_1\mathrm{Tr}\left\{\mathcal{N}_E\left[\mathrm{Tr}_{A'}(|\Psi_1\rangle_{A'A_1A_2}\langle\Psi_1|)\right](|01\rangle_{B_1B_2}\langle 01| + |10\rangle_{B_1B_2}\langle 10|)\right\}. \tag{23}$$

Up to the less-than-unity factor c_1 that arises from the data post-selection in key mapping, the formulae are the same as the complementary-basis result in the coherent-state-based BB84 protocol [47]. It can also be seen that the phase-error rate of the rounds where Alice transmits two photons and Bob accepts one photon involves in the probability where Alice transmits $(|02\rangle \pm |20\rangle)/\sqrt{2}$ and Bob receives $(|01\rangle \mp |10\rangle)/\sqrt{2}$. In a pure-loss channel, the superimposed two-photon state $(|02\rangle \pm |20\rangle)/\sqrt{2}$ would lose coherence if one photon is lost during the channel, thus giving 50% phase-error rate. This observation validates the intuition of the PNS attack.

- For the two-photon subspace, based on Eq. (9) and Eq. (20), we have,

$$\begin{aligned}\frac{Q_{2,2}e^X_{2,2}}{\Pr(2)} =&\frac{1}{2}c_2^-\mathrm{Tr}\left[\mathcal{N}_E^{A_1A_2\to B_1B_2}(|\Psi_2^+\rangle_{A_1A_2}\langle\Psi_2^+|)\frac{1}{2}(|02\rangle_{B_1B_2} - |20\rangle_{B_1B_2})(\langle 02|_{B_1B_2} - \langle 20|_{B_1B_2})\right] \\ &+\frac{1}{2}c_2^+\mathrm{Tr}\left[\mathcal{N}_E^{A_1A_2\to B_1B_2}(|\Psi_2^-\rangle_{A_1A_2}\langle\Psi_2^-|)\frac{1}{2}(|02\rangle_{B_1B_2} + |20\rangle_{B_1B_2})(\langle 02|_{B_1B_2} + \langle 20|_{B_1B_2})\right] \\ &+c_2^{11}\mathrm{Tr}\left[\mathcal{N}_E^{A_1A_2\to B_1B_2}(|\Psi_2^-\rangle_{A_1A_2}\langle\Psi_2^-|)\,|11\rangle_{B_1B_2}\langle 11|\right],\end{aligned} \tag{24}$$

where

$$\begin{aligned}c_2^+ &= \int_{\mathbf{R_0}} dq_1dq_2[\psi_0(q_1)\psi_2(q_2) + \psi_2(q_1)\psi_0(q_2)]^2, \\ c_2^- &= \int_{\mathbf{R_0}} dq_1dq_2[\psi_0(q_1)\psi_2(q_2) - \psi_2(q_1)\psi_0(q_2)]^2, \\ c_2^{11} &= \int_{\mathbf{R_0}} dq_1dq_2[2\psi_1^2(q_1)\psi_1^2(q_2)],\end{aligned} \tag{25}$$

and the two-photon gain is given by

$$\begin{aligned}\frac{Q_{2,2}}{\Pr(2)} =&c_2^+\mathrm{Tr}\left\{\mathcal{N}_E^{A_1A_2\to B_1B_2}[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\frac{1}{2}(|02\rangle_{B_1B_2} + |20\rangle_{B_1B_2})(\langle 02|_{B_1B_2} + \langle 20|_{B_1B_2})\right\} \\ &+c_2^-\mathrm{Tr}\left\{\mathcal{N}_E^{A_1A_2\to B_1B_2}[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\frac{1}{2}(|02\rangle_{B_1B_2} - |20\rangle_{B_1B_2})(\langle 02|_{B_1B_2} - \langle 20|_{B_1B_2})\right\} \\ &+c_2^{11}\mathrm{Tr}\left\{\mathcal{N}_E^{A_1A_2\to B_1B_2}[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\,|11\rangle_{B_1B_2}\langle 11|\right\}.\end{aligned} \tag{26}$$

- The probability of accepting a vacuum state when employing reverse reconciliation is given by

$$Q_{*,0} = \mathrm{Tr}\left[\hat{P}_0^{B_1B_2}\mathcal{N}_E^{A_1A_2\to B_1B_2}\left(\hat{\rho}^Z\right)\hat{P}_0^{B_1B_2}\right]\int_{\mathbf{R_0}} 2\psi_0^2(q_1)\psi_0^2(q_2)dq_1dq_2, \tag{27}$$

where $\hat{\rho}^Z$ is the Z-basis state sent by the source given in Eq. (8); hence $Q_{*,0}$ is given by the product of the probability of receiving a vacuum-state in the Z-basis rounds and a post-selection-related integration factor. Note that the former value is independent of the post-selection.

IV. PARAMETER ESTIMATION AND PRACTICAL PROTOCOL

We briefly show how to estimate the parameters derived in Sec. III C with a practical setup. In the actual protocol, we do not have photon-number-resolving detectors, with which one can directly measure the above parameters. In addition, the phase-error probabilities and gains are defined by particular Fock-basis states, yet the actual photon source emits coherent states. Nevertheless, we can construct unbiased estimators with the available states and detection settings to evaluate these values. On the detection side, we apply the homodyne tomography technique to evaluate the photon-number observables [34–39]. The homodyne tomography allows unbiased estimation of the expected value of a variety of observables, including the photon-number observables, of measuring an unknown quantum state. On the source side, we extend the decoy-state method [29, 30] to evaluate the statistics defined by the non-classical Fock states with the use of the coherent states at hand. We will give a practical version of the protocol at the end of this section. A fully-detailed discussion is placed in Appendix B on how the specific parameters related to key rate calculation can be practically estimated.

A. Effective photon-number resolving via homodyne tomography

Since the eigenstates of the quadrature observables, $|q(\varphi)\rangle$, form a complete basis on an optical mode, one can reconstruct a general observable on an optical mode with homodyne measurements. In our study, the parameters to be estimated involve photon-number measurements on two modes in the form of $\hat{O}_1\otimes\hat{O}_2 = |n_1\rangle_{B_1}\langle m_1|\otimes|n_2\rangle_{B_2}\langle m_2|$. Their measurements on an arbitrary state, $\hat{\rho}$, can be obtained from two independent homodyne measurements with randomized LO phases,

$$\begin{aligned}\langle\hat{O}_1\otimes\hat{O}_2\rangle &= \mathrm{Tr}[(\hat{O}_1\otimes\hat{O}_2)\hat{\rho}]\\ &:= \int_0^\pi\frac{d\varphi_1}{\pi}\int_{-\infty}^{\infty}dq_1\int_0^\pi\frac{d\varphi_2}{\pi}\int_{-\infty}^{\infty}dq_2\\ &\quad\mathcal{R}[\hat{O}_1](q_1,\varphi_1)\mathcal{R}[\hat{O}_2](q_2,\varphi_2)p(q_1,q_2|\varphi_1,\varphi_2),\end{aligned} \tag{28}$$

where $p(q_1,q_2|\varphi_1,\varphi_2)$ is the joint probability of the quadrature measurements on the two modes conditioned on phases φ_1 and φ_2. The estimators, $\mathcal{R}[\hat{O}_1](q_1,\varphi_1)$ and $\mathcal{R}[\hat{O}_2](q_2,\varphi_2)$, link the quadrature measurement statistics with $\langle\hat{O}_1\otimes\hat{O}_2\rangle$. For a homodyne detector with efficiency η, the estimator for observable $|n\rangle\langle n+d|$ is given by

$$\begin{aligned}\mathcal{R}_\eta[|n\rangle\langle n+d|](q,\varphi) &= e^{id(\varphi+\frac{\pi}{2})}\sqrt{\frac{n!}{(n+d)!}}\\ &\int_{-\infty}^{\infty}dk|k|\exp\left(\frac{1-2\eta}{2\eta}k^2-ikq\right)k^dL_n^d(k^2),\end{aligned} \tag{29}$$

where L_n^d is the generalized Laguerre polynomial. The estimator is shown to be bounded for detector efficiency $\eta > 1/2$ [37, 39], a mild requirement for current technologies [48, 49]. Consequently, repeated measurements allow the users to obtain an unbiased estimation of the photon-number observables that converges in probability. Note that the detector imperfection does not need to be trusted. The homodyne tomography is valid as long as the detector is well-calibrated so that the quadrature measurement is genuine. In Appendix B 1, we shall provide more details of the homodyne tomography techniques.

B. Generalized decoy-state method

To effectively realize the non-classical states on the source side, we extend the standard decoy-state method [29, 30]. We take advantage of two-mode coherent states with simultaneous phase randomization on the two modes. We denote the state with phase difference φ as

$$\begin{aligned}\hat{\rho}_\mu^\varphi &= \int_0^{2\pi}\frac{d\theta}{2\pi}\left|\sqrt{\frac{\mu}{2}}e^{i\theta}\right\rangle\left\langle\sqrt{\frac{\mu}{2}}e^{i\theta}\right|\otimes\left|\sqrt{\frac{\mu}{2}}e^{i(\theta+\varphi)}\right\rangle\left\langle\sqrt{\frac{\mu}{2}}e^{i(\theta+\varphi)}\right|\\ &= \sum_{m=0}^{\infty}\sum_{k=0,l=0}^{m}\frac{e^{-\mu}\left(\frac{\mu}{2}\right)^N e^{i(l-k)\varphi}}{\sqrt{k!l!(m-k)!(m-l)!}}|k,m-k\rangle\langle l,m-l|,\end{aligned} \tag{30}$$

where we specify the light intensity with the subscript, μ. With proper linear combination of these states, we can effectively construct the photon-number-cat states that we are interested in. It is well-known that $(|01\rangle\pm|10\rangle)/\sqrt{2}$ is the single-photon component of $\hat{\rho}_\mu^{0(\pi)}$,

$$\Pr_\mu(1)\left|\Psi_1^{+(-)}\right\rangle\left\langle\Psi_1^{+(-)}\right| = \hat{P}_1\hat{\rho}_\mu^{0(\pi)}\hat{P}_1, \tag{31}$$

where $\Pr_\mu$ represents the Poisson distribution determined by light intensity μ, as given in Eq. (14). Thus, the estimation problem is transformed into the estimation of the single-photon yields of $\hat{\rho}_\mu^0$ and $\hat{\rho}_\mu^\pi$. For the multi-photon components $(|0m\rangle \pm |m0\rangle)/\sqrt{2}$, a direct calculation shows

$$\Pr_\mu(m) \left|\Psi_m^+\right\rangle \left\langle\Psi_m^+\right| = \hat{P}_m \left(\hat{\rho}_\mu^Z + \frac{2^{m-2}}{m} \sum_{k=0}^{m-1} \hat{\rho}_\mu^{\frac{2\pi k}{m}} - \frac{2^{m-2}}{m} \sum_{k=0}^{m-1} \hat{\rho}_\mu^{\frac{2\pi k}{m}+\delta} \right) \hat{P}_m, \tag{32}$$

$$\Pr_\mu(m) \left|\Psi_m^-\right\rangle \left\langle\Psi_m^-\right| = \hat{P}_m \left(\hat{\rho}_\mu^Z - \frac{2^{m-2}}{m} \sum_{k=0}^{m-1} \hat{\rho}_\mu^{\frac{2\pi k}{m}} + \frac{2^{m-2}}{m} \sum_{k=0}^{m-1} \hat{\rho}_\mu^{\frac{2\pi k}{m}+\delta} \right) \hat{P}_m, \tag{33}$$

where $\delta = \pi$ for odd m and $\pi/2$ for even m, and $\hat{\rho}_\mu^Z$ is the state emitted from the source in a key generation round. Consequently, the terms that define $e_{m,m}^X$ and $Q_{m,m}$ can be constructed from the statistics when emitting the states of $\hat{\rho}_\mu^Z$ and $\hat{\rho}_\mu^\varphi$ with $\varphi \in \{2\pi k/m, 2\pi k/m + \delta\}_{k=0}^{m-1}$. Notably, the extended decoy method allows estimating the gains with the number of parameters increasing only linearly in the photon number. In later discussions, we shall utilize up to the two-photon components. Specifically, for $m = 2$,

$$\begin{aligned} \Pr_\mu(2) \left|\Psi_2^\pm\right\rangle \left\langle\Psi_2^\pm\right| = & \hat{P}_2 \Big[\hat{\rho}_\mu^Z \pm \left(\frac{1}{2}\hat{\rho}_\mu^0 + \frac{1}{2}\hat{\rho}_\mu^\pi \right) \\ & \mp \left(\frac{1}{2}\hat{\rho}_\mu^{\frac{\pi}{2}} + \frac{1}{2}\hat{\rho}_\mu^{\frac{3\pi}{2}} \right) \Big] \hat{P}_2. \end{aligned} \tag{34}$$

One may notice in Eq. (34) there are states outside the encoding subspace $|02\rangle$ and $|20\rangle$ being introduced, which gives Eve possibility to distinguish the X-basis states. In fact, the X basis is comprised of the mixture of $(|02\rangle \pm |20\rangle)/\sqrt{2}$ and $|11\rangle$. As a result, it is not possible for Eve to distinguish between the Z-basis states and the $(|02\rangle \pm |20\rangle)/\sqrt{2}$ states of the X basis. It is possible for Eve to distinguish the $|11\rangle$ state, yet it does not yield knowledge on the encoded key information since it is orthogonal to the $|02\rangle$ and $|20\rangle$ space. Hence, the standard decoy argument still applies even if the parameter-estimation space consists of a direct sum of the key-encoding space and some orthogonal spaces.

C. General parameter estimation under the coherent attack

In this section, we discuss the security analysis and parameter estimation in the most general case. In the most general adversarial scenario, namely the coherent attack, Eve can apply a joint quantum operation over the rounds for eavesdropping, which may correlate or even entangle the states transmitted to Bob. Eve collects all the side information leaked to her in the protocol and then guesses the legitimate users' keys. Under such an attack, the measurement statistics obtained by Bob are generally correlated over the rounds [41].

The complementarity-based security analysis remains valid with finite statistics under a coherent attack [22]. The information leakage is quantified via the number of phase errors, while the occurrence of a phase error in each round may be non-i.i.d. That is, one should interpret the gains and phase-error rates in Eq. (12) as frequencies in non-i.i.d. statistics. For instance, $Q_{1,1}$ should be regarded as the frequency of the events that Alice sends a single-photon state, and Bob accepts a single-photon state among key generation rounds in the virtual experiment. The remaining problem is to estimate these parameters via observed statistics.

To tackle the non-i.i.d. parameter estimation problem, we can apply a martingale-based analysis. We shall present the details in Appendix C. Here, we explain its basic idea. As the starting point, in the i'th round, the users can evaluate the probability of choosing some experimental setting and observing a particular event conditioned on the experimental history, including the events of sending an m-photon state and accepting an n-photon state and the occurrence of a phase error if they choose the key generation setting, and observing a particular homodyne detection result if they choose to perform the parameter estimation operations. The events' correlations with the experimental history are inherently taken into account in the definitions of conditional probabilities. We can set up martingales for a series of events, such as the occurrence of phase errors in each round of the virtual protocol, and link their frequencies with the associated conditional probabilities via concentration results like Azuma's inequality [50]. Note that such concentration results work for general non-i.i.d. correlations. Furthermore, the setting choices randomly chosen by Alice and Bob are independent of the experimental history and unknown to Eve. Therefore, conditioned on the experimental history, the probabilities of different possible events in a round are linked. For instance, the probability that the users take key generation measurements and a phase error occurs in a round is measurable via the probability that they instead take parameter estimation measurements and observe certain statistics. The relation is in the form of Eq. (20), while now the probabilities are interpreted as conditional ones that cover the correlations. The relations between conditional probabilities then link the martingales for the parameter estimation measurement with the ones for the gains and phase-error rates, completing the parameter estimation. In the end, the total number of keys that can be securely distilled from finite statistics under the coherent attack is given by a formula of the following form:

Theorem 2 (Informal)**.** *For the CV QKD protocol with N_μ^{zz} rounds for key generation, given the failure probability in parameter estimation ε_{pe}, suppose the gains have lower bounds $Q_{*,0}^L$ and $Q_{m,m}^L$, and the phase-error rates have upper bounds $e_{m,m}^{X(U)}$. Then, given the failure probability in privacy amplification ε_{pa}, conditioned on the success of information reconciliation, except a total failure probability $\varepsilon = \varepsilon_{\text{pe}} + \varepsilon_{\text{pa}}$, the finite-size key rate r is lower bounded by:*

$$\begin{aligned} r \geq & Q_{*,0}^L + \sum_{m=1}^{\infty} \left(Q_{m,m}^L \left\{ 1 - h[e_{m,m}^{X(U)}] \right\} \right) \\ & - fQ^Z h(e^Z) - \frac{1}{N_\mu^{zz}} \log \frac{1}{\varepsilon_{\text{pa}}}, \end{aligned} \tag{35}$$

where f is the information reconciliation efficiency, Q^Z is the Z-basis gain, and e^Z is the bit error rate.

The term $\log \varepsilon_{\text{pa}}$ in the key-rate formula originates from the failure probability in privacy amplification [22, 51]. The parameter estimation failure probability ε_{pe} comes from the use of martingale-based concentration results. In the asymptotic limit of infinite data size, ε_{pe} converges to zero, and the effect of ε_{pa} on the key rate becomes negligible; hence the key rate formula degenerates to that in Eq. (12). In Appendix C, we provide the details of non-i.i.d. parameter estimation and the formal description of the key-rate formula.

D. Practical protocol

Combining the above ingredients, we provide a practical protocol that utilizes up to the two-photon components in Table III. In parameter estimation, Bob applies homodyne tomography to estimate the statistics of measuring photon-number observables, including $|00\rangle$, $(|01\rangle \pm |10\rangle)/\sqrt{2}$, $(|02\rangle \pm |20\rangle)/\sqrt{2}$, and $|11\rangle$, on various states transmitted from the source, originally $\hat{\rho}_{\mu_a}^Z$ and $\hat{\rho}_\mu^{\varphi_a}$. Afterward, the users can obtain upper and lower bounds on the gains and phase-error rates by applying the extended decoy-state method. We provide the detailed parameter estimation procedures in Appendix B and discuss dealing with general non-i.i.d. statistics under a coherent attack in Appendix C.

In the end, we make some remarks on the protocol. Notice that in contrast to the conventional BB84-type protocols, our protocol also uses for parameter estimation the signals where Alice chooses Z basis and Bob chooses X basis. Alice's announcement of the relative phase does not reveal key information since the key is encoded in the relative intensity between the two modes. We assume Alice and Bob apply continuous phase randomization, although it is only practical to use discrete random phases. The effect of the discretization requires further investigation. In addition, in the X basis, Alice only transmits coherent states with relative phases in $\{0, \pi/2, \pi, 3\pi/2\}$. These relative phases are enough to estimate the phase-error rate of an up-to-two-photon protocol according to Eq. (34).

V. PERFORMANCES AND COMPARISON

We demonstrate in this section the asymptotic key rate-distance performances of the time-bin CV QKD protocol. We consider a thermal noise channel with a unit-efficiency homodyne detector. An inefficient detector with thermal electronic noise can be equated to a fiber section with transmittance equal to the detector efficiency, and the electronic noise absorbed into the channel excess noise (Eq. (D2)). The fiber attenuation is 0.2 dB/km, and the error-correction efficiency f is taken to be 1. The simulation formulae can be found in Appendix D. According to the key rate formula Eq. (12), the rounds where Alice sends m photons and Bob receives m photons can assure to generate secure keys. We plot in Fig. 3a the asymptotic key rate of the i-photon protocol assuming perfect decoy estimation and no excess noise, where in an i-photon protocol we only extract secure keys from a maximal i-photon components. In this ideal case, the phase error rates of all the protocols are zero. The optimized source intensities μ and the post-selection thresholds τ are listed in Table IV, as well as the resulted Z-basis error rate. Notice that the two-photon-protocol key rate derived from our DV method is similar to that from Ref. [24] using CV method, both reversely reconciled. This implies the connection between DV and CV security analysis, as well as the validity of the DV reverse reconciliation idea in Section III B. To facilitate the discussion, we also plot in Fig. 3b the contribution of each photon components to the key rate at different distances. In each group of bars, the relative contribution of the vacuum, one, two, three, four-photon components are plotted respectively, where the m-photon contribution of the i-photon protocol is defined to be $Q_{m,m}/(Q_{*,0} + \sum_{m=1}^{i} Q_{m,m})$ and the vacuum contribution is $Q_{*,0}/(Q_{*,0} + \sum_{m=1}^{i} Q_{m,m})$, i.e., the relative contribution to the raw key rate.

It can be seen that the key rate improves as we make use of the multi-photon components. The improvement is most remarkable between the one and two-photon protocols. This is reasonable since in the one-photon protocol, the multi-photon components are considered insecure, thus limiting the source intensity. The low source

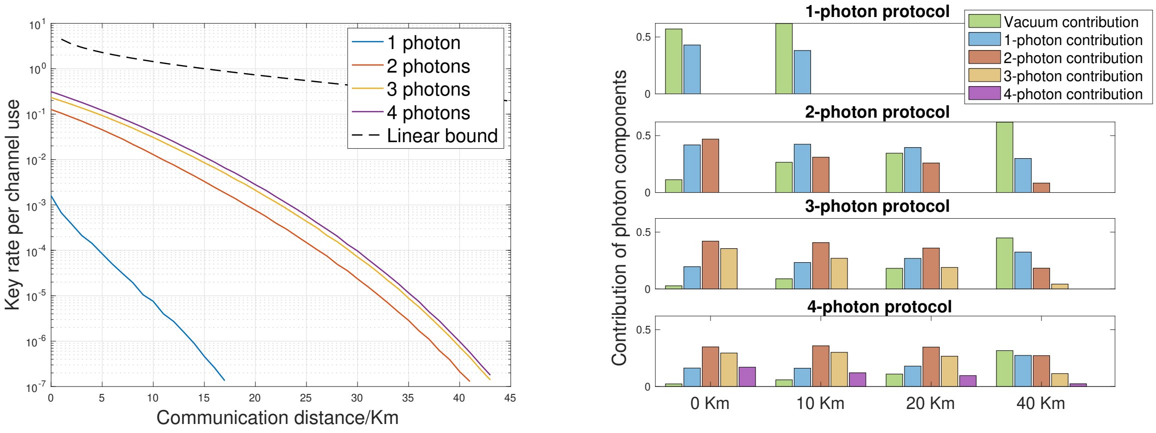
TABLE III: Practical time-bin CV QKD with decoy states using up to two photons

1. On Alice's side (source):
   - *Z-basis*:
     (a) Randomly select a key bit $k_a \in \{0, 1\}$, a phase factor $\varphi_a \in [0, 2\pi)$, and a light intensity $\mu_a \in \{\mu, \nu_1, \nu_2, 0\}$.
     (b) Prepare a coherent state of $|0\rangle_{A1} |\sqrt{\mu_a} e^{i\varphi_a}\rangle_{A2}$ for $k_a = 0$ or $|\sqrt{\mu_a} e^{i\varphi_a}\rangle_{A1} |0\rangle_{A2}$ for $k_a = 1$.
   - *X-basis*:
     (a) Randomly select a phase factor $\varphi_a^1 \in [0, 2\pi)$ and another phase factor with relative phase φ_a randomly in $\varphi_a^2 - \varphi_a^1 \in \{0, \pi/2, \pi, 3\pi/2\}$. Randomly select a light intensity $\mu_a \in \{\mu, \nu_1, \nu_2, 0\}$.
     (b) Prepare a coherent state of $|\sqrt{\mu_a/2} e^{i\varphi_a^1}\rangle |\sqrt{\mu_a/2} e^{i\varphi_a^2}\rangle$.
2. Alice sends the state through an authenticated channel to Bob.
3. On Bob's side (detection):
   - *Z-basis*:
     (a) Randomly select a phase factor $\varphi_b \in [0, 2\pi)$.
     (b) Use homodyne detectors with LO phases φ_b to measure the modes and obtain quadratures q_1 and q_2.
     (c) Decode the key bit as 0 if $|q_1| < \tau \wedge |q_2| > \tau$, 1 if $|q_1| > \tau \wedge |q_2| < \tau$, and $\emptyset$ otherwise.
   - *X-basis*:
     (a) Randomly select two phases $\varphi_b^1, \varphi_b^2 \in [0, \pi)$.
     (b) Use homodyne detectors with LO phases φ_b^1 and φ_b^2 to measure the modes and obtain quadratures q_1 and q_2.
4. Alice announces the light intensity in each round and relative phase between the two modes in X-basis states $\varphi_a = \varphi_a^2 - \varphi_a^1$.
5. Alice and Bob perform basis sifting, where they obtain raw keys in the rounds they both choose Z-basis with light intensity $\mu_a = \mu$ and $k_b \neq \emptyset$.
6. Bob estimates the gains and phase-error rates from the statistics in the rounds where Alice sends the Z-basis states $\hat{\rho}_{\mu_a}^Z$ or X-basis states $\hat{\rho}_{\mu_a}^{\varphi_a}$ with $\varphi_a \in \{0, \pi/2, \pi, 3\pi/2\}$.
7. Alice and Bob perform reverse information reconciliation and privacy amplification to obtain final keys.

intensity would result in severe bit error rate and higher post-selection thresholds, which in turn suppress the key rate. Whilst in the two-photon protocol where the two-photon components are considered secure, the limit on the source intensity can be lifted, and the bit error rate would drop, resulting in higher key rates. This is manifested in Fig. 3b, where the single-photon protocol sees significant vacuum contribution, whilst the two-photon protocol, at short distances, does not. Since the vacuum component would yield 50% bit error rate, we see the lower bit error rate of the two-photon protocol than the single-photon protocol as in Table IV.

When we further make use of the three-photon components, the key rate as well as the source intensity still increase, yet less obviously. This is mainly because the fraction of the rounds where three photons are sent and three photons are received, decaying cubically with the channel transmittance, are not dominating, especially at longer distances. For example, we see in Fig. 3b that at 20 km, the contribution of the three-photon component is less than that of the single and two-photon components, and at 40 km the three-photon component rarely has contribution to the key rate. This trend is justified further in the four-photon protocol, where in Fig. 3b we see the four-photon-component contribution is quite small for longer distances, and in turn the key rate of the four-photon protocol only improves marginally than that of the three-photon protocol. Simulation shows that resorting to higher-than-four photon-number components has negligible increase to the key rate. Hence, If we consider the protocol with infinite photon-number components, the 0-km key rate is around 0.31 bit/channel, and the BB84 protocol with currently the best single-photon detector of 80% efficiency [54, 55] has 0-km key rate 0.29 bit/channel, based on the model from Ref. [45]. Our key rate thus matches the best BB84 key rate with practically favorable devices.

The practical performances of the two-photon time-bin CV QKD protocol are illustrated in Fig. 4. For a reasonable range of excess noise ξ from 10^{-3} to 10^{-2} with respect to channel output, the key rate decays mildly as shown in Fig. 4a. Notice that the key rate is almost unaffected at 0 km since no noise photon is introduced to give phase error, and the bit error is almost unchanged



(a)

(b)

FIG. 3: **(a)** The solid lines illustrate the asymptotic key rates of protocols using maximal one, two, three and four photons to generate keys. The dotted line is the linear key rate bound [52, 53]. We plot the PLOB bound here. The channel and devices are assumed to be ideal with no excess noise and inefficiency. **(b)** The relative contribution of $Q_{m,m}$, i.e. the gain of the rounds where m photons are sent and m photons are received. The m-photon contribution of the i-photon protocol is relative to the raw key rate. Each group of bars illustrate the contribution of vacuum, one, two, three and four-photon components of the protocol at a certain distance.

TABLE IV: The optimized intensities and post-selection thresholds of protocols using one to four photons respectively at different distances. μ_i, τ_i and e_Z^i denote the optimized intensity, post-selection threshold and the Z-basis error rate of the i-photon protocol. These parameters generate the four key rate plots in Fig. 3a, assuming infinite decoy levels.

	μ_1	μ_2	μ_3	μ_4	τ_1	τ_2	τ_3	τ_4	e_Z^1	e_Z^2	e_Z^3	e_Z^4
0 km	0.356	1.487	2.395	2.395	1.437	1.641	1.845	1.845	30.95%	10.52%	5.31%	5.31%
10 km	0.137	0.924	1.887	2.395	3.476	2.253	2.457	2.457	29.80%	14.84%	5.66%	4.17%
20 km	—	0.728	1.487	1.887	—	3.068	3.068	3.272	—	15.48%	6.91%	3.85%
40 km	—	0.356	0.728	1.172	—	4.495	4.495	4.699	—	28.52%	17.07%	8.81%

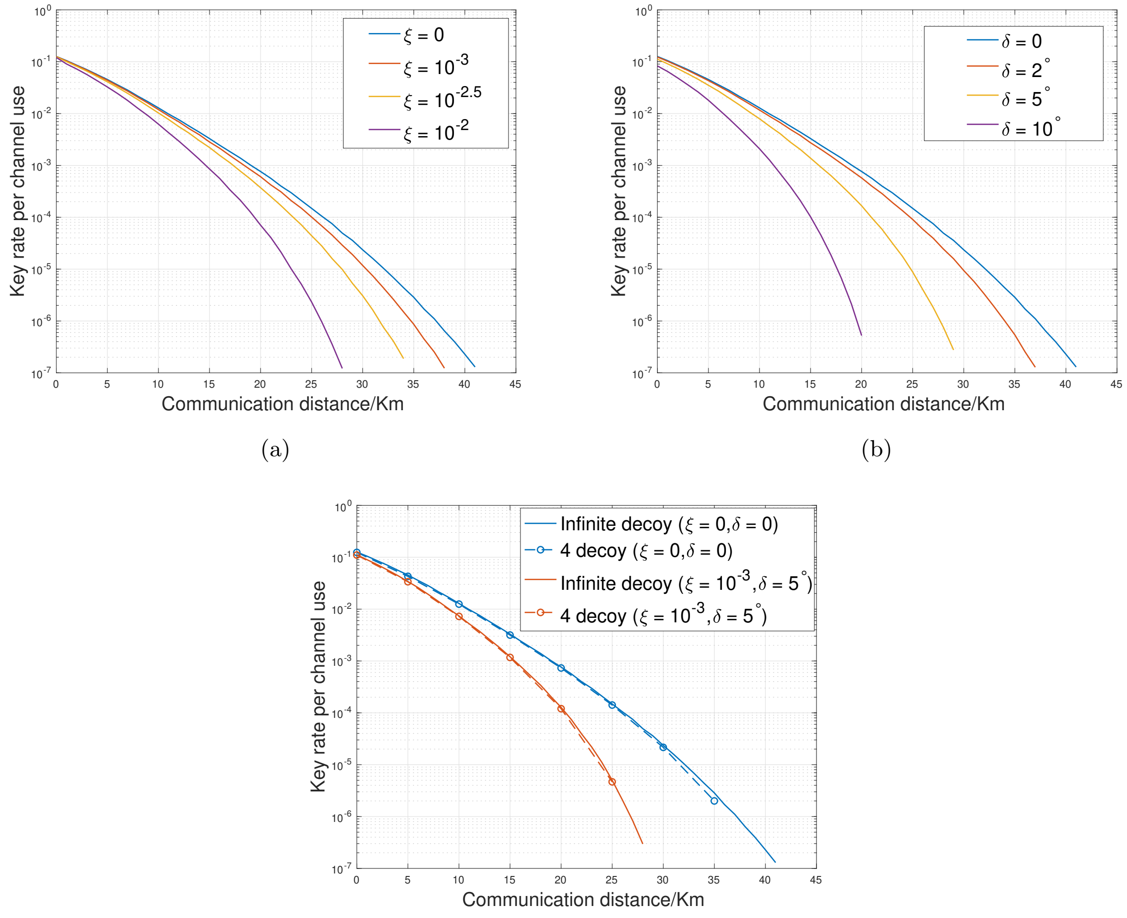
for a negligible increase in the shot-noise variance. This demonstrates the robustness of the phase-error analysis to the excess noise.

Fig. 4b illustrates the key rate against the mode reference misalignment, where the two optical modes generating the time-bin qubit differ by δ in the reference phases intrinsically. The misalignment in relative phases does not affect the Z basis as we encode the key bits into the relative intensities, and it only affects the X basis where the phase error is defined as the flips in relative phases. Our protocol thus has robustness against misalignment.

Fig. 4c illustrates the key rates of the decoy-state protocol in Sec. IV B. We set one decoy level at vacuum, and heuristically optimize the two decoy intensities ν_1 and ν_2 and the signal intensity μ. The decoy estimations are done by linear programming with a cutoff photon number 10 [56, 57]. A detailed treatment of the decoy estimation of the two-photon protocol is placed in Appendix B. We see for both the noiseless setup, with no excess noise and misalignment, and the practical setup, with 10^{-3} excess noise and 5° misalignment, the 4-level decoy estimation is almost exact. This clearly surpassed the practical performance of the protocol in Ref. [24], since our protocol uses simpler estimation of the phase error by identifying the principal components in key generation. The optimized parameters of the practical setup are listed in Table V.

VI. REFINED KEY MAPPING SCHEME

In the time-bin-encoded CV QKD protocol in Table I, we consider a simple key mapping strategy with a threshold value τ illustrated in Fig. 5a. It can be seen that the security analysis in Sec. III does not rely on the specific shapes of the key mapping regions $\mathbf{R_0}$ and $\mathbf{R_1}$, as long as they differ by a swap of the two optical modes. As a result, we can optimize $\mathbf{R_0}$ and $\mathbf{R_1}$ for a higher key-rate



(a)

(b)

(c)

FIG. 4: Practical performances of the two-photon protocol. **(a)** Key rate against excess noise with respect to channel output, assuming infinite decoy levels. **(b)** Key rate against misalignment, i.e. the phase-reference difference between the two optical modes generating the time-bin qubit, assuming infinite decoy levels. **(c)** Key rate derived using decoy methods. The noiseless setup (blue curves) uses fixed decoy levels at 1.2×10^{-4}, 1×10^{-4} and vacuum, and the optimized protocol parameters of the practical setup (red curves) are listed in Table V.

TABLE V: Optimal protocol parameters in generating the key rate plot with 10^{-3} excess noise and 5° misalignment, using 4 decoy levels, as in Fig. 4c. The heuristically optimized signal intensity, post-selection threshold and the decoy intensities are as given. There is one more decoy intensity set to be vacuum. The decoy estimation is done by linear programming with cutoff photon number 10.

Distance (km)	Signal intensity μ	Threshold τ	Decoy intensity ν_1	Decoy intensity ν_2
0	1.487	1.641	1.737×10^{-1}	1.000×10^{-4}
5	1.172	2.049	3.406×10^{-3}	2.740×10^{-4}
10	0.924	2.457	2.993×10^{-2}	1.000×10^{-4}
15	0.924	3.068	1.861×10^{-2}	1.000×10^{-4}
20	0.728	3.476	1.355×10^{-2}	2.441×10^{-4}
25	0.728	4.291	1.355×10^{-2}	1.562×10^{-4}

performance indicated by r in Eq. (12).

To get a higher key rate r, we want to avoid the post-selection of the detected signal region (q_1, q_2) as long as the bit error rate e^Z can be ensured low. To this end, we introduce a maximum-likelihood-based key mapping and analyze its performance. Corresponding to bit 0 or 1, Bob would receive coherent states $|0\rangle\,|\alpha e^{i\varphi_a}\rangle$ or $|\alpha e^{i\varphi_a}\rangle\,|0\rangle$ for some randomized phase φ_a and α after attenuation in a pure-loss channel. Corresponding to bit value 0 and 1, the probability distributions f_0 and f_1 of the homodyne measurement results (q_1, q_2) are given by

$$f_0(q_1,q_2) = \int_0^{2\pi} \frac{d\varphi}{4\pi^2} \exp\frac{\left[-q_1^2 - (q_2 - 2|\alpha|\cos\varphi)^2\right]}{2}, \tag{36}$$

$$f_1(q_1,q_2) = \int_0^{2\pi} \frac{d\varphi}{4\pi^2} \exp\frac{\left[-q_2^2 - (q_1 - 2|\alpha|\cos\varphi)^2\right]}{2}, \tag{37}$$

where φ is the difference between the source and detector phase randomization.

Upon detecting a specific pair of quadratures (q_1, q_2), the maximum-likelihood key mapping scheme requires to decode bit 0 if $f_0(q_1,q_2) > f_1(q_1,q_2)$ and bit 1 if $f_1(q_1,q_2) > f_0(q_1,q_2)$. According to Eq. (36) and (37), the maximum-likelihood key mapping is equivalent to the decoding of bit 0 if $q_1^2 < q_2^2$ and bit 1 if $q_1^2 > q_2^2$. This refined key mapping takes in detection results such as point A in Fig. 5a where q_1^2 is significantly different from q_2^2, thus reducing the post-selection loss of the gain. However, in the region where q_1^2 and q_2^2 are comparable, the key mapping error will be large, making a large contribution to the final bit error rate e^Z. Conditioned on the detection outcome (q_1, q_2), the key mapping error $e_0^Z(q_1,q_2)$ in $\mathbf{R_0}$ is related to the likelihood function by

$$e_0^Z(q_1,q_2) = \Pr((q_1,q_2) \in \mathbf{R_0} | k_a = 1) = \frac{f_1(q_1,q_2)}{Q(q_1,q_2)}, \tag{38}$$

with the key mapping gain $Q(q_1,q_2) = f_0(q_1,q_2) + f_1(q_1,q_2)$. We can similarly define $e_1^Z(q_1,q_2)$ for the $\mathbf{R_1}$ region. The final bit error rate e^Z is

$$\begin{aligned} e^Z = &\frac{1}{2}\int_{\mathbf{R_0}} dq_1 dq_2\, e_0^Z(q_1,q_2)\, Q(q_1,q_2) \\ &+ \frac{1}{2}\int_{\mathbf{R_1}} dq_1 dq_2\, e_1^Z(q_1,q_2)\, Q(q_1,q_2). \end{aligned} \tag{39}$$

For example, at point B in Fig. 5a, the key mapping error is 50%. To discard the erroneous results, we can set a threshold $t > 1$ and require to decode bit 0 if $f_0(q_1,q_2) > tf_1(q_1,q_2)$ and bit 1 if $f_1(q_1,q_2) > tf_0(q_1,q_2)$. The region in between will be discarded. Fig. 5b below illustrates the numerically plotted key mapping regions given the light amplitude $\alpha = 1$ at $t = 10$, where the grey region is discarded. It can be seen that the key mapping regions are nearly isosceles right triangles with non-zero intercepts $\pm\tau$ with the quadrature axes. We thus present the approximately maximum-likelihood key mapping scheme as the following:

$$k_b = \begin{cases} 0 & \text{if } (q_2 - \tau > \pm q_1) \vee (q_2 + \tau < \pm q_1), \\ 1 & \text{if } (q_1 - \tau > \pm q_2) \vee (q_1 + \tau < \pm q_2), \\ \emptyset & \text{otherwise.} \end{cases} \tag{40}$$

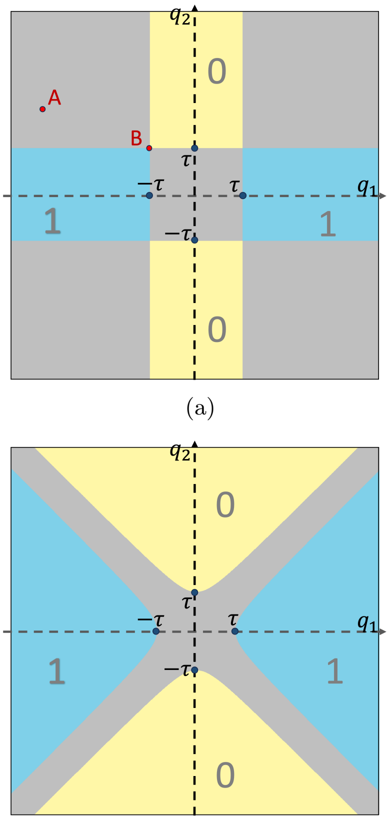
As in Sec. V, we regard the intercept τ as a protocol parameter. We optimize it and the source intensity μ for each distance to yield the optimal key rate. However, numerical optimization shows that this refined key mapping would only improve the key-rate performances marginally. It increases the key rate at 0 km of the ideal 2-photon protocol from 0.1261 bit/channel to 0.1314 bit/channel and that of the ideal 4-photon protocol from 0.3131 bit/channel to 0.3242 bit/channel, with almost no increase to the maximal transmission distance. This is due to the low gain of the newly-accepted region such as point A in Fig. 5a. Considering the experimental cost as well, we thus suggest that using the simple threshold key mapping as in Sec. II is good enough in practice.

VII. CONCLUSION AND OUTLOOK

In summary, we present the time-bin-encoding CV QKD protocol with a phase-error-based security analysis. Similar to the ideas in DV protocols [31] and other CV protocols [5], we introduce a squashing channel to “squash” the original privacy-estimation problem on two optical modes to a single qubit, enabling the definition of phase-error rate. The phase randomization on both the source and detector enables the introduction of the photon-number-tagging method, identifying the central components for key generation. Combined with the decoy-state estimation, the parameter estimation is made simple and efficient. We expect our methods of constructing squashing models and applying phase randomization can be applied to many other CV protocols.

One of our major observations is that coherent detectors can be used to estimate the privacy of multi-photon signals. This is also pointed out in Ref. [24]. Such detectors may also be helpful to the DV protocols. In fact, we may consider a hybrid protocol: single-photon detectors for key generation and homodyne detectors for parameter estimation. The multi-photon components in this protocol can contribute to key generation compared with the single-photon BB84 protocol.

We provide a general framework for the finite-size analysis of this CV protocol based on martingale theory. The photon-number tagging method greatly simplifies the finite-size analysis. A direct follow-up of this work is to complete the finite-size analysis, encompassing the effects on the distillable key rate, the decoy-method accuracy, and the deviation of the homodyne tomography. In the literature, variants of Azuma’s inequality have been applied for faster convergence of parameter estimation in



(a)

(b)

FIG. 5: The simple and the maximum-likelihood-based key mapping. The two axes represent the two homodyne measurement results (q_1, q_2). The yellow region is decoded as 0 and the blue decoded as 1. The grey region is discarded. **(a)** The simple key mapping scheme used throughout this paper, being rectangular. Point A has key mapping error 0.02% and point B 50%, yet point A is discarded whilst B is accepted. **(b)** The maximum-likelihood key mapping scheme, being approximately triangular. The post-selection is done for coherent light amplitude $\alpha = 1$, where only the region with likelihood ratio greater than 10 is kept in this showcase. In this refined key mapping, point A is accepted and point B is discarded.

quantum key distribution [58, 59], such as Kato's inequality [60]. One can bring such techniques to the protocol in this work for better practicality.

It is tempting to further enhance the key rate and the maximal distance of this protocol. We may consider the high-dimensional time-bin encoding, which is relatively easy to implement experimentally [61–63]. The high-dimensional complementarity security analysis [64] can be invoked, and the squashing channel should map the optical modes to a qudit. We can also apply the trusted-noise model to alleviate the effect of the detector noise [65, 66]. The model requires the modification of the detector POVM, which is still block-diagonal on the Fock basis [24]. One may also consider using squeezed states as the light source to reduce the shot noise in one quadrature and use the other only for parameter estimation. This may tackle the large bit error rate due to the shot noise, the issue that renders the 0-km performance of our protocol not as good as the usual CV QKD scheme. We can also examine the variations of our protocol based on the combination with new DV QKD schemes such as the measurement-device-independent-type schemes [67, 68] and their extensions, including the twin-field-type [69–71] and the mode-pairing schemes [72, 73].

Appendix A: Phase-error calculation details

We give the detailed derivation of the phase-error probability expressions Eq. (21) to (27) for the zero, one and two-photon components. According to Eq. (20), the calculation involves in expanding the X-basis measurement operator $M_\pm$ based on Eq. (9). For the single-photon subspace, we have

$$\begin{aligned}\hat{P}_1\left(\int_0^{2\pi}\frac{d\varphi}{2\pi}\left|q_1(\varphi)\right\rangle\left\langle q_1(\varphi)\right|\otimes\left|q_2(\varphi)\right\rangle\left\langle q_2(\varphi)\right|\right)\hat{P}_1 &= \psi_0^2(q_1)\psi_1^2(q_2)\left|01\right\rangle\left\langle 01\right| + \psi_1^2(q_1)\psi_0^2(q_2)\left|10\right\rangle\left\langle 10\right| + \\ &\psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|01\right\rangle\left\langle 10\right| + \psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|10\right\rangle\left\langle 01\right|\end{aligned} \tag{A1}$$

$$\begin{aligned}\hat{P}_1\left(\int_0^{2\pi}\frac{d\varphi}{2\pi}\left|q_2(\varphi)\right\rangle\left\langle q_2(\varphi)\right|\otimes\left|q_1(\varphi)\right\rangle\left\langle q_1(\varphi)\right|\right)\hat{P}_1 &= \psi_1^2(q_1)\psi_0^2(q_2)\left|01\right\rangle\left\langle 01\right| + \psi_0^2(q_1)\psi_1^2(q_2)\left|10\right\rangle\left\langle 10\right| + \\ &\psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|01\right\rangle\left\langle 10\right| + \psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|10\right\rangle\left\langle 01\right|\end{aligned} \tag{A2}$$

$$\begin{aligned}\hat{P}_1\left(\int_0^{2\pi}\frac{d\varphi}{2\pi}\left|q_1(\varphi)\right\rangle\left\langle q_2(\varphi)\right|\otimes\left|q_2(\varphi)\right\rangle\left\langle q_1(\varphi)\right|\right)\hat{P}_1 &= \psi_0^2(q_1)\psi_1^2(q_2)\left|01\right\rangle\left\langle 10\right| + \psi_1^2(q_1)\psi_0^2(q_2)\left|10\right\rangle\left\langle 01\right| + \\ &\psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|01\right\rangle\left\langle 01\right| + \psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|10\right\rangle\left\langle 10\right|\end{aligned} \tag{A3}$$

$$\begin{aligned}\hat{P}_1\left(\int_0^{2\pi}\frac{d\varphi}{2\pi}\left|q_1(\varphi)\right\rangle\left\langle q_2(\varphi)\right|\otimes\left|q_2(\varphi)\right\rangle\left\langle q_1(\varphi)\right|\right)\hat{P}_1 &= \psi_1^2(q_1)\psi_0^2(q_2)\left|01\right\rangle\left\langle 10\right| + \psi_0^2(q_1)\psi_1^2(q_2)\left|10\right\rangle\left\langle 01\right| + \\ &\psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|01\right\rangle\left\langle 01\right| + \psi_0(q_1)\psi_0(q_2)\psi_1(q_1)\psi_1(q_2)\left|10\right\rangle\left\langle 10\right|\end{aligned} \tag{A4}$$

Hence the single-photon phase-error operator is given by

$$\begin{aligned}\hat{P}_1\hat{M}_\pm\hat{P}_1 &= \int_{\mathbf{R_0}} dq_1dq_2[\psi_0(q_1)\psi_1(q_2)\pm\psi_0(q_2)\psi_1(q_1)]^2 \quad \frac{1}{2}(\left|01\right\rangle\pm\left|10\right\rangle)(\left\langle 01\right|\pm\left\langle 10\right|) \\ &= \int_{\mathbf{R_0}} dq_1dq_2[\psi_0^2(q_1)\psi_1^2(q_2)+\psi_1^2(q_1)\psi_0^2(q_2)] \quad \frac{1}{2}(\left|01\right\rangle\pm\left|10\right\rangle)(\left\langle 01\right|\pm\left\langle 10\right|),\end{aligned} \tag{A5}$$

Note that the second equality is deduced as the cross terms are odd functions with respect to q_1 and q_2, and the key-mapping region is symmetrical. This gives Eq. (21). The gain $Q_{1,1}$ involves in measuring $\hat{P}_1(\hat{M}_+ + \hat{M}_-)\hat{P}_1$ which is clearly in the form of Eq. (23).

The two-photon case involves in more terms, but we can make use of the symmetry of the key mapping region $\mathbf{R_0}$ to eliminate the odd terms. The calculation goes by:

$$\begin{aligned}\hat{P}_2\left(\int_0^{2\pi}\frac{d\varphi}{2\pi}\left|q_1(\varphi)\right\rangle\left\langle q_1(\varphi)\right|\otimes\left|q_2(\varphi)\right\rangle\left\langle q_2(\varphi)\right|\right)\hat{P}_2 &= \psi_0^2(q_1)\psi_2^2(q_2)\left|02\right\rangle\left\langle 02\right| + \psi_0(q_1)\psi_0(q_2)\psi_2(q_1)\psi_2(q_2)\left|02\right\rangle\left\langle 20\right| \\ + \psi_0(q_1)\psi_0(q_2)\psi_2(q_1)\psi_2(q_2)\left|20\right\rangle\left\langle 02\right| &+ \psi_0^2(q_2)\psi_2^2(q_1)\left|20\right\rangle\left\langle 20\right| + \psi_1^2(q_1)\psi_1^2(q_2)\left|11\right\rangle\left\langle 11\right| + \text{ odd terms}\end{aligned} \tag{A6}$$

The X-basis measurement is thus given by:

$$\begin{aligned}\hat{P}_2\hat{M}_+\hat{P}_2 &= \int_{\mathbf{R_0}} dq_1dq_2[\psi_0(q_1)\psi_2(q_2)+\psi_2(q_1)\psi_0(q_2)]^2 \quad \frac{1}{2}(\left|02\right\rangle+\left|20\right\rangle)(\left\langle 02\right|+\left\langle 20\right|) \\ &+ \int_{\mathbf{R_0}} dq_1dq_2 2\psi_1^2(q_1)\psi_1^2(q_2)\left|11\right\rangle\left\langle 11\right|\end{aligned} \tag{A7}$$

$$\hat{P}_2\hat{M}_-\hat{P}_2 = \int_{\mathbf{R_0}} dq_1dq_2[\psi_0(q_1)\psi_2(q_2)-\psi_2(q_1)\psi_0(q_2)]^2 \quad \frac{1}{2}(\left|02\right\rangle-\left|20\right\rangle)(\left\langle 02\right|-\left\langle 20\right|) \tag{A8}$$

This recovers Eq. (24), and adding the two equations together gives the expression for the gain $Q_{2,2}$ as in Eq. (26). Expanding the vacuum subspace according to Eq. (9) gives the coefficients as in Eq. (27).

Appendix B: Parameter estimation

In this section, we show how to estimate the quantities in the key-rate formula with realistic devices. We first state parameter estimation in terms of probabilities in a single round, and one can interpret the results as obtained from sufficiently many rounds under a collective attack. In the next section, we will generalize the results to the finite-size regime under a coherent attack. For convenience, we first review the terms to be estimated in the virtual protocol that utilizes up to the two-photon component, as given in Sec. III C. As a reminder, note that we distinguish the terms "receiving" and "accepting."

1. $Q_{*,0}$: The probability of accepting a vacuum state, given by Eq. (27).
2. $Q_{1,1}$: The probability of sending $|\Psi_1\rangle_{A'A_1A_2}$ and accepting a single-photon state, given by Eq. (23).
3. $Q_{2,2}$: The probability of sending $|\Psi_2\rangle_{A'A_1A_2}$ and accepting a two-photon state, given by Eq. (26).
4. $e^X_{1,1}$: the phase-error probability when sending a single-photon state and accepting a single-photon state, determined by the probabilities of sending $(|01\rangle \pm |10\rangle)/\sqrt{2}$ and accepting $(|01\rangle \mp |10\rangle)/\sqrt{2}$, given by Eq. (21).
5. $e^X_{2,2}$: the phase-error probability when sending a two-photon state and accepting a two-photon state, determined by the probabilities of sending $(|02\rangle \pm |20\rangle)/\sqrt{2}$ and accepting $(|02\rangle \mp |20\rangle)/\sqrt{2}$ and sending $(|02\rangle - |20\rangle)/\sqrt{2}$ and accepting $|11\rangle$, given by Eq. (24).

1. Homodyne tomography

The first issue we need to tackle is the estimation of photon-number statistics. Due to the lack of photon-number-resolving detectors, these operators are not directly measurable. Nevertheless, we can apply homodyne tomography and obtain unbiased estimation [34–39]. For a systematic review, we recommend the tutorial textbook of Ref. [32].

We start with a single-mode system. Consider the displacement operators given by

$$\begin{aligned}\hat{D}(\alpha) =& \exp(\alpha\hat{a}^\dagger - \alpha^*\hat{a})\\ =& \exp\left[(-ik)\left(\hat{a}^\dagger e^{i\varphi} + \hat{a}e^{-i\varphi}\right)\right]\\ :=& \exp(-ik\hat{Q}_\varphi),\end{aligned} \tag{B1}$$

where $\hat{a}$ and $\hat{a}^\dagger$ are the annihilation and creation operators of the mode, respectively, α is a complex scalar, and α^* denotes the complex conjugate of α. In the second equation, we use the polar variables to represent α, $\alpha = -ike^{i\varphi}$. We call $\hat{Q}_\varphi$ the quadrature operator. Measuring $\hat{Q}_\varphi$ corresponds to the homodyne measurement, where the phase of the LO is φ. By definition, $\hat{D}(\alpha)$ is a Hermitian operator. The set of all displacement operators forms an orthogonal and complete function basis on a mode; hence any linear operator on a mode, $\hat{O}$, can be expanded with displacement operators,

$$\hat{O} = \int_0^\pi \frac{d\varphi}{\pi}\int_{-\infty}^\infty \frac{dk|k|}{4}\mathrm{Tr}(\hat{O}e^{ik\hat{Q}_\varphi})e^{-ik\hat{Q}_\varphi}. \tag{B2}$$

When measuring $\hat{O}$ on a state, $\hat{\rho}$, the expected value is given by

$$\begin{aligned}\langle\hat{O}\rangle =& \mathrm{Tr}(\hat{O}\hat{\rho})\\ =& \int_0^\pi \frac{d\varphi}{\pi}\int_{-\infty}^\infty \frac{dk|k|}{4}\mathrm{Tr}(\hat{O}e^{ik\hat{Q}_\varphi})\mathrm{Tr}(\hat{O}e^{-ik\hat{Q}_\varphi})\\ :=& \int_0^\pi \frac{d\varphi}{\pi}\int_{-\infty}^\infty dq\mathrm{Tr}[\hat{O}K(\hat{Q}_\varphi - q)]p(q|\varphi)\\ :=& \int_0^\pi \frac{d\varphi}{\pi}\int_{-\infty}^\infty dq\mathcal{R}[\hat{O}](q,\varphi)p(q|\varphi),\end{aligned} \tag{B3}$$

where the value of the term

$$K(q) := \int_{-\infty}^\infty \frac{dk}{4}|k|e^{ikq} \tag{B4}$$

should be determined by the Cauchy principal value, $p(q|\varphi)$ is the conditional probability of obtaining quadrature q when the phase of the homodyne measurement is φ, and $\mathcal{R}[\hat{O}](q,\varphi)$ is the kernel function of $\hat{O}$ with respect to the homodyne measurement. Eq. (B3) gives a sampling procedure to estimate $\langle\hat{O}\rangle$ for a general unknown system using homodyne measurements [36, 37, 39]. Namely,

1. Repeat the following process for N times:
   (a) Choose the LO phase of the homodyne measurement, $\varphi_i \in [0,\pi]$, uniformly at random.
   (b) Measure the system and record the result, q_i.
2. Calculate the average value of the kernel function with respect to the observed statistics, $\sum_{i=1}^{N}\mathcal{R}[\hat{O}](q_i,\varphi_i)/N$.

When the kernel function is bounded, the law of large numbers guarantees the convergence,

$$\langle\hat{O}\rangle = \lim_{N\to\infty}\frac{1}{N}\sum_{i=1}^{N}\mathcal{R}[\hat{O}](q_i,\varphi_i). \tag{B5}$$

Note that, when $\hat{O}$ is an Hermitian operator or we know that $\mathrm{Im}\left(\langle\hat{O}\rangle\right)=0$, we have

$$\begin{aligned}\langle\hat{O}\rangle &= \mathrm{Re}\left(\langle\hat{O}\rangle\right)\\ &= \int_0^{\pi}\frac{d\varphi}{\pi}\int_{-\infty}^{\infty}dq\,\mathrm{Re}\left(\mathcal{R}[\hat{O}](q,\varphi)\right)p(q|\varphi).\end{aligned} \tag{B6}$$

That is, we can redefine the estimator to be the real part of $\mathcal{R}[\hat{O}](q,\varphi)$, which is still unbiased.

In our protocol, we are interested in the photon-number operators, $|n\rangle\langle n+d|$, where $|n\rangle$ is the eigenstate of the n-photon eigenstate. For a single mode, the estimator of this operator is given by

$$\mathcal{R}_\eta[|n\rangle\langle n+d|](q,\varphi) = e^{id(\varphi+\frac{\pi}{2})}\sqrt{\frac{n!}{(n+d)!}}\int_{-\infty}^{\infty}dk|k|\exp\left(\frac{1-2\eta}{2\eta}k^2-ikq\right)k^d L_n^d(k^2), \tag{B7}$$

where η is the detector efficiency, and L_n^d is the generalized Laguerre polynomial [36, 37, 74]. The kernel function is bounded when $\eta > 1/2$, allowing for a converging tomography result by increasing samples [37, 39].homodyne tomography can be generalized to estimate the statistics of a multiple-mode observable. In our case, one needs to estimate separable observables on two modes, $\hat{O}_1\otimes\hat{O}_2$, where we specify the modes with subscripts. One can apply independent homodyne measurements to each mode for the estimation. Notably, as $\hat{D}(\alpha_1)\otimes\hat{D}(\alpha_2)$ forms a complete basis on the joint system, then

$$\hat{O}_1\otimes\hat{O}_2 = \int_0^{\pi}\frac{d\varphi_1}{\pi}\int_{-\infty}^{\infty}\frac{dk_1|k_1|}{4}\mathrm{Tr}(\hat{O}_1e^{ik_1\hat{Q}_{\varphi_1}})\int_0^{\pi}\frac{d\varphi_2}{\pi}\int_{-\infty}^{\infty}\frac{dk_2|k_2|}{4}\mathrm{Tr}(\hat{O}_2e^{ik_2\hat{Q}_{\varphi_2}})(e^{-ik_1\hat{Q}_{\varphi_1}}\otimes e^{-ik_2\hat{Q}_{\varphi_2}}). \tag{B8}$$

Consequently,

$$\begin{aligned}\langle\hat{O}_1\otimes\hat{O}_2\rangle &= \mathrm{Tr}[(\hat{O}_1\otimes\hat{O}_2)\hat{\rho}]\\ &= \int_0^{\pi}\frac{d\varphi_1}{\pi}\int_{-\infty}^{\infty}dq_1\int_0^{\pi}\frac{d\varphi_2}{\pi}\int_{-\infty}^{\infty}dq_2\mathcal{R}[\hat{O}_1](q_1,\varphi_1)\mathcal{R}[\hat{O}_2](q_2,\varphi_2)p(q_1,q_2|\varphi_1,\varphi_2).\end{aligned} \tag{B9}$$

As a remark, note that the quantum state of the two modes, $\hat{\rho}$, can generally be entangled. In the experiment, the users simply need two independently phase-randomized homodyne detectors and record the joint conditional probability distribution of quadratures (q_1,q_2) given the LO phases (φ_1,φ_2).

In practical homodyne measurements, due to the usage of analog-to-digital converters (ADC), the measured quadrature value q will be discrete with a finite resolution Δ. In the former CV QKD protocols like Ref. [24], the parameter estimation is done by linear programming [75] instead of optical homodyne tomography; as a result, the finite resolution Δ will not affect the estimation accuracy as long as Δ is small.

To characterize how the finite resolution Δ will disturb the parameter estimation by optical homodyne tomography, we numerically estimate the bias caused by Δ. We estimate the expectation values of the (non-Hermitian) observables $\hat{O}_{01} := |0\rangle\langle 1|$ and $\hat{O}_{02} := |0\rangle\langle 2|$ with a coherent state $|\sqrt{\mu}\rangle$ input ($\mu = 0.5$). We choose $\hat{O}_{01}$ and $\hat{O}_{02}$ since they are directly related to the phase error operator in Proposition 1.

When the homodyne detection results is quantized with the bin width Δ, if we use the observable estimator $\mathcal{R}_\eta[|n\rangle\langle n+d|](q,\phi)$ given by Eq. (B7), the expectation value becomes

$$\mathbb{E}\left(\mathcal{R}[\hat{O}](q,\phi)\right) = \int_0^\pi \frac{d\phi}{\pi} \sum_{t=-\infty}^{\infty} \Pr(q = t\Delta|\phi)\, \mathcal{R}[\hat{O}](q = t\Delta, \phi), \tag{B10}$$

where

$$\Pr(q = t\Delta|\phi) = \int_{t\Delta}^{(t+1)\Delta} p(q|\phi), \tag{B11}$$

is the quantized version of the probabilistic distribution of the homodyne detection result q. The finite-bin effect is then characterized by the estimation bias $\left|\mathbb{E}\left(\mathcal{R}[\hat{O}](q,\phi)\right) - \hat{O}\right|$.

We plot the estimator bias of $\hat{O}_{01}$ and $\hat{O}_{02}$ with respect to the bin width Δ in Fig. 6. We see that the bias is almost proportional to Δ^2, i.e., it decays rapidly if we reduce the bin width Δ. With a width $\Delta = 0.01$ shot noise unit which is easily achievable in the experiment, the bias of $\hat{O}_{01}$ and $\hat{O}_{02}$ are smaller than 10^{-5}. As a result, the estimation bias is negligible with practical homodyne measurement devices.

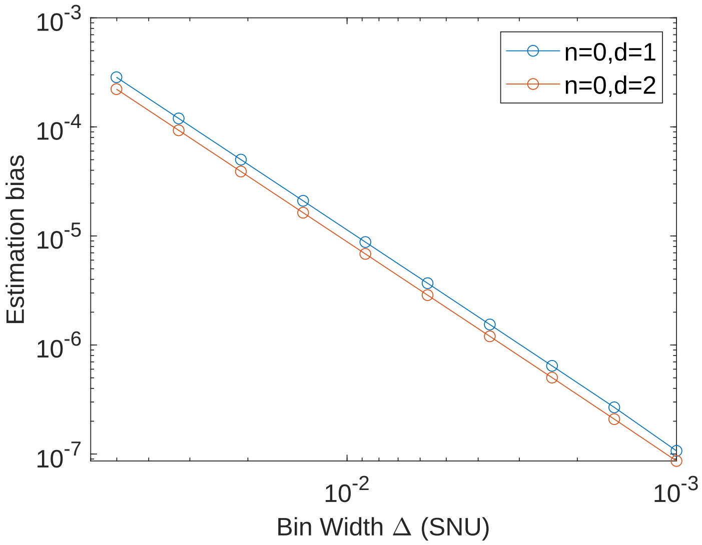

FIG. 6: Estimation bias of the observable $|n\rangle\langle n+d|$ with respect to the homodyne bin width Δ. The input state is a coherent state $|\sqrt{\mu}\rangle$ with $\mu = 0.5$. The detection efficiency $\eta_{det} = 1$.

2. Parameter estimation procedures

Now we present the parameter estimation procedures based on the homodyne tomography and extended decoy methods. In the experiment, given that they choose certain bases and light intensity, the users can collect data and evaluate the conditional probabilities for taking $(\varphi_b^1, \varphi_b^2) = \vec{\varphi}_b$ and observing $(q_1, q_2) = \vec{q}$ in the homodyne measurements, or the yields. For simplicity, we use notations of $Y^Z_{\mu_a,(\vec{\varphi}_b,\vec{q})}$ and $Y^\varphi_{\mu_a,(\vec{\varphi}_b,\vec{q})}$. In the subscript, μ_a denotes the light intensity, and $(\vec{\varphi}_b, \vec{q})$ denotes the homodyne measurement results of Bob. When the superscript writes Z, it denotes that Alice chooses the Z-basis; when the superscript writes φ, it denotes that Alice chooses the X-basis and $\varphi_a^2 - \varphi_a^1 = \varphi$. Via homodyne tomography, these values can be used to estimate $Y^Z_{\mu_a,\hat{O}}$ and $Y^\varphi_{\mu_a,\hat{O}}$, namely, the expected value of measuring observable $\hat{O}$ conditioned on the corresponding input settings. Following Eq. (B3), the yields are given by

$$\begin{aligned} Y^Z_{\mu_a,\hat{O}} &= \int_0^\pi d\varphi_b^1 \int_0^\pi d\varphi_b^2 \int_{-\infty}^{\infty} dq_1 \int_{-\infty}^{\infty} dq_2 \mathcal{R}[\hat{O}](\vec{q}, \vec{\varphi}_b) Y^Z_{\mu_a,(\vec{\varphi}_b,\vec{q})}, \\ Y^\varphi_{\mu_a,\hat{O}} &= \int_0^\pi d\varphi_b^1 \int_0^\pi d\varphi_b^2 \int_{-\infty}^{\infty} dq_1 \int_{-\infty}^{\infty} dq_2 \mathcal{R}[\hat{O}](\vec{q}, \vec{\varphi}_b) Y^\varphi_{\mu_a,(\vec{\varphi}_b,\vec{q})}. \end{aligned} \tag{B12}$$

In the second step, we apply the extended decoy state methods to estimate the gains and phase-error probabilities in Eq. (12), the key-rate formula. With finite decoy states, the users can obtain upper and lower bounds on these quantities [28]. We take the estimation of $e^X_{2,2}$ for example, which is the most complicated task for a two-photon protocol. According to Eq. (24) we have

$$\frac{Q_{2,2}e^X_{2,2}}{\Pr(2)} = \frac{1}{2}c_2^- Y_{|\Psi_2^+\rangle,|\Psi_2^-\rangle} + \frac{1}{2}c_2^+ Y_{|\Psi_2^-\rangle,|\Psi_2^+\rangle} + c_2^{11} Y_{|\Psi_2^-\rangle,|11\rangle}. \tag{B13}$$

We then invoke the extended decoy method. To upper-bound $Y_{|\Psi_2^+\rangle,|\Psi_2^-\rangle}$, i.e. the probability of transmitting $|\Psi_2^+\rangle$ whilst receiving $|\Psi_2^-\rangle$, we have according to Eq. (34)

$$Y_{|\Psi_2^+\rangle,|\Psi_2^-\rangle} \leq Y^{Z,U}_{m=2,|\Psi_2^-\rangle} + \frac{1}{2}Y^{\varphi=0,U}_{m=2,|\Psi_2^-\rangle} + \frac{1}{2}Y^{\varphi=\pi,U}_{m=2,|\Psi_2^-\rangle} - \frac{1}{2}Y^{\varphi=\frac{\pi}{2},L}_{m=2,|\Psi_2^-\rangle} - \frac{1}{2}Y^{\varphi=\frac{3\pi}{2},L}_{m=2,|\Psi_2^-\rangle}, \tag{B14}$$

where $Y^{\varphi,U(L)}_{m=2,|\Psi_2^-\rangle}$ denotes the upper(lower) bound of the two-photon subspace contribution of $Y^{\varphi}_{\mu,|\Psi_2^-\rangle}$, i.e. the probability of transmitting ρ^φ_μ whilst receiving $|\Psi_2^-\rangle$. This is found by the following standard linear programming for decoy analysis:

$$\begin{aligned} &\text{max.(min.) } Y^{\varphi}_{m=2,|\Psi_2^-\rangle} \\ &\text{s.t. } \sum_{m=0}^{N_c} e^{-\mu_a}\frac{\mu_a^m}{m!}Y^{\varphi}_{m,|\Psi_2^-\rangle} = Y^{\varphi}_{\mu_a,|\Psi_2^-\rangle}, \\ &\mu_a \in \{\mu, \nu_1, \nu_2, 0\}. \end{aligned} \tag{B15}$$

Note that N_c is a cut-off photon number chosen to be 10 in this work.

We list the estimation procedures and the involved quantities in Table VI. Note that the original data can be re-used to estimate various quantities in homodyne tomography by varying the kernel function with respect to the observable under consideration.

TABLE VI: Parameter estimation with homodyne tomography and decoy states. In our work, the light intensity is chosen from the set $\mu_a \in \{\mu, \nu_1, \nu_2, 0\}$. For simplicity, we denote the photon-number operator, $|n_1 n_2\rangle\langle n_1 n_2|$, as $|n_1 n_2\rangle$ in the subscripts of the yields, and similarly for $|\Psi_n^\pm\rangle$. We denote the lower and upper bounds with additional superscripts of L and U, respectively. Note that one can directly estimate $Q_{*,0}$ in the rounds of $\mu_a = \mu$. The estimation of $e^X_{2,2}$ involves statistics in the rounds that Alice chooses the Z-basis and X-basis with $\varphi = k\pi/2$.

Original data	Estimation via homodyne tomography	Final estimation with decoy states
	$Y^Z_{\mu,\lvert 00\rangle}$	$Q_{*,0}$
$Y^Z_{\mu_a,(\vec{\varphi}_b,\vec{q})}$	$Y^Z_{\mu_a,\lvert 01\rangle}, Y^Z_{\mu_a,\lvert 10\rangle}$	$Q^L_{1,1}, Q^U_{1,1}$
	$Y^Z_{\mu_a,\lvert 02\rangle}, Y^Z_{\mu_a,\lvert 20\rangle}, Y^Z_{\mu_a,\lvert 11\rangle}$	$Q^L_{2,2}, Q^U_{2,2}$
$Y^\varphi_{\mu_a,(\vec{\varphi}_b,\vec{q})}$	$Y^{\varphi=\pi}_{\mu_a,\lvert\Psi_1^+\rangle}, Y^{\varphi=0}_{\mu_a,\lvert\Psi_1^+\rangle}, Y^{\varphi=\pi}_{\mu_a,\lvert\Psi_1^-\rangle}, Y^{\varphi=0}_{\mu_a,\lvert\Psi_1^-\rangle}$	$e^{X,L}_{1,1}, e^{X,U}_{1,1}$
	$Y^{\varphi=k\pi/2}_{\mu_a,\lvert\Psi_2^+\rangle}, Y^{\varphi=k\pi/2}_{\mu_a,\lvert\Psi_2^-\rangle}, Y^{\varphi=k\pi/2}_{\mu_a,\lvert 11\rangle}$	$e^{X,L}_{2,2}, e^{X,U}_{2,2}$
$Y^Z_{\mu_a,(\vec{\varphi}_b,\vec{q})}$	$Y^Z_{\mu_a,\lvert\Psi_2^+\rangle}, Y^Z_{\mu_a,\lvert\Psi_2^-\rangle}, Y^Z_{\mu_a,\lvert 11\rangle}$	

Appendix C: Martingale-based analysis against coherent attacks

To tackle the most general attack, namely, a coherent attack, we apply a martingale-based approach. We first review the basics of martingale theory.

Definition 1 (Martingale)**.** *Consider a probability space, $(\Omega, \mathcal{F}, P)$, where Ω is the sample space, $\mathcal{F}$ is the event space, and P is the probability measure, and a filtration $\mathbb{F} = \{\mathcal{F}_i\}_{i\in\mathbb{N}}, \mathcal{F}_i \subseteq \mathcal{F}_j \subseteq \mathcal{F}, \forall i \leq j$. A sequence of random variables, $X_0, X_1, \cdots$, such that $\forall i, X_i$ is $\mathcal{F}_i$-measurable, is called a martingale with respect to filtration $\mathbb{F}$ if $\forall i$,*

$$\begin{aligned} \mathbb{E}(|X_i|) &< \infty, \\ \mathbb{E}(X_{i+1}|\mathcal{F}_i) &= X_i. \end{aligned} \tag{C1}$$

For a martingale, the summation of its composed random variables converges to the expected value in probability, as shown by Azuma's inequality [50] and its variants.

Theorem 3 (Azuma's inequality [50])**.** *Given a probability space, $(\Omega, \mathcal{F}, P)$, and a filtration, $\mathbb{F} = \{\mathcal{F}_i\}_{i\in\mathbb{N}}$, suppose $\mathbb{X} = \{X_i\}_{i\in\mathbb{N}}$ is a real-valued martingale bounded by two sets of predictable processes with respect to $\mathbb{F}$, $\mathbb{A} = \{A_i\}_{i\in\mathbb{N}}$ and $\mathbb{B} = \{B_i\}_{i\in\mathbb{N}}$, such that*

$$\begin{aligned} A_i \leq X_i - X_{i-1} \leq B_i, \\ B_i - A_i \leq c_i, \end{aligned} \tag{C2}$$

where $c_i \in [0, \infty)$ are constants. Then $\forall \delta > 0$ and $\forall n \in \mathbb{N}^+$,

$$\begin{aligned} \Pr(X_n - X_0 \geq \delta) \leq \exp\left(-\frac{2\delta^2}{\sum_{i=1}^n c_i^2}\right), \\ \Pr(X_n - X_0 \leq -\delta) \leq \exp\left(-\frac{2\delta^2}{\sum_{i=1}^n c_i^2}\right). \end{aligned} \tag{C3}$$

By applying the union bound, we have the inequality

$$\Pr(|X_n - X_0| \geq \delta) \leq 2\exp\left(-\frac{2\delta^2}{\sum_{i=1}^n c_i^2}\right). \tag{C4}$$

In our discussion, we also encounter martingales that may take complex values. We can apply Azuma's inequality for real-valued variables to the real and imaginary parts separately and bound the absolute values of the martingale variables. In this work, we apply a result from Ref. [76].

Theorem 4. *Given a probability space, $(\Omega, \mathcal{F}, P)$, and a filtration, $\mathbb{F} = \{\mathcal{F}_i\}_{i\in\mathbb{N}}$, suppose $\mathbb{X} = \{X_i\}_{i\in\mathbb{N}}$ is a complex-valued martingale with a bounded difference, such that*

$$\begin{aligned} X_0 = 0, \\ |X_i - X_{i-1}| \leq c_i, \end{aligned} \tag{C5}$$

where $c_i \in [0, \infty)$ are constants. Then $\forall \delta > 0$ and $\forall n \in \mathbb{N}^+$,

$$\Pr(|X_n| \geq \delta) \leq 2e^2 \exp\left(-\frac{2\delta^2}{\sum_{i=1}^n c_i^2}\right). \tag{C6}$$

1. Estimation of $Q_{1,1}$

In this section, we present a thorough analysis on the estimation of $Q_{1,1}$, showing how to apply the martingale analysis to obtain a non-i.i.d. estimation result that holds against coherent attacks. Note that in the finite-data-size analysis under a coherent attack, $Q_{1,1}$ should be understood as a frequency, and $N_\mu^{zz} Q_{1,1}$ is the number of key generation rounds in the virtual experiment where Alice sends a single-photon state and Bob accepts a single-photon state. Here, we denote the number of key generation rounds as N_μ^{zz} in accordance with the basis choise and light intensity. In particular, the statistics over the rounds can be correlated. Consider the following random variable in the i'th round,

$$\zeta_{\{\mu,(1,1)\}}^{(i)} = \begin{cases} 1, \text{ if } \mu_a^{(i)} = \mu \wedge ZZ \wedge n^{(i)} = 1 \wedge m^{(i)} = 1 \wedge (q_1^{(i)}, q_2^{(i)}) \in \mathbf{R_0} \cup \mathbf{R_1} , \\ 0, \text{ otherwise.} \end{cases} \tag{C7}$$

where we write ZZ to denote the bases choices, with the former denoting Alice's choice and the latter denoting Bob's, and specify the round number in the superscript, (i). We call $\zeta_{\{\mu,(1,1)\}}^{(i)}$ a counter variable, which adds one in the virtual experiment when the light intensity is μ, both Alice and Bob choose the Z-basis, Alice sends a single-photon state, and Bob receives a single-photon state and accepts the signal in the post-selection. Note that $\zeta_{\{\mu,(1,1)\}}^{(i)}$ embeds randomness from both the experimental setting and measurement outcomes. We have

$$\sum_{i=1}^{N} \zeta_{\{\mu,(1,1)\}}^{(i)} = N_\mu^{zz} Q_{1,1}, \tag{C8}$$

and conditioned on the history before the i'th round, $\mathcal{F}_{i-1}$, the expected value of $\zeta^{(i)}_{\{\mu,(1,1)\}}$ is given by

$$\mathbb{E}\left[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}\right] = p_\mu p_{zz} c_1 \mathrm{Pr}_\mu(1)\mathrm{Tr}\left\{\mathcal{N}_E\left[\mathrm{Tr}_{A'}(|\Psi_1\rangle_{A'A_1A_2}\langle\Psi_1|)\right](|01\rangle_{B_1B_2}\langle 01| + |10\rangle_{B_1B_2}\langle 10|)\right\}, \tag{C9}$$

where p_μ is the probability that the light intensity is μ, p_{zz} is the probability that both users choose the Z-basis, and c_1 relates to the accepting probability, as given in Eq. (22). The quantum channel controlled by Eve, $\mathcal{N}_E$, may introduce correlated statistics among rounds that are not independent and identically distributed. Then, the following random variables form a martingale,

$$\Delta^{(t)}_{\{\mu,(1,1)\}} = \begin{cases} 0, & \text{if } t=0, \\ \sum_{i=1}^{t}\left\{\zeta^{(i)}_{\{\mu,(1,1)\}} - \mathbb{E}\left[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}\right]\right\}, & \text{if } t=1,\cdots,N, \end{cases} \tag{C10}$$

where N is the total number of rounds in the experiment. In addition, the martingale has a bounded difference,

$$-\mathbb{E}\left[\zeta^{(t)}_{\{\mu,(1,1)\}}|\mathcal{F}_{t-1}\right] \leq \Delta^{(t)}_{\{\mu,(1,1)\}} - \Delta^{(t-1)}_{\{\mu,(1,1)\}} \leq 1 - \mathbb{E}\left[\zeta^{(t)}_{\{\mu,(1,1)\}}|\mathcal{F}_{t-1}\right]. \tag{C11}$$

We denote $c_{\mu,(1,1)} := 1$. In a virtual experiment where Alice and Bob perform the photon-number measurements, the value of $\Delta^{(N)}_{\{\mu,(1,1)\}}$ can be bounded on both sides by applying Azuma's inequality; hence the value of $\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu,(1,1)\}}$ can be bounded with respect to the expected values in Eq. (C9). Given the estimation failure probability

$$\varepsilon_{\{\mu,(1,1)\}} = \exp\left[-\frac{2{\delta_{\{\mu,(1,1)\}}}^2}{N{c_{\{\mu,(1,1)\}}}^2}\right] = \exp\left[-\frac{2{\delta_{\{\mu,(1,1)\}}}^2}{N}\right], \tag{C12}$$

we have

$$\begin{aligned} \mathrm{Pr}\left\{\Delta^{(N)}_{\{\mu,(1,1)\}} - \Delta^{(0)}_{\{\mu,(1,1)\}} \geq \delta_{\{\mu,(1,1)\}}\right\} &= \mathrm{Pr}\left\{\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu,(1,1)\}} - \sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}] \geq \delta_{\{\mu,(1,1)\}}\right\} \leq \varepsilon_{\{\mu,(1,1)\}}, \\ \mathrm{Pr}\left\{\Delta^{(N)}_{\{\mu,(1,1)\}} - \Delta^{(0)}_{\{\mu,(1,1)\}} \leq -\delta_{\{\mu,(1,1)\}}\right\} &= \mathrm{Pr}\left\{\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu,(1,1)\}} - \sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}] \leq -\delta_{\{\mu,(1,1)\}}\right\} \leq \varepsilon_{\{\mu,(1,1)\}}. \end{aligned} \tag{C13}$$

For brevity, we shall use the big-O notation. Then, except a negligible failure probability, we have the upper and lower bounds on $Q_{1,1}$,

$$\frac{1}{N^{zz}_\mu}\left\{\sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}] - O(\sqrt{-N\ln\varepsilon_{\{\mu,(1,1)\}}})\right\} \leq Q_{1,1} \leq \frac{1}{N^{zz}_\mu}\left\{\sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}] + O(\sqrt{-N\ln\varepsilon_{\{\mu,(1,1)\}}})\right\}. \tag{C14}$$

Notwithstanding, the expected value, $\mathbb{E}[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}]$, is not directly accessible. For this purpose, we link it with the parameter estimation measurement results, which involve the decoy state method and homodyne tomography. By applying the decoy state method, we can effectively lower and upper bound the fraction of single-photon component in the key generation rounds,

$$\begin{aligned} \mathbb{E}\left[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}\right] &\leq p_\mu p_{zz}\mathrm{Pr}_\mu(1)\left(c_1\sum_{\mu_a} d^U_{\{\mu_a,(1,1)\}}\mathrm{Tr}\left\{\mathcal{N}_E\left[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})\right](|01\rangle_{B_1B_2}\langle 01| + |10\rangle_{B_1B_2}\langle 10|)\right\} + c^U_{Q_{1,1}}\right), \\ \mathbb{E}\left[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}\right] &\geq p_\mu p_{zz}\mathrm{Pr}_\mu(1)\left(c_1\sum_{\mu_a} d^L_{\{\mu_a,(1,1)\}}\mathrm{Tr}\left\{\mathcal{N}_E\left[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})\right](|01\rangle_{B_1B_2}\langle 01| + |10\rangle_{B_1B_2}\langle 10|)\right\} + c^L_{Q_{1,1}}\right), \end{aligned} \tag{C15}$$

where we specify the upper and lower bounds obtained by the decoy-state method with superscripts U and L, respectively. As discussed in Appendix B 2, by applying a linear programming either analytically or numerically [28], we can derive the optimal coefficients in the decoy-state method for each light intensity μ_a, $d^{U(L)}_{\{\mu_a,(1,1)\}}$. Note that there may be an additional constant term returned by the linear programming, which we denote as $c^{U(L)}_{Q_{1,1}}$. Here, we overload the notation, μ_a, with the meaning of a specific light intensity in $\{\mu,\nu_1,\nu_2,0\}$ and distinguish it from Alice's choice in a round, $\mu_a^{(i)}$. Using the homodyne tomography method,

$$\mathrm{Tr}\left\{\mathcal{N}_E\left[\hat{\rho}^Z_{\mu_a}\right]|n_0n_1\rangle_{B_1B_2}\langle n_0n_1|\right\}=\int_0^\pi\frac{d\varphi_b^1}{\pi}\int_{-\infty}^{\infty}dq_1\int_0^\pi\frac{d\varphi_b^2}{\pi}\int_{-\infty}^{\infty}dq_2\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0n_1|](\vec{q},\vec{\varphi}_b)p^Z_{\mu_a}(\vec{q}|\vec{\varphi}_b),\tag{C16}$$

where $(\vec{q},\vec{\varphi}_b)$ represents the homodyne measurement result, with LO phases $\vec{\varphi}_b=(\varphi_1,\varphi_2)$ and quadratures $\vec{q}=(q_1,q_2)$ on the two modes, and the value of $\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0n_1|](\vec{q},\vec{\varphi}_b)$ comes from the kernel function in homodyne tomography by using homodyne detectors with efficiency η. The expressions of the kernel functions can be obtained through Eq. (B7) and (B9). For the estimation of $Q_{1,1}$, we shall use kernel functions with $|n_0n_1\rangle=|01\rangle$ and $|10\rangle$. To explicitly express the quantum state being measured, namely $\mathcal{N}_E\left[\hat{\rho}^Z_{\mu_a}\right]$, we specify it with sub- and superscripts in the probability distribution $p^Z_{\mu_a}(\vec{q}|\vec{\varphi}_b)$. The measurement results are collected in the rounds where the light intensity is chosen as μ_a, Alice chooses the Z-basis, and Bob chooses the X-basis. Combining Eq. (C9), (C15) and (C16), we have

$$\begin{aligned}\mathbb{E}\left[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}\right]\leq&p_\mu p_{zz}\mathrm{Pr}_\mu(1)\Bigg(c_1\sum_{\mu_a}d^U_{\{\mu_a,(1,1)\}}\Bigg\{\int_0^\pi\frac{d\varphi_b^1}{\pi}\int_{-\infty}^{\infty}dq_1\int_0^\pi\frac{d\varphi_b^2}{\pi}\int_{-\infty}^{\infty}dq_2\mathcal{R}_\eta[|01\rangle\langle 01|](\vec{q},\vec{\varphi}_b)p^Z_{\mu_a}(\vec{q}|\vec{\varphi}_b)\\&+\int_0^\pi\frac{d\varphi_b^1}{\pi}\int_{-\infty}^{\infty}dq_1\int_0^\pi\frac{d\varphi_b^2}{\pi}\int_{-\infty}^{\infty}dq_2\mathcal{R}_\eta[|10\rangle\langle 10|](\vec{q},\vec{\varphi}_b)p^Z_{\mu_a}(\vec{q}|\vec{\varphi}_b)\Bigg\}+c^U_{Q_{1,1}}\Bigg),\\\mathbb{E}\left[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}\right]\geq&p_\mu p_{zz}\mathrm{Pr}_\mu(1)\Bigg(c_1\sum_{\mu_a}d^L_{\{\mu_a,(1,1)\}}\Bigg\{\int_0^\pi\frac{d\varphi_b^1}{\pi}\int_{-\infty}^{\infty}dq_1\int_0^\pi\frac{d\varphi_b^2}{\pi}\int_{-\infty}^{\infty}dq_2\mathcal{R}_\eta[|01\rangle\langle 01|](\vec{q},\vec{\varphi}_b)p^Z_{\mu_a}(\vec{q}|\vec{\varphi}_b)\\&+\int_0^\pi\frac{d\varphi_b^1}{\pi}\int_{-\infty}^{\infty}dq_1\int_0^\pi\frac{d\varphi_b^2}{\pi}\int_{-\infty}^{\infty}dq_2\mathcal{R}_\eta[|10\rangle\langle 10|](\vec{q},\vec{\varphi}_b)p^Z_{\mu_a}(\vec{q}|\vec{\varphi}_b)\Bigg\}+c^L_{Q_{1,1}}\Bigg).\end{aligned}\tag{C17}$$

Note that we assess the probability distribution $p^Z_{\mu_a}(\vec{q}|\vec{\varphi}_b)$ also via a finite sample of data. For this purpose, we apply the martingale analysis once more. Consider the following random variables for the i'th round in the experiment,

$$\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}=\begin{cases}\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0n_1|](\vec{q},\vec{\varphi}_b),\text{ if }\mu_a^{(i)}=\mu_a\wedge ZX\wedge(q_1^{(i)},q_2^{(i)})=\vec{q},(\varphi_b^{1(i)},\varphi_b^{2(i)})=\vec{\varphi}_b,\\\qquad\qquad 0,\qquad\qquad\text{otherwise,}\end{cases}\tag{C18}$$

which relate to the parameter estimation measurements when the light intensity is μ_a and Alice chooses the Z-basis. We also call $\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}$ counter variables. According to homodyne tomography, we have

$$\mathbb{E}[\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}|\mathcal{F}_{i-1}]=p_{\mu_a}p_{zx}\mathrm{Tr}\left\{\mathcal{N}_E\left[\mathrm{Tr}_{A'}(|\Psi_1\rangle_{A'A_1A_2}\langle\Psi_1|)\right](|n_0n_1\rangle_{B_1B_2}\langle n_0n_1|)\right\},\tag{C19}$$

and

$$\sum_{i=1}^N\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}=\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0n_1|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}),\tag{C20}$$

where the summation of the right-hand side is taken over the rounds with light intensity μ_a and basis choices of Alice choosing the Z-basis and Bob choosing the X-basis, and $\vec{q}^{(i)},\vec{\varphi}_b^{(i)}$ represent the observed quadrature measurement statistics in the i'th round. While the weighted expectation with respect to the kernel function in Eq. (C16) is a real value, in the experiment, the summation in Eq. (C20) may take a complex value due to the kernel function value. One can simply take the real part of the summation as the estimation result. In the following discussion, we omit this specification for brevity.

Similar to Eq. (C10), the following random variables form a martingale,

$$\Delta^{(t)}_{\{\mu_a,Z,|n_0n_1\rangle\}}=\begin{cases}0,&\text{if }t=0,\\\sum_{i=1}^t\left\{\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}-\mathbb{E}\left[\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}|\mathcal{F}_{i-1}\right]\right\},&\text{if }t=1,\cdots,N.\end{cases}\tag{C21}$$

For $\eta > 1/2$, the above martingale has a bounded difference. One can numerically evaluate the maximum absolute value of $\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0n_1|](\vec{q},\vec{\varphi}_b)$, which we denote as $r_{\{\eta,|n_0n_1\rangle\}}$. Then, the martingale has a bounded difference,

$$|\Delta^{(t)}_{\{\mu_a,Z,|n_0n_1\rangle\}} - \Delta^{(t-1)}_{\{\mu_a,Z,|n_0n_1\rangle\}}| < 2r_{\{\eta,|n_0n_1\rangle\}}. \tag{C22}$$

We denote $c_{\{\mu_a,Z,|n_0n_1\rangle\}} := 2r_{\{\eta,|n_0n_1\rangle\}}$. By applying Azuma's inequality, we can link the observed statistics, $\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}$, with their expected values. Given the estimation failure probability

$$\varepsilon_{\{\mu_a,Z,|n_0n_1\rangle\}} = 2e^2\exp\left[-\frac{2\delta_{\{\mu_a,Z,|n_0n_1\rangle\}}{}^2}{Nc_{\{\mu_a,Z,|n_0n_1\rangle\}}{}^2}\right], \tag{C23}$$

we have

$$\begin{aligned}&\Pr\left\{\left|\Delta^{(N)}_{\{\mu_a,Z,|n_0n_1\rangle\}} - \Delta^{(0)}_{\{\mu_a,Z,|n_0n_1\rangle\}}\right| \geq \delta_{\{\mu_a,Z,|n_0n_1\rangle\}}\right\}\\ =&\Pr\left\{\left|\sum_{i=1}^N \zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}} - \sum_{i=1}^N \mathbb{E}[\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}|\mathcal{F}_{i-1}]\right| \geq \delta_{\{\mu_a,Z,|n_0n_1\rangle\}}\right\}\\ \leq&\varepsilon_{\{\mu_a,Z,|n_0n_1\rangle\}},\end{aligned} \tag{C24}$$

Combining all these results, we arrive at the final result: except for a given failure probability

$$\varepsilon_{Q_{1,1}} = \varepsilon_{\{\mu,(1,1)\}} + \sum_{\mu_a}\left(\varepsilon_{\{\mu_a,Z,|01\rangle\}} + \varepsilon_{\{\mu_a,Z,|10\rangle\}}\right), \tag{C25}$$

$$\begin{aligned}Q_{1,1} \leq& Q^U_{1,1}\\ :=&\frac{p_\mu p_{zz}\mathrm{Pr}_\mu(1)}{N^{zz}_\mu}\Bigg[c_1\sum_{\mu_a}\frac{d^U_{\{\mu_a,(1,1)\}}}{p_{\mu_a}p_{zx}}\Bigg\{\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|01\rangle\langle 01|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|01\rangle\}}}\right)\\ &+\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|10\rangle\langle 10|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|10\rangle\}}}\right)\Bigg\} + Nc^U_{Q_{1,1}} + O\left(\sqrt{-N\ln\varepsilon_{\{\mu,(1,1)\}}}\right)\Bigg],\end{aligned} \tag{C26}$$

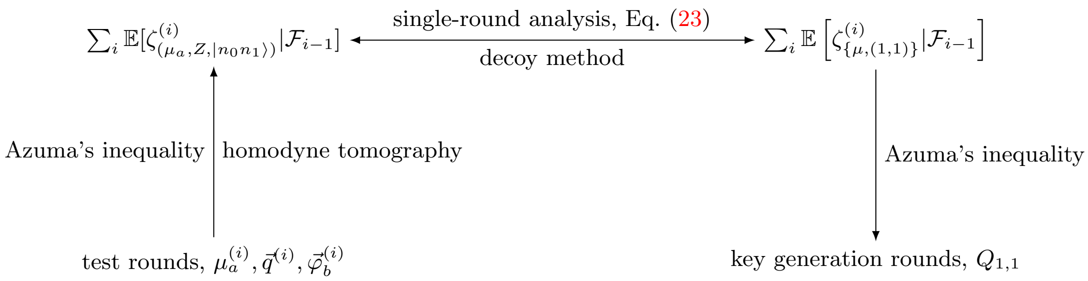
$$\begin{aligned}Q_{1,1} \geq& Q^L_{1,1}\\ :=&\frac{p_\mu p_{zz}\mathrm{Pr}_\mu(1)}{N^{zz}_\mu}\Bigg[c_1\sum_{\mu_a}\frac{d^L_{\{\mu_a,(1,1)\}}}{p_{\mu_a}p_{zx}}\Bigg\{\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|01\rangle\langle 01|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|01\rangle\}}}\right)\\ &+\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|10\rangle\langle 10|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|10\rangle\}}}\right)\Bigg\} + Nc^L_{Q_{1,1}} - O\left(\sqrt{-N\ln\varepsilon_{\{\mu,(1,1)\}}}\right)\Bigg].\end{aligned} \tag{C27}$$

To sum up, we depict the flowchart of estimating $Q_{1,1}$ from the observed statistics in Fig. 7.

2. Estimation of $Q_{2,2}$

In this section, we discuss the estimation of $Q_{2,2}$. While conceptually the same as the estimation of $Q_{1,1}$, the two-photon component makes the estimation procedure complex. First, construct the counter variable in the i'th round,

$$\zeta^{(i)}_{\{\mu,(2,2)\}} = \begin{cases}1, \text{ if } \mu_a^{(i)} = \mu \wedge ZZ \wedge n^{(i)} = 2 \wedge m^{(i)} = 2 \wedge (q_1^{(i)}, q_2^{(i)}) \in \mathbf{R_0}\cup\mathbf{R_1}, \\ 0, \text{ otherwise.}\end{cases} \tag{C28}$$



$\sum_i \mathbb{E}[\zeta^{(i)}_{(\mu_a,Z,|n_0 n_1\rangle)}|\mathcal{F}_{i-1}]$
single-round analysis, Eq. (23)
decoy method
$\sum_i \mathbb{E}\left[\zeta^{(i)}_{\{\mu,(1,1)\}}|\mathcal{F}_{i-1}\right]$
Azuma's inequality
homodyne tomography
Azuma's inequality
test rounds, $\mu_a^{(i)}, \vec{q}^{(i)}, \vec{\varphi}_b^{(i)}$
key generation rounds, $Q_{1,1}$

FIG. 7: Flowchart of martingale-based parameter estimation procedures. Here, we take the estimation of $Q_{1,1}$ as an example. The users start with the observed statistics in the test rounds and aim to estimate $Q_{1,1}$. Azuma's inequality is applied twice in the estimation. The single-round analysis in terms of conditional probabilities links the two martingales and hence relates the observed statistics in the test rounds with the target value in the key generation rounds.

which adds one in the virtual experiment when the light intensity is μ, both Alice and Bob choose the Z-basis, Alice sends a two-photon state, and Bob receives a two-photon state and accepts the signal in the post-selection. We have

$$\sum_{i=1}^{N} \zeta^{(i)}_{\{\mu,(2,2)\}} = N_\mu^{zz} Q_{2,2}, \tag{C29}$$

and conditioned on the history before the i'th round, $\mathcal{F}_{i-1}$, the expected value of $\zeta^{(i)}_{\{\mu,(2,2)\}}$ is given by

$$\begin{aligned}\mathbb{E}\left[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}\right] = p_\mu p_{zz}\mathrm{Pr}(2)\Bigg(&\frac{1}{2}(c_2^+ + c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\,|02\rangle_{B_1B_2}\langle 02|\right\}\\ &+\frac{1}{2}(c_2^+ - c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\,|02\rangle_{B_1B_2}\langle 20|\right\}\\ &+\frac{1}{2}(c_2^+ - c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\,|20\rangle_{B_1B_2}\langle 02|\right\}\\ &+\frac{1}{2}(c_2^+ + c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\,|20\rangle_{B_1B_2}\langle 20|\right\}\\ &+c_2^{11}\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(|\Psi_2\rangle_{A'A_1A_2}\langle\Psi_2|)]\,|11\rangle_{B_1B_2}\langle 11|\right\}\Bigg).\end{aligned} \tag{C30}$$

where p_μ is the probability that the light intensity is μ, p_{zz} is the probability that both users choose the Z-basis, and c_2^+, c_2^-, c_2^{11} relate to the accepting probability, as given in Eq. (26). Going through a similar analysis as for $Q_{1,1}$, where we construct a martingale sequence based on the variables $\zeta^{(i)}_{\{\mu,(2,2)\}}$ and apply Azuma's inequality, we arrive at the estimation result that given the failure probability

$$\varepsilon_{\{\mu,(2,2)\}} = \exp\left[-\frac{2\delta_{\{\mu,(2,2)\}}{}^2}{N}\right], \tag{C31}$$

we have

$$\begin{aligned}\mathrm{Pr}\left\{\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu,(2,2)\}} - \sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}] \geq \delta_{\{\mu,(2,2)\}}\right\} \leq \varepsilon_{\{\mu,(2,2)\}},\\ \mathrm{Pr}\left\{\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu,(2,2)\}} - \sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}] \leq -\delta_{\{\mu,(2,2)\}}\right\} \leq \varepsilon_{\{\mu,(2,2)\}}.\end{aligned} \tag{C32}$$

Then, except for a negligible failure probability, we have the upper and lower bounds on $Q_{2,2}$,

$$\frac{1}{N_\mu^{zz}}\left\{\sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}] - O(\sqrt{-N\ln\varepsilon_{\{\mu,(2,2)\}}})\right\} \leq Q_{2,2} \leq \frac{1}{N_\mu^{zz}}\left\{\sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}] + O(\sqrt{-N\ln\varepsilon_{\{\mu,(2,2)\}}})\right\}. \tag{C33}$$

To estimate the sum of expected values $\sum_{i=1}^{N} \mathbb{E}[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}]$, on the source side, we apply the decoy state method. This part is similar to the single-photon case, where we simply need to use the data where Alice chooses the Z-basis. By running the linear programming, we shall have a result in the form of

$$\begin{aligned}\mathbb{E}\left[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}\right] \leq p_\mu p_{zz}\mathrm{Pr}_\mu(2)\Bigg(\sum_{\mu_a} d^U_{\{\mu_a,(2,2)\}}\Bigg\{&\frac{1}{2}(c_2^+ + c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|02\right\rangle_{B_1B_2}\left\langle 02\right|\right\} \\ &+\frac{1}{2}(c_2^+ - c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|02\right\rangle_{B_1B_2}\left\langle 20\right|\right\} \\ &+\frac{1}{2}(c_2^+ - c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|20\right\rangle_{B_1B_2}\left\langle 02\right|\right\} \\ &+\frac{1}{2}(c_2^+ + c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|20\right\rangle_{B_1B_2}\left\langle 20\right|\right\} \\ &+c_2^{11}\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|11\right\rangle_{B_1B_2}\left\langle 11\right|\right\}\Bigg\} + c^U_{Q_{2,2}}\Bigg),\end{aligned} \tag{C34}$$

$$\begin{aligned}\mathbb{E}\left[\zeta^{(i)}_{\{\mu,(2,2)\}}|\mathcal{F}_{i-1}\right] \geq p_\mu p_{zz}\mathrm{Pr}_\mu(2)\Bigg(\sum_{\mu_a} d^L_{\{\mu_a,(2,2)\}}\Bigg\{&\frac{1}{2}(c_2^+ + c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|02\right\rangle_{B_1B_2}\left\langle 02\right|\right\} \\ &+\frac{1}{2}(c_2^+ - c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|02\right\rangle_{B_1B_2}\left\langle 20\right|\right\} \\ &+\frac{1}{2}(c_2^+ - c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|20\right\rangle_{B_1B_2}\left\langle 02\right|\right\} \\ &+\frac{1}{2}(c_2^+ + c_2^-)\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|20\right\rangle_{B_1B_2}\left\langle 20\right|\right\} \\ &+c_2^{11}\mathrm{Tr}\left\{\mathcal{N}_E[\mathrm{Tr}_{A'}(\hat{\rho}^Z_{\mu_a})]\left|11\right\rangle_{B_1B_2}\left\langle 11\right|\right\}\Bigg\} + c^L_{Q_{2,2}}\Bigg).\end{aligned} \tag{C35}$$

On the detection side, nonetheless, more terms are involved. With respect to Eq. (C30), besides the Hermitian operators $\left|n_0n_1\right\rangle_{B_1B_2}\left\langle n_0n_1\right|$ with $\left|n_0n_1\right\rangle = \left|02\right\rangle, \left|20\right\rangle, \left|11\right\rangle$, we also need to use homodyne tomography to estimate the terms with $\left|n_0n_1\right\rangle_{B_1B_2}\left\langle n_0'n_1'\right|$, namely the terms involving $\left|20\right\rangle\left\langle 02\right|$ and $\left|02\right\rangle\left\langle 20\right|$. Note that though these operators are not directly measurable, homodyne tomography allows us to link the physically measured statistics, $\vec{q}$ and $\vec{\varphi}_b$, with them through the kernel function. The expressions of the kernel functions can be obtained through Eq. (B7) and (B9). Consider the following random variables for the i'th round in the experiment,

$$\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}} = \begin{cases}\mathcal{R}_\eta[\left|n_0n_1\right\rangle\left\langle n_0'n_1'\right|](\vec{q},\vec{\varphi}_b), & \text{if } \mu_a^{(i)} = \mu_a \wedge ZX \wedge (q_1^{(i)},q_2^{(i)}) = \vec{q}, (\varphi_b^{1(i)},\varphi_b^{2(i)}) = \vec{\varphi}_b, \\ 0, & \text{otherwise},\end{cases} \tag{C36}$$

which relate to the parameter estimation measurements when the light intensity is μ_a and Alice chooses the Z-basis. For simplicity, we write $\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\}}$ when $n_0 = n_0', n_1 = n_1'$, as in the case of the single-photon term estimation. According to homodyne tomography, we have

$$\mathbb{E}[\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}}|\mathcal{F}_{i-1}] = p_{\mu_a}p_{zx}\mathrm{Tr}\left\{\mathcal{N}_E\left[\mathrm{Tr}_{A'}(\left|\Psi_1\right\rangle_{A'A_1A_2}\left\langle\Psi_1\right|)\right](\left|n_0n_1\right\rangle_{B_1B_2}\left\langle n_0'n_1'\right|)\right\}, \tag{C37}$$

and

$$\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}} = \sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[\left|n_0n_1\right\rangle\left\langle n_0'n_1'\right|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}), \tag{C38}$$

where the summation of the right-hand side is taken over the rounds with light intensity μ_a and basis choices of Alice choosing the Z-basis and Bob choosing the X-basis, and $\vec{q}^{(i)},\vec{\varphi}_b^{(i)}$ represent the observed quadrature measurement statistics in the i'th round. By constructing relative martingale sequences and applying Azuma's inequality, we can link the observed statistics, $\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}}$, with their expected values. Given the estimation failure probability

$$\varepsilon_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}} = 2e^2\exp\left[-\frac{2\delta_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}}{}^2}{Nc_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}}{}^2}\right], \tag{C39}$$

where $c_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}} := 2\max|\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0'n_1'|](\vec{q},\vec{\varphi}_b)|$ is a bounded value for $\eta > 1/2$, we have

$$\Pr\left\{\left|\sum_{i=1}^N \zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}} - \sum_{i=1}^N \mathbb{E}[\zeta^{(i)}_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}}|\mathcal{F}_{i-1}]\right| \geq \delta_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}}\right\} \leq \varepsilon_{\{\mu_a,Z,|n_0n_1\rangle\langle n_0'n_1'|\}}. \tag{C40}$$

Combining all these results, we arrive at the final result: except for a given failure probability

$$\varepsilon_{Q_{2,2}} = \varepsilon_{\{\mu,(2,2)\}} + \sum_{\mu_a}\left(\varepsilon_{\{\mu_a,Z,|02\rangle\}} + \varepsilon_{\{\mu_a,Z,|02\rangle\langle 20|\}} + \varepsilon_{\{\mu_a,Z,|20\rangle\langle 02|\}} + \varepsilon_{\{\mu_a,Z,|20\rangle\}} + \varepsilon_{\{\mu_a,Z,|11\rangle\}}\right), \tag{C41}$$

$$\begin{aligned}
Q_{2,2} \leq & Q_{2,2}^U \\
= & \frac{p_\mu p_{zz}\Pr_\mu(2)}{N_\mu^{zz}}\left[\sum_{\mu_a}\frac{d^U_{\{\mu_a,(2,2)\}}}{p_{\mu_a}p_{zx}}\left\{\frac{1}{2}(c_2^+ + c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|02\rangle\}}}\right)\right.\right. \\
& + \frac{1}{2}(c_2^+ - c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|02\rangle\langle 20|\}}}\right) \\
& + \frac{1}{2}(c_2^+ - c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|20\rangle\langle 02|\}}}\right) \\
& + \frac{1}{2}(c_2^+ + c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|20\rangle\}}}\right) \\
& \left.\left. + c_2^{11}\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|11\rangle\langle 11|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|11\rangle\}}}\right)\right\} + Nc^U_{Q_{2,2}} + O\left(\sqrt{-N\ln\varepsilon_{\{\mu,(2,2)\}}}\right)\right],
\end{aligned} \tag{C42}$$

$$\begin{aligned}
Q_{2,2} \geq & Q_{2,2}^L \\
= & \frac{p_\mu p_{zz}\Pr_\mu(2)}{N_\mu^{zz}}\left[\sum_{\mu_a}\frac{d^L_{\{\mu_a,(2,2)\}}}{p_{\mu_a}p_{zx}}\left\{\frac{1}{2}(c_2^+ + c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|02\rangle\}}}\right)\right.\right. \\
& + \frac{1}{2}(c_2^+ - c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|02\rangle\langle 20|\}}}\right) \\
& + \frac{1}{2}(c_2^+ - c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|20\rangle\langle 02|\}}}\right) \\
& + \frac{1}{2}(c_2^+ + c_2^-)\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|20\rangle\}}}\right) \\
& \left.\left. + c_2^{11}\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|11\rangle\langle 11|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|11\rangle\}}}\right)\right\} + Nc^L_{Q_{2,2}} - O\left(\sqrt{-N\ln\varepsilon_{\{\mu,(2,2)\}}}\right)\right].
\end{aligned} \tag{C43}$$

3. Estimation of $Q_{*,0}$

In comparison with other terms, the estimation of $Q_{*,0}$ is simple, as we do not need to apply the decoy state method. Corresponding to Eq. (27), construct the counter variable in the i'th round,

$$\zeta^{(i)}_{\{\mu,(*,0)\}} = \begin{cases} 1, \text{ if } \mu_a^{(i)} = \mu \wedge ZZ \wedge m^{(i)} = 0 \wedge (q_1^{(i)}, q_2^{(i)}) \in \mathbf{R_0} \cup \mathbf{R_1}, \\ 0, \text{ otherwise.} \end{cases} \tag{C44}$$

which adds one in the virtual experiment when the light intensity is μ, both Alice and Bob choose the Z-basis, and Bob receives a vacuum state and accepts the signal in the post-selection. We have

$$\sum_{i=1}^{N} \zeta^{(i)}_{\{\mu,(*,0)\}} = N^{zz}_{\mu} Q_{*,0}, \tag{C45}$$

and conditioned on the history before the i'th round, $\mathcal{F}_{i-1}$, the expected value of $\zeta^{(i)}_{\{\mu,(*,0)\}}$ is given by

$$\mathbb{E}\left[\zeta^{(i)}_{\{\mu,(*,0)\}}|\mathcal{F}_{i-1}\right] = p_{\mu} p_{zz} \int_{\mathbf{R_0}} 2\psi_0^2(q_1)\psi_0^2(q_2) dq_1 dq_2 \mathrm{Tr}\left[\hat{P}_0 \mathcal{N}_E\left(\hat{\rho}^Z\right)\hat{P}_0\right], \tag{C46}$$

where p_μ is the probability that the light intensity is μ, and p_{zz} is the probability that both users choose the Z-basis. By constructing a martingale sequence based on the variables $\zeta^{(i)}_{\{\mu,(*,0)\}}$ and applying Azuma's inequality, we arrive at the estimation result that given the failure probability

$$\varepsilon_{\{\mu,(*,0)\}} = \exp\left[-\frac{2\delta_{\{\mu,(*,0)\}}{}^2}{N}\right], \tag{C47}$$

we have

$$\Pr\left\{\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu,(*,0)\}} - \sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(*,0)\}}|\mathcal{F}_{i-1}] \leq -\delta_{\{\mu,(*,0)\}}\right\} \leq \varepsilon_{\{\mu,(*,0)\}}. \tag{C48}$$

Then, except for a negligible failure probability, we have the lower bound on $Q_{*,0}$,

$$Q_{*,0} \geq Q^L_{*,0} := \frac{1}{N^{zz}_{\mu}}\left\{\sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,(*,0)\}}|\mathcal{F}_{i-1}] - O(\sqrt{-N\ln\varepsilon_{\{\mu,(*,0)\}}})\right\}. \tag{C49}$$

On the detection side, consider the following random variables for the i'th round in the experiment,

$$\zeta^{(i)}_{\{\mu,Z,|00\rangle\}} = \begin{cases} \mathcal{R}_\eta[|00\rangle\langle 00|](\vec{q},\vec{\varphi}_b), \text{ if } \mu_a^{(i)} = \mu \wedge ZX \wedge (q_1^{(i)}, q_2^{(i)}) = \vec{q}, (\varphi_b^{1(i)}, \varphi_b^{2(i)}) = \vec{\varphi}_b, \\ 0, \qquad\qquad \text{otherwise}, \end{cases} \tag{C50}$$

which relate to the parameter estimation measurements when the light intensity is μ and Alice chooses the Z-basis. By constructing martingale sequences and applying Azuma's inequality, we can link the observed statistics, $\zeta^{(i)}_{\{\mu,Z,|00\rangle\}}$, with their expected values. Given the estimation failure probability

$$\varepsilon_{\{\mu,Z,|00\rangle\}} = 2e^2\exp\left[-\frac{2\delta_{\{\mu,Z,|00\rangle\}}{}^2}{Nc_{\{\mu,Z,|00\rangle\}}{}^2}\right], \tag{C51}$$

where $c_{\{\mu,Z,|00\rangle\}} := 2\max|\mathcal{R}_\eta[|00\rangle\langle 00|](\vec{q},\vec{\varphi}_b)|$ is a bounded value for $\eta > 1/2$, we have

$$\Pr\left\{\left|\sum_{i=1}^{N}\zeta^{(i)}_{\{\mu,Z,|00\rangle\}} - \sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{\mu,Z,|00\rangle\}}|\mathcal{F}_{i-1}]\right| \geq \delta_{\{\mu,Z,|00\rangle\}}\right\} \leq \varepsilon_{\{\mu,Z,|00\rangle\}}. \tag{C52}$$

Combining all these results, we arrive at the final result: except for a given failure probability

$$\varepsilon_{Q_{*,0}} = \varepsilon_{\{\mu,(*,0)\}} + \varepsilon_{\{\mu,Z,|00\rangle\}}, \tag{C53}$$

$$\begin{aligned} Q_{*,0} \geq & Q^L_{*,0} \\ := & \frac{p_{zz}}{p_{zx}N^{zz}_{\mu}}\int_{\mathbf{R_0}} 2\psi_0^2(q_1)\psi_0^2(q_2)dq_1dq_2\left[\sum_{i:\mu_a^{(i)}=\mu_a,ZX}\mathcal{R}_\eta[|00\rangle\langle 00|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\right. \\ & \left. - O\left(\sqrt{-N\ln\varepsilon_{\{\mu_a,Z,|00\rangle\}}}\right) - O\left(\sqrt{-N\ln\varepsilon_{\{\mu,(*,0)\}}}\right)\right]. \end{aligned} \tag{C54}$$

4. Estimation of $e^X_{1,1}$

In this section, we discuss the estimation of $e^X_{1,1}$ based on the single-round result in Eq. (21). While conceptually similar to the estimation of the gains, there are two additional issues that make its estimation more involved:

1. We shall first estimate lower and upper bounds on the value $N^{zz}_\mu Q_{1,1} e^X_{1,1}$, the total number of phase errors in the virtual protocol. Afterward, combined with the estimation of $Q_{1,1}$ in Appendix C 1, we obtain estimations of $e^X_{1,1}$, the phase error rate in key generation rounds where the signal is accepted by Bob.

2. On the source side, to evaluate the terms $|\Psi_1^\pm\rangle$, we need to apply the extended decoy method given in Eq. (31). This involves the rounds where Alice chooses the X-basis.

For simplicity, we shall simply list the counter variables and their estimation results. The relevant martingale variables are constructed similarly to the above sections, which are also conditioned on the filtration $\{\mathcal{F}_i\}_i$. First, construct the counter variable in the i'th round for the phase error variable,

$$\zeta^{(i)}_{\{e^X_{1,1}\}} = \begin{cases} 1, \text{ if } \mu_a^{(i)} = \mu \wedge ZZ \wedge n^{(i)} = 2 \wedge m^{(i)} = 2 \wedge (q_1^{(i)}, q_2^{(i)}) \in \mathbf{R_0} \cup \mathbf{R_1} \wedge \text{ a phase error occurs },\\ 0, \text{ otherwise.} \end{cases} \tag{C55}$$

which adds one in the virtual experiment when the light intensity is μ, both Alice and Bob choose the Z-basis, Alice sends a single-photon state, Bob receives a single-photon state and accepts the signal in the post-selection, and a phase error occurs. We have

$$\sum_{i=1}^{N} \zeta^{(i)}_{\{e^X_{1,1}\}} = N^{zz}_\mu Q_{1,1} e^X_{1,1}, \tag{C56}$$

and conditioned on the history before the i'th round, $\mathcal{F}_{i-1}$, the expected value of $\zeta^{(i)}_{\{e^X_{1,1}\}}$ is given by

$$\begin{aligned}\mathbb{E}\left[\zeta^{(i)}_{\{e^X_{1,1}\}}|\mathcal{F}_{i-1}\right] = \frac{1}{2}p_\mu p_{zz} c_1 \mathrm{Pr}(1)\Big\{&\mathrm{Tr}\left[\mathcal{N}_E(|\Psi_1^+\rangle_{A_1A_2}\langle\Psi_1^+|)\frac{1}{2}(|01\rangle_{B_1B_2} - |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} - \langle 10|_{B_1B_2})\right]\\ &+\mathrm{Tr}\left[\mathcal{N}_E(|\Psi_1^-\rangle_{A_1A_2}\langle\Psi_1^-|)\frac{1}{2}(|01\rangle_{B_1B_2} + |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} + \langle 10|_{B_1B_2})\right]\Big\}.\end{aligned} \tag{C57}$$

Except a given failure probability $\varepsilon_{\{e^X_{1,1}\}}$, we have upper and lower bounds on $Q_{1,1}e^X_{1,1}$,

$$\frac{1}{N^{zz}_\mu}\left\{\sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{e^X_{1,1}\}}|\mathcal{F}_{i-1}] - O(\sqrt{-N\ln\varepsilon_{\{e^X_{1,1}\}}})\right\} \le Q_{1,1}e^X_{1,1} \le \frac{1}{N^{zz}_\mu}\left\{\sum_{i=1}^{N}\mathbb{E}[\zeta^{(i)}_{\{e^X_{1,1}\}}|\mathcal{F}_{i-1}] + O(\sqrt{-N\ln\varepsilon_{\{e^X_{1,1}\}}})\right\}. \tag{C58}$$

On the source side, we apply the decoy state method given in Eq. (31), where we need to use the data where Alice chooses the X-basis with relative phase 0 and π between the two modes,

$$\begin{aligned}\mathbb{E}\left[\zeta^{(i)}_{\{e^X_{1,1}\}}|\mathcal{F}_{i-1}\right] =&\frac{1}{2}p_\mu p_{zz} c_1 \mathrm{Pr}(1)\Big\{\mathrm{Tr}\left[\mathcal{N}_E(|\Psi_1^+\rangle_{A_1A_2}\langle\Psi_1^+|)\frac{1}{2}(|01\rangle_{B_1B_2} - |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} - \langle 10|_{B_1B_2})\right]\\ &+\mathrm{Tr}\left[\mathcal{N}_E(|\Psi_1^-\rangle_{A_1A_2}\langle\Psi_1^-|)\frac{1}{2}(|01\rangle_{B_1B_2} + |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} + \langle 10|_{B_1B_2})\right]\Big\}\\ =&\frac{1}{2}p_\mu p_{zz} c_1\Big\{\mathrm{Tr}\left[\mathcal{N}_E[\hat{P}_1\hat{\rho}^0_\mu\hat{P}_1]\frac{1}{2}(|01\rangle_{B_1B_2} - |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} - \langle 10|_{B_1B_2})\right]\\ &+\mathrm{Tr}\left[\mathcal{N}_E[\hat{P}_1\hat{\rho}^\pi_\mu\hat{P}_1]\frac{1}{2}(|01\rangle_{B_1B_2} + |10\rangle_{B_1B_2})(\langle 01|_{B_1B_2} + \langle 10|_{B_1B_2})\right]\Big\},\end{aligned} \tag{C59}$$

which has the upper and lower bounds of

$$
\begin{aligned}
\mathbb{E}\left[\zeta^{(i)}_{\{e^X_{1,1}\}}|\mathcal{F}_{i-1}\right] \leq & \frac{1}{2}p_\mu p_{zz}\mathrm{Pr}(1)\Bigg(c_1\sum_{\mu_a}\Bigg\{d^{\varphi=0,U}_{\{\mu_a,(1,1)\}}\mathrm{Tr}\left[\mathcal{N}_E(\hat{\rho}^0_{\mu_a})\frac{1}{2}(|01\rangle_{B_1B_2}-|10\rangle_{B_1B_2})(\langle 01|_{B_1B_2}-\langle 10|_{B_1B_2})\right] \\
& + d^{\varphi=\pi,U}_{\{\mu_a,(1,1)\}}\mathrm{Tr}\left[\mathcal{N}_E(\hat{\rho}^\pi_{\mu_a})\frac{1}{2}(|01\rangle_{B_1B_2}+|10\rangle_{B_1B_2})(\langle 01|_{B_1B_2}+\langle 10|_{B_1B_2})\right]\Bigg\} + c^{\varphi=0,U}_{(1,1)} + c^{\varphi=\pi,U}_{(1,1)}\Bigg), \\
\mathbb{E}\left[\zeta^{(i)}_{\{e^X_{1,1}\}}|\mathcal{F}_{i-1}\right] \geq & \frac{1}{2}p_\mu p_{zz}\mathrm{Pr}(1)\Bigg(c_1\sum_{\mu_a}\Bigg\{d^{\varphi=0,L}_{\{\mu_a,(1,1)\}}\mathrm{Tr}\left[\mathcal{N}_E(\hat{\rho}^0_{\mu_a})\frac{1}{2}(|01\rangle_{B_1B_2}-|10\rangle_{B_1B_2})(\langle 01|_{B_1B_2}-\langle 10|_{B_1B_2})\right] \\
& + d^{\varphi=\pi,L}_{\{\mu_a,(1,1)\}}\mathrm{Tr}\left[\mathcal{N}_E(\hat{\rho}^\pi_{\mu_a})\frac{1}{2}(|01\rangle_{B_1B_2}+|10\rangle_{B_1B_2})(\langle 01|_{B_1B_2}+\langle 10|_{B_1B_2})\right]\Bigg\} + c^{\varphi=0,L}_{(1,1)} + c^{\varphi=\pi,L}_{(1,1)}\Bigg).
\end{aligned}
\tag{C60}
$$

To deal with the Fock-basis terms, we utilize the homodyne tomography results, where we construct martingales based on the counter variables

$$
\zeta^{(i)}_{\{\mu_a,\varphi,|n_0n_1\rangle\langle n_0'n_1'|\}} = \begin{cases} \mathcal{R}_\eta[|n_0n_1\rangle\langle n_0'n_1'|](\vec{q},\vec{\varphi}_b), \text{ if } \mu_a^{(i)} = \mu_a \wedge XX \wedge \varphi_a = \varphi \wedge (q_1^{(i)},q_2^{(i)}) = \vec{q}, (\varphi_b^{1(i)},\varphi_b^{2(i)}) = \vec{\varphi}_b, \\ \quad\quad 0, \quad\quad\quad \text{otherwise,} \end{cases}
\tag{C61}
$$

which relate to the parameter estimation measurements when the light intensity is μ_a and Alice chooses the X-basis. According to homodyne tomography, we have

$$
\mathbb{E}[\zeta^{(i)}_{\{\mu_a,\varphi,|n_0n_1\rangle\langle n_0'n_1'|\}}|\mathcal{F}_{i-1}] = p_{\mu_a}p_{xx}\mathrm{Tr}\left\{\mathcal{N}_E\left[\hat{\rho}^\varphi_{\mu_a}\right](|n_0n_1\rangle_{B_1B_2}\langle n_0'n_1'|)\right\},
\tag{C62}
$$

and

$$
\sum_{i=1}^N \zeta^{(i)}_{\{\mu_a,\varphi,|n_0n_1\rangle\langle n_0'n_1'|\}} = \sum_{i:\mu_a^{(i)}=\mu_a,XX,\varphi_a=\varphi}\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0'n_1'|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}),
\tag{C63}
$$

where the summation of the right-hand side is taken over the rounds with light intensity μ_a, Alice choosing the X-basis with relative phase $\varphi_a = \varphi$, and Bob choosing the X-basis, and $\vec{q}^{(i)}, \vec{\varphi}_b^{(i)}$ represent the observed quadrature measurement statistics in the i'th round. When homodyne detectors have an efficiency $\eta > 1/2$, except a given estimation failure probability $\varepsilon := \varepsilon_{\{\mu_a,\varphi,|n_0n_1\rangle\langle n_0'n_1'|\}}$, we have

$$
\left|\sum_{i:\mu_a^{(i)}=\mu_a,XX,\varphi_a=\varphi}\mathcal{R}_\eta[|n_0n_1\rangle\langle n_0'n_1'|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - \sum_{i=1}^N\mathbb{E}[\zeta^{(i)}_{\{\mu_a,\varphi,|n_0n_1\rangle\langle n_0'n_1'|\}}|\mathcal{F}_{i-1}]\right| \leq O(\sqrt{-N\ln\varepsilon}).
\tag{C64}
$$

Combining all the above results, except for a given failure probability, we have the upper bound on the phase error rate,

$$\begin{aligned}
Q_{1,1}e^X_{1,1} \leq & E^X_{1,1} \\
:= & \frac{p_\mu p_{zz}\mathrm{Pr}(1)}{N^{zz}_\mu}\left(\frac{1}{4}c_1\left\{\sum_{\mu_a}\frac{1}{p_{\mu_a}p_{xx}}\right.\right. \\
& \times\left[d^{\varphi=0,U}_{\{\mu_a,(1,1)\}}\left(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|01\rangle\langle 01|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|01\rangle\langle 10|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\right.\right. \\
& \quad - \left.\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|10\rangle\langle 01|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|10\rangle\langle 10|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O(\sqrt{N})\right) \\
& \quad + d^{\varphi=\pi,U}_{\{\mu_a,(1,1)\}}\left(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|01\rangle\langle 01|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|01\rangle\langle 10|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\right. \\
& \quad \left.\left.\left. + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|10\rangle\langle 01|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|10\rangle\langle 10|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + O(\sqrt{N})\right)\right]\right\} \\
& \left. + Nc^{\varphi=0,U}_{(1,1)} + Nc^{\varphi=\pi,U}_{(1,1)} + O(\sqrt{N})\right).
\end{aligned} \tag{C65}$$

For simplicity and better readability, we omit the failure probabilities in the expressions. Note that each big-O term corresponds to uses of Azuma's inequality. Finally, $e^X_{1,1}$ can be upper bounded by

$$e^X_{1,1} \leq e^{X,U}_{1,1} := \frac{E^X_{1,1}}{Q^L_{1,1}}, \tag{C66}$$

where $Q^L_{1,1}$ is given by Eq. (C27).

5. Estimation of $e^X_{2,2}$

The estimation of $e^X_{2,2}$ follows the same procedures as the above quantities. This involves all the cumbersome issues, including both the rounds where Alice chooses the Z-basis and the X-basis, the use of extended decoy state, and the homodyne tomography for non-Hermitian operators. Nevertheless, we have shown how to tackle each issue in the above discussions. Here, we simply present the final result. Except for a given failure probability, we have that

$$Q_{2,2}e^X_{2,2} \leq E^X_{2,2} := \frac{p_\mu p_{zz}\mathrm{Pr}_\mu(2)}{N^{ZZ}_\mu}[N_1 + N_2 + N_3 + O(\sqrt{N})], \tag{C67}$$

where the big-O term here corresponds to a use of Azuma's inequality, N_1, N_2, N_3 refer to the upper bounds on the numbers of three types of errors: $|\Psi_2^+\rangle$ received as $|\Psi_2^-\rangle$, $|\Psi_2^-\rangle$ received as $|\Psi_2^+\rangle$, and $|\Psi_2^-\rangle$ received as $|11\rangle$, with values

$$
\begin{aligned}
N_1 = \frac{c_2^-}{2}\sum_{\mu_a}\frac{1}{p_{\mu_a}}\Bigg\{ \frac{1}{2p_{xx}}\Bigg[& d^{\varphi=0,U}_{\{\mu_a,|\Psi_2^-\rangle\}}\Bigg(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) \\
& - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\Bigg) \\
& + d^{\varphi=\pi,U}_{\{\mu_a,|\Psi_2^-\rangle\}}\Bigg(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) \\
& - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi}}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\Bigg) \\
& - d^{\varphi=\pi/2,L}_{\{\mu_a,|\Psi_2^-\rangle\}}\Bigg(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi/2}}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi/2}}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) \\
& - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi/2}}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=\pi/2}}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\Bigg) \\
& - d^{\varphi=3\pi/2,L}_{\{\mu_a,|\Psi_2^-\rangle\}}\Bigg(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=3\pi/2}}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=3\pi/2}}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) \\
& - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=3\pi/2}}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=3\pi/2}}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\Bigg)\Bigg] \\
& + \frac{1}{p_{zx}} d^{Z,U}_{\{\mu_a,|\Psi_2^-\rangle\}}\Bigg(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ ZX}}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ ZX}}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) \\
& - \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ ZX}}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)}) + \sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ ZX}}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\Bigg) \\
& + Nc^{\varphi=0,U}_{|\Psi_2^-\rangle} + Nc^{\varphi=\pi,U}_{|\Psi_2^-\rangle} + Nc^{\varphi=\pi/2,U}_{|\Psi_2^-\rangle} + Nc^{\varphi=3\pi/2,U}_{|\Psi_2^-\rangle} + Nc^{Z,U}_{|\Psi_2^-\rangle} + O(\sqrt{N})\Bigg\},
\end{aligned}
\tag{C68}
$$

$$
\begin{aligned}
N_2 = \frac{c_2^+}{2}\sum_{\mu_a}\frac{1}{p_{\mu_a}}\Bigg\{\frac{1}{2p_{xx}}\Bigg[& -d^{\varphi=0,L}_{\{\mu_a,|\Psi_2^+\rangle\}}\Bigg(\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|02\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})+\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|02\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\\
& +\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|20\rangle\langle 02|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})+\sum_{\substack{i:\mu_a^{(i)}=\mu_a,\\ XX,\varphi_a=0}}\mathcal{R}_\eta[|20\rangle\langle 20|](\vec{q}^{(i)},\vec{\varphi}_b^{(i)})\Bigg)\\

$$

In the above formulae, $d^{\varphi=0,U}_{\mu_a,|\Psi_2^-\rangle}$, for instance, refers to the coefficient of the upper-bound decoy-state terms for the case where the light intensity is μ_a, the relative phase between the modes sent by Alice is $\varphi = 0$, and the phase error belongs to the case that $|\Psi_2^+\rangle$ is measured as $|\Psi_2^-\rangle$. The other terms follow the same terminology rule. The big-O terms come from applications of Azuma's inequality. Finally, $e^X_{2,2}$ can be upper bounded by

$$e^X_{2,2} \leq e^{X,U}_{2,2} := \frac{E^X_{2,2}}{Q^L_{2,2}}, \tag{C71}$$

where $Q^L_{2,2}$ is given by Eq. (C43).

6. Summary of the finite-size analysis

To summarize, we list the counter variables to establish martingales in parameter estimation in Fig. 8. The general approach goes as follows: In the i'th round, for a specific experimental setting and observable $\hat{O}$, consider a counter variable, $\zeta^{(i)}_{\{\text{setting},\hat{O}\}}$, which is in the form of Eq. (C7) and Eq. (C18). In the figure, we list the non-trivial values that the counter variables may take in the (virtual) experiment. Each blue box represents the outcome of a random variable, where randomness originates from either the random choice for the experimental setting or the measurement outcome. The counter variable takes a non-trivial value if the experiment takes the path that leads to its associating event. Otherwise, it takes the value 0. Then, for each setting and observable, the following series of random variables form a martingale,

$$\Delta^{(t)}_{\{\text{setting},\hat{O}\}} = \begin{cases} 0, & \text{if } t = 0, \\ \sum_{i=1}^{t} \left\{ \zeta^{(i)}_{\{\text{setting},\hat{O}\}} - \mathbb{E}\left[\zeta^{(i)}_{\{\text{setting},\hat{O}\}} | \mathcal{F}_{i-1} \right] \right\}, & \text{if } t = 1, \cdots, N. \end{cases} \tag{C72}$$

As we embed all possible randomness origins in the experiment in defining these observables, all the counter variables in the i'th round, $\zeta^{(i)}_{\{\text{setting},\hat{O}\}}$, are defined over the same filtration. Therefore, we can link their expected values via the single-round analysis and hence the parameter estimation measurement statistics with the quantities we are interested in.

FIG. 8: The counter variables to set up martingales in parameter estimation. For each experimental setting and observable that is involved in parameter estimation, we set up a corresponding counter random variable in each round, $\zeta^{(i)}_{\{\text{setting},\hat{O}\}}$. We list the values that should be given to these random variables when an associating path is taken in the experiment. In other circumstances, the counter variables take the value 0.

To end this section, we give a formal theorem of the finite-size key generation result.

Theorem 5. *For the time-bin CV QKD protocol in Table III with reverse reconciliation, suppose the total number of rounds is N and the number of key generation rounds is N_μ^{zz}. Given the failure probability in parameter estimation $\varepsilon_{\mathrm{pe}} \in (0,1)$, which involves the estimation of the gains $Q_{1,1}, Q_{2,2}, Q_{*,0}$ and phase-error rates $e_{1,1}^X, e_{2,2}^X$, and the failure probability in privacy amplification $\varepsilon_{\mathrm{pa}} \in (0,1)$, then conditioned on the success of information reconciliation, except a total failure probability $\varepsilon = \varepsilon_{\mathrm{pe}} + \varepsilon_{\mathrm{pa}}$, the number of secure key bits that can be obtained from the protocol is lower-bounded by*

$$n \geq n_{\mathrm{rev}} = N_\mu^{zz}\left\{Q_{*,0}^L + Q_{1,1}^L\left[1 - h\left(e_{1,1}^{X,U}\right)\right] + Q_{2,2}^L\left[1 - h\left(e_{2,2}^{X,U}\right)\right] - fQ^Z h(e^Z)\right\} - \log\frac{1}{\varepsilon_{\mathrm{pa}}}, \tag{C73}$$

where Q^Z is the Z-basis gain, e^Z is the bit error rate, f is the efficiency of information reconciliation, $Q_{*,0}^L$ is the lower bound on $Q_{*,0}$ given in Eq. (C49), $Q_{1,1}^L$ and $Q_{1,1}^U$ are the lower and upper bounds on $Q_{1,1}$ given in Eq. (C27) and (C26), $Q_{2,2}^L$ and $Q_{2,2}^U$ are the lower and upper bounds on $Q_{2,2}$ given in Eq. (C43) and (C42), $e_{1,1}^{X,U}$ is the upper bound on $e_{1,1}^X$ given in Eq. (C66), and $e_{2,2}^{X,U}$ is the upper bound on $e_{2,2}^X$ given in Eq. (C71).

Appendix D: Simulation formulae under thermal-noise channel

We present the simulation formulae of the asymptotic time-bin CV QKD under a thermal-noise channel with excess noise ξ from the output. We set $\hbar = 2$ so that the vacuum variance is 1. A thermal noise channel is characterized as a Gaussian completely positive map transforming the first and second moment $(\bar{r}, V)$, representing the mean vector and covariance matrix of the quadrature operators, of the input state as [33]:

$$\begin{aligned} &\bar{r} \mapsto \sqrt{\eta}\bar{r}, \\ &V \mapsto \eta V + (1-\eta)\mathbb{I} + \xi\mathbb{I}, \end{aligned} \tag{D1}$$

where η is the channel transmittance. Two thermal channels with transmittance η and η' and excess noise ξ and ξ' concatenate to another thermal channel with transmittance $\eta\eta'$ and excess noise $(\eta'\xi + \xi')$ since

$$\begin{aligned} &\bar{r} \mapsto \sqrt{\eta'\eta}\bar{r}, \\ &V \mapsto \eta'(\eta V + (1-\eta)\mathbb{I} + \xi\mathbb{I}) + (1-\eta')\mathbb{I} + \xi'\mathbb{I} \\ &= \eta'\eta V + (1-\eta'\eta)\mathbb{I} + (\eta'\xi + \xi')\mathbb{I}. \end{aligned} \tag{D2}$$

On the bit-error side, the thermal noise can be seen as adding ξ to the unity variance of the coherent states. Hence, if Alice transmits a coherent state $|\sqrt{\mu}e^{i\theta}\rangle$ through a thermal-noise channel with transmittance η and excess noise ξ, and Bob applies homodyne detection with LO phase φ, the detection result q will follow a distribution

$$\Pr(q|\mu, \theta - \varphi) = \frac{1}{\sqrt{2\pi}}\exp\left\{-\frac{[q - 2\sqrt{\eta\mu}\cos(\theta-\varphi)]^2}{2(1+\xi)}\right\}. \tag{D3}$$

Since both the signal states and the receiver LO are uniformly phase randomized, $(\theta - \varphi)$ is also uniformly randomized with $[0, 2\pi)$ in a cyclic manner. The bit error rate e_μ^Z and the Z-basis gain Q_μ^Z can thus be calculated according to the post-selection threshold τ, uniformly randomizing over $[0, 2\pi)$.

The calculation of the vacuum gain $Q_{*,0}$, according to Eq. (27), requires the probability of sending the Z-basis state whilst receiving vacuum. This can be calculated via the Wigner function for Gaussian state, and in specific

$$\mathrm{Tr}\left[\hat{P}_0^{B_1B_2}\mathcal{N}_E^{A_1A_2\to B_1B_2}\left(\hat{\rho}^Z\right)\hat{P}_0^{B_1B_2}\right] = \left(\frac{2}{2+\xi}\right)^2\exp\left(-\frac{2\eta\mu}{2+\xi}\right). \tag{D4}$$

The single- and two-photon gains, $Q_{1,1}$ and $Q_{2,2}$, and phase-error rates, $e_{1,1}^X$ and $e_{2,2}^X$, are more complicated in calculation. In the infinite-decoy setup, we calculate the photon gains directly. We decompose the thermal noise $\hat{\rho}_{\mathrm{th}}$ into Fock states,

$$\hat{\rho}_{\mathrm{th}} = \sum_{k=0}^{\infty}\frac{\bar{k}^k}{(\bar{k}+1)^{k+1}}|k\rangle\langle k|, \tag{D5}$$

where $\bar{k} = \xi/2(1-\eta)$ is the average photon number of the thermal noise. The optical mode from Alice can be seen as mixing with the thermal noise through an η-transmittance beam splitter. We calculate the effect of the thermal noise in an ensemble manner, that is, we calculate the case where the channel injects k and l noise photons to the two consecutive optical modes respectively, and mix the results according to the noise photon-number distribution in Eq. (D5). We set a cutoff photon-number at $N_c = 3$ since the thermal noise is relatively low. Simulation shows that higher cutoffs have negligible effects on the key rate. We also account for the effects of the misalignment angle δ, which introduces a $\sin^2(m\delta/2)$ error to the m-photon phase error rate. We ignore the correlation between the misalignment and thermal noise photon as a second-order small quantity.

The calculations of the quantities of interest are listed below. The notation of (k, l) represents the conditional probability that the thermal sources emit k and l photons respectively to the two optical modes:

1. The probability of sending $(|01\rangle\langle 01| + |01\rangle\langle 01|)/2$ whilst accepting one photon in total (Eq. (23)):

$$Q_{1,1}(k,l) = c_1 \mathrm{Pr}(1)\eta^{k+l-1}\left\{[(k+1)\eta - k]^2 + l(k+1)(1-\eta)^2\right\}, \tag{D6}$$

$$Q_{1,1} = \sum_{k=0,l=0}^{N_c} \mathrm{P_{th}}(k)\mathrm{P_{th}}(l)Q_{1,1}(k,l), \tag{D7}$$

where

$$\mathrm{P_{th}}(k) = \frac{\bar{k}^k}{(\bar{k}+1)^{k+1}} \text{ with } \bar{k} = \frac{\xi}{2(1-\eta)}. \tag{D8}$$

2. The probability of sending $(|01\rangle \pm |10\rangle)/\sqrt{2}$ whilst receiving $(|01\rangle \mp |10\rangle)/\sqrt{2}$ (Eq. (21)):

$$\frac{e^X_{1,1}(k,l)Q_{1,1}}{\mathrm{Pr}(1)} = \frac{c_1}{4}\eta^{k+l-1}(1-\eta)^2(k^2+l^2+k+l) + c_1\sin^2\left(\frac{\delta}{2}\right), \tag{D9}$$

$$e^X_{1,1} = \sum_{k=0,l=0}^{N_c} \mathrm{P_{th}}(k)\mathrm{P_{th}}(l)e^X_{1,1}(k,l). \tag{D10}$$

3. The probability of sending $(|02\rangle\langle 02| + |20\rangle\langle 20|)/2$ whilst accepting within the $(|02\rangle\langle 02| + |20\rangle\langle 20|)$ and $|11\rangle\langle 11|$ subspace (Eq. (26)):

$$Q^{02}_{2,2}(k,l) = \frac{1}{2}c^{02}_2\,\mathrm{Pr}(2)\eta^{k+l-2}\left\{\left[\eta^2 - 2k\eta(1-\eta) + \frac{1}{2}k(k-1)(1-\eta)^2\right]^2 + \frac{1}{4}l^2(l-1)^2(1-\eta)^4\right\} + \{k \leftrightarrow l\}, \tag{D11}$$

$$Q^{11}_{2,2}(k,l) = \frac{1}{2}c^{11}_2\,\mathrm{Pr}(2)\eta^{k+l-2}\left[\sqrt{2(k+1)l}\eta(1-\eta) - \sqrt{\frac{1}{2}kl(k+1)(1-\eta)^2}\right]^2 + \{k \leftrightarrow l\}, \tag{D12}$$

$$Q_{2,2} = \sum_{k=0,l=0}^{N_c} \mathrm{P_{th}}(k)\mathrm{P_{th}}(l)\left[Q^{02}_{2,2}(k,l) + Q^{11}_{2,2}(k,l)\right], \tag{D13}$$

where the expression $\{k \leftrightarrow l\}$ denotes exchanging the k's and l's in the term ahead.

4. The probability of sending $(|02\rangle \pm |20\rangle)/\sqrt{2}$ whilst receiving $(|02\rangle \mp |20\rangle)/\sqrt{2}$ and $|11\rangle$ (Eq. (24)).

$$\frac{e^{02,X}_{2,2}(k,l)Q_{2,2}}{\mathrm{Pr}(2)} = \frac{c^{02}_2}{4}\eta^{k+l-2}\left[2(k-l)(1-\eta)\eta + (k^2-k-l^2-l)(1-\eta)^2\right]^2 + c^{02}_2\sin^2(\delta), \tag{D14}$$

$$\frac{e^{11,X}_{2,2}(k,l)Q_{2,2}}{\mathrm{Pr}(2)} = c^{11}_2\eta^{k+l-2}(1-\eta)^2\left\{l(k+1)\left[\eta - \frac{1}{2}k(1-\eta)\right]^2 + k(l+1)\left[\eta - \frac{1}{2}l(1-\eta)\right]^2\right\}, \tag{D15}$$

$$\frac{e^X_{2,2}Q_{2,2}}{\mathrm{Pr}(2)} = \sum_{k=0,l=0}^{N_c} \mathrm{P_{th}}(k)\mathrm{P_{th}}(l)\left[e^{02,X}_{2,2}(k,l) + e^{11,X}_{2,2}(k,l)\right]. \tag{D16}$$

In the finite-decoy setup, the estimations of photon gains are derived from the statistics of coherent-state gains. We need to calculate the probability of transmitting certain coherent states whilst receiving certain photon states. This can be also be done by the Gaussian-state Wigner function. Let $\kappa = 2/(2+\xi)$. Denote the output of a thermal noise channel when transmitting the coherent state $|\alpha\rangle$ as ρ_α. Its Fock-basis matrix elements are:

$$\langle 0|\,\rho_\alpha\,|0\rangle = \kappa\exp(-\kappa|\alpha|^2), \tag{D17}$$

$$\langle 1|\,\rho_\alpha\,|1\rangle = \kappa(\kappa^2|\alpha|^2 + 1 - \kappa)\exp(-\kappa|\alpha|^2), \tag{D18}$$

$$\langle 0|\,\rho_\alpha\,|1\rangle = -\kappa^2\alpha^*\exp(-\kappa|\alpha|^2), \tag{D19}$$

$$\langle 2|\,\rho_\alpha\,|2\rangle = \kappa(\frac{1}{2}\kappa^4|\alpha|^4 + 2(\kappa^2-\kappa^3)|\alpha|^2 + (1-\kappa^2))\exp(-\kappa|\alpha|^2), \tag{D20}$$

$$\langle 0|\,\rho_\alpha\,|2\rangle = \frac{1}{\sqrt{2}}\kappa^3(\alpha^*)^2\exp(-\kappa|\alpha|^2). \tag{D21}$$

The statistics required by the decoy method are all based on the gains of separable coherent states. For example, the probability of sending $|\alpha\rangle\otimes|\beta\rangle$ whilst receiving $(|02\rangle + |20\rangle)/\sqrt{2}$ can be computed by

$$\begin{aligned}&\frac{1}{2}(\langle 02| + \langle 20|)\rho_\alpha\otimes\rho_\beta(|02\rangle + |20\rangle)\\ =\ &\frac{1}{2}\left(\langle 0|\,\rho_\alpha\,|0\rangle\,\langle 2|\,\rho_\beta\,|2\rangle + \langle 2|\,\rho_\alpha\,|2\rangle\,\langle 0|\,\rho_\beta\,|0\rangle + \langle 0|\,\rho_\alpha\,|2\rangle\,\langle 2|\,\rho_\beta\,|0\rangle + \langle 2|\,\rho_\alpha\,|0\rangle\,\langle 0|\,\rho_\beta\,|2\rangle\right).\end{aligned} \tag{D22}$$

Abstract. We explore a hybrid QKD protocol that leverages advantages of discrete and continuous-variable protocols to enhance the feasibility for near-term implementation of global quantum communications and compatibility with existing telecommunications architectures. Security proofs for hybrid protocols inherit challenges associated with unbounded dimensions. We address these challenges by exploiting symmetry. Our approach enables truncation of the Hilbert space with precise control of the approximation errors, leading to tight, semi-analytical expressions for the asymptotic key rate under collective attacks. We explore the performance of our protocol under passive attacks, linear loss, and Gaussian noise.

Keywords: Hybrid quantum information theory, quantum key distribution, quantum networking.

Global quantum communications are in the vanguard of early application of quantum technologies [1, 2]. A pressing challenge in transforming quantum cryptographic protocols to implementation is the disparity between theory and experiments. Closing this disparity in *discrete-variable* (DV) and *continuous-variable* (CV) *quantum key distribution* (QKD) has been the subject of significant effort [3, 4]. A hybrid approach has recently emerged as an exciting and promising solution towards practical implementation [5, 6, 7]. The central motivation behind hybrid protocols is to assimilate the best features of both DV and CV protocols to generate mature security proofs, simplify implementation, and improve compatibility with existing telecommunication infrastructures.

An immediate difficulty in the maturity of hybrid protocols is that they inherit an infinite-dimensional Hilbert space from CV protocols, which introduces technical challenges for their security proofs. In this work, we explore the potential of single-photon-based hybrid QKD, where information is encoded in discrete polarisation variables and decoded continuously via heterodyne detection. We provide the first rigorous security proof for hybrid protocols within the collective attack framework to establish a tight lower bound on the asymptotic key rate, allowing for semi-analytical expressions. We conclude by assessing the practical implementation and deployment of our hybrid protocol across large-scale quantum networks. For complete details, see Ref. [8].

One of the central results in this work is our use of state symmetries to establish novel invariant states that are exploited in our security proof. In particular, the symmetry we appeal to is the invariance of two-party composite states under $(U \otimes U^*)$ transformations, where U belongs to the special unitary SU(2) Lie group that physically represents a linear-optics passive unitary acting on two polarisation modes. Crucially, the invariant states we derive have a significantly reduced parameterisation, which provides a quadratic speedup in the numerical calculation of the secret key rate [9, 10, 11] and enables an truncation of the Hilbert space with precise control of the approximation errors. The tightness of our method enables higher key rates and increased robustness to noise over previous security proofs. We quantify this improvement within an experimentally feasible parameter space, providing insights into the current readiness for implementation. Additionally, we compare the performance of hybrid protocols with DV and CV protocols to discuss their current viability for applications in quantum networking, which remains an important open question in the field. As such, this work is first to quantify tradeoffs in the use of hybrid protocols that would be instrumental in guiding future research into their use for quantum networking.

To start, we provide an outline of the hybrid protocol. Two polarisation modes are used by the transmitter (Alice) to encode quantum information. The receiver (Bob) uses an independent detection model to infer the encoded bit value [5]. This detection model uses a heterodyne measurement on the state to compare the output with a given threshold value $\tau > 0$. Threshold measurements are described by the *positive operator-valued measure* (POVM) elements $M_H = R_1^H \otimes R_0^V$ and $M_V = R_0^H \otimes R_1^V$, where

$$\begin{aligned} R_0^u &= \frac{1}{\pi}\int_{|\beta|^2 \le \tau} d^2\beta \, |\beta\rangle_u\langle\beta| = \sum_{n=0}^{\infty}(1-\lambda_n)\,|n\rangle_u\langle n| \,, \\ R_1^u &= \frac{1}{\pi}\int_{|\beta|^2 > \tau} d^2\beta \, |\beta\rangle_u\langle\beta| = \sum_{n=0}^{\infty}\lambda_n\,|n\rangle_u\langle n| \,, \end{aligned} \tag{1}$$

with $u \in \{H, V\}$, $\lambda_n = \Gamma[1+n,\tau]/n!$ and Γ the incomplete gamma function. This inference is a key map that identifies a horizontally (vertically) polarised photon following a successful detection associated to the measurement outcome M_H (M_V). Events corresponding to the null outcome $M_0 = I - M_H - M_V$ are discarded and do not contribute to key generation. Alice and Bob repeat this procedure m times. The raw keys are post-processed for parameter estimation, error correction, and privacy amplification, in a manner equivalent to standard BB84.

We use the *entanglement-based* (EB) representation to assess the security of our protocol, where Alice prepares the entangled polarisation state

$$|\phi\rangle_{AA'} = (|H\rangle_A|H\rangle_{A'} + |V\rangle_A|V\rangle_{A'})/\sqrt{2}\,. \tag{2}$$

[*] jsmdrsidhu@gmail.com
[†] cosmo.lupo@poliba.it

A noisy communication channel $\mathcal{N}_{A'\to B}$ maps this state into $\rho_{AB} = I_A \otimes \mathcal{N}_{A'\to B}(|\phi\rangle_{AA'}\langle\phi|)$ where I_A is the identity channel acting on photon A. In the limit of $m \to \infty$, the asymptotic secret key rate rate for collective attacks is given by [9, 10, 11]

$$r = \max_{\tau>0} \min_{\rho_{AB}\in\mathcal{S}} D\left[\mathcal{G}(\rho_{AB})\|\mathcal{Z}(\mathcal{G}(\rho_{AB}))\right] - Qh_2(E)\,, \quad (3)$$

where $D[\cdot\|\cdot]$ is the quantum relative entropy, $\mathcal{G}$ is a partial isometry key map that gives a coherent representation of the measurement and decoding applied by the receiver

$$\mathcal{G}(\rho_{AB}) = (I \otimes K)\rho_{AB}(I \otimes K^\dagger)\,, \quad (4)$$

with

$$K = |H\rangle_{B_1} \otimes \sqrt{M_H} + |V\rangle_{B_1} \otimes \sqrt{M_V}\,, \quad (5)$$

and where $\mathcal{Z}$ is a pinching map that induces complete dephasing to the auxiliary system B_1. The second term in Eq. (3) accounts for the number of bits per photon leaked during error correction and is determined through the gain Q, which defines the probability that Bob obtains a valid measurement output, and the *qubit error rate* (QBER) E, with $h_2(x)$ the binary Shannon entropy. Since the communication channel $\mathcal{N}_{A'\to B}$ is generally unknown, the asymptotic key rate is determined from Eq. (3). The minimisation is constrained over the set $\mathcal{S}$ of feasible states that are compatible with an experimental implementation. These constraints ensure: **(I)** the reduced state of Alice photon remains maximally mixed, **(II)** the gain Bob estimates from experimental data matches the trace of the state $\mathcal{G}(\rho_{AB})$, such that $Q = \mathrm{Tr}[(M_H + M_V)\rho_B]$, **(III)** the experimentally estimated error, c, matches the expectation value $\mathrm{Tr}[(|H\rangle\langle H| \otimes M_V + |V\rangle\langle V| \otimes M_H)\rho_{AB}]/2$, such that $E = 2c/Q$ [12], and **(IV)** experimental estimates for the photon number distribution, P_j, of the unknown state ρ_{AB} obtained by Bob via heterodyne detection [13] matches $P_j = \sum_{a=0}^{j} \mathrm{Tr}[(|a\rangle_H\langle a| + |j-a\rangle_V\langle j-a|)\rho_B]$ up to a certain photon number k. Constraints **(II)-(IV)** define an experimentally feasible optimisation region. The key rate in Eq. (3) is optimised over the detector threshold.

As a first example, we explore the performance of our hybrid protocol over a pure loss channel. The communication channel $\mathcal{N}_{A'\to B}$ is a wiretap channel that induces polarisation-independent loss with transmissivity factor $\eta \in [0,1]$. Since all qubits reaching Bob are secure, we find $Q = D[\rho_{AB}]$ allowing a simple analytic expression for the asymptotic secret key rate $r = Q(1 - h_2(E))$. From this, we find that our hybrid protocol scales as $\mathcal{O}(\eta^2)$ in the limit of large communication distances ($\eta \ll 1$). Most DV and CV protocols are characterised by a linear scaling $\mathcal{O}(\eta)$. The worse scaling of hybrid protocols than discrete-variable ones is due to decreasing gain with increasing range, and is the penalty to pay for improved compatibility with terrestrial networks. This work is the first to quantify this tradeoff that would be instrumental in guiding future research into the use of hybrid protocols for quantum networking. We find the optimal value for the detector threshold is $\tau \simeq 1.59$ at large distances.

For communication channels beyond pure-loss, the key rate must be evaluated numerically using Eq. (3) since we no longer know ρ_{AB}. The security of our protocol becomes challenging on two accounts. First, since the Hilbert space associated with the receiver is infinite-dimensional, a cutoff into a finite-dimensional subspace is required. Despite this, the joint state ρ_{AB} truncated to k photons on Bob's side, scales quadratically with k, maintaining a significant bottleneck for efficient numerical optimisation. Second, such a truncation introduces a cutoff error, which could impact the security of the keys.

We solve both challenges by exploiting symmetries to make the protocol invariant under local *linear-optics passive* (LOP) transformations of the form $(U \otimes U^*)$, where U belongs to the SU(2) Lie group [14]. In the EB representation, this invariance maps any joint state ρ_{AB} into the invariant state,

$$\rho_{AB}^{(\mathrm{inv})} = \int d\mu_U\ (U \otimes U^*)\rho_{AB}(U \otimes U^*)^\dagger\,, \quad (6)$$

where $d\mu_U$ is the Haar measure on the group. Since LOP unitaries are passive, our invariant states are block-diagonal in the photon number basis. The invariant states we derive have a significantly reduced parameterisation from quadratic to linear in the cutoff photon number k. By symmetrising our hybrid protocol, we greatly simplify the security analysis to provide an exact numerical optimisation with full control of the error due to finite-dimensional cut-off, and semi-analytical expressions for the key rate. Explicit expressions for the invariant states associated with different photon number subspaces are derived in our supporting technical manuscript in Ref. [8].

To take advantage of our invariant states, note that Bob will observe a distribution of photon numbers after a general attack. Since the invariant states are block-diagonal in the number basis, we can write

$$\rho_{AB}^{(\mathrm{inv})} = \sum_{j=0}^{\infty} P_j \rho_{1:j}^{(\mathrm{inv})} \geq P_0\rho_{1:0}^{(\mathrm{inv})} + \sum_{j=1}^{k} P_j \rho_{1:j}^{(\mathrm{inv})}(f_j)\,, \quad (7)$$

where $\rho_{1:j}^{(\mathrm{inv})}$ is an invariant state with one photon on Alice side and j photons on Bob side, P_j is the probability of having j, and k is the photon number cutoff. In our supporting technical paper (Ref. [8]), we demonstrate that for $j = 0$ the invariant state associated with the vacuum subspace is unique and for all $j > 0$ there exists a one-parameter family of invariant states, $\rho_{1:j}^{(\mathrm{inv})}(f_j)$, with $f_j \in [0,1]$, which accounts for the second term within the inequality in Eq. (7). Similarly, by linearity, constraints **(II)-(IV)** generalise to a sum over each photon subspace. Since $\mathcal{G}(\rho_{1:j}^{(\mathrm{inv})})$ and $\mathcal{Z}(\mathcal{G}(\rho_{1:j}^{(\mathrm{inv})}))$ have orthogonal support for all $j \neq j'$, the relative entropy in Eq. (3) is the sum of relative entropies evaluated on each photon subspace. By using invariant states, the optimisation of the asymptotic key rate in Eq. (3) for a cutoff photon number k is suppressed from k^2 parameters to k parameters $f_j \in [0,1]$, for $j = 1, \ldots, k$, demonstrating a quadratic speedup.

Our key rate framework can be immediately used to model any general communication channel $\mathcal{N}$. We first consider passive attacks, which preserve the number of photons in the channel thereby limiting the minimisation of the key rate to the vacuum and single-photon subspace on Bob's side $\rho_{AB}^{(\mathrm{inv})} = (1-\eta)\rho_{1:0}^{(\mathrm{inv})} + \eta\rho_{1:1}^{(\mathrm{inv})}(f_1)$, where η is the channel transmissivity. We show it is possible to

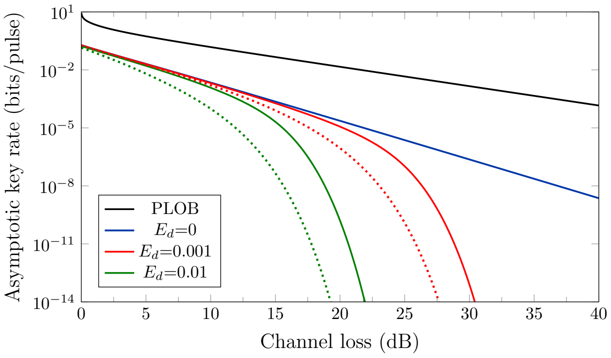

Figure 1: **Protocol comparison**: Asymptotic key rate vs loss (dB) for our symmetrised hybrid protocol (solid lines) and Ref. [5] (dotted lines), for different error probabilities, E_d. Black line illustrates PLOB bound [15].

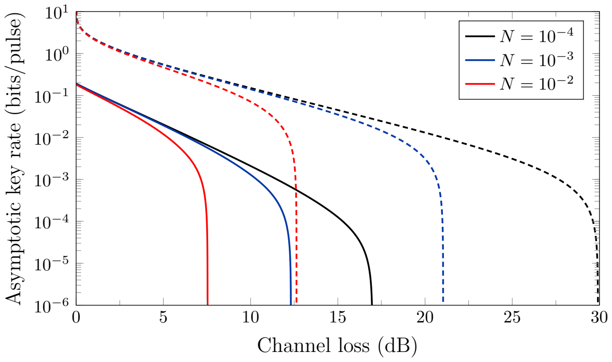

Figure 2: **Comparing with continuous-modulation**: Asymptotic key rates vs loss (dB) for our theory (solid lines) and continuous-modulation CV QKD (dashed lines) for different excess noise, quantified through N.

analytically solve the key rate optimisation in our technical manuscript, where we also derive a solution for f_1 in terms of the two experimentally accessible parameters Q and c. We also use the passive channel to compare the performance of our symmetrised hybrid protocol with the unsymmetrised variant in Ref. [5]. This comparison is illustrated in Fig. 1 as a function of the detector misalignment, quantified by the parameter E_d. The ideal case of $E_d = 0$ reduces the key rate to that of passive attacks and matches the result in Ref. [5]. For practical scenarios with $E_d > 0$, our theory (solid lines) provides higher rates than previous methods (dashed lines) and can also tolerate higher channel losses.

Since electronic noise is a significant challenge for QKD protocols based on coherent detection, we include its effects in a general communication channel to explore the robustness of our hybrid protocol against noisy heterodyne detection. We model electronic noise as a Gaussian noise with zero mean and variance N, which transforms each mode of the field according to map

$$\rho \to \int \frac{d^2\alpha}{\pi N} e^{-|\alpha|^2/N} \mathcal{D}(\alpha)\rho\mathcal{D}(\alpha)^{\dagger}\,, \tag{8}$$

where $\mathcal{D}(\alpha)$ is the displacement operator. Note that this map preserves $(U \otimes U^*)$ symmetry. The communication channel, $\mathcal{N}_{A'\to B}$, we model from Alice to Bob is a Gaussian channel that first applies a pure-loss channel of transmissivity η, followed by mode-wise application of the channel in Eq. (8).

The asymptotic key rate can then be lower bounded with the number of bits per photon leaked for error correction given by $Q_{(3)}h_2[2c_{(3)}/Q_{(3)}]$. The rate must be determined by choosing suitable bounds for both the gain and error parameter, $Q_{(3)}$ and $c_{(3)}$ respectively that do not impact the security. Since the error correction function monotonically increases with both parameters, an upper bound on the number of bits per photon leaked during error correction is obtained from upper bounds on $Q_{(3)}$ and $c_{(3)}$. Suitable upper bounds are derived in our technical paper. Note that in this example, the rate is expected to be tight if the variance N of the Gaussian noise is not too large, a condition that implies a small value for the probability $(1 - \sum_{j=0}^{3} P_j)$.

The key rate is illustrated in Fig. 2. The hybrid protocol is sensitive to excess noise in the detector with $N = 10^{-6}$ closely approximating the ideal scenario of no electronic noise. Suppression of excess noise down to the 10^{-4} regime in CV-QKD is possible through carrier frequency switching [16]. In Fig. 2 we compare the performance of our hybrid protocol with CV QKD. In particular, we used the reverse coherent information from Ref. [17], which gives an upper bound on the key rate achievable in CV QKD with heterodyne detection and reverse reconciliation. For an excess noises of $N = 10^{-4}$, our scheme can tolerate losses up to ∼17 dB, corresponding to an optical fibre transmission of 85 km. The protocol can therefore deliver high-rate QKD in terrestrial or free-space quantum networks over metropolitan scales.

In conclusion, hybrid protocols combine the salient features of DV and CV protocols to adopt mature security proofs and improved compatibility with existing telecommunication infrastructures. Returning to the original motivation of improving the implementation of QKD protocols, our symmetrised hybrid protocol achieves this in a number of ways. First, in contrast to DV QKD, our hybrid protocol allows for the use of faster receivers and does not require sifting since a single decoding measurement applies to both encoding bases. Second, in contrast to CV QKD, our hybrid protocol does not require a shared local oscillator or a pilot tone. This significantly reduces transmitter and receiver complexity and the potential for side-channel attacks [18, 19]. Combined with a key rate optimiser that is closely aligned to an experimental implementation, our work provides a feasible route towards practical implementation of the protocol.

This work introduces several technical results. First, we establish a rigorous security proof under collective attacks to yield a tight lower bound on the asymptotic key rate for single-photon-based hybrid QKD. Second, we introduce a method to derive invariant states by exploiting state symmetries allowing for a quadratic speed-up in the numerical rate optimisation and providing a general utility. We explore the performance of our hybrid protocol within an experimentally feasible parameter space, to show it can deliver high rate metropolitan-scale QKD. We also quantify the tradeoff between hybrid QKD protocols and CV/DV approaches that would be instrumental to guide future research in quantum networking. Collectively, these technical results constitute an advance in understanding the utility of hybrid QKD.

Generation of three-dimensional cluster entangled state

Young-Sik Ra[1] *

[1] *Korea Advanced Institute of Science and Technology (KAIST), Daejeon 34141, South Korea*

Abstract. Measurement-based quantum computing is a promising paradigm of quantum computation, where universal computing is achieved through a sequence of local measurements. The backbone of this approach is the preparation of multipartite entanglement, known as cluster states. While a cluster state with two-dimensional (2D) connectivity is required for universality, a three-dimensional (3D) cluster state is necessary for additionally achieving fault tolerance.

In this talk, I will present the experimental generation of a 3D cluster state based on the continuous-variable optical platform (arXiv:2309.05437 (2023)). To realize 3D connectivity, we harness a crucial advantage of time-frequency modes of ultrafast quantum light: an arbitrary complex mode basis can be accessed directly, enabling connectivity as desired.

In the second part of my talk, I will discuss another topic: the characterization of multimode quantum channels. Specifically, I will present our recent experiment on the complete characterization of Bosonic Gaussian channels in multiple time-frequency modes.

This work aims to answer the following question: what is the difference between 'low-magic' entanglement and 'high-magic' entanglement? We take an operational approach to understanding the relationship between magic and entanglement by studying tasks such as entanglement estimation, distillation, and dilution. This approach reveals that magic has notable implications for entanglement. Specifically, we find an operational separation that divides Hilbert space into two distinct regimes: the entanglement-dominated (ED) phase and magic-dominated (MD) phase. Roughly speaking, ED states have entanglement that significantly surpasses their magic, while MD states have magic that dominates their entanglement. The competition between the two resources in these two phases induces a computational phase separation between them: there are sample- and time-efficient quantum algorithms for almost any entanglement task on ED states, while these tasks are provably computationally intractable in the MD phase. Our results find applications in diverse areas such as quantum error correction, many-body physics, and the study of quantum chaos, providing a unifying framework for understanding the behavior of quantum systems.

Keywords: Entanglement theory, Magic-state resource theory, computational phase-transition, computationally bounded observers, entanglement estimation, entanglement cost, entanglement distillation, entanglement reversibility, entanglement witnessing, multipartite entanglement, topological entanglement, entanglement robustness.

This work is based on Refs. [1, 2].

I. Overview

Entanglement serves as a foundational pillar in quantum information theory, delineating the boundary between what is classical and what is quantum [3, 4]. The common assumption is that higher entanglement corresponds to a greater degree of 'quantumness'. However, this folk belief is challenged by the fact that classically simulable operations, such as Clifford circuits, can create highly entangled states [5]. The simulability of these states is suggestive: are there qualitative differences between the 'low-magic' entanglement generated by Clifford circuits, and 'high-magic' entanglement generated by non-Clifford circuits? Perhaps there are finer-grained aspects of entanglement, even in the bipartite case, that cannot be captured by quantifying it along a single axis. For a full understanding of the nature of entanglement in a state, might it be necessary to know something about the state's magic?

Motivated by these questions, this work presents a rigorous investigation on the role of magic in entanglement theory. We take an operational approach to understanding their relationship. While this perspective has long been used to study entanglement [6], the role of magic has never been addressed in such analyses; indeed, there has been no reason to expect that magic has any implications for entanglement tasks. In this work, we show that not only does magic have surprisingly strong implications for entanglement, but we also offer a complete characterization of these implications. We find a sharp operational distinction that splits Hilbert space into two distinct phases: the entanglement-dominated (ED) phase and magic-dominated (MD) phase. Roughly speaking, the ED phase contains states whose entanglement significantly surpasses their magic, while the MD phase corresponds to cases where magic dominates entanglement. These two phases are demarcated by a computational separation induced by the competition between the two resources. That is, there are sample- and time-efficient quantum algorithms that solve a number of entanglement detection and manipulation problems for ED states. Conversely,

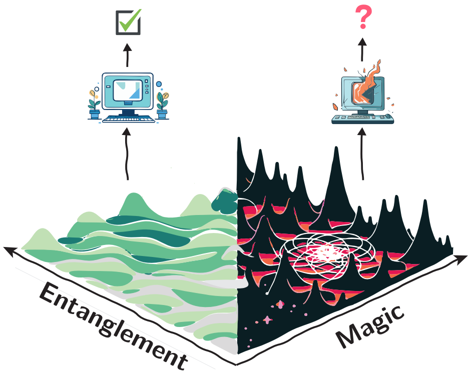

FIG. 1. Entanglement structure of states in the ED and MD phases.

[*] andigu@g.harvard.edu
[†] salvatore.oliviero@sns.it
[‡] lorenzo.leone@fu-berlin.de

we show that entanglement detection and manipulation is provably computationally intractable in the MD phase.

The first problem we study is the ubiquitous task of measuring entanglement entropy. We begin by describing an efficient algorithm to estimate the entanglement entropy of any ED state with vanishing error, even for volume-law states; in contrast, we show that in the MD phase, accurate entanglement estimation is inefficient beyond logarithmic entanglement (below this, the swap test allows for efficient estimation). We then turn to entanglement manipulation — specifically, entanglement distillation and dilution. We show that within the class of ED states, we can always efficiently find a polynomial-depth circuit that distills almost all of the entanglement into Bell pairs. We also prove the converse, which says that, in the MD phase, it is impossible to find such efficient and optimal distillation protocols. This reveals a sharp computational separation in distillable entanglement. Similarly, we demonstrate that we can always identify an efficient dilution protocol that utilizes an optimal number of Bell pairs to prepare any state in the ED phase. Conversely, for MD states, we rule out the existence of an efficient dilution protocol that consumes an optimal number of Bell pairs. These findings reveal a computational separation in entanglement cost between ED and MD states. Combining insights from both entanglement dilution and distillation, we uncover a sharp distinction in the entanglement structure of ED and MD states, illustrated in the ED-MD phase diagram (Fig. 1). Within the ED phase, entanglement is structured in a manner that can always be manipulated efficiently and (almost) reversibly. In contrast, within the MD phase, entanglement manipulation is generally inefficient and irreversible.

As applications of our theory, we present efficient entanglement witnesses for noisy ED states, which in turn reveals that the entanglement of ED states is far more robust than typical states, whose entanglement robustness is limited by the Fannes inequality. We also develop an efficient testing algorithm which can classify states within the ED and MD phases. To conclude, we highlight the relevance of our findings in many-body physics by showcasing a broad class of physically relevant Hamiltonians whose eigenstates are all in the ED phase. As one application of this, we demonstrate the robustness of topological entanglement entropy in 3D topological models such as the X-cube model and Haah's code. We also find connections between stabilizer code Hamiltonians and ED states, which extends the applicability of our results to quantum error correcting codes.

II. Computational ED-MD separation

We first formally define the entanglement- and magic-dominated phases. We note that the majority of states in the Hilbert space are MD. However, it is well-known that most states in Hilbert space also cannot be prepared in polynomial time, hence are irrelevant in practice [7–9]. In contrast, ED states are ubiquitous. For instance, typical Clifford-dominated circuits with $o(n)$ non-Clifford gates (importantly, this far exceeds the classical simulability limit $O(\log n)$) produces ED states almost surely. This is just one example; ED states can be generated by circuits that have up to $o(\exp(n))$ non-Clifford gates. Let us now define ED and MD states, using *stabilizer nullity* ν as a measure of magic [10] and *entanglement entropy* S as an entanglement measure.

Definition 1 (Entanglement and magic-dominated phases)**.** *Let $|\psi\rangle$ be a state with $2^{n-\nu}$ Pauli stabilizers; we say that this state has stabilizer nullity ν. Let $A|B$ a bipartition and let $S(\psi_A)$ be the von Neumann entropy of $\psi_A \equiv \mathrm{Tr}_B |\psi\rangle\langle\psi|$. $|\psi\rangle$ is entanglement-dominated if $S(\psi_A) = \omega(\nu)$, and it is magic-dominated if $S(\psi_A) = O(\nu)$.*

We will study the measurability and manipulability of entanglement in these two classes of states. For entanglement manipulation, there are two tasks: entanglement distillation and dilution. The goal of entanglement distillation is to use LOCC to transform a state ψ into as many Bell pairs M_+ as possible. This number is the *distillable entanglement* of ψ. For the reverse of entanglement distillation, namely entanglement dilution, the aim is to prepare ψ via LOCC using a minimal number of Bell pairs M_-, which is called the *entanglement cost* of ψ.

Theorem 1 (Efficient entanglement measurement and manipulation for ED states)**.** *Let $|\psi\rangle$ be an ED state across the bipartition $A|B$. There exists sample- and time-efficient algorithms for each of the following tasks.*

1. Entanglement estimation: *Estimates $S(\psi_A)$ up to an $o(1)$ relative error.*
2. Entanglement distillation: *Distills M_+ Bell pairs from ψ using LOCC operations, with $M_+/S(\psi_A) = 1 - o(1)$. Unlike more conventional protocols [11], this protocol requires only a single copy of the input state and makes no error: it is a* one-shot, zero error protocol.
3. Entanglement dilution: *Prepares ψ across the bipartition $A|B$ using LOCC, M_- Bell pairs, where $M_-/S(\psi_A) = 1 + o(1)$, and $N_{\mathrm{CC}} = o(S(\psi_A))$ bits of classical communication.*

Theorem 2 (Hardness of entanglement estimation and manipulation for MD states)**.** *There are no sample- and time-efficient quantum algorithms for entanglement characterization and manipulation within the MD phase.*

1. Entanglement estimation*: There is no efficient protocol which can estimate $S(\psi_A)$ to within a constant relative error for arbitrary MD states.*
2. Entanglement distillation*: The (efficient) distillable entanglement for general MD states is $M_+/S(\psi_A) = o(1)$.*
3. Entanglement dilution*: The (efficient) entanglement cost for arbitrary MD states. is $M_-/S(\psi_A) = \omega(1)$.*

Protocol	Entanglement-dominated	Magic-dominated
An efficient state-agnostic protocol which produces an estimate $\tilde{S}(\psi_A)$ of the true entanglement $S(\psi_A)$.	$\frac{\lvert S(\psi_A)-\tilde{S}(\psi_A)\rvert}{S(\psi_A)} = o(1)$	$\frac{\lvert S(\psi_A)-\tilde{S}(\psi_A)\rvert}{S(\psi_A)} = \omega(1)$
An efficient state-agnostic LOCC protocol which distills M_+ Bell pairs from the state ψ.	$M_+/S(\psi_A) = 1 - o(1)$	$M_+/S(\psi_A) = o(1)$
An efficient state-agnostic LOCC protocol which uses M_- Bell pairs to prepare ψ across $A\vert B$.	$M_-/S(\psi_A) = 1 + o(1)$	$M_-/S(\psi_A) = \omega(1)$

TABLE I. Schematic of the ED-MD separation within entanglement theory. Based on Theorem 1 and Theorem 2.

III. Applications of ED-MD separation

Multipartite entanglement distillation. Besides bipartite entanglement distillation, there's also the challenge of multipartite entanglement distillation. In this scenario, if k parties share an entangled state, their goal is to distill some target k-partite entangled state (e.g., a GHZ state) using LOCC operations. Interestingly, it has been established that this task is unachievable for the vast majority of states [12, 13]. However, identifying a generalization of the ED phase in k-partite setting, we show that we can *deterministically* distill many copies of a k-partite GHZ state from ED states using an efficient LOCC protocol.

Entanglement witnessing and robustness. While precisely measuring entanglement can be a challenging and noise-sensitive task, the less ambitious goal of merely witnessing entanglement can be easier and more noise-resilient [14, 15]. The purpose of a witness is to experimentally validate the presence of genuine entanglement in an imperfectly prepared version of the target state. We define an entanglement witness for ED states that can be measured with $O(1)$ sample complexity. We strengthen this result by defining a similar witness for multipartite entanglement. This witness verifies entanglement across k parties — that is, it rules out the possibility of the state being unentangled across any of the k given partitions. As a corollary of this, we find that entanglement for ED states can be far more robust than the entanglement of generic states. The reason for this is as follows. The Fannes inequality roughly says that $|S(\rho_A) - S(\psi_A)| \lesssim n_A T$, where T is the trace distance between ψ and its noisy version ρ. If ψ were a generic state with $S(\psi_A) \sim \sqrt{n_A}$, then we would generally need $T < 1/\sqrt{n_A}$ to guarantee that ρ were not separable across $A|B$. On the other hand, if ψ were in the ED phase, we show that we could tolerate up to $T \lesssim 1 - 2^{-\Omega(\sqrt{n_A})}$, showing that the entanglement within the ED phase is extremely robust.

Phase classification and testing. In light of the clear divide between ED-MD phases, one might ask whether it is possible, given query access to an unknown state $|\psi\rangle$, to determine the phase in which it resides. We formalize this task as a property testing problem and show that the separation between ED-MD phases can indeed be efficiently tested. More precisely, we present a polynomial-time algorithm that can discriminate whether $|\psi\rangle$ is an ED state or it is ϵ-far from any state in the ED phase and, as such, lies in the MD phase.

Applications to physics. We conclude by discussing the implications of our results in the context of many-body physics by first showcasing a broad class of many-body Hamiltonians whose eigenstates are all ED states. We use these Hamiltonians to study the robustness of topological entanglement entropy to perturbations in models such as the X-cube model or Haah's code. Taking advantage of the fact that the topological entanglement entropy in these models scales extensively, we show that this topological entanglement persists under any perturbation to the Hamiltonian that has a subextensive (i.e., $o(n)$) number of terms.

IV. Summary

We believe our findings will captivate the AQIS audience for several reasons. Our work links two ostensibly unrelated quantum resources — entanglement and magic. We rigorously establish the surprising existence of a sharp computational separation, across various entanglement-related tasks, between two classes of states which are characterized by the dominance of either entanglement or magic. We introduce a variety of innovative techniques, including a 'deformed' stabilizer formalism, and a new encoding strategy for pseudorandom quantum states. Moreover, our approach goes beyond the mere information-theoretic framework. The existence of these two phases has strong implications for entanglement detection in noisy experiments. Additionally, our techniques have profound consequences for many seemingly unrelated areas. For instance, we apply our results to many-body physics, showing the robustness of topological entanglement entropy. In summary, this work not only offers a fresh perspective on resource theories but also makes conceptual and theoretical contributions to multiple research areas.

Notions of nonstabilizerness, or "magic", quantify how non-classical quantum states are in a precise sense: states exhibiting low nonstabilizerness preclude quantum advantage. We introduce 'pseudomagic' ensembles of quantum states that, despite low nonstabilizerness, are computationally indistinguishable from those with high nonstabilizerness. Our work is driven by the observation that only quantities measurable by a *computationally bounded observer* – intrinsically limited by finite-time computational constraints – hold physical significance. Ultimately, our findings suggest that nonstabilizerness is a 'hide-able' characteristic of quantum states: some states are much more magical than is apparent to a computationally bounded observer.

Keywords: Magic-state resource theory, computational indistinguishability, computationally bounded observer, Clifford computation, magic-state distillation, entanglement distillation, stabilizer entropy, quantum chaos, quantum scrambling, quantum cryptography, EFI pairs, property testing

This work is based on Ref. [1].

I. Overview

The delicate and elusive boundary between quantum and classical computation is a central question in current research, with a focus on identifying uniquely quantum resources that contribute to a quantum advantage. One such resource is so-called *magic* ("nonstabilizerness"), which is a measure of the non-Clifford resources needed to prepare a quantum state [2–4]. Among other relations, it has been shown that the amount of magic is directly connected to the hardness of classically simulating a quantum state [5–13], the yield of magic state distillation protocols [2, 14–23], the overhead required for fault-tolerant quantum computation [24–27], and is directly proportional to the degree of chaos in a system [28–31]. Given this multitude of interpretations, one might naturally expect that quantum states with high magic are inherently different, and operationally more non-classical, than states with low magic. This work challenges that intuition. Indeed, we find that the situation can be more intricate than that. We demonstrate the surprising existence of families of states with actually small values of magic while they operationally appear as states with maximum values of magic. We call this phenomenon pseudomagic. In our work, we make a number of contributions that comprehensively elucidate the remarkable implications of this phenomenon, including an *independence theorem* that allows us to tune the magic and entanglement of pseudorandom states independently from one another.

Pseudomagic quantum states are ensembles of states with low magic that are *computationally indistinguishable* in polynomial time from an ensemble of states with maximally high magic. Because they masquerade as maximally-magical ensembles, we say that these ensembles display 'pseudomagic'. Our construction of the low-magic ensembles is simple but powerful: they are simply the *subset phase states* introduced in Ref. [32]. Moreover, their magic can also be finely *tuned*: for any value of magic strictly greater than $\log(n)$ and up to n, we demonstrate the existence of a pseudomagic ensemble with that amount of magic. Our pseudomagic ensembles force us to reconsider quantum chaos, give rise to a fundamental cryptographic primitive and allow us to prove bounds on testing stabilizerness and certain forms of magic-state distillation.

The astute reader may notice that the states that display pseudomagic are the *same* states that display pseudoentanglement [32]. However, this connection is merely a happy coincidence: we show that both the entanglement and magic of these ensembles can be *varied independently* of one another to obtain any legal value of magic and any legal value of entanglement. Here, 'legal' means a value compatible with the defini-

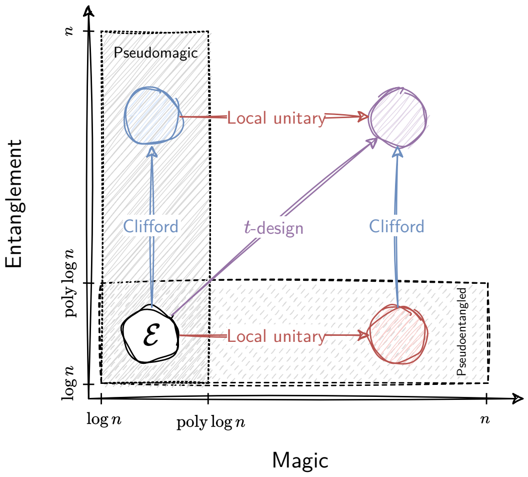

FIG. 1. Efficient conversion of pseudorandom states in all four entanglement/magic quadrants.

tions of pseudomagic or pseudoentanglement. This is not obvious–not even conceptually–as most sufficiently general random states (Haar random states, t-designs, etc) are expected to feature both high entanglement and magic.

Our independence theorem allows us to make a 'lemons-into-lemonade' conceptual shift: the fact that pseudomagic and pseudoentanglement can be tuned independently allows us to strengthen not only our theorems, but also the theorems relating to pseudoentanglement presented in Ref. [32]. Namely, this switch allows us to significantly limit the possibilities for devising efficient algorithms for magic state distillation or nonstabilizerness testing that are tuned to specific levels of entanglement in the input state. Similarly, this imposes limits on entanglement distillation or entanglement testing protocols that are tuned to specific levels of magic in the input states. We expect our independence theorem to be an important tool in the computational study of resource theories in the future.

We end with a meta-perspective. The field of quantum computing is testament to the fact that physics enhances our understanding of what and how we can compute. Our work provides the philosophical counterpart to this statement. It says that computational limits should, conversely, be a sanity check for theoretical physics: if certain physical quantities, say those that purport to assess quantum chaotic behaviour, are in fact not efficiently computationally detectable, in what sense can they be considered real?

II. Pseudomagic quantum states

We start by introducing our central object of study:

Definition 1 (Pseudomagic (informal))**.** *For magic measure $\mathcal{M}$, we say that a pair of n-qubit state ensembles A, B are a pseudomagic pair with gap $(g(n), f(n))$ (where $f(n) > g(n)$) if:*

(a) A is a 'high magic' ensemble $\{|\phi_{k_1}\rangle\}$ such that $\mathcal{M}(\phi_{k_1}) = f(n)$ with high probability over k_1, and

(b) B is a 'low magic' ensemble $\{|\psi_{k_2}\rangle\}$ such that $\mathcal{M}(\phi_{k_1}) = g(n)$ with high probability over k_2;

moreover the two ensembles are indistinguishable by any polynomial time algorithm.

Many distinct magic measures can be used to define pseudomagic. While we elect to primarily use the stabilizer Rényi entropies M_α (for non-negative integer α) in the rest of this work, in the main text, we show that our specific constructions also immediately extend to other measures: robustness of magic [14], stabilizer fidelity [9], stabilizer extent [9] and max relative entropy of magic [33]. We additionally identify conditions that would guarantee that our arguments would go through for a given magic measure.

While we typically use the Haar-random ensemble, which has maximal magic of $\Theta(n)$ with high probability, as the high-magic ensemble, we also construct low-magic ensembles with *tunable* magic – that is, for every value of $g(n)$ not ruled out by computational limitations, we can construct a B displaying that amount of magic. These are known as the *subset phase states*, and are indexed by a binary pseudorandom function f and subset $S \subseteq \{0,1\}^n$ of size 2^k such that $\omega(\log n) < k \leq n$ as $|\psi_{f,S}\rangle = |S|^{-1/2} \sum_{x\in S}(-1)^{f(x)}|x\rangle$. We can control the magic in these states by varying the size of the subset: $M_\alpha(\psi_{f,S}) = O(\log|S|)$. Subset phase states were first introduced in Ref. [32], where it was demonstrated that they also display tunable entanglement depending similarly on the log of the size of the subset. However, we show that for any pseudorandom ensemble, in fact we can tune its entanglement and magic independently, in the following sense:

Theorem 1. *For any value of magic $a \in [poly\log n, n]$, and any value of entanglement $b \in [poly\log n, n]$, there exists an ensemble of states that has magic a and entanglement b with high probability with respect to the states in the ensemble. This ensemble is also indistinguishable from Haar-random states, which have magic $\Theta(n)$ and entanglement $\Theta(n)$.*

The fact that magic and entanglement can be tuned independently of one another is illustrated in Fig. 1. This independence theorem turns out to be a powerful tool that we will exploit to strengthen our applications, which we now describe. Indeed, our general framework allows for a wealth of *further applications.*

III. Applications of pseudomagic

Quantum chaos and scrambling. The resource theory of magic is an essential component of what understanding we have of quantum chaos [34–36]. For a unitary evolution to be deemed as chaotic, meaning it attains the universal (Haar) value of *out-of-time-order correlators* [37, 38], it must necessarily produce maximal $\Theta(n)$ magic [39, 40]. Given that, the mere existence of pseudomagic states suggests the existence of non-chaotic unitaries that nonetheless generate states indistinguishable from those produced by chaotic ones, like Haar random states. We formalize this intuition in the following theorem:

Theorem 2. *Let $\mathcal{E}$ be an ensemble of pseudomagic states that is also pseudorandom. Let $|\psi\rangle \in \mathcal{E}$ and let U such that $|\psi\rangle = U|0\rangle^{\otimes n}$. The $2k$-point OTOCs of U (for $k \geq 4$) are exponentially separated from the Haar value. Therefore, although it generates a state that is on-average computationally indistinguishable from Haar-random, U cannot be considered chaotic.*

In other words, our pseudomagic states are provably not chaotic, even though they are computationally indistinguishable from maximally chaotic Haar random states. This apparently innocuous result carries a profound implication: no physical observer, that is naturally subject to computational limits, can distinguish chaotic from non-chaotic evolution solely based on the observed resultant state.

Implications to resource distillation. We also explore a task of significance for notions of *quantum error correction.* This is the transformation of generic non-stabilizer states into specific, useful non-stabilizer states, such as the canonical magic state vector $|T\rangle$, a task we term as *black-box magic-state distillation.* It is well-known that magic monotones cannot increase under stabilizer operations, imposing a resource-theoretic maximum of the number of distillable magic states from a given starting state. As a preliminary result, we show that this theoretical maximum is a vast overestimate for the output of any *efficient* algorithm.

Theorem 3. *Given a magic monotone $\mathcal{M}$, any efficient stabilizer protocol that synthesizes a state $|B\rangle\langle B|$ from an arbitrary (and potentially also mixed) input state ρ requires $\Omega(\mathcal{M}(|B\rangle\langle B|)/\log^{1+c}\mathcal{M}(\rho))$ copies of ρ, for any constant $c > 0$.*

In short, under this setting, we demonstrate a logarithmic reduction in the 'value' of the magic in the input state. One could contend, however, that our theorem only constrains input state *agnostic* algorithms – whereas many magic state or entanglement distillation protocols are hand-crafted to work on input states with certain assumed structure [2, 41]. Does our lower bound in Theorem 3 still hold up against such tailored algorithms? Could one, as Ref. [42] proposed, distill magic from highly entangled states – if we limit ourselves to computationally efficient distillers? We use our independence theorem 1 to answer in the negative:

Theorem 4. *Consider an entanglement distillation protocol that distills EPR pairs from states drawn from an ensemble $\{\psi_k\}$. For any $f(n) \in [\operatorname{poly}\log n, n]$, even if we are guaranteed that the states ψ_k have magic $\Theta(f(n))$ with overwhelming probability, the protocol can distill at most $O(\log^{1+c} S(\rho))$ Bell pairs with high probability, where $S(\rho)$ is the entanglement entropy of an input state ρ across a bipartition of the system that is linear in n. Similarly, the bound on magic state distillation in Theorem 3 holds even if we are promised that the input state ρ has entanglement $\Theta(g(n))$ across exponentially-many linearly-sized cuts, with any $g(n) \in [\operatorname{poly}\log n, n]$.*

Remarkably, thanks to Theorem 1, it is possible to generalize this theorem to states that display on average *any* amount of magic/entanglement bounded between $\omega(\log n)$ and n.

Other applications A cornerstone of classical cryptography is the *one-way function* (OWF), a function that is easy to compute but challenging to invert. Quantumly, however, OWFs are not essential for certain cryptographic structures to remain secure [43, 44]. Instead, we show that a candidate cryptographic building block known as "EFI pairs" [45] is implied by the bare existence of pseudomagic pairs.

Theorem 5. *Efficiently-generatable pseudo-magic ensembles with stabilizer 1-entropy that can be tuned between $\omega(\log n)$ and n imply EFI pairs.*

Finally, we consider the problem of property testing for non-stabilizerness.

Theorem 6. *Let $0 \leq m < M \leq n$. Any tester for the stabilizer entropy M_α that determines whether for a given state $|\psi\rangle$ $M_\alpha(\psi) \notin [m, M]$ with success proba-*

bility $\geq 2/3$ *requires* $K = \Omega(2^{\frac{m}{4+c}})$ *copies of* $|\psi\rangle$ *for any constant* $c > 0$.

This restriction also extends to a number of other magic monotones, and can be strengthened to hold against non-stabilizerness testers designed for input states with bounded entanglement. We may similarly strengthen the property testing lower bounds in Section 3 of Ref. [32] to hold for input states with bounded magic.

IV. Summary

Pseudomagic highlights the significance of computational limitations in theoretical physics, introducing a unique perspective where the observer plays the main character: from a mere verifier of quantum theories to an integral part of the theory itself. Our insights lay the groundwork for a grand unified theory of 'pseudoresourcefulness' with pseudoentanglement and pseudomagic as special cases. Such a theory would be a modern reinterpretation of the *observer effect* that is at the heart of quantum mechanics: it is not only the information the observer can obtain, but also what she can *process* that matters.

Abstract. We discuss protocols for quantum position verification schemes based on the standard quantum cryptographic assumption that a tagging device can keep classical data secure [1]. Our schemes use a classical key replenished by quantum key distribution. The position verification requires no quantum communication or quantum information processing. The security of classical data makes the schemes secure against non-local spoofing attacks that apply to schemes that do not use secure tags. The schemes are practical with current technology and allow for errors and losses. We describe how a proof-of-principle demonstration might be carried out.

Keywords: quantum position verification, practical quantum cryptography, mistrustful quantum cryptography

Our paper is on the arXiv [2].

Position verification or authentication is a well studied problem in cryptography (e.g., [3]). The task comprises to challenge a tag (or prover) to authenticate its location by sending it communications at light speed, with instructions to process the signals instantaneously and return responses at light speed. If the challenges are sent from several appropriately located test stations (or verifiers), relativistic signalling constraints can ensure that if the tag functions correctly, but at a different location from that expected, this will be detected by the verifiers, because there will necessarily either be time delays or incorrect or missing responses. Realistically, the signals should be sent as close as possible to light speed, the processing should be as fast as possible, and the protocol aims to guarantee location within as small a region as possible.

It has been shown that in a purely classical setting, where the tag only receives and processes classical messages, unconditionally secure position verification cannot be achieved [4]. This is because a set of spoofers surrounding the tag can communicate with the verifiers, faking the intended communication with the tag.

Quantum position verification or authentication (QPV or QPA), also called quantum tagging, was first discussed in a patent [5] published in 2006. In the idealized version, the key idea is that the challenges sent to the tag comprise quantum communications. As spoofers cannot copy quantum information chosen from a non-classical ensemble (for example qubits in BB84 states), quantum tagging schemes are not generally vulnerable to the simple copy-and-redirect spoofing attacks applicable to purely classical schemes [4]. However, they may be vulnerable to other attacks, as we now review.

QPV was first discussed in the academic literature in-Ref. [6], which proposed schemes that were claimed to be unconditionally secure. However, as first pointed out in Ref. [7], although the schemes in Refs. [5, 6] indeed protect against simple attacks that (only) copy and broadcast classical signals and reroute quantum signals, they are vulnerable to teleportation attacks, which effectively simulate the operation of the tag at distant sites. Hence none of them are unconditionally secure.

More generally, Ref. [8] showed that, for any scheme in this general class, the operations carried out by the tag can in principle be simulated (for the verifiers) by spoofers who are located between the tag and verifiers. These spoofing attacks involve non-local quantum computations using pre-distributed quantum entanglement. Since the known attacks require large amounts of pre-distributed entanglement and error-corrected quantum computation, the schemes may guarantee security given presently very credible technological assumptions. Nonetheless, they are not unconditionally secure.

The no-go theorem of Ref. [8] is a theoretically beautiful result, one of several (im)possibility theorems in relativistic quantum information processing that are either based on, or act as counterpoints to, fundamental results in non-relativistic quantum information processing.

However, in many (perhaps most?) plausible scenarios the possibility of quantum teleportation and non-local computation attacks is either unnecessary or insufficient to establish that practical quantum position verification is necessarily insecure. In essence, these non-local attacks establish that spoofers can deceive distant verifiers into believing that a tagging device is present at the expected location, when in fact it is not. But there is an important prior question: do verifiers generally really care about the location of a tagging device *per se*? A quantum tag is essentially a small device that measures and perhaps applies unitaries to incoming quantum states, according to classical instructions, following a fixed public algorithm. As the name suggests, its purported role is to ensure the location of a tagged object or person, and *this* is what the verifiers care about.

This implies that security for any form of quantum tagging or position verification has to be based on some physical assumptions. For example, in principle, the tagging device can be destroyed or removed from the tagged object and replaced by another tagging device that be-

[*] apak@damtp.cam.ac.uk

[†] D.Pitalua-Garcia@damtp.cam.ac.uk

haves identically to the original one. Thus, precluding these attacks must necessarily make some physical assumptions, for example, that such replacement of tagging devices cannot be arbitrarily fast in practice, and that in this way cannot pass unnoticed by the verifiers.

Since we need physical assumption anyway, we consider tagging schemes based on a standard assumption in classical and quantum cryptography, that it is possible to store secret classical data. This assumption seems particularly justifiable in scenarios aiming to verify that the location of the tagged object or person is within a highly secure perimeter, for example, a military base or a bank branch. In these scenarios, it is usually necessary that such perimeters are able to store secret information securely. In particular, this is a standard cryptographic requirement if such locations are able to communicate secretly with other locations (for example, with other bank branches or other military bases).

Ref. [1] introduced tagging schemes that are unconditionally secure, modulo this assumption, in the sense that the tag itself cannot (except with small probability) be spoofed or replaced so long as it remains intact and the data it contains remains secret. In this paper, we explore further versions of this scheme with a security analysis and discuss their practical implementation.

In our paper, we present schemes for position verification in which the position verification queries and responses are purely classical, involving no quantum communication or quantum information processing. These communications are authenticated using a key previously shared between the prover and verifiers. Quantum information transmission and measurement is required only to refresh the key via quantum key distribution. Our schemes are practical to implement with current technology. Their security is based on a standard assumption in quantum cryptography, also made in QKD, that a classical key can be stored securely (by the prover in our schemes), as initially proposed in Ref. [1].

When QPV schemes use position verification queries and/or responses that involve quantum communications, they typically use photons to encode quantum states. This poses challenges, including errors in state preparation, processing and measurement, losses, and security problems due to imperfect single-photon sources and single-photon detectors (e.g., photon-number splitting attacks [9, 10] and multiphoton attacks [11]) and side-channel attacks (e.g., [11]). The problem of losses is particularly challenging in schemes with large distances between the tagging device and the verifiers. An advantage of our schemes is that the queries and responses are purely classical. Quantum communications are needed only to replenish the key via QKD, which is secure against errors and losses. Moreover, the QKD communications, unlike the position verification queries and responses, are not tightly time constrained.

Given our assumptions, our schemes are secure against arbitrarily powerful quantum spoofers, who may share an arbitrary amount of entanglement. This is also an advantage compared to the best known quantum schemes, which have only been proved secure against spoofers that share an amount of entanglement linear in the classical information [12, 13].

(Dated: November 14, 2023)

We discuss protocols for quantum position verification schemes based on the standard quantum cryptographic assumption that a tagging device can keep classical data secure [1]Our schemes use a classical key replenished by quantum key distribution. The position verification requires no quantum communication or quantum information processing. The security of classical data makes the schemes secure against non-local spoofing attacks that apply to schemes that do not use secure tags. The schemes are practical with current technology and allow for errors and losses. We describe how a proof-of-principle demonstration might be carried out.

I. INTRODUCTION

The task of quantum position verification or authentication (QPV or QPA), also called quantum tagging, was first discussed in a patent [2] published in 2006. In the idealized version, the key idea is to challenge a tag (or prover) to authenticate its location by sending it quantum and classical communications at light speed, with instructions to process the signals instantaneously and return responses at light speed. If the challenges are sent from several appropriately located test stations (or verifiers), relativistic signalling constraints can ensure that if the tag functions correctly, but at a different location from that expected, this will be detected by the verifiers, because there will necessarily either be time delays or incorrect or missing responses. Realistically, the signals should be sent as close as possible to light speed, the processing should be as fast as possible, and the protocol aims to guarantee location within as small a region as possible.

As spoofers cannot copy quantum information chosen from a non-classical ensemble (for example qubits in BB84 states), quantum tagging schemes are not generally vulnerable to the simple copy-and-redirect spoofing attacks applicable to purely classical schemes. However, they may be vulnerable to other attacks, as we now review.

QPV was first discussed in the academic literature in Refs. [3, 4], which proposed schemes that were claimed to be unconditionally secure. However, as first pointed out in Ref. [5], although the schemes in Refs. [2–4] indeed protect against simple attacks that (only) copy and broadcast classical signals and reroute quantum signals, they are vulnerable to teleportation attacks, which effectively simulate the operation of the tag at distant sites. Hence none of them are unconditionally secure.

More generally, Ref. [6] showed that, for any scheme in this general class, the operations carried out by the tag can in principle be simulated (for the verifiers) by spoofers who are located between the tag and verifiers. These spoofing attacks involve non-local quantum computations using pre-distributed quantum entanglement. Since the known attacks require large amounts of pre-distributed entanglement and error-corrected quantum computation, the schemes may guarantee security given presently very credible technological assumptions. Nonetheless, they are not unconditionally secure.

The no-go theorem of Ref. [6] is a theoretically beautiful result, one of several (im)possibility theorems in relativistic quantum information processing (e.g., [7–16]) that are either based on, or act as counterpoints to, fundamental results in non-relativistic quantum information processing (e.g. [17–24]).

However, in many (perhaps most?) plausible scenarios the possibility of quantum teleportation and non-local computation attacks is either unnecessary or insufficient to establish that practical quantum position verification is necessarily insecure. In essence, these non-local attacks establish that spoofers can deceive distant verifiers into believing that a tagging device is present at the expected location, when in fact it is not. But there is an important prior question: do verifiers generally really care about the location of a tagging device *per se*? A quantum tag is essentially a small device that measures and perhaps applies unitaries to incoming quantum states, according to classical instructions, following a fixed public algorithm. As the name suggests, its purported role is to ensure the location of a tagged object or person, and *this* is what the verifiers care about.

In one scenario commonly considered in the literature, a position verification protocol is defined to allow a prover to prove their location (L) to distant verifiers. The protocol is said to be insecure if spoofers at other locations (not including L) can simulate the actions of an honest prover when the prover is in fact absent. This is an important scenario, which captures the type of insecurity established by the results of Refs. [5, 6].

However it is also important to keep in mind that there are other interesting scenarios. For example, the prover might be mislocated but still active, with spoofers using

[*] apak@cam.ac.uk

[†] D.Pitalua-Garcia@damtp.cam.ac.uk

the prover's actions as part of their spoofing strategy in order to persuade the verifiers that the prover remains at L. The prover here might be oblivious to their mislocation (having wandered or been unwittingly deceived about their location), or might be cooperating with the spoofers (if, for example, they are a tagged prisoner attempting to escape confinement with outside help).

It is also crucial to note that the term "prover" is ambiguous and potentially misleading when considering practical applications. As used in theoretical analyses, it generally represents the actions of a proving device (i.e. some form of tag). However, the term suggests a person or agent. If Bob carries a mobile device to respond to challenges from Alice's various verifying stations, but he and the device are separable, then the protocol may verify the device's location but not his.

Moreover, to the extent that QPV protocols in the prover-verifier model are secure (given suitable technological bounds on the spoofers), they only establish the location of *a* suitable tagging device, not necessarily *Bob's* tagging device. Any substitute device with the same functionality can implement the protocol correctly. We emphasize that, in the scenario under discussion, the spoofers know every detail of the tagging device's operations: the teleportation attacks of Ref. [5] and the more general non-local computation attacks of Ref. [6] require this. So, if these attacks apply, constructing an identical tag is indeed an option for the spoofers.

Now, if spoofers want to deceive verifiers that someone or something is somewhere they are not, it is presumably either because the object or person has been destroyed or has been moved, or encouraged or deceived (perhaps by GPS spoofing) into moving, to the wrong location. To achieve this, one option is to detach the tag and leave it in position, while dislocating the taggee. Another is to dislocate or destroy both tag and taggee, leaving an identical replica tag in the required position. Either way, the verifiers are left with the false impression that the tagged object remains in place, while in fact they have been untagged and/or dislocated and/or destroyed.

It is true that, if the spoofers dislocate a tag but leave it operational, it may continue to receive and respond to at least some of the verifiers' signals, and this might alert them to interference. Alternatively, some alarm device on the tagged object might alert the verifiers by signalling to them, or the tagged person might do so (in scenarios where they are cooperating with the verifiers). But note that these are also issues if spoofers apply teleportation or non-local computation attacks. To apply these, the spoofers must intercept (at least) quantum signals from the verifiers and use these to generate their spoofed responses. The prover will thus either not receive the quantum information components of their challenges (in which case they might send an alarm signal) or else spoofed quantum information components generated by the spoofers. These spoofed quantum information components may be drawn from the same distribution as the original challenges but will not be identical to them. So, the prover's responses will not generally be valid for the original challenges. If these responses reach the verifiers, they will, again be alerted.

However, in both cases, the spoofers can in principle prevent any alarm or false responses reaching the verifiers by screening the first tag and object/person, jamming all possible communications between them and the verifiers. We emphasize, though, that they also need to do this if they apply teleportation [5] or non-local computation [6] attacks, if the tag/object/person is dislocated but not destroyed. So the need for jamming does not differentiate between these attacks and pure dislocation attacks.

There are conceivable scenarios that do differentiate between these attacks. For example, the prover could be in a region that the spoofers can surround, and signal into, but not enter. The spoofers may be able to spoof GPS within the region, causing the prover to move to the wrong location. They may also be able to spoof the prover's responses to the verifiers using teleportation or non-local computation attacks, giving the verifiers the impression that the prover is at the correct location. And they may be able to jam any communication from the prover to the verifiers, so that the verifiers receive only the spoofed responses. However, the spoofers may not be able to apply direct attacks involving physical dislocation or detachment. The security assumptions here are somewhat delicate, because the spoofers must be able to send physical signals into the region in order to spoof the prover's GPS, but the power of anything they send into the region must be limited. They might perhaps be assumed to be able to send low-energy microwave and radio signals into the region but not, for instance, robots. This scenario requires quite strong and specific physical limitations on the spoofers, and so evidently does not allow unconditional cryptographic security.

More generally, precluding object dislocation/destruction and tag detachment/substitution attacks inevitably requires physical assumptions. For example, it must be hard to detach, destroy or move the tag quickly enough that the tagging protocol can continue with a substitute tag without an interruption being evident. The light speed signalling bound does give an unconditional constraint on movement. For example, a tag responding every microsecond could be moved no more than $\approx$ 300m between responses. However, the signalling bound gives no effective unconditional constraint on attacks involving destruction and replacement: in principle, a tag could be progressively destroyed on one side and replaced on the other side of a boundary that moves at near light speed, without detection. Defences against such attacks must be based on physical assumptions that cannot be unconditionally guaranteed. Also, in many scenarios, the light speed movement bound may be too weak, and stronger bounds again rely on further physical assumptions (for example, that the tag cannot be moved faster than the speed of sound, or perhaps than the fastest aeroplane developed to date).

In summary, security for any form of quantum tagging or position verification has to be based on some physical assumptions. We emphasize that this is not only because of non-local computation attacks, which can only be precluded by technological assumptions bounding the power of spoofers. Dislocation/destruction and detachment/substitution attacks can also only be precluded by physical assumptions on the properties of the tag (and its attachment).

Given that we need such assumptions anyway, there are strong reasons for exploring tagging schemes based on a physical assumption that is standard in classical and quantum cryptography, namely that a piece of infrastructure (in this case the tag) is able to store secret classical data. Ref. [1] introduced tagging schemes that are unconditionally secure, modulo this assumption, in the sense that the tag itself cannot (except with small probability) be spoofed or replaced so long as it remains intact and the data it contains remains secret. In this paper, we explore further versions of this scheme and discuss their practical implementation.

II. SECURITY SCENARIO

We assume that the verifiers, referred to collectively as Alice and individually as $A_1, \ldots, A_M$, and the prover (Bob), are human or other agents, all of whom trust one another. They have a fixed agreed reference frame F. For simplicity, we assume that Bob is supposed to remain at a constant location during the position verification scheme. We assume that Alice has some prior unreliable knowledge of Bob's location (e.g. a reported GPS reading from Bob, or knowledge of a pre-agreed location which Bob is supposed to reach), and wishes to verify it to within as small an error margin as possible, at some sequence of times T_j, for $j = 1, \ldots, N$. We assume that the A_i can communicate with each other via authenticated channels.

In this simple scenario, the aim of the scheme is that, if Bob does remain at a fixed location L during the scheme, he can allow Alice to verify that he is close to L at the given times. In more general scenarios, Bob may move (perhaps up to some speed bound), and the aim may be to identify his position (up to some uncertainty) at any given time. The protocols we describe can be adapted to these more general scenarios, but for clarity we focus here on the simple scenario.

Position verification is non-trivial because of the potential presence of adversaries, who may interfere with, jam, or substitute signals between Alice and Bob. They may also apply physical attacks – for example physically dislocating Bob.

We assume spacetime is Minkowski, as is approximately the case near the Earth surface. The small general relativistic corrections required can easily be allowed for if needed (i.e. if they are significant enough), but we ignore them here. Our discussions assume an asymmetry between Alice, whose agents A_i each are within and control separate secure laboratories, which we might imagine as well-resourced fixed bases, and Bob, who is a single agent in a single laboratory. To simplify the discussion, we suppose Alice has a master agent, A_0, with whom the A_i communicate: A_0 may be A_i for some i, or at a separate location. We assume the locations of Alice's laboratories are reliably known to A_0 and that all Alice's agents (including A_0) have reliable clocks within their laboratories that are all synchronized. We also assume that Alice's laboratories are robust and secure enough that destruction/dislocation attacks on them are not a concern – or at least, that it is a reasonable working assumption that such attacks will not succeed, perhaps because if they did then the loss would be so devastating that the failure to verify Bob's location securely becomes irrelevant. However, Bob cannot directly verify his position: there is no trusted global GPS and any incoming reference data he might use could be spoofed. His laboratory may also be technologically more limited than Alice's and may be vulnerable to destruction/dislocation attacks.

The A_i are at separate sites that are also separated (and may be quite distant) from the location L, which lies within their convex hull. We can consider 1D or 2D position verification, which assume that Bob and the A_i are constrained to lie on a given line or plane. In the 3D case, there is no such constraint, of course. In d dimensions, we must have $M \geq (d+1)$ to satisfy the convex hull condition. The A_i send classical or quantum signals at appropriate times. They receive classical or quantum signals from Bob and verify that these are the prescribed responses (up to a stipulated error rate) and are received at the correct times (up to stipulated timing errors).

Following Ref. [1], we additionally assume that B and the A_i can keep some classical information secure within their respective laboratories, i.e. that adversaries cannot obtain this information unless and until the relevant agent chooses to transmit it outside their laboratory. We assume this holds true even if adversaries are able to move or destroy Bob's laboratory. While this is a strong assumption, it is a standard one in quantum key distribution (QKD) and other areas of cryptography. It effectively counters replacement attacks, since if a tagging device within Bob's laboratory contains a significant amount of secret information, adversaries have only a small probability of constructing an identical replacement.

More precisely, there is only a small probability that *any given attempted replacement* will be identical. Adversaries could construct a set of replacements R_i, where R_i contains key k_i, so that each possible key is contained within one of the replacements. This guarantees that the tag has been precisely replicated, but does not give the adversary a way of identifying which replacement is the replica, and does not facilitate a useful spoofing attack. Even for a relatively short key of 62 bits (as in the security analysis provided in section V), a successful attack of this form requires $2^{62} \approx 10^{18}$ replacements.

III. SCHEME 1: BOB CAN KEEP A CLASSICAL KEY SECRET BUT HAS NO TRUSTED CLOCK

We work with the following slight variation of the scheme of Ref. [1]. Let Alice have M agents $A_1, \ldots, A_M$ surrounding the expected location L of Bob. We assume this expected location L is initially known to Alice, and may not necessarily be known to Bob. We assume that in the absence of adversarial interference L is fixed throughout the position verification protocol, i.e. that Bob remains stationary.

Alice and Bob agree on a sufficiently large integer n, and on a sufficiently small tolerable error rate $0 \leq \gamma << 1$, which act as security parameters. In this scheme we assume Bob does not possess a trusted clock.

We simplify the description by making the idealized assumption that all communications take place at or near the speed of light through vacuum, which we denote by c. The scheme tolerates small delays, at the cost of reducing the precision to which Alice can verify Bob's precision.

In essence, the scheme requires Alice and Bob to authenticate to each other using previously distributed secret keys. For all $i = 1, 2, \ldots, M$, Alice's agent A_i and B perform the following actions.

1. At some time prior to the position verification protocol, A_i and B share a secret key $k_i = \{k_{i1}, \ldots, k_{iN}\}$, where each substring k_{ij} has n bits, and N is as large as required. They keep this secret from eavesdroppers, although A_i may share it securely with other A_j. The key sharing may be done arbitrarily far in advance. Let $k_{ij} = (q_{ij}, r_{ij})$, where q_{ij} and r_{ij} are sub-strings of k_{ij} comprising the first m bits and the last $(n - m)$ bits of k_{ij}, respectively. Here 'q' and 'r' stand for 'query' and 'reply'. For simplicity, we assume the key-sharing is error-free, i.e. that A_i and B have identical versions of k_i. This can be achieved, with high probability, by standard key reconciliation methods. A small allowed key sharing error rate can also be incorporated in the error-tolerant ($\gamma > 0$) versions of the position verification protocol, as described below.

2. A and B may also, prior to the position verification protocol, share a separate secret key k. This key may be expanded as and when needed by QKD, if A and B have the appropriate resources, and used to extend the secret keys k_i (i.e. to increase the number of substrings N).

   The position verification protocol typically involves many rounds of queries and replies. We describe here round j.

3. Each A_i sends query-message-ij, comprising the plain text 'Query ij' followed by q_{ij} (the query substring of k_{ij}) to B. The messages are sent at light speed, timed so that they should arrive at location L at time T_j. The messages are sent in such a way that, in the absence of interference, they can be distinguished even if they arrive simultaneously. For example, they may be sent using different frequencies, or using a code that allows superimposed classical messages to be distinguished.

4. B processes the messages purportedly received from the various A_i sequentially, using some ordering algorithm for distinguishable messages received simultaneously. We thus, in the next step, describe his response to a single message in the sequence.

5. B receives the message ('Query ij'',$q'_{ij'}$), purportedly from A_i. Because of possible adversarial interference, we do not assume that $j' = j$, even if the message arrives at T_j, nor that A_i has in fact sent query-message-ij, nor that $q'_{ij'} = q_{ij'}$. B keeps a register R_i recording the second index j of the last query-message-ij that he received and validated with first index i. If $R_i = (j'-1)$, then B sets R_i to j'. If not, he aborts the protocol (i.e. does not continue with the steps below) and stops responding to any future queries. (Here and below, we give the simplest response to detection of an apparent spoofing. B stops communicating; the A_i become aware that the protocol has failed; they presumably take appropriate action. Of course, other ways of proceeding are possible and in some circumstances preferable. For example, B may continue to respond to valid queries so long as the proportion of invalid queries is smaller than some pre-agreed threshold. With suitable adjustments of security parameters, this modified protocol can continue to give useful security guarantees.)

6. B checks whether the Hamming distance $d(q'_{ij'}, q_{ij'}) \leq \gamma m$. If so, he accepts the query as authentic. If not, he aborts, as above.

   Timing: If B is indeed at location L, the messages arrive at time T_j, and his authentication takes place within the time interval $[T_j, T_j + \delta_1]$, where δ_1 is the processing time required.

7. If B authenticates the query purporting to come from A_i in the previous step, he sends the plain text 'Reply ij'' followed by $r_{ij'}$ (i.e, the reply sub-string of $k_{ij'}$) to A_i. Otherwise B does not respond, and accepts no subsequent queries from any A_i, even if they are authenticated.

   Depending on which option is more technologically convenient, B either broadcasts his response to all the A_i. or sends it just to the agent A_i identified by the authenticated Query ij'. (Note that it is possible that A_i is not the sender even though Bob has authenticated the query.) We call these respectively the *broadcast* and *narrowcast* versions of the protocol. In the broadcast version, if B broadcasts simultaneous messages to more than one A_i, the messages are sent in such a way that, in the absence of interference, they can be distinguished even if they arrive simultaneously (as above).

Timing: If B is indeed at L, he sends his reply by the time $T_j + \delta_1 + \delta_2$, where δ_2 is the time taken by B to transmit.

8. In the narrowcast version, suppose that A_i receives ('Reply $i'j'$', $r'_{i'j'}$), purportedly from Bob. If $i = i'$, and $j' = j$ (where j is the current round, i.e. A_i has received and authenticated replies from all rounds $k < j$), A_i verifies that the Hamming distance $d(r_{ij}, r'_{ij}) \leq \gamma(n - m)$ and that she has received the reply r'_{ij} not later than the time $T_j + \frac{d_i}{c} + \delta_L$, where δ_L has been agreed in advance by Bob and Alice and must satisfy $\delta_L \geq \delta_1 + \delta_2$. If so, she accepts the reply as authentic and sends the confirmation message '$s_{ij} = 1$' via an authenticated channel to the master agent A_0. Otherwise, she sends the message '$s_{ij} = 0$'.

   In the broadcast version, A_i ignores all messages not of the form ('Reply ij'', $r'_{ij'}$) for some string r' and some j'. That is, A_i considers only replies apparently addressed to her. For those messages, she follows the verification steps for j' and r' above, and sends confirmation messages as above.

   Timing: If B is indeed at L, then A_i authenticates his reply by the time $T_j + \frac{d_i}{c} + \delta_1 + \delta_2 + \delta_3$, where d_i is the distance from L to A_i and δ_3 is the time taken for A_i to authenticate. She sends her confirmation message at time $T_j + \frac{d_i}{c} + \delta_1 + \delta_2 + \delta_3 + \delta_4$, where δ_4 is the time taken by Alice to generate and transmit the confirmation message.

9. If A_0 receives $s_{ij} = 1$ and authenticates it as a message from A_i for all $i = 1, 2, \ldots, M$, then she authenticates that the location of B at time T_j was L, within some position uncertainty given by $c\delta_L$. If she receives $s_{ij} = 0$ for some i then the position verification in round j fails.

   Timing: Suppose that the authenticated channel from A_i to A_0 had length d'_i and that messages travel on it at speed $c'_i \leq c$. A_0 completes the authentication by the time

$$T_A = T_j + \max_i \left\{ \frac{d_i}{c} + \frac{d'_i}{c'_i} \right\} + \delta_1 + \delta_2 + \delta_3 + \delta_4 + \delta_5 \,,$$

   where δ_5 is the time taken for A_0 to compute whether all confirmation messages satisfy $s_{ij} = 1$.

Comments on Geometry: A successful verification by A_i guarantees that, at time T_j, B was within a ball B_i with A_i at the centre, with radius $d_i + c\delta_L$. Using the information of her agents, A_0 can verify B's location to have been within the intersection of the balls $B_1, \ldots, B_M$. In the ideal case $\delta_L = 0$, this intersection is exactly the location L. Thus, by increasing M, and appropriately locating Alice's agents we can reduce the uncertainty of B's location in the verification scheme.

Note that a proof of principle implementation for 3D position verification could be carried out for $M = 2$, with A_1 and A_2 approximately collinear with L, on opposite sides of L. If the collinearity is a good approximation, this may verify location to good precision. The precision is greater if we may assume A_1, A_2 and B are constrained to lie exactly on a line, so that we effectively carry out position verification in 1D.

An implementation with $M = 1$ can only guarantee that B is within a ball surrounding Alice's sole agent A_1. Nonetheless, implementation of $M = 1$ would allow a proof of principle test of the technology, since we can extrapolate the results to $M > 1$ and estimate the precision that would be obtained for any given configuration of the A_i and B.

Comment on key lengths and error tolerance: It may be useful to vary the key lengths in some scenarios, so that k_{ij} has length n_{ij}. It may also be useful to allow the error thresholds to vary, so that communications in round j from A_i to B have threshold $\gamma_{ij}^{\rightarrow}$, and from B to A_i have threshold $\gamma_{ij}^{\leftarrow}$. For simplicity we consider fixed n and γ in our discussion.

IV. TIME DELAYS OF SCHEME 1

We identify three main types of time delays.

1. $\Delta_L = \delta_1 + \delta_2$ provides the uncertainty in A_i's estimate of $d(A_i, L)$, assuming that she is confident of the value of δ_3, which is determined by her own equipment. (In practice there will presumably be at least slight uncertainties in δ_3. We neglect these for simplicity; they can be included in the calculation of Δ_L if significant.) We would like to make Δ_L as short as possible in order for the location L to be verified as precisely as possible. As mentioned above, we require $\Delta_L \leq \delta_L$.

2. $\Delta_V = \delta_3 + \delta_4 + \delta_5$ comprises the delay that A_0 takes in learning A_i's estimate $d(A_i, B)$, after A_i receives B's response. During the interval $\Delta_L + \Delta_V$, B could be displaced, with A_0 learning this (if at all) only later. So we would also like to make Δ_V as short as possible, all else being equal.

3. Δ_R denotes the time difference between one verification and the following one, where R denotes 'repetition'. All else being equal, we would like to repeat the location verification protocol as frequently as possible and thus minimize Δ_R.

The relative importance of minimizing Δ_L, Δ_V and Δ_R, and the value of tradeoffs among them, depends on the scenario. One factor is whether Bob's potential displacement (either by wandering or by the action of adversaries) is bounded only by c, or whether in practice a significantly lower bound (such as the speed of sound in air, or the speed of the fastest planes currently available) is justified.

V. SOME POSSIBLE ATTACKS ON SCHEME 1

Our security analysis below applies for arbitrarily powerful spoofers, who might have arbitrarily advanced quantum technology and who could share an arbitrarily large amount of entanglement. Our analysis is based on the assumption that Bob can keep classical information secret from spoofers. The assumption that collaborating parties have laboratories in which they can keep data secure is standard (and necessary) for quantum key distribution schemes and many other quantum cryptographic protocols. We believe it is equally reasonable in many scenarios in which position verification is required. Nonetheless, it is ultimately a technological assumption, whose validity should be examined in any given application and scenario.

A. Desynchronizing Alice's clocks

As mentioned above, Alice's agents must keep their laboratories securely synchronized to a common reference frame F during the verification scheme. We assume they trust their locations. This is reasonable in scenarios in which Alice has a secure and stable infrastructure. They also require secure clock synchronization. This is a general issue in relativistic quantum cryptography. In practice, it is often partially addressed by keeping clocks synchronized using GPS devices within the required time uncertainty [25–29]. However, adversaries may spoof the GPS signals [30], desynchronizing Alice's clocks.

To defend against such attacks, the A_i may initially synchronize their clocks in a single secure laboratory (for example A_0's) and then displace these securely to their separate laboratories. To counter clock drift, this process could in principle be repeated at suitably short intervals during the protocol, ensuring that the A_i's clocks are repeatedly re-synchronized with new incoming synchronized clocks. Note that this requires not only a supply of accurate clocks, but also secure distribution channels that ensure the clocks remain very well synchronized as they are distributed.

B. Impersonating Alice and Bob

The spoofer may have multiple agents S_k at separate locations: we refer to them collectively as S. The spoofer S could try to impersonate B in an strategy that combines spoofing A_i to B, with the aim of learning the strings r_{ij}, and spoofing B to A_i. We consider this for a single A_i; the discussion obviously extends to multiple agents.

Suppose that rounds up to $(j-1)$ have been honestly completed by A_i and B. Before B receives A_i's communication for round j, S could send the plain text 'Query ij' to B followed by some string q'_{ij} of m bits. Assuming S has no previous information about q_{ij}, with probability 2^{-m}, $q'_{ij} = q_{ij}$ and B sends r_{ij} to S. S can then send r_{ij} to A_i, impersonating B when A_i later sends the authentic 'Query ij' with string q_{ij}.

With probability $1-2^{-m}$, $q'_{ij} \neq q_{ij}$, in which case B does not transmit r_{ij} in following queries by S or Alice. In this case, S generates a random guess r'_{ij} of r_{ij} and sends it to A_i after the plain text 'Reply ij', assuming she does not have any previous knowledge about r_{ij}. S succeeds in this case with probability $2^{-(n-m)}$.

Thus, if the keys k_{ij} are perfectly random and secret, S's probability to succeed in impersonating B in the previous strategy is

$$P_{\rm S} = \left(\frac{1}{2}\right)^m + \left[1-\left(\frac{1}{2}\right)^m\right]\left(\frac{1}{2}\right)^{n-m}. \qquad (1)$$

We have assumed here that $\gamma = 0$, i.e., neither A nor B accept errors in the received strings. P_S is minimized (for fixed even n) for $m = \frac{n}{2}$, when,

$$P_S = 2\left(\frac{1}{2}\right)^{\frac{n}{2}} - \left(\frac{1}{2}\right)^n \leq 2^{1-\frac{n}{2}}\,. \qquad (2)$$

This gives a strong security bound of $P_S \approx 10^{-9}$ with relatively short keys of $n = 62$ bits.

We now consider the case $\gamma > 0$. We have

$$P_S(\gamma) = \left(\frac{1}{2}\right)^m |Q_m^\gamma| + \left[1-\left(\frac{1}{2}\right)^m |Q_m^\gamma|\right]\left(\frac{1}{2}\right)^{n-m} |Q_{n-m}^\gamma|, \qquad (3)$$

where $Q_N^\gamma = \{x \in \{0,1\}^N | w(x) \leq \gamma N\}$, and where $w(x)$ denotes the Hamming weight of the bit string x.

We assume that n is even and that $m = \frac{n}{2}$. We obtain from (3) that

$$\begin{aligned} P_S(\gamma) &= 2\left(\frac{1}{2}\right)^m |Q_m^\gamma| - \left(\frac{1}{2}\right)^{2m} \left(|Q_m^\gamma|\right)^2 \\ &\leq 2^{(1-m)}|Q_m^\gamma| \\ &\leq 2^{(1-m)} 2^{mh(\gamma)} \\ &= 2^{\left[1-m(1-h(\gamma))\right]}, \end{aligned} \qquad (4)$$

where in the third line we used that $|Q_m^\gamma| \leq 2^{mh(\gamma)}$, which is shown in Sec. 1.4 of Ref. [31], and where $h(\gamma) = -\gamma \log_2 \gamma - (1-\gamma)\log_2(1-\gamma)$ is the binary entropy of γ.

For example, even with a high error tolerance, $\gamma = 0.05$ (giving $h(0.05) = 0.2864$) and taking $n = 88$, we obtain from (4) that $P_S(0.05) < 10^{-9}$.

We have assumed the keys are perfectly random, i.e., that S has zero information about them. In practice this will not be quite correct, but keys can be made close enough to random to make corrections negligible.

C. Obtaining the keys

S could try to learn the keys k_{ij} before they are used, i.e., before B sends the k_{ij}'s to Alice's agents. But by assumption the scheme is secure against these attacks: we assume Alice and Bob generate and distribute the keys secretly, and store them secretly until Bob communicates the secret keys.

D. Adding time delays

S can add time delays in any communications between any of Alice's agents and B. This can increase the uncertainty in B's location authenticated by Alice and/or delay Alice's verification. If S thereby causes the time delays between the A_i and B to be larger than acceptable thresholds, or for the communications in one or both directions to become out of sequence, then this causes the position verification to fail. We assume in this case Alice responds, for example by inspecting B's location with other physical means.

A limiting case is that S can jam the communications altogether. These delay or jamming attacks are unavoidable in practice unless the communication channels cannot be accessed by S. Inaccessible private channels is a strong assumption not generally made in quantum cryptography. One practical reason not to make this assumption is that it requires secure laboratories linked by a network of securely hardened channels. In position verification applications, these channels might typically be $\sim 10 - 10^5$km long (ranging from small scale networks on Earth to high Earth orbit satellites) and would need to be approximately straight line. A theoretical reason not to make it is that it trivialises position verification (PV) as a task. Given inaccessible private channels, PV can be securely implemented simply by exchanging messages, without using secret keys or any quantum communications, provided the channel transmission times are reliably known.

If S adds suitably short time delays, A can verify B's location within tolerable error bounds. If she adds longer time delays, she prevents A from verifying B's position, but alerts A to her interference. So the protocol is secure (in the sense claimed) against delay or jamming attacks.

E. Altering Bob's records

If S can, without detection, alter Bob's record of whether previous queries were authenticated, she can send repeated queries of the form query-message-ij, altering the record so that Bob has no record of each failed authentication. Bob will thus continue the protocol after failed authentication. S can thus continue until she successfully guesses the query string q_{ij}, and Bob's response will provide her with r_{ij}. If she is able thus to obtain r_{ij} before the authentic query-message-ij is sent, she can spoof a response to this challenge. If she is able to do this for all ij, she can systematically and indefinitely mislead the A_i as to B's location.

Timing constraints may restrict the scope of this attack, since as described it requires S to make $\sim 2^m$ guesses at q_{ij} to obtain r_{ij}. However, if S is also able to alter the data in Bob's register R_i, she can set it so that Bob will accept a query-message-ij for some value of j that may not authentically be sent until some (perhaps far) future time. This enlarges the time window during which she can send guesses at query-message-ij.

Also, if S can, without detection, alter Bob's records of the q_{ij}, in a way that allows her to choose the altered string (although not read the original string), she can create new query keys q_{ij}^S that she knows. If she is able to do this before the authentic query-message-ij is sent, she can use q_{ij}^S to send a spoof query-message-ij, obtain the response $_{ij}$, and use this to spoof responses to authentic queries. If she is able to do this for all ij, she can systematically and indefinitely mislead the A_i as to B's location.

The protocol thus requires that B can keep classical data secure against alteration, as well as keeping the key strings private (i.e. secure against reading). The ability to ensure that classical data within a secured site is unalterable is also a standard cryptographic assumption. However it is worth noting that it neither necessarily implies nor is necessarily implied by data privacy.

VI. QUANTITATIVE CONSIDERATIONS FOR SCHEME 1

We consider for simplicity a 1D implementation in which Alice has two agents (case $M = 2$), A_1 and A_2. Let A_1, A_2 and B be on the same line, with B between Alice's agents at equal distance from each of them.

We assume that the communication channel between A_1 (A_2) and B is optical and in free space, transmitting at the speed of light c.

A. Bob performs information processing with electronic circuits

Steps 6 and 7 comprise B receiving Alice's query signal encoded in light or other electromagnetic signals, converting these to electronic signals, authenticating the request originated from Alice, and then encoding the reply in light or other electromagnetic signals and transmitting to A_i, for $i = 1, 2$. In practice, a circuit comprising FPGAs could be used to perform these computations as fast as possible. Note that the signals exchanged between Alice and Bob in the position verification protocol are classical. Hence they can be sufficiently intense to deal with losses and errors. This is a significant practical advantage compared to position authentication schemes that need to transmit quantum states between Alice and Bob (e.g., [2–4, 32, 33]).

As an illustration, we take $n \sim 62$, with $\gamma = 0$. We note that because our scheme only involves classical communication and classical processing, it is sensible to assume zero errors, in contrast to schemes that require quantum communication or quantum information processing. An FPGA simply needs to compare received and stored key strings. Ref. [28] performed in 2016 completed a round including more complex computations and communication between adjacent FPGAs with a string of 128 bits in 1.8 μs. With these devices, assuming processing time is approximately linear in string length, our simpler computation with $n = 62$ bits should be completed within $\leq 0.88\mu$s, giving uncertainty of $\leq$ 264m in B's location.

With state of the art FPGAs, we estimate that B's verification might be completed within $\sim$ 10ns, giving an uncertainty of $\sim$ 3m in B's location.

If verification rounds take place every μs, the light speed signalling bound implies that the tag can move $\leq$ 300m between rounds. For 4 verifiers, this round frequency consumes $\approx 4 \times 124 \times 10^6 \approx 5 \times 10^8$ key bits per second.

If we assume, perhaps plausibly in many scenarios, that the tag will not move faster than the speed of sound (in air at sea level) from its expected location, verification rounds every μs mean that the tag cannot move more than $\approx 3 \times 10^{-4}$m between rounds. With rounds every ms, this becomes $\approx 3 \times 10^{-1} m$. This round frequency consumes $\approx 5 \times 10^5$ key bits per second. While still demanding, these resource requirements seem achievable with present technology, and give (modulo assumptions) good enough location precision to be useful in many scenarios.

VII. SCHEME 2: BOB HAS A TRUSTED SYNCHRONIZED CLOCK

Our second scheme introduces the assumption that B possesses a clock synchronised with Alice's clocks. This allows Alice to specify a signalling schedule in advance so B can transmit at specified times. Of course, it makes extra technological demands on B and on the size and security of his laboratory.

The main difference between Schemes 1 and 2, is that Scheme 2 does not require Alice to send a query signal every time she wishes to verify B's location. Instead, she shares an authenticated signalling schedule with B in advance, with B relying on his synchronised clock to follow the schedule. This removes the need for B to authenticate each individual query from Alice in real time, as he can authenticate the whole signalling schedule in advance. This removes one source of delay in the protocol, namely B's authentication time, denoted as δ_1 in the description of Scheme 1. It also potentially removes a second source of delay, B's transmission time δ_2, since if Bob knows δ_2 he can adjust for it by starting the transmission so that it *completes* (rather than starts) at the time T_j stipulated for his round j communication in A's schedule. More precisely, it potentially replaces δ_2 by the uncertainty Δ_2 in Bob's transmission time, and typically we expect $\Delta_2 \ll \delta_2$. We assume this adjustment below.

(We consider schemes involving only classical communication between A and B here, but it is worth noting that removing these delays is potentially even more valuable for schemes involving quantum communications from A and B and quantum measurement and/or information processing by B, since the latter steps are potentially significantly slower than their classical counterparts. It thus seems potentially advantageous, in scenarios in which it is justifiable, also to allow B and A to share synchronized clocks in such schemes. However, the advantage is lost if B is not able to keep information secret, since storing information for later use exposes it to spoofers. And if B is able to keep secret, the protocols discussed here using classical queries and responses may generally be more efficient. So this option may perhaps be useful only in the restricted scenario where B is able to keep quantum information secret but not classical information.)

Scheme 2 again assumes that Alice has M agents $A_1, \ldots, A_M$ surrounding the location L of B. Alice and B agree on a sufficiently large integer n, and on a sufficiently small error rate $0 \leq \gamma << 1$, which act as security parameters. We also assume that all communications take place at the speed of light through vacuum, which we denote by c. For all $i = 1, 2, \ldots, M$, Alice's agent A_i and B perform the following actions.

1. A and B share a secret key k that is used to authenticate communications and may also be used as a one-time pad to keep communications secret. This key may be expanded as and when needed by QKD.

2. At some time prior to the position verification protocol, A_i and B share a secret key $k_i = \{r_{i1}, \ldots, r_{iN}\}$, where each substring r_{ij} has n bits, and N is as large as required. They keep this secret from spoofers, although A_i may share it securely with other A_j. The key sharing may be done arbitrarily far in advance. For simplicity, we assume the key-sharing is error-free, i.e. that A_i and B have identical versions of k_i. This can be achieved, with high probability, by standard key reconciliation methods. A small allowed key sharing error rate can also be incorporated in the error-tolerant ($\gamma > 0$) versions of the position verification protocol, as described below.

3. A sends an authenticated message to B, specifying the times at which he is required to verify his location. This can be done arbitrarily far in advance of step 3, and possibly after or concurrent with step 2. In the simplest version, this message is public. Alternatively, it could be encrypted, to prevent S from learning the verification schedule.

4. If T_j is the j-th time B is required to verify his location, then to each A_i he sends the plain text 'Reply ij' followed by r_{ij} , completing his transmission at time T_j, according to his clock. As in Scheme 1, B may either broadcast or narrowcast his replies. We describe the narrowcast version below; the minor modifications required for the broadcast version are as for Scheme 1.

   Timing: this takes place by the time $T_j + \delta_d + \Delta_2$, where Δ_2 is the uncertainty in the time it takes B to transmit (consistently defined as in Scheme 1) and δ_d is the time difference between Alice and B's clocks, which may be non-zero if they are not perfectly synchronised. Note that we cannot assume $\delta_d > 0$. We assume that A_i and B are confident that their clock technology will ensure, in the absence of adversarial attacks on their clocks, there is some bound $\delta_d^{\max} > 0$ such that $|\delta_d| \leq \delta_d^{\max}$. In practice, this bound will be time-dependent. For simplicity here we consider a single bound that is valid throughout the duration of the protocol.

5. A_i receives ('Reply $i'j'$', $r'_{i'j'}$). She verifies that $i' = i$, that $j' = j$ (where j is the current round, i.e. A_i has received and authenticated replies from all rounds $k < j$), that the Hamming distance $d(r'_{ij}, r_{ij}) \leq \gamma(n - m)$ and that she has received the reply r'_{ij} not later than the time $T_j + \frac{d_i}{c} + \tilde{\delta}_L$, where $\tilde{\delta}_L$ has been agreed in advance by Bob and Alice, and which must satisfy $\tilde{\delta}_L \geq \delta_d^{\max} + \Delta_2$. If so, she sends the confirmation message '$s_{ij} = 1$' together with the time that she received r'_{ij} to A_0. Otherwise she sends the message '$s_{ij} = 0$'.

   Timing: If B is indeed at L, then A_i authenticates his reply by the time $T_j + \frac{d_i}{c} + \delta_d + \Delta_2 + \delta_3$, where d_i is the distance from L to A_i and δ_3 is the time taken for A_i to authenticate. She sends her confirmation message at time $T_j + \frac{d_i}{c} + \delta_d + \Delta_2 + \delta_3 + \delta_4$, where δ_4 is the time taken by Alice to generate and transmit the confirmation message.

6. If A_0 receives $s_{ij} = 1$ and authenticates it as a message from A_i for all $i = 1, 2, \ldots, M$, then she authenticates that the location of B was L, within some uncertainty given by $c(\tilde{\delta}_L - \delta_d^{\max})$, at some time T'_j, where $|T'_j - T_j| \leq \delta_d^{\max}$. This implies that the location of B at time T_j was L, within some uncertainty given by $c\tilde{\delta}_L$.

   Timing: Suppose that the authenticated channel from A_i to A_0 had length d'_i and that messages travel on it at speed $c'_i \leq c$. A_0 completes the authentication by the time

$$T_A = T_j + \max_i \left\{ \frac{d_i}{c} + \frac{d'_i}{c'_i} \right\} + \delta_d + \Delta_2 + \delta_3 + \delta_4 + \delta_5 \, ,$$

   where δ_5 is the time taken for A_0 to compute whether all confirmation messages satisfy $s_{ij} = 1$.

VIII. FURTHER ATTACKS ON SCHEME 2

As in section V, our security analysis here applies for spoofers who may have arbitrarily advanced quantum technology and share an arbitrarily large amount of entanglement, given our assumption that Bob can keep classical information secure from the spoofers.

A. Acting outside schedule

S may gain knowledge of the signalling schedule, potentially providing her with information about ΔR, the time difference between subsequent location requests. This exacerbates the problem illustrated in point 3 in section III, as S would know when she is able to move B (or encourage him to move, by spoofed GPS or other means) without risking a location check. This risk could be mitigated either by keeping the schedule suitably secret (by sending it encrypted) and unpredictable, or by ensuring the scheduled times are frequent enough that S could not move B a significant distance before the next verification is due. Note that the first option consumes a potentially large amount of shared secret key and the second requires a potentially high key refresh rate.

B. Clock desynchronization

Bob's clock may become desynchronized, either naturally or as a result of S's interference, introducing a time difference δ_d between Alice and Bob's clocks. At least theoretically, this is a significant concern: if S is able to move B physically at speeds arbitrarily close to c, she can cause his clock to run arbitrarily slowly with respect to A's lab frame. However, slowing B's clock delays his responses, which means that A will not incorrectly verify his position as guaranteed to be close to L. In principle, S could also desynchronize B's clock by altering the gravitational field in his vicinity. Such attacks are usually ignored in relativistic cryptography, given that it is impractical to create any significant effect. In most applications of relativistic cryptography, security is threatened only if the effect is large enough that points believed by one party to be spacelike separated are in fact timelike separated. In this case, though, any degree of desynchronization affects the precision of the position verification. However, in practice any effect seems likely negligible compared to other uncertainties.

A and B might attempt to counter accidental or deliberate desynchronization by exchanging authenticated messages to keep their clocks synchronized. This is complicated by the fact that a simple synchronisation protocol requires knowledge of B's position, or at least his distance from the relevant A_i. Synchronization schemes involving exchanges with several A_i in parallel still appear useful, but we will not pursue their analysis here.

IX. CONCLUSION

We have presented schemes for position verification in which the position verification queries and responses are purely classical, involving no quantum communication or quantum information processing. Quantum information transmission and measurement is required only to refresh the key via QKD. Our schemes are practical to implement with current technology. Their security is based on a standard assumption in quantum cryptography, also made in QKD, that a classical key can be stored securely, as initially proposed in Ref. [1].

When QPV schemes use position verification queries and/or responses that involve quantum communications, they typically use photons to encode quantum states. This poses challenges, including errors in state preparation, processing and measurement, losses, and security problems due to imperfect single-photon sources and single-photon detectors (e.g., photon-number splitting attacks [34, 35] and multiphoton attacks [36]) and side-channel attacks (e.g., [36]). The problem of losses is particularly challenging in schemes with large distances between the tagging device and the verifiers. An advantage of our schemes is that the queries and responses are purely classical. Quantum communications are needed only to replenish the key via QKD, which is secure against errors and losses. Moreover, the QKD communications, unlike the position verification queries and responses, are not tightly time constrained.

Given our assumptions, our schemes are secure against arbitrarily powerful quantum spoofers, who may share an arbitrary amount of entanglement. This is also an advantage compared to the best known quantum schemes, which have only been proved secure against spoofers that share an amount of entanglement linear in the classical information) [32, 33].

Abstract. Many "quantum supremacy" claims, notably by Google in 2019, rest upon the Linear Cross Entropy Benchmarking (Linear XEB) verification metric. However, the hardness of classically spoofing Linear XEB depends on the Cross-Entropy Quantum Threshold (XQUATH) assumption, which has been disproven for sublinear depth circuits. System Linear Cross Entropy Score (sXES), a Linear XEB variant, is a promising quantum supremacy verification metric for quantum Hamiltonian simulations as it relies on a different assumption called the System Linear Cross-Entropy Quantum Threshold (sXQUATH). Here, we disprove sXQUATH for sublinear depth circuits and construct an efficient spoofing algorithm for sXES of sufficiently noisy experiments.

Keywords: Quantum computation benchmarking, Quantum computational complexity, Linear cross-entropy benchmarking, Random quantum circuit sampling, Classical simulation of quantum computation

In 2019, the Google quantum AI team claimed the first experimental demonstration of "quantum supremacy," [2] or computational quantum advantage using a 53 qubits superconducting circuit [3], signifying a major leap forward in practical quantum computing and challenging the extended Church-Turing thesis [4]. In verifying that their circuit is correctly performing a task called quantum random circuit sampling (RCS), they tested their samples using a metric called "Linear Cross-Entropy Benchmarking (Linear XEB)" [5–10]. Since then, multiple RCS experiments [11–13] have their quantum supremacy claims verified by Linear XEB method, or a variant thereof. Skepticism on these claims have been raised, particularly by classical simulations of Google's RCS experiment [14–19] showing significantly shorter classical runtime compared to their initial estimation of $10,000$ years. Moreover, theoretical results on classical simulation of different RCS variants [20–25] cast doubts on the complexity-theoretic hardness of spoofing Linear XEB that rests on the cross entropy quantum threshold assumption (XQUATH) conjecture proposed by Aaronson and Gunn [26]. Recent demonstration that XQUATH does not hold for sublinear depth RCS [24], further diminishes the legitimacy of Linear XEB as a benchmark for quantum supremacy.

In the ongoing pursuit of quantum supremacy by the way of near-term quantum Hamiltonian simulation, a variant of Linear XEB called the System Linear Cross Entropy Score (sXES) has been proposed [27]. Structural difference between the circuits assessed by sXES and other Linear XEB variants renders it unclear whether existing Linear XEB spoofing methods such as [20, 22, 24] can be used for sXES. Moreover the hardness of spoofing sXES lies upon a complexity-theoretic conjecture known as the System Linear Cross-Entropy Quantum Threshold Assumption (sXQUATH), the formal relationship of which to XQUATH is unknown. These fundamental distinctions from other Linear XEB variants thus renders sXES a promising verification method in future claims of quantum supremacy experiments.

In this work, we go beyond the technique in [24] to show that there exists an efficient classical algorithm that approximates the experiment sufficiently well to refute sXQUATH (see Theorem 1). At the same time, we also show explicitly that our algorithm spoofs the sXES benchmark (see Theorem 2) for noisy experiments. Our algorithm approximates the output probability distribution of a family of quantum circuits known as the Minimal Quantum Singular Value Transform (mQSVT) circuit [27], which sXES assessed upon. While the mQSVT circuits bear the power to implement any quantum algorithm that falls into the Quantum Singular Value Transform (QSVT) framework [28] (such as Szegedy quantum walk [29] and quantum solver for system of linear equations [30] and Hamiltonian simulation tasks [31, 32]), our results suggest that a more robust benchmarking method is necessary for any claim of quantum supremacy experiment.

1 Hardness of spoofing mQSVT circuit benchmarking

An mQSVT circuit $\texttt{mQSVT}(U)$ (see Fig. 1) consists of d "blocks", each containing a copy of $n+1$ qubit uni-

[*] andrew.tanggara@gmail.com
[†] mgu@quantumcomplexity.org
[‡] kishor.bharti1@gmail.com

tary U and a copy of its conjugate $U^\dagger$. Denote the depth of U as d_U so that we can write $U = U_{d_U} \dots U_1$ where U_j is the j-th layer of U. These unitaries are interleaved by phase shift gates $R(\varphi)$ at the top register with carefully chosen phases (as discussed in the supplementary material of [27]). Samples from an mQSVT circuit are obtained from measuring the bottom n registers conditioned on measurement of the top register being 0. The outcome probability of an n-bit string x is therefore $p(U,x) = |\langle 0x|\texttt{mQSVT}(U)|0^{n+1}\rangle|^2$. Here we consider unitaries U consisting only of two-qubit gates such that in each layer, every qubit register is evolved by precisely one two-qubit gate without any geometric locality assumption (hence $n+1$ is even). This is the unitary architecture assumed for the RCS simulation result in [24].

For a noisy mQSVT Hamiltonian simulation experiment, a benchmarking scheme similar to XEB benchmarking used in RCS experiment [3, 11, 12], called the average system linear cross-entropy score (sXES) [27] was proposed. For a given ideal mQSVT circuit $\texttt{mQSVT}(U)$ and (empirically approximated) experimental probability $p_{\text{exp}}(U,x)$ of output x, its sXES is given by

$$\mathbb{E}_U[\text{sXES}(U)] = \sum_{x \neq 0^n} \mathbb{E}_U[p(U,x)\, p_{\text{exp}}(U,x)] \,, \qquad (1)$$

where $\mathbb{E}_U$ is expectation over random U. An experiment with high sXES indicates a high circuit fidelity as it assigns a high probability $p_{\text{exp}}(U,x)$ to string x with high ideal probability $p(U,x)$, hence higher sXES.

Computational hardness of classically spoofing sXES can be reduced to a statement which essentially says that: The average error of any efficient classical algorithm that takes a description of unitary U and output bit string x as input and outputs an approximation of $p(U,x)$ cannot be exponentially smaller than the average error of uniformly sampling x. This is a statement captured by the System Linear Cross-entropy Quantum Threshold Assumption (sXQUATH) [27], which the hardness of spoofing sXES relies upon. More precisely, sXQUATH conjecture states that there is no polynomial-time classical algorithm taking an efficient description of $n+1$-qubit unitary U and n bit string x as inputs and outputs an approximation $q(U,x)$ of mQSVT output probability $p(U,x)$ such that

$$\text{sXQ} = \mathcal{E}\Big(p(U,X), \frac{1}{2^n}\Big) - \mathcal{E}\Big(p(U,X), q(U,X)\Big) \geq c2^{-3n} \qquad (2)$$

for some constant c and large enough n. Here, $\mathcal{E}(f,g) := \mathbb{E}_{U,X}[(f(U,X) - g(U,X))^2]$ is the mean-squared error (MSE) between functions f and g and $\mathbb{E}_{U,X}$ is expectation over uniformly random variable $X \in \{0,1\}^n \backslash \{0^n\}$ and over Haar-random two-qubit gates in $n+1$-qubit unitary U.

Now we present the first main result below in Theorem 1, which states that sXQUATH generally does not hold. Particularly for a single-block mQSVT circuit (i.e. with $d = 1$) and a sublinear depth unitary U, one can construct a classical algorithm running in time polynomial in n with a non-negligibly less MSE than the trivial approximation.

Theorem 1 *There exists an efficient classical algorithm taking an efficient description of $n+1$-qubit unitary U with sublinear depth $d_U = o(n)$ and n bit string x as inputs and outputs an approximation $q(U,x)$ of a single-block mQSVT circuit output probability $p(U,x)$ that satisfies eqn. (2).*

Our second result further shows that the same algorithm spoofs sXES for mQSVT circuits with sufficiently large noise. As mQSVT circuits with completely depolarizing noise have uniform output probability, its sXES is $\mathbb{E}_U[\text{sXES}(U)] = 2^{-n}\sum_{x\neq 0}\mathbb{E}_U[p(U,x)]$, indicating no correlation with the ideal probability $p(U,x)$. Our algorithm spoofs sXES of all mQSVT circuits with depolarizing noise above a certain threshold (such that it is close to $2^{-n}\sum_{x\neq 0}\mathbb{E}_U[p(U,x)]$).

Theorem 2 *There exists an efficient classical algorithm spoofing sXES for all noisy single-block mQSVT circuit with $n+1$-qubit unitary U such that its sXES is at most $2^{-n}(\sum_{x\neq 0}\mathbb{E}_U[p(U,x)] + c^{d_U})$ for some constant $c > 0$.*

If we consider mQSVT circuit corrupted with depolarizing noise with noise strength $\gamma \in [0,1]$ on each of its register in each layer, then for sufficiently large γ its sXES score is going to be less than $2^{-n}(\sum_{x\neq 0}\mathbb{E}_U[p(U,x)] + c^{d_U})$. Theorem 2 indicates that the sXES all such noisy mQSVT circuit is spoofed by our algorithm.

Classical algorithm that refutes sXQUATH and spoofs sXES benchmark in Theorem 1 and Theorem 2 above is from a family of algorithms called the Pauli path algorithms. Below we discuss how the Pauli path algorithm works in showing the theorems above. Additionally we discuss how the existing instances of Pauli path algorithm used to classically simulate quantum circuits [20, 24, 33] are not directly applicable to mQSVT circuit, mainly due to the existence of multiple copies of random unitaries.

2 Pauli path algorithm for disproving sXQUATH and spoofing sXES

This section is slightly more technical as we define the Pauli path algorithm, how existing results using Pauli paths are not applicable in our case, and how can we make the Pauli path algorithm work to show Theorem 1 and Theorem 2. Nevertheless here we only outline the steps, for which a more rigorous treatment can be found in the full manuscript [1].

Given an n-qubit quantum circuit $C = C_d C_{d-1} \dots C_1$ (where C_j is its j-th layer), Pauli path algorithm classically computes its output probabilities by expanding density matrices at every layer in terms of normalized n-qubit Pauli matrices $\mathcal{P}_n = \{I/\sqrt{2}, X/\sqrt{2}, Y/\sqrt{2}, Z/\sqrt{2}\}^{\otimes n}$. At the input, we get $|0^n\rangle\langle 0^n| = \sum_{s_1 \in \mathcal{P}_n} s_1 \text{Tr}(s_1|0^n\rangle\langle 0^n|)$. We can substitute this expansion to the density matrix after the first layer, $\rho_1 := C_1|0^n\rangle\langle 0^n|C_1^\dagger$ then expand it in the same manner to get $\rho_1 = \sum_{s_1,s_2 \in \mathcal{P}_n} s_2 \text{Tr}(s_2 C_1 s_1 C_1^\dagger)\text{Tr}(s_1|0^n\rangle\langle 0^n|)$. Repeating this for the remaining layers and for measurement $|x\rangle\langle x|$, we obtain *transition amplitudes* defined by $\langle\!\langle s_1|0^n\rangle\!\rangle := \text{Tr}(s_1|0^n\rangle\langle 0^n|)$ and $\langle\!\langle s_{j+1}|C_j|s_j\rangle\!\rangle := \text{Tr}(s_{j+1}C_j s_j C_j^\dagger)$ and

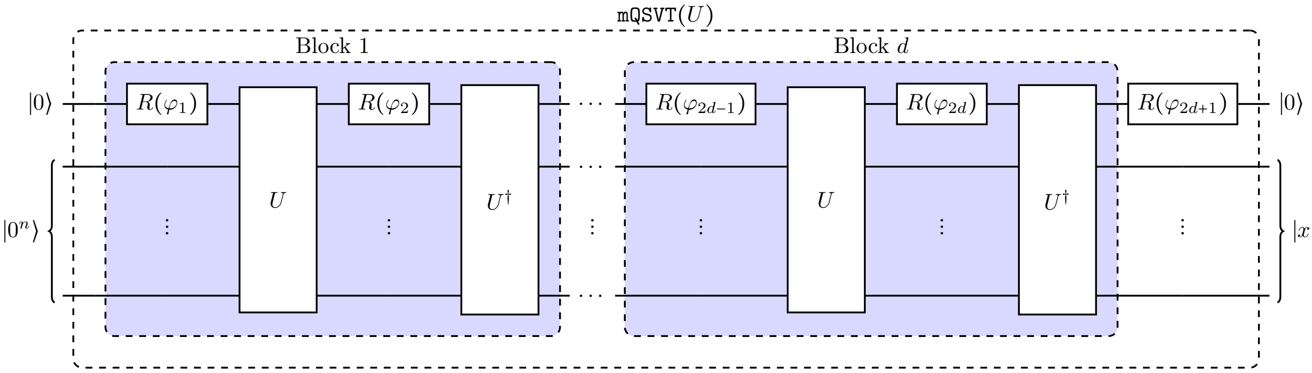

Figure 1: mQSVT circuit `mQSVT(`U`)` where U is a random $n+1$ qubit unitary made out of 2 qubit Haar-random unitaries and $R(\varphi)$ is Z-rotation gate with angle φ.

$\langle\!\langle x|s_{d+1}\rangle\!\rangle := \mathrm{Tr}(|x\rangle\!\langle x|s_{d+1})$. For transition amplitude $\langle\!\langle s_{j+1}|C_j|s_j\rangle\!\rangle$, we call s_j an *input Pauli* and s_{j+1} an *output Pauli.* A sequence of normalized n-qubit Paulis $\mathbf{s} = s_1, s_2, \ldots, s_{d+1}$ is called a *Pauli path.* Then, the probability of n bit string x is

$$|\langle x|C|0^n\rangle|^2 = \sum_{\mathbf{s}\in\mathcal{P}_n^{d+1}} f(C,\mathbf{s},x)\ , \tag{3}$$

where each Pauli path defines a *Fourier coefficient* $f(C,\mathbf{s},x) = \langle\!\langle x|s_{d+1}\rangle\!\rangle\langle\!\langle s_{d+1}|C_d|s_d\rangle\!\rangle \ldots \langle\!\langle s_2|C_1|s_1\rangle\!\rangle\langle\!\langle s_1|0^n\rangle\!\rangle$.

In computing the output probabilities of mQSVT circuit, a Pauli path algorithm expands density matrices at each layer in the copies of $n+1$-qubit random unitary U and its conjugate $U^\dagger$, as well as the single-qubit rotation gates $R(\varphi)$ interleaving them. So for a Pauli path $\mathbf{s}$ through a mQSVT circuit with unitary U and n-bit string output x, we denote an mQSVT circuit Fourier coefficient as $F(U,\mathbf{s},x)$, which consists of $2d(d_U+1)$ transition amplitudes. Hence the probability of output x from an mQSVT circuit with unitary U is

$$p(U,x) = \sum_{\mathbf{s}} F(U,\mathbf{s},x)\ . \tag{4}$$

Computing the *exact* output probabilities $p(U,x)$ using Pauli paths is exponentially hard due to exponentially many Fourier coefficients (one for each Pauli path $\mathbf{s}$). However it has been shown in [24] that for a unitary random circuit C, a carefully chosen *single* Pauli path can approximate $p(C,0^n)$ sufficiently well to refute XQUATH and spoof Linear XEB for sublinear depth circuits. The performance of this carefully chosen Pauli path approximation is due to the so-called "orthogonality property" of Pauli paths [24, 34] which states that the expectation of product of Fourier coefficient between distinct Pauli paths is equal to zero. Namely, $\mathbb{E}_C[f(C,\mathbf{s},x)f(C,\mathbf{r},x)] = 0$ if $\mathbf{s} \neq \mathbf{r}$. This value appears in both eqn. (2) and eqn. (1) when one expands the ideal probability $p(U,x)$ as in eqn. (4) and if $q(U,x)$ is a Pauli path approximation.

Unfortunately, orthogonality condition does not hold in general for mQSVT circuits due to a random unitary U appearing $2d$ number of times in a d-block mQSVT circuit. In fact it can take positive and negative values, complicating the analysis even more. But as noted in [34] on how the expectation of product between Fourier coefficients are closely related to Haar-random unitary moment matrix, we can use the random matrix theory of unitary Weingarten calculus [35–38] to compute this quantity for mQSVT circuits. This allows us to show that there is a Pauli path approximation using only a single Pauli path that disproves sXQUATH as stated in Theorem 1, as well as spoofs sXES in the sense of Theorem 2. This approximation for unitary U and outcome x takes the form of

$$q(U,x) = \frac{1}{2^n} + F(U,\mathbf{r},x)\ , \tag{5}$$

for Pauli path $\mathbf{r} = (Z\otimes I^{\otimes l-1}\otimes Z\otimes I^{\otimes n-l}, Z\otimes I^{\otimes n}, \ldots, Z\otimes I^{\otimes n})$ (up to normalization). With the chosen Pauli path $\mathbf{r}$, giving Fourier coefficient $F(U,\mathbf{r},x)$, the MSE error $\mathcal{E}(p(U,X),q(U,X))$ in the left-hand side of eqn. (2) turns out to be c^{d_U} smaller than the MSE error of the uniform-random sampling $\mathcal{E}(p(U,X),2^{-n})$ for some constant c. By taking depth d_U of unitary U to be sublinear, $d_U = o(n)$ eqn. (2) is then satisfied. Similarly for eqn. (1), using approximation $q(U,x)$ in place of experimental probability $p_{\exp}(U,x)$ gives a nontrivial sXES score stated in Theorem 2.

3 Future work and open questions

Our results along with [24], highlight the need for a novel benchmarking task with a stronger complexity-theoretic guarantee for future quantum supremacy experiments. In particular, such guarantee needs to rule out any possibility of spoofing by the Pauli algorithms. Moreover, one can also ask the question: What is the hardness relationship between different benchmarking methods, such as sXES, Linear XEB, XHOG, and their predecessor HOG [5]? What is the complexity theoretic relationship between their assumptions, sXQUATH, XQUATH, and QUATH [5] (assumption for the hardness of HOG)? Can one also disprove QUATH for sublinear-depth circuits using Pauli paths? To understand how to construct a more robust benchmarking method, it would be insightful to explore these questions.

Abstract. To achieve reliable measurement-based quantum computation, it is crucial to verify whether the resource graph states are accurately prepared in the adversarial scenario. Previous verification protocols for this task are resource consuming or noise susceptible. Here, we propose a robust and efficient protocol for verifying arbitrary graph states with any prime local dimension in the adversarial scenario, which can be applied immediately to verifying measurement-based quantum computation. Our protocol requires only local Pauli measurements and is easy to realize with current technologies. It achieves the optimal scaling behaviors with respect to the system size and the target precision, and exponentially enhances the scaling behavior with the significance level.

Keywords: robust verification, MBQC, graph state, adversarial scenario

The technical version of this work is available on arXiv:2305.10742.

1 Introduction

Quantum computation offers the promise of exponential speedups over classical computation on certain important problems [1–3]. The very power of quantum computation raises the challenging problem of verifying the correctness of computation results. This problem lies at the heart of the active research field of quantum characterization, verification, and validation (QCVV) [4–9]. However, it is extremely difficult to construct robust and efficient verification protocols that apply to noisy, intermediate-scale quantum (NISQ) devices [3, 10, 11].

Measurement-based quantum computation (MBQC) [12–16] is a powerful and flexible model of quantum computation, where graph states are used as resources and local projective measurements on qudits are used to drive the computation. Compared with the preparation of multipartite entangled states, it is in general much easier to perform local projective measurements accurately. So the main challenge in the verification of MBQC lies in the verification of the underlying resource states.

In this paper, we consider the problem of verifying the resource graph states in the following adversarial scenario [17–23], which is pertinent to blind and cloud quantum computing [19, 24–26]: Alice is a client who can only perform single-qudit projective measurements, and Bob is a server who can prepare arbitrary quantum states. To perform MBQC, Alice delegates the preparation of the resource graph state $|G\rangle \in \mathcal{H}$ to Bob, who then prepares a state ρ on the whole system $\mathcal{H}^{\otimes M}$ and sends it to Alice qudit by qudit. If Bob is honest, then he is supposed to generate M copies of $|G\rangle$; while if he is malicious, then he can mess up the computation of Alice by generating an arbitrary correlated or even entangled state. To obtain reliable computation results, Alice needs to verify the resource state prepared by Bob with suitable tests on some systems of ρ. If the test results satisfy certain conditions, then she can guarantee that the reduced state on the remaining system is close enough to $|G\rangle$, and can safely use it for MBQC; otherwise, she rejects Bob's state. Since there is no communication from Alice to Bob after the preparation of ρ, the client's privacy is kept against the server by the no-signaling principle [24]. Hence, the procedure above is also suitable to verifying blind MBQC.

According to the above discussion, the problem of verifying MBQC reduces to the problem of verifying the resource graph state in the adversarial scenario [17, 19, 27]. However, it is highly nontrivial to construct robust and efficient verification protocols in the adversarial scenario. Although various protocols have been proposed [17–23], most protocols known so far are too resource consuming. Moreover, most protocols are not robust to experimental noise: the state prepared by Bob will be rejected with a high probability even if it has a very small deviation from the ideal state $|G\rangle$. However, in practice, it is unrealistic to ask honest Bob to generate the perfect resource state. In addition, if the state deviation from $|G\rangle$ is small enough, then it is still useful for MBQC [21, 22]. Therefore, a practical protocol should accept nearly ideal quantum states with a sufficiently high probability. Otherwise, Alice needs to repeat the verification protocol many times to accept such states, which may substantially increase the sampling complexity. Unfortunately, no protocol known in the literature can achieve this goal. A fault-tolerant verification protocol [26] that accepts noisy but still error-correctable states has been proposed, but it is robust only to certain correctable errors, and is difficult to realize in the current era of NISQ devices [3, 10, 11].

In this work, we propose a robust and efficient protocol for verifying blind MBQC. To achieve this goal we propose a robust and efficient protocol for verifying general qudit graph states with a prime local dimension in the

[*] zhuhuangjun@fudan.edu.cn

[†] hmasahito@cuhk.edu.cn

adversarial scenario. Our protocol is appealing to practical applications because it only requires stabilizer tests based on local Pauli measurements, which are easy to implement with current technologies. It is robust against arbitrary types of noise in state preparation, as long as the fidelity is sufficiently high. Moreover, our protocol can achieve optimal scaling behaviors with respect to the system size and target precision, and the sampling cost is comparable to the counterpart in the nonadversarial scenario. As far as we know, such a high efficiency has never been achieved before when robustness is taken into account. In addition to verifying MBQC, our approach can also be applied to verifying many other important quantum states in the adversarial scenario.

2 Verification of MBQC

Recently, a homogeneous strategy [17, 27] for testing qudit stabilizer states was proposed [17, 28]. Here we use a variant strategy for testing qudit graph states (d is a prime), which serves as an important subroutine of our verification protocol. The strategy is based on stabilizer tests with local Pauli measurements (see the technical version for details), and can be characterized by a two-outcome measurement $\{\Omega, \mathbb{I}-\Omega\}$, where the outcome Ω corresponds to passing the test, and the outcome $\mathbb{I}-\Omega$ corresponds to the failure. The operator Ω is called a strategy, and can be constructed as the form

$$\Omega = |G\rangle\langle G| + \lambda(\mathbb{I} - |G\rangle\langle G|) \qquad (1)$$

for any $1/d \leq \lambda < 1$. We denote by $\nu := 1-\lambda$ the spectral gap of Ω from the largest eigenvalue.

Suppose Alice intends to perform MBQC on the graph state $|G\rangle$ prepared by Bob. Our verification protocol runs as follows. First, Bob produces a state ρ on the whole space $\mathcal{H}^{\otimes(N+1)}$ with $N \geq 1$ and sends it to Alice. After receiving the state, Alice randomly permutes the $N+1$ systems of ρ (due to this procedure, we can assume that ρ is permutation invariant without loss of generality) and applies the strategy Ω in Eq. (1) to the first N systems. If at most k failures are observed among the N tests, Alice accepts the reduced state σ_{N+1} on the remaining system and uses it for MBQC; otherwise, she rejects it. Here the integer k is called the number of allowed failures, which is chosen by Alice before performing the tests.

With this verification protocol, Alice aims to achieve three goals: completeness, soundness, and robustness. The completeness means Alice does not reject the correct state. Since $|G\rangle$ can always pass each test, this goal is automatically guaranteed. The soundness means the following: once accepting, Alice needs to ensure with a small significance level δ that her state σ_{N+1} for MBQC has a sufficiently high fidelity (at least $1-\epsilon$) with $|G\rangle$. The threshold ϵ is called the target infidelity, which together with δ characterize the target verification precision. Among all known verification protocols, only the protocol of Refs. [17, 27] achieves the optimal sampling complexity with respect to all δ, ϵ, and the qudit number n of $|G\rangle$, even without considering the robustness. Although the condition of soundness looks simple, it is highly nontrivial to determine the degree of soundness. Even in the special case $k=0$, this problem was resolved only very recently after quite a lengthy analysis [17, 27].

To characterize the robustness of a protocol, we need to consider the case in which honest Bob prepares independent and identically distributed (i.i.d.) quantum states, that is, $\rho = \tau^{\otimes(N+1)}$ with $\tau \in \mathcal{D}(\mathcal{H})$. Due to inevitable noise, τ may not equal the ideal state $|G\rangle\langle G|$. Nevertheless, if the infidelity $\epsilon_\tau := 1 - \langle G|\tau|G\rangle$ is smaller than ϵ, then τ is still useful for MBQC. For a robust verification protocol, such a state should be accepted with a high probability. On the other hand, the probability that Alice accepts τ reads

$$p^{\mathrm{iid}}_{N,k}(\tau) = B_{N,k}\big(1-\mathrm{tr}(\Omega\tau)\big) = B_{N,k}(\nu\epsilon_\tau), \qquad (2)$$

where N is the number of tests, k is the number of allowed failures, and $B_{N,k}(p) := \sum_{j=0}^{k}\binom{N}{j}p^j(1-p)^{N-j}$ is the binomial cumulative distribution function.

To construct a robust verification protocol, k should be sufficiently large, so that $p^{\mathrm{iid}}_{N,k}(\tau)$ is sufficiently high. However, most previous protocols can only reach a meaningful conclusion when $k=0$ [17–20, 27], in which case the probability $p^{\mathrm{iid}}_{N,k=0}(\tau) = (1-\nu\epsilon_\tau)^N$ decreases exponentially with N, which is not satisfactory. Consequently, many repetitions are necessary to ensure that Alice accepts the state τ at least once. When $\epsilon_\tau = \epsilon/2$ for example, the number of repetitions is at least $\Theta(\exp[1/(4\delta)])$ for the protocol in [19] and $\Theta(\delta^{-1/2})$ for the protocol in [17, 27] as shown in the technical version, which substantially increases the actual sampling cost. Therefore, although some protocols known in the literature are reasonably efficient in achieving the soundness, they are not useful in verifying blind MBQC in a realistic scenario.

3 Results

3.1 Guaranteed infidelity

Suppose ρ is permutation invariant. Then the probability that Alice accepts ρ reads

$$p_k(\rho) = \sum_{i=0}^{k}\binom{N}{i}\mathrm{tr}\Big(\big[\Omega^{\otimes(N-i)}\otimes\overline{\Omega}^{\otimes i}\otimes\mathbb{I}\big]\rho\Big), \qquad (3)$$

where $\overline{\Omega} := \mathbb{I}-\Omega$. Denote by σ_{N+1} the reduced state on the remaining system when at most k failures are observed. The fidelity between σ_{N+1} and the ideal state $|G\rangle$ reads $F_k(\rho) = f_k(\rho)/p_k(\rho)$ [assuming $p_k(\rho) > 0$], where

$$f_k(\rho) = \sum_{i=0}^{k}\binom{N}{i}\mathrm{tr}\Big(\big[\Omega^{\otimes(N-i)}\otimes\overline{\Omega}^{\otimes i}\otimes|G\rangle\langle G|\big]\rho\Big). \qquad (4)$$

The actual verification precision can be characterized by the following figure of merit with $0 < \delta \leq 1$,

$$\bar{\epsilon}_\lambda(k,N,\delta) := 1 - \min_\rho\{F_k(\rho)\,|\,p_k(\rho) \geq \delta\}, \qquad (5)$$

where λ is determined by Eq. (1), and the minimization is taken over permutation-invariant states ρ on $\mathcal{H}^{\otimes(N+1)}$.

If Alice accepts the state prepared by Bob, then she can guarantee (with significance level δ) that the reduced state σ_{N+1} has infidelity at most $\bar{\epsilon}_\lambda(k,N,\delta)$ with $|G\rangle$. Consequently, the deviation of any measurement outcome probability from the ideal value is not larger than $\sqrt{\bar{\epsilon}_\lambda(k,N,\delta)}$. In the technical version we present the analytical formula and many useful properties of $\bar{\epsilon}_\lambda(k,N,\delta)$.

3.2 Verification with a fixed error rate

Now we set the number k to be proportional to the number of tests, that is, $k = \lfloor s\nu N\rfloor$, where $0 \le s < 1$ is the error rate. In this case, when Bob prepares i.i.d. states τ with infidelity $\epsilon_\tau < s$, the acceptance probability approaches one as N increases. In addition, we have the following theorems as proved in the technical version.

Theorem 1 *Suppose* $0 < s, \lambda < 1$, $0 < \delta \le 1/4$. *Then*

$$s - \frac{1}{\nu N} < \bar{\epsilon}_\lambda(\lfloor \nu s N\rfloor, N, \delta) \le s + \frac{1}{\nu\lambda}\sqrt{\frac{s\ln\delta^{-1}}{N}} + \frac{\ln\delta^{-1}}{2\nu^2\lambda N} + \frac{2}{\lambda N}. \qquad (6)$$

Theorem 1 implies that $\bar{\epsilon}_\lambda(\lfloor \nu s N\rfloor, N, \delta)$ converges to s when the number N of tests gets large. To achieve a given ϵ and δ, which means $\bar{\epsilon}_\lambda(\lfloor \nu s N\rfloor, N, \delta) \le \epsilon$, it suffices to set $s < \epsilon$ and choose a sufficiently large N.

Theorem 2 *Suppose* $0 < \delta \le 1/2$, $0 \le s < \epsilon < 1$, *and* $0 < \lambda < 1$. *Then we have* $\bar{\epsilon}_\lambda(\lfloor \nu s N\rfloor, N, \delta) \le \epsilon$ *as long as*

$$N \ge \frac{\epsilon}{[\lambda\nu(\epsilon - s)]^2}\left(\ln\delta^{-1} + 4\lambda\nu^2\right). \qquad (7)$$

Notably, if the ratio s/ϵ is a constant, then the sampling cost is only $O(\epsilon^{-1}\ln\delta^{-1})$, which is optimal with respect to all parameters ϵ, δ, and the qudit number n.

3.3 Sampling complexity of robust verification

Let ρ be the state on $\mathcal{H}^{\otimes(N+1)}$ prepared by Bob and σ_{N+1} be the reduced state after Alice performs suitable tests and accepts the state ρ. To verify the target state within infidelity ϵ, significance level δ, and robustness r (with $0 \le r < 1$) entails the following two conditions.

1. (Soundness) If the infidelity of σ_{N+1} with the $|G\rangle$ is larger than ϵ, then the acceptance probability $< \delta$.

2. (Robustness) If $\rho = \tau^{\otimes(N+1)}$ with $\tau \in \mathcal{D}(\mathcal{H})$ and $\epsilon_\tau \le r\epsilon$, then the acceptance probability $\ge 1 - \delta$.

Let k be the number of allowed failures; then the conditions of soundness and robustness can be expressed as

$$\bar{\epsilon}_\lambda(k,N,\delta) \le \epsilon, \qquad B_{N,k}(\nu r\epsilon) \ge 1 - \delta. \qquad (8)$$

Denote by $N_{\min}(\epsilon,\delta,\lambda,r)$ the minimum positive integer N such that Eq. (8) holds for some $k \le N - 1$. Then $N_{\min}(\epsilon,\delta,\lambda,r)$ is the minimum number of tests required for robust verification; it can be calculated numerically by using Algorithm 1 presented in the technical version.

Our following theorem provides an informative upper bound for $N_{\min}(\epsilon,\delta,\lambda,r)$ and clarifies the sampling complexity of robust verification.

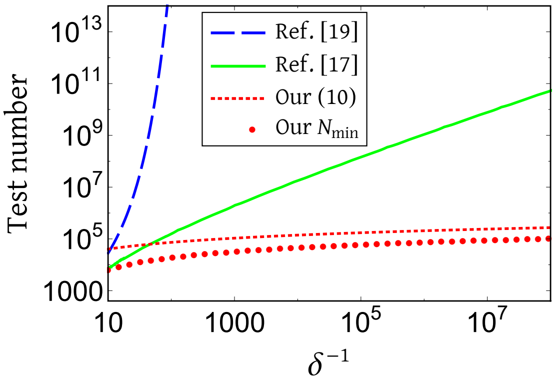

Figure 1: Number of tests required to verify a qudit graph state in the adversarial scenario within infidelity $\epsilon = 0.01$, significance level δ, and robustness $r = 1/2$. The red dots correspond to $N_{\min}(\epsilon,\delta,\lambda,r)$ with $\lambda = 1/2$; the red dashed curve corresponds to the RHS of Eq. (10), which is an upper bound for $N_{\min}(\epsilon,\delta,\lambda,r)$. The blue curve corresponds to the protocol in [19]; and the green curve corresponds to the protocol in [17] with $\lambda = 1/2$. The performances of the protocols in [21, 22] are not shown since the numbers of tests required are too large.

Theorem 3 *Suppose* $0 < \lambda, \epsilon < 1$, $0 < \delta \le 1/2$, *and* $0 \le r < 1$. *Then the conditions in Eq.* (8) *hold as long as*

$$k = \left\lfloor \left(\frac{\lambda\sqrt{2\nu} + r}{\lambda\sqrt{2\nu} + 1}\right)\nu\epsilon N\right\rfloor, \qquad (9)$$

$$N \ge \left\lceil \left[\frac{\lambda\sqrt{2\nu} + 1}{\lambda\nu(1 - r)}\right]^2 \frac{\ln\delta^{-1} + 4\lambda\nu^2}{\epsilon}\right\rceil. \qquad (10)$$

For given λ and r, the minimum number of tests is only $O(\epsilon^{-1}\ln\delta^{-1})$, which is independent of the qudit number n of $|G\rangle$ and achieves the optimal scaling behaviors with respect to the infidelity ϵ and significance level δ. If we choose $r = \lambda = 1/2$ for example, then Theorem 3 implies that $N_{\min}(\epsilon,\delta,\lambda,r) \le \lceil 144\,\epsilon^{-1}(\ln\delta^{-1} + 0.5)\rceil$, while numerical calculation shows $N_{\min}(\epsilon,\delta,\lambda,r) \le 67\,\epsilon^{-1}\ln\delta^{-1}$. Compared with previous protocols [17, 19, 27], our protocol improves the scaling behavior with respect to the significance level δ exponentially and even doubly exponentially, as illustrated in Fig. 1.

4 Discussion

We have proposed a highly robust and efficient protocol for verifying qudit (d is a prime) graph states in the adversarial scenario, which can be applied immediately to verifying blind MBQC. In addition to graph states, our protocol can also be used to verify many other important pure quantum states in the adversarial scenario (see the technical version for details), where the state preparation is controlled by a potentially malicious adversary, who can produce an arbitrary correlated or entangled state ρ on the whole system $\mathcal{H}^{\otimes(N+1)}$. Therefore, our verification protocol is of interest not only to blind MBQC, but also to many other tasks in quantum information processing that entail high-security.

Abstract. In this work, we discover a quantum pseudo-telepathy phenomenon that requires quantum magic, the essential ingredient for universal quantum computation. Translating the nonlocal phenomenon into a relation task, we provide the first unconditional proof of quantum magic advantage in computation. With recent experimental progress, we expect the computational task in this work to be faithfully realized on an upcoming early fault-tolerant quantum computing platform. We hope our results can inspire further explorations in this direction, eventually going beyond shallow circuits and solidifying the "magic" of universal quantum computation.

Keywords: quantum magic, shallow circuit computation, binary constraint system, quantum nonlocality

1 Introduction

Quantum theory promises computational speed-ups than classical means. The celebrated Gottesman-Knill Theorem implies that the full power of quantum computation resides in the specific resource of "magic" states — the secret sauce to establish universal quantum computation [1–3]. However, it is still questionable whether "magic" indeed brings the believed quantum advantage, ridding unproven complexity assumptions or black-box oracles. In this work, we study this issue and demonstrate the first unconditional magic advantage: a separation between the power of generic constant-depth or "shallow" quantum circuits and magic-free counterparts.

To establish the unconditional separation, we link the shallow circuit computation with the strongest form of quantum nonlocality — quantum "pseudo-telepathy," [4] where distant non-communicating observers generate perfectly synchronous statistics. Inspired by the linear binary constraint system [5], for the first time, we explicitly construct a quantum pseudo-telepathy correlation requiring magic resources and prove strict upper bounds on the correlation strength of solely magic-free operations. Then, we design a computational task that requires the output and the input to satisfy the constructed magic-necessary pseudo-telepathy correlations. This task separates the capabilities of generic quantum shallow circuits and their magic-free counterparts. We summarized our approach in Fig. 1.

As a by-product, we provide an efficient algorithm to solve a general linear binary constraint system over the Pauli group, in contrast to the broad undecidability in constraint systems [6, 7].

2 Basic Notions

2.1 Quantum magic

Quantum magic originates from the study of the classical simulation of quantum computation, closely related to the stabilizer formalism [1]. Consider an n-qubit quantum system. The Clifford group $\mathbb{C}_n$ is defined as the normalizer group of the Pauli group $\mathbb{P}_n$, namely the set of unitary operators that map a Pauli operator $P \in \mathbb{P}_n$ to a Pauli operator. Elements in the Clifford group are called Clifford operators or gates. A quantum circuit initialized in a computational-basis state and containing only Clifford gates and Pauli measurements is called a stabilizer circuit. Clearly, some unitary operators do not belong to the Clifford group, termed non-Clifford gates. Correspondingly, there are quantum states that cannot be prepared by any stabilizer circuit, even allowing post-selecting a subsystem upon Pauli measurement results. We call such states "magic" states [2].

2.2 Circuit classes

To realize universal quantum computation and achieve quantum advantage, some sort of "magic" must be involved, which can be either some magic states or non-Clifford gates [2, 3, 8–10]. In later discussions, we consider a model where all the magic comes from the non-Clifford gates. That is, the quantum state is initialized in $|0\rangle^{\otimes n}$, and the quantum measurement is performed on the computational basis. Depending on the type of computational resources, we categorize the circuits into three types. In a generic quantum circuit, the state undergoes operations in a universal gate set. Without quantum subsystems, the circuit degenerates into a classical one. In between, we define the Clifford or magic-free circuit, in which the quantum gates must be Clifford.

When the circuit is restricted to a constant depth, we call it a "shallow circuit." Furthermore, we consider the fan-in of gates to be bounded. Corresponding to a generic quantum circuit [11], a Clifford circuit, and a classical circuit [12, 13], we categorize the shallow circuits into classes of QNC^0, ClifNC^0, and NC^0, respectively.

2.3 Binary constraint systems (BCS)

Our starting point will be a special nonlocal game originating from the linear BCS [5]. A BCS comprises a set of Boolean functions, namely constraints, over binary variables $v_\gamma \in \{+1, -1\}$. For a linear BCS, the constraints are given in the form of $\prod_{\gamma\in\mathcal{S}_\alpha} v_\gamma = c_\alpha \in \{+1, -1\}$, where $\mathcal{S}_\alpha$ defines a subset of the variables. We say the

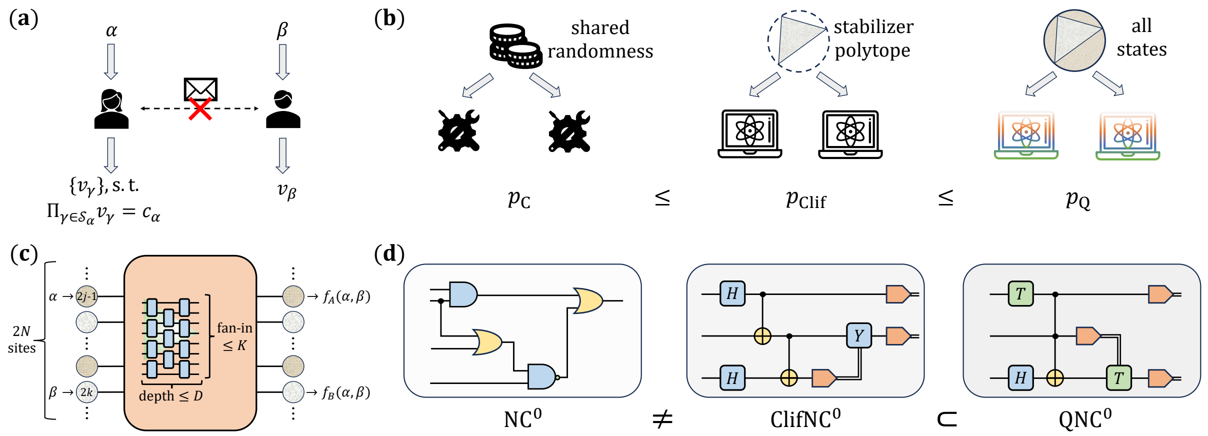

Figure 1: **(a)** A general BCS nonlocal game with non-communicating players. **(b)** Different game strategies. The three subfigures correspond to classical strategies, Clifford strategies, and general quantum strategies. **(c)** Solving a relation problem via a shallow circuit with bounded fan-in gates. **(d)** Categories of shallow circuits. Roughly speaking, the shallow circuit power corresponds to the corresponding strategies in nonlocal games given in (b).

BCS has a classical solution iff there exists a satisfying assignment to all the variables. The BCS can be generalized to an operator-valued set of functions, where the scalar variables are replaced with Hermitian operators A_γ with eigenvalues $\{+1,-1\}$, and the constraints are given in terms of $\prod_{\gamma\in\mathcal{S}_\alpha} A_\gamma = c_\alpha \mathbb{I}$ with $\mathbb{I}$ an identity operator of a finite dimension. In addition, the operators in each constraint need to be simultaneously measurable. We say the BCS has an operator-valued solution iff there exists an operator-valued satisfying assignment to all the Hermitian operators with an appropriate dimension.

2.4 BCS-based nonlocal games

Given a linear BCS, consider a corresponding nonlocal game with two non-communicating parties, Alice and Bob [Fig. 1(a)]. In each round of the game, a referee picks a constraint from the BCS labelled by α and a variable labelled by $\beta \in \mathcal{S}_\alpha$. The referee asks Alice to assign values to the variables satisfying the constraint and Bob to assign a value for v_β. The players win the game if and only if Alice gives a satisfying assignment for the constraint, and her assignment to v_β coincides with Bob's. Alice and Bob can agree on a game strategy in advance. We consider a hierarchy of their capabilities [Fig. 1(b)]:

1. *Classical strategies:* Players share common randomness and apply local classical operations;

2. *Clifford strategies:* Players share entanglement created by Clifford circuits and apply local Clifford operations and Pauli measurements;

3. *General strategies:* Players share general entanglement and apply general local quantum operations.

In the field of nonlocality, a perfect winning quantum strategy is termed "quantum pseudo-telepathy" [4]. The existence of a perfect winning classical/quantum strategy in the nonlocal game is equivalent to the existence of a classical/operator-valued solution to the underlying BCS [5, 14]. Specifically, a perfect winning Clifford strategy corresponds to a Pauli-string solution.

3 Main Results

Previously, a strict inclusion between NC^{0}and QNC^{0}was proved [15, 16]. In this work, we unconditionally confirm magic makes a strict hierarchy among shallow circuits [Fig. 1(d)]:

$$\mathsf{ClifNC}^0 \subset \mathsf{QNC}^0. \tag{1}$$

We take the following steps toward this main result: (1) Find a BCS that does not have classical or Pauli-string solutions but has generic observable solutions; (2) Based on the above BCS, construct a nonlocal game in which magic is necessary to win perfectly; (3) Transform the magic-necessary BCS nonlocal game to a relation problem separating ClifNC^{0}and QNC^0(Sec. 3.3).

For step (1), we develop an efficient approach to solving a linear BCS over the Pauli group (Sec. 3.1), which can then rule out BCS nonlocal games with perfect-winning Clifford/classical strategies. Afterward, we construct a BCS that has a non-trivial magic-necessary operator-valued solution and complete step (2) (Sec. 3.2).

3.1 Solving linear BCS over the Pauli group

To study Clifford strategies in the BCS nonlocal game, note that the Pauli strings are either anti-commuting, like $\{X, Z\} = 0$, or commuting, like $[X \otimes X, Z \otimes Z] = 0$. In addition, for two Pauli strings A, B, we have $\langle \Phi^+ | A \otimes B | \Phi^+ \rangle = \mathrm{tr}(AB^{\mathrm{T}})/d \in \{0, \pm 1\}$, where d is the system dimension. When restricting solving the BCS over the Pauli group, we can transform the original operator-valued BCS into a classically valued BCS for the commutators between the variables. We prove the following results for general linear BCS.

Theorem 1 *Given a linear BCS with l variables and m constraints, there exists a classical algorithm that finishes* *in* poly(l, m) *steps to determine whether the BCS has a Pauli-string operator-valued solution. If the answer is affirmative, the algorithm returns one such solution.*

Theorem 2 *Suppose a linear BCS does not have a Pauli-string solution. Then, for its associated nonlocal game, if Alice and Bob are restricted to Clifford strategies, either Alice fails to give satisfying assignments for all the constraints, or there exists one pair of questions (α, β), where the probability that Alice and Bob's assignments to v_β coincide does not exceed $1/2$.*

3.2 Magic-necessary BCS

Next, we construct a BCS family, some of which have a general quantum solution but no Pauli-string solution. This result explicitly falsifies a previous conjecture [17].

We present the BCS family in the language of graph theory. Consider an undirected complete graph $G = (V, E)$ with n vertices. The BCS contains the following variables: (1) Each vertex $v \in V$ corresponds to one variable a_v; (2) Each undirected edge $e = (u, v) \in E$ corresponds to three variables x_{uv}, y_{uv}, and z_{uv}; (3) Every two disjoint edges $e_1 = (u, v) \in E$ and $e_2 = (s, t) \in E$, where s, t, u, and v are different vertices, correspond to (i) variable $b_{e_1e_2} \equiv b_{uv|st}$, where $b_{e_1e_2} = b_{e_2e_1}$; (ii) variables $c_{e_1e_2} \equiv c_{uv|st}$ and $c_{e_2e_1} \equiv c_{st|uv}$, where $c_{e_1e_2} \neq c_{e_2e_1}$ in general. The smallest non-trivial BCS is defined on a graph with four vertices (Fig. 2). Based on these variables, the BCS contains the following constraints,

$$\begin{aligned} a_u a_v y_{uv} &= 1, \forall (u, v) \in E, \\ x_{uv} y_{uv} z_{uv} &= 1, \forall (u, v) \in E, \\ x_{uv} x_{st} b_{uv|st} &= 1, \forall (u, v), (s, t) \in E, \\ x_{uv} z_{st} c_{uv|st} &= 1, \forall (u, v), (s, t) \in E, \\ b_{uv|st} b_{vs|ut} b_{su|vt} &= 1, \forall u, v, s, t \in V, \\ c_{uv|st} c_{vs|ut} c_{su|vt} &= 1, \forall u, v, s, t \in V, \\ \prod_{v \in V} a_v &= -1. \end{aligned} \tag{2}$$

This BCS family exhibits a hierarchy among classical, Clifford, and general quantum resources. Based on the BCS nonlocal game construction, we state the result in terms of perfect winning strategies in the nonlocal games.

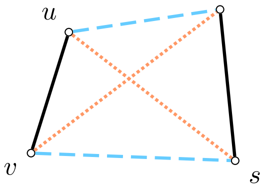

Figure 2: A subgraph illustrating the variables in Eq. (2).

Theorem 3 *For the nonlocal game defined through the BCS in Eq. (2),*

1. *$n = 4$: $\exists$ perfect-winning Clifford strategy, but it does not have a perfect-winning classical strategy;*
2. *$n \in 2\mathbb{N} + 5$: $\exists$ perfect-winning classical strategy;*
3. *$n \in 2\mathbb{N}+6$: $\exists$ strategies that exploit quantum magic to win perfectly, but it does not have a perfect-winning Clifford or classical strategy.*

As a corollary of Theorem 2, for the nonlocal game with $n \in 2\mathbb{N} + 6$, with uniformly distributed random questions, the winning probabilities of all Clifford and classical strategies can be upper-bounded by

$$p_{\text{Clif}} \leq 1 - \frac{1}{2|\mathcal{Q}|}, \tag{3}$$

where $\mathcal{Q}$ denotes the set of questions.

Here, we present one operator-valued solution to the BCS when $n = 8$. Labelling the vertices from 1 to 8, a realization of a_v and x_{uv} in the above BCS is

$$\begin{aligned} &a_v = \mathbb{I}_8 - 2\mathbf{e}_{vv}, v = 1, \cdots, 8, \\ &x_{uv} = \mathbb{I}_8 - \mathbf{e}_{uu} - \mathbf{e}_{vv} + \mathbf{e}_{uv} + \mathbf{e}_{vu}, u, v = 1, \cdots, 8, u \neq v, \end{aligned} \tag{4}$$

where $\mathbb{I}_8$ is an eight-dimensional identity operator, and $\mathbf{e}_{ij}$ denotes an elementary matrix. The other operators can be determined via a_v's and x_{uv}'s. The measurements corresponding to x_{uv} require non-Clifford operations, which can be realized by applying a Toffoli gate up to a local unitary operation, which is a non-Clifford gate, followed by the computational-basis measurement.

3.3 Magic advantage in shallow circuits

Building on the BCS nonlocal game defined through Eq. (2), we design a computational task that requires the output and the input to satisfy the constructed magic-necessary pseudo-telepathy correlations. Roughly speaking, consider a relation problem with $2N$ sites: two randomly chosen computing sites $2j-1$ and $2k$ are input with α and β and required to output the desired nonlocal outputs up to an allowed transformation depending on other sites [Fig. 1(c)]. Using a light-cone-type argument [15, 16], we prove that the only way a shallow circuit solves the relation problem is to apply the quantum pseudo-telepathy strategy as a subroutine, which necessarily requires magic.

Theorem 4 (Informal) *Given the nonlocal game defined by the BCS in Eq. (2) with size $n \in 2\mathbb{N} + 6$, $\exists$ relation problem R_N^n and a constant K, such that for circuits restricted to K-bounded fan-in gates,*

- *R_N^n can be perfectly solved by a* QNC^0 *circuit, where some gates are non-Clifford operations;*
- *Any Clifford circuit that solves R_N^n with probability larger than $(1 + p_{\text{Clif}})/2$ with p_{Clif} given in Eq. (3) must have a circuit depth $\Omega(\log N)$.*

Quantum theory promises computational speed-ups than classical means. The celebrated Gottesman-Knill Theorem implies that the full power of quantum computation resides in the specific resource of “magic” states — the secret sauce to establish universal quantum computation. However, it is still questionable whether “magic” indeed brings the believed quantum advantage, ridding unproven complexity assumptions or black-box oracles. In this work, we demonstrate the first unconditional magic advantage: a separation between the power of generic constant-depth or “shallow” quantum circuits and magic-free counterparts. For this purpose, we link the shallow circuit computation with the strongest form of quantum nonlocality — quantum “pseudo-telepathy,” where distant non-communicating observers generate perfectly synchronous statistics. We prove quantum magic is indispensable for such correlated statistics in a specific nonlocal game inspired by the linear binary constraint system. Then, we translate generating quantum pseudo-telepathy into a relation problem, where magic is necessary for a shallow circuit to solve it perfectly. As a by-product, we provide an efficient algorithm to solve a general linear binary constraint system over the Pauli group, in contrast to the broad undecidability in constraint systems. We anticipate our results will enlighten the final establishment of the unconditional advantage of universal quantum computation.

I. INTRODUCTION

Starting from Richard Feynman’s proposal of simulating physics with quantum means [1], it has been an appealing quest to exploit phenomena unique to quantum theory to accelerate computation. A series of results, such as Shor’s factoring algorithm [2] and Grover’s search [3], strengthen the belief in the power of quantum computation. Notwithstanding the prosperity in the zoo of quantum algorithms, it is still intriguing to answer the basic questions: Does quantum theory really bring a computational advantage over classical means, and if yes, what is the origin of such power? A well-known statement that seems to respond to both questions is quantum “magic” [4]. The so-called quantum magic states are beyond the reach of stabilizer circuits, the ones initialized in the computational-basis state and composed of only Clifford gates and Pauli measurements. The Gottesman-Knill Theorem shows that stabilizer circuits can be perfectly simulated by classical computers in a polynomial time of the input size, deemed as efficient [5–7]. On the other hand, attempts from the simulation field suggest a strong relevance between the quantity of magic and the extent of quantum advantage [8–16]. Quantum algorithms richer in magic are often more difficult for a classical computer to simulate.

Indeed, considering the structure of quantum state space, magic states, or equivalently non-Clifford operations, is indispensable for a complete picture [4, 17]. In contrast, whether they bring a super-polynomial or even an exponential quantum computational advantage as promised remains to be proved. Despite numerous good reasons to believe in its validity [18, 19], unfortunately, explorations to date have not got rid of assumptions of unproven hardness for classical algorithms, such as factoring a large number in Shor’s algorithm [2], or reliance on queries to a black-box oracle as in Grover’s search [3], where the oracle construction may be hard work.

To firmly establish the quantum advantage, one may alternatively start from a more restrictive regime in complexity. Instead of defining “efficient” as a polynomially growing time, a notable regime is the set of shallow circuits [20, 21], where the circuit depth, or equivalently the computing time, is restricted to a constant irrelevant to the problem size. The consideration of quantum shallow circuits was partly attributed to an experimental perspective, as it is relatively simpler to deal with system decoherence within a fixed time [22]. More importantly, theorists have rich toolkits from quantum information theory to aid the investigations. A particular instrument is quantum nonlocality, a most distinguishing property of quantum theory [23, 24]. As shown by the renowned Bell theorem [25], entanglement leads to purely quantum

[*] zxj24@hku.hk

[†] pzk20@mails.tsinghua.edu.cn

[‡] lgd22@mails.tsinghua.edu.cn

correlations between nonlocal observers beyond the scope of classical physics [26]. One can translate quantum nonlocality into a computational task to generate nonlocal statistics among distant computing sites [27–30]. While classical circuits require a growing time with respect to the input size to scramble the information for computation, quantum shallow circuits are competent to the task, bringing an unconditional advantage.

Despite the recent progress in shallow circuits, a vague question arises: Is "magic" indispensable for the full power of quantum computation in the low-complexity regime? Indeed, among all the existing explorations of quantum shallow circuits, the essential ingredient for the quantum advantage — long-range entanglement, can be generated with Clifford circuits without using the magic resource [31]. On the other hand, though not rigorous, with our experiences in the complexity theory such as the padding argument [32], we may be inclined to think of a collapse of the power of universal quantum computation if magic makes no difference in the low-complexity regime. Following the logic of relating nonlocality with shallow circuit computation, a relevant question is the role of quantum magic in nonlocality, which is much unexplored compared to the more prevalent quantum features like entanglement.

In this work, we unconditionally confirm that quantum magic brings an advantage, at least in a shallow circuit. For this purpose, we consider the strongest form of nonlocality, where nonlocal observers generate perfectly synchronous statistics, namely quantum "pseudo-telepathy" [23]. For the first time, we explicitly construct a quantum pseudo-telepathy correlation requiring magic resources and prove strict upper bounds on the correlation strength of solely magic-free operations. Then, we design a computational task that requires the output and the input to satisfy the constructed magic-necessary pseudo-telepathy correlations. This task separates the capabilities of generic quantum shallow circuits and their magic-free counterparts. We summarize our approach in Fig. 1.

II. BASIC NOTIONS AND MAIN RESULT

The concept of quantum magic originates from the study of the classical simulation of quantum computation, closely related to the stabilizer formalism [5]. Consider an n-qubit quantum system on which the Pauli group is defined as the set of operators

$$\mathbb{P}_n = \{\pm 1, \pm i\} \times \{\mathbb{I}, \sigma_x, \sigma_y, \sigma_z\}^{\otimes n}, \tag{1}$$

together with operator multiplication. Here, $\mathbb{I}$ is the two-dimensional identity operator, and $\sigma_x, \sigma_y, \sigma_z$ are the qubit Pauli matrices. The Clifford group is defined as the normalizer group of the Pauli group $\mathbb{P}_n$:

$$\mathbb{C}_n = \{C \in \mathbb{U}_n | \forall P \in \mathbb{P}_n, CPC^\dagger \in \mathbb{P}_n\}, \tag{2}$$

where $\mathbb{U}_n$ is the set of all n-qubit unitary operators. Elements in the Clifford group are called Clifford operators or gates. A quantum circuit initialized in the computational-basis state and containing only Clifford gates and Pauli measurements is called a stabilizer circuit. Note that the Pauli measurements are equivalent to applying some Clifford gates, followed by computational-basis measurements. The Gottesman-Knill theorem states that the measurement results can be well-simulated by a classical circuit running in a time that is polynomial in the number of qubits [5, 6].

Clearly, there are unitary operators that do not belong to the Clifford group. Well-known non-Clifford operations include the T-gate, which adds a non-trivial relative phase to basis state superposition:

$$a|0\rangle + b|1\rangle \to a|0\rangle + e^{i\pi/4} b|1\rangle, \tag{3}$$

and the Toffoli gate, the quantum generalization of the NAND gate:

$$|c_1\rangle|c_2\rangle|t\rangle \to |c_1\rangle|c_2\rangle|t \oplus (c_1 \cdot c_2)\rangle, \tag{4}$$

where $c_1, c_2, t \in \{0, 1\}$ represent the values in the two control qubits and the target qubit, respectively. Correspondingly, there are quantum states that cannot be prepared by any stabilizer circuit, even allowing post-selecting a subsystem upon Pauli measurement results. We call such states "magic" states. As an example, the state

$$|H\rangle = \cos\frac{\pi}{8}|0\rangle + \sin\frac{\pi}{8}|1\rangle \tag{5}$$

is a qubit magic state.

To realize universal quantum computation and achieve quantum advantage, some sort of "magic" must be involved, which can be either some magic states or non-Clifford gates [4, 6, 9, 33, 34]. In later discussions, we consider a model where all the magic comes from the gates. That is, the quantum state is initialized in $|0\rangle^{\otimes n}$, and the quantum measurement is performed on the computational basis. Depending on the type of computational resources, we categorize the circuits into three types. In a generic quantum circuit, the state undergoes operations in a universal gate set. Without quantum subsystems, the circuit degenerates into a classical one. We further define the Clifford or magic-free circuit, in which the quantum gates must be Clifford. Note that in generic quantum circuits or magic-free circuits, we also allow intermediate quantum measurements for feedback and classically controlled operations for assistance. In Clifford circuits, we restrict the classical feedback to perform the logical operations of parity and negation and controlled-Pauli operations [35].

Besides the accessible computational resources, the power of a circuit is also influenced by the circuit depth and the gate fan-in. The circuit depth is defined as the number of steps to perform all the gates and measurements. Note that in one step, multiple gates acting on

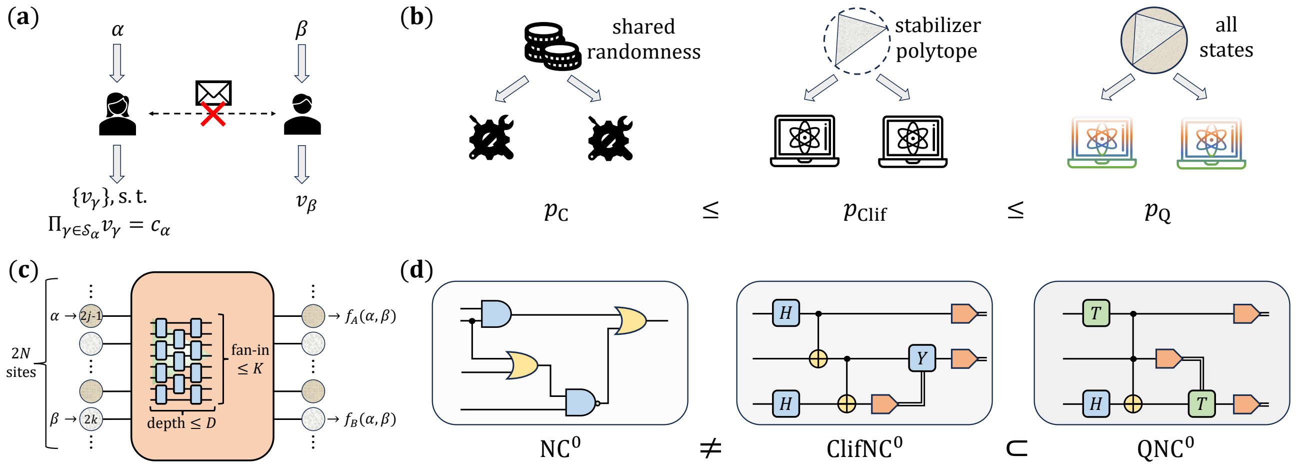

FIG. 1: **(a)** A general BCS nonlocal game with non-communicating players. Given a BCS, the input or the question to Alice is a constraint indexed by α, and the question to Bob is a variable indexed by β, with $\beta \in \mathcal{S}_\alpha$, where $\mathcal{S}_\alpha$ corresponds to the set of variables in constraint labeled with α. The players win the game if and only if Alice outputs an assignment to the variables $\{v_\gamma\}_\gamma$ satisfying the constraint $\prod_{\gamma\in\mathcal{S}_\alpha} v_\gamma = c_\alpha$, and Alice and Bob give an identical assignment to v_β. **(b)** Different game strategies. (1) Classical strategy: players share randomness and apply local classical operations. (2) Clifford strategy: players share entanglement prepared by stabilizer circuits and apply local Clifford operations and local Pauli measurements. The set of stabilizer states forms a convex polytope [7, 8]. (3) General strategy: players share a general entangled state and apply general local quantum operations. The set of all quantum states is a convex set. There is a hierarchy among the maximum winning probabilities in each level: $p_{\mathrm{C}} \leq p_{\mathrm{Clif}} \leq p_{\mathrm{Q}}$. We present a family of nonlocal games via Eq. (9), which manifest levelled quantum pseudo-telepathy, namely $p_{\mathrm{C}} < p_{\mathrm{Clif}} = 1$ and $p_{\mathrm{Clif}} < p_{\mathrm{Q}} = 1$ under different game parameters. **(c)** Solving a relation problem via a shallow circuit with bounded fan-in gates. The circuit depth D and the maximum gate fan-in K are both fixed constants. The BCS nonlocal game can be translated to a relation problem on $2N$ sites: two randomly chosen computing sites $2j-1$ and $2k$ are input with α and β and required to output $f_A(\alpha,\beta)$ and $f_B(\alpha,\beta)$, respectively, up to a transformation depending on other sites. The bounded fan-in and constant depth conditions restrict each output site to be affected only by a constant number of input sites, as shown by the lightcone shaded in green. **(d)** Categories of shallow circuits. (1) NC^0: classical shallow circuits with bounded fan-in gates, comprising classical gates like $\mathsf{AND}, \mathsf{OR}, \mathsf{NOT}, \mathsf{NAND}$. (2) ClifNC^0: magic-free shallow circuits with bounded fan-in gates, comprising a magic-free initial quantum state, Clifford gates like $\mathsf{H}, \mathsf{S}, \mathsf{CNOT}$, and (intermediate) Pauli measurements. Classical feedback is allowed. (3) QNC^0: general quantum shallow circuits with bounded fan-in gates, allowing a generic initial state and non-Clifford gates like the T gate and the Toffoli gate. In this work, we prove the strict inclusion of $\mathsf{ClifNC}^0 \subset \mathsf{QNC}^0$.

different subsystems can be implemented in parallel. The gate fan-in is defined as the number of input (quantum) bits a gate can act on. For instance, the T gate has fan-in 1, and the Toffoli gate has fan-in 3. In our definition, the fan-in includes both classical bits and qubits, as depicted and explained in Fig. 2, e.g., a T gate controlled by a classical bit has fan-in 2. In this way, we unify the discussions for classical logical gates, quantum gates, classically controlled quantum gates, and measurements.

In this work, we are interested in the computational power of shallow circuits with bounded fan-in gates. That is, the circuit depth is a constant, and the fan-in of all the operations in the circuit has a constant upper bound. Within this restriction, we denote the classes of classical circuits [20, 36], Clifford circuits, and generic quantum circuits [37] as NC^0, ClifNC^0, and QNC^0, respectively. We depict examples of these circuits in Fig. 1(d). As a remark, we overuse the complexity class notations for the associated circuits, like previous works in the field.

Previously, a strict inclusion between $\mathsf{NC}^0$and $\mathsf{QNC}^0$was proved [27, 28]. Here, we show magic makes a strict hierarchy among shallow circuits:

$$\mathsf{ClifNC}^0 \subset \mathsf{QNC}^0. \tag{6}$$

III. BINARY-CONSTRAINT-SYSTEM-BASED NONLOCAL GAMES

A. Preliniminaries of binary constraint systems

To prove the main result in Eq. (6), essentially, we manifest nonlocal correlations where magic states or non-Clifford operations play a non-trivial role. Our starting point is a special nonlocal game originating from the lin-

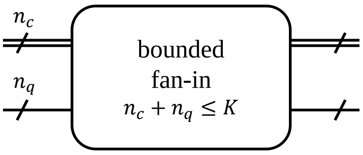

FIG. 2: A general K-bounded fan-in gate. In general, it acts on n_c bits and n_q qubits, with $n_c + n_q \le K$. When $n_c = 0$, it becomes a normal quantum gate characterized by a unitary operation. When $n_q = 0$, it becomes a normal classical gate.

ear binary constraint system (BCS) [38]. A BCS comprises a set of Boolean functions, namely constraints, over binary variables v_γ. We take the variable values over $\{+1, -1\}$ for later convenience. For a linear BCS, the constraints are given by functions in the form of $\prod_{\gamma \in \mathcal{S}_\alpha} v_\gamma = c_\alpha \in \{+1, -1\}$, where $\mathcal{S}_\alpha$ defines a subset of the variables. Given a linear BCS, consider a corresponding nonlocal game with two parties, Alice and Bob, as shown in Fig. 1(a). In each round of the game, a referee picks a constraint from the BCS labeled by α and a variable labeled by $\beta \in \mathcal{S}_\alpha$. The referee asks Alice to assign values to the variables satisfying the constraint and Bob to output a value for v_β. The nonlocal players win the game if and only if

1. Alice gives a satisfying assignment for the constraint c_α, and
2. Alice's assignment to v_β coincides with Bob's.

Alice and Bob cannot communicate with each other once the game starts. Nevertheless, they can agree on a game strategy in advance.

Naturally, the existence of a perfect winning strategy is related to the properties of the underlying linear BCS. If and only if the linear BCS has a solution where a fixed value assignment to the variables satisfies all the constraints, Alice and Bob can win the associated nonlocal game with certainty by classical means [38]. Otherwise, the winning probability by any classical strategy, where the players are restricted to shared randomness and local classical operations, is strictly upper-bounded from 1.

Notwithstanding, even if a fixed satisfying assignment does not exist, the nonlocal players may still win the game perfectly by exploiting quantum strategies. For a systematic study, we first generalize the BCS to a set of operator-valued functions. The scalar variables are replaced with Hermitian operators A_γ of a finite dimension with eigenvalues $\{+1, -1\}$, and the constraints become $\prod_{\gamma \in \mathcal{S}_\alpha} A_\gamma = c_\alpha \mathbb{I}$ with $\mathbb{I}$ an identity operator. In addition, the observables corresponding to the variables in each constraint are required to be compatible, namely jointly measurable. The existence of a quantum perfect winning strategy is equivalent to the operator-valued BCS having a solution [38]. Suppose the solution to the operator-valued BCS is given by a set of d-dimensional operators, $\{A_\gamma\}_\gamma$, then the perfect winning strategy in the corresponding nonlocal game goes as follows:

1. Alice and Bob first share a maximally entangled state, $|\Phi^+\rangle = \sum_{i=0}^{d-1} |ii\rangle / \sqrt{d}$;
2. After the game starts, Alice measures the observables $\{A_\gamma\}_\gamma$, and Bob measures the observables $\{A_\gamma^{\mathrm{T}}\}_\gamma$ to assign values to the variables, where T denotes the operator transpose.

By construction, Alice's measurement results satisfy the constraint. Also, as the maximally entangled state has the property

$$\langle \Phi^+ | A_\gamma \otimes A_\gamma^{\mathrm{T}} | \Phi^+ \rangle = \frac{1}{d} \mathrm{tr}\left(A_\gamma^2\right) = 1, \tag{7}$$

the assignments of Alice and Bob to the same variable thus coincide.

Due to the intrinsic randomness in quantum measurements, an observable may take different outcomes in each constraint, hence assigning a different value to the same variable. Such flexibility brings an advantage over classical means, where quantum resources bring Alice and Bob "pseudo-telepathy" as if they knew what was going on at the other side via a "spooky action" [23]. We shall further discuss this issue and review relevant existing results in the Supplementary Information (SI) Sec. IB, such as the famous Mermin-Peres nonlocal game [39, 40].

B. Clifford strategies in BCS-based nonlocal games

Among quantum strategies for the nonlocal game, there are different levels of capabilities, as shown in Fig. 1(b). Instead of having access to all quantum states and operations, we consider constraining the players to apply only Clifford strategies. Specifically, Alice and Bob can apply Clifford operations to a state initialized in $|0\rangle$ before the nonlocal game to create entanglement. Afterward, they each take a share of the state and apply only Pauli-string measurements to the state for the game. If the nonlocal game has a Clifford strategy that wins perfectly, then the underlying BCS has a Pauli-string solution, and *vice versa*. Notably, we derive the following results for general linear BCS. We prove Theorem 1 in SI Sec. VB and Theorem 2 in SI Sec. III.

Theorem 1. *Given a linear BCS with l variables and m constraints, there exists a classical algorithm that finishes in* $\mathrm{poly}(l, m)$ *steps to determine whether the BCS has a Pauli-string operator-valued solution. If the answer is affirmative, the algorithm returns one such solution.*

Theorem 2. *Suppose a linear BCS does not have a Pauli-string solution. Then, for its associated nonlocal game, if Alice and Bob are restricted to Clifford strategies, either Alice fails to give satisfying assignments for all the constraints, or there exists one pair of questions (α, β), where the probability that Alice and Bob's assignments to v_β coincide does not exceed $1/2$.*

Theorem 1 improves previous attempts of searching for a Pauli-string solution to a linear BCS [41, 42], which poses additional requirements on the appeared times of each variable. Besides, Theorem 1 sharply contrasts the common undecidability in the field of constraint systems, such as determining the existence of an operator-valued solution to a general BCS, which may not be Pauli strings [43].

Theorem 2 constraints the capability of Clifford strategies when the underlying BCS does not have Pauli-string solutions. In later discussions, we will apply Theorem 2 to compute the maximum winning probability of Clifford strategies playing magic-necessary BCS nonlocal games.

Here, we describe the algorithm for finding Pauli-string solutions to a general linear BCS. The algorithm highly relies on the following properties of Pauli operators, as shown by the following lemma.

Lemma 1. *Suppose $A_1, A_2, \cdots, A_l$ are Pauli-string observables. For $j, k = 1, \cdots, l$, define $C_{jk} = A_j A_k A_j A_k$ as the commutator between A_j and A_k. Then, C_{jk}'s have the following properties:*

1. *$C_{jk} \in \{\pm\mathbb{I}\}$. Specifically, $C_{jk} = \mathbb{I}$ when $A_j A_k - A_k A_j = 0$, and $C_{jk} = -\mathbb{I}$ when $A_j A_k + A_k A_j = 0$;*
2. *$C_{jk} = C_{kj}$ and $C_{jj} = \mathbb{I}$;*
3. *$A_j A_k = C_{jk} A_k A_j$.*

The proof of Lemma 1 is straightforward. Now, suppose there exists a Pauli-string solution to the BCS with l variables and m constraints. Using this lemma, we can apply variable substitution and exchange the order between variables A_j and A_k similarly as solving a classical linear BCS, up to a sign change due to the Pauli operator commutation. In the end, we can express each variable A_i in the BCS via a set of independent variables $\{A_r\}_r$ and sign variables C_i's. In SI Sec. VB, we prove that with a further substitution of the expressions into the original BCS, we can transform the BCS into a linear BCS of solely the sign variables C_i's and commutators C_{jk}'s between independent variables. The substitution thus far is efficient, namely in poly(l, m) steps. Since the new BCS is defined over $\mathbb{Z}_2$, it can be efficiently solved. If the new BCS does not have a solution, then by contradiction, the original BCS does not have a Pauli-string solution.

If the new BCS has a solution, we can assign Pauli-string operators to the independent variables $\{A_r\}_r$ in the original BCS, which satisfies the required commutation conditions. Here, we give an explicit construction. Suppose there are p commutators equal to -1, given by $C_{j_1k_1}, C_{j_2k_2}, \cdots, C_{j_pk_p}$. Then, we can construct Pauli strings over p qubits according to the following rule: For every q'th qubit in each Pauli string, where $1 \leq q \leq p$, assign σ_x for A_{j_q} and σ_z for A_{k_q}; assign all the other qubits as $\mathbb{I}$. That is,

$$\text{the } q\text{'th qubit of } A_r = \begin{cases} \sigma_x, & \text{if } r = j_q, \\ \sigma_z, & \text{if } r = k_q, \\ \mathbb{I}, & \text{otherwise.} \end{cases} \tag{8}$$

It can be directly checked that this construction satisfies the requirements. The rest of the variables are then determined by the independent variables and sign variables C_i's. This finishes the algorithm.

IV. MAGIC-NECESSARY QUANTUM PSEUDO-TELEPATHY

A. Magic-necessary BCS

Previously, it was conjectured that whenever a linear BCS nonlocal game has a perfect winning strategy, it is either a Clifford or a classical one [41]. Recent group embedding results evidence the falseness of the above conjecture [43, 44]. Here, we take a relevant yet different approach and directly present a linear BCS nonlocal game to disprove the conjecture. To make it illustrative, we state the underlying BCS in the language of graph theory. Consider an undirected complete graph $G = (V, E)$ with n vertices. An undirected graph indicates that for any two connected vertices, u and v, the tuples (u, v) and (v, u) represent the same edge. The BCS contains the following variables:

1. Each vertex $v \in V$ corresponds to one variable a_v.
2. Each undirected edge, denoted by $e = (u, v) \in E$, corresponds to three variables x_{uv}, y_{uv}, and z_{uv}.
3. Every two disjoint edges, denoted by $e_1 = (u, v) \in E$ and $e_2 = (s, t) \in E$, where s, t, u, and v are different vertices, correspond to
   (a) one variable $b_{e_1e_2} \equiv b_{uv|st}$, where $b_{e_1e_2} = b_{e_2e_1}$;
   (b) two variables $c_{e_1e_2} \equiv c_{uv|st}$ and $c_{e_2e_1} \equiv c_{st|uv}$, where $c_{e_1e_2} \neq c_{e_2e_1}$ in general.

For clarity, we express the variables with respect to the underlying vertices and denote the BCS (nonlocal game) size with the number of vertices. The smallest non-trivial BCS is defined on a graph with four vertices, as shown in Fig. 3. Based on these variables, the BCS contains the following constraints,

$$\begin{aligned} a_u a_v y_{uv} &= 1, \forall (u, v) \in E, \\ x_{uv} y_{uv} z_{uv} &= 1, \forall (u, v) \in E, \\ x_{uv} x_{st} b_{uv|st} &= 1, \forall (u, v), (s, t) \in E, \\ x_{uv} z_{st} c_{uv|st} &= 1, \forall (u, v), (s, t) \in E, \\ b_{uv|st} b_{vs|ut} b_{su|vt} &= 1, \forall u, v, s, t \in V, \\ c_{uv|st} c_{vs|ut} c_{su|vt} &= 1, \forall u, v, s, t \in V, \\ \prod_{v \in V} a_v &= -1. \end{aligned} \tag{9}$$

This family of BCS's exhibits a hierarchy among classical, Clifford, and general quantum resources, as shown by the following theorem.

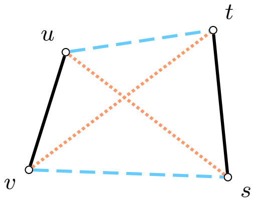

FIG. 3: A subgraph with four vertices to illustrate the BCS variables in Eq. (9). Each vertex v corresponds to one variable a_v, and there are four such variables in the subgraph. Each undirected edge $e = (u, v)$ corresponds to three variables x_{uv}, y_{uv}, z_{uv}. With six edges in the subgraph, there are six variables for each kind. Every two disjoint edges $e_1 = (u, v), e_2 = (s, t)$ correspond to two kinds of variable $b_{uv|st} = b_{st|uv}$ and $c_{uv|st}, c_{st|uv}$. The subgraph has three sets of disjoint edges, denoted by black solid lines, blue dashed lines, and orange dotted lines, respectively. Consequently, there are three variables of the kind $b_{uv|st}$ and six variables of the kind $c_{uv|st}$.

Theorem 3. *For the nonlocal game defined through the BCS in Eq.* (9),

1. *when $n = 4$, it has a perfect-winning Clifford strategy, but it does not have a perfect-winning classical strategy;*
2. *when $n \in 2\mathbb{N} + 5 = \{5, 7, 9, \cdots\}$, it has a perfect-winning classical strategy;*
3. *when $n \in 2\mathbb{N} + 6 = \{6, 8, 10, \cdots\}$, it has strategies that exploit quantum magic to win perfectly, but it does not have a perfect-winning Clifford strategy or classical strategy.*

The full proof of Theorem 3 is presented in SI Sec. II. One can apply Theorem 1 to check that the BCS defined in Eq. (9) with $n \in 2\mathbb{N}+6$ does not have Pauli-string solutions. As a consequence, the associated nonlocal game does not have a perfect-winning Clifford strategy or classical strategy.

As a corollary of Theorem 2, for the nonlocal game with $n \in 2\mathbb{N} + 6$, with uniformly distributed random questions, the winning probabilities of all Clifford and classical strategies can be upper-bounded by

$$p_{\text{Clif}} \leq 1 - \frac{1}{2|\mathcal{Q}|}, \tag{10}$$

where $\mathcal{Q}$ denotes the set of questions in the nonlocal game. For the BCS given in Eq. (9), we denote the set of questions for Alice as $\tilde{\mathcal{Q}}_A$, namely the BCS constraints, and the set of questions for Bob as $\tilde{\mathcal{Q}}_B$, namely the BCS variables. In Table I and II, we give the expressions to calculate the set sizes. We also provide the concrete numbers for the case of $n = 8$. For the BCS game of size n with uniformly distributed questions, by applying Theorem 2, we obtain a direct upper bound on the average winning probability of Clifford strategies as $1 - 1/(2[3(|\tilde{\mathcal{Q}}_A| - 1) + n])$. Note that the constraint $\prod_{v\in V} a_v = -1$ comprises n variables, while every other constraint consists of three variables.

constraint format	expression	number $(n = 8)$
$aa'y = 1$	$\binom{n}{2}$	28

TABLE II: Number of variables in the BCS game.

B. Non-Clifford gates to realize the magic-necessary BCS

In SI Sec. II, we present a group-theoretic method to determine the magic-necessary perfect-winning strategies [45, 46] when $n \in 2\mathbb{N} + 6$. A notable property is that there are non-unique solutions to the BCS and thus nonequivalent perfect winning quantum strategies in general. Here, we present one operator-valued solution to the BCS when $n = 8$. Labelling the vertices from 1 to 8, a realization of a_v and x_{uv} in the above BCS is

$$\begin{aligned} a_v &= \mathbb{I}_8 - 2\mathbf{e}_{vv}, v = 1, \cdots, 8, \\ x_{uv} &= \mathbb{I}_8 - \mathbf{e}_{uu} - \mathbf{e}_{vv} + \mathbf{e}_{uv} + \mathbf{e}_{vu}, u, v = 1, \cdots, 8, u \neq v \end{aligned} \tag{11}$$

where $\mathbb{I}_8$ is an eight-dimensional identity operator, and $\mathbf{e}_{ij}$ denotes an elementary matrix, of which the element in the i'th row and j'th column is one, and all the other elements are zero. The other operators can be determined via a_v's and x_{uv}'s. The perfect winning strategy of the nonlocal game thus takes three pairs of the Einstein-Podolsky-Rosen (EPR) state, $(|00\rangle + |11\rangle)/\sqrt{2}$. In this strategy, the measurements corresponding to x_{uv} require non-Clifford operations, which can be realized by applying a Toffoli gate up to a local unitary operation followed by the computational-basis measurement.

To illustrate the circuit operations for the nonlocal game, in Fig. 4, we depict the observables of x_{78}, y_{78}, z_{78} and the implementation for the constraint $x_{78}y_{78}z_{78} = 1$. The observable x_{78} is the same as the Toffoli gate. To measure this observable, one can use the Hadamard test, in which the required non-Clifford gate is the controlled-controlled-controlled-X (CCCX) gate. Similarly, the non-Clifford gates required to measure y_{78} and z_{78} are the controlled-controlled-Z (CCZ) and controlled-controlled-controlled-(-X) gates, respectively.

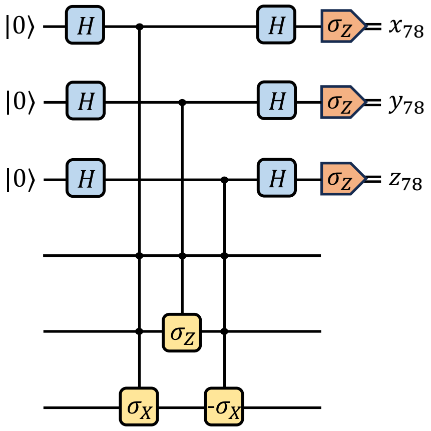

FIG. 4: The circuit with non-Clifford gates to realize the simultaneous measurement of x_{78}, y_{78}, and z_{78} by using the Hadamard test. The Hadamard test uses an ancilla initialized in $|0\rangle$, followed by a Hadamard gate, applying controlled-O and again a Hadamard gate, and measuring in the computational basis to get measurement results of O. Here, the non-Clifford gates are CCCX, CCZ, and CCC(-X) for x_{78}, y_{78}, and z_{78}, respectively.

C. Modified BCS for shallow circuit computation

For the convenience of the shallow circuit computational task, we slightly modify the BCS in Eq. (9). For the n-variable constraint $\prod_{v\in V} a_v = -1$, we can introduce $(n-3)$ new variables and turn them into an equivalent set of $(n-2)$ constraints with three variables each. That is, we introduce new variables $a_{12}, a_{123}, \cdots, a_{1\cdots n-2}$ and convert the constraint as

$$a_1a_2a_3\cdots a_n = -1 \Longleftrightarrow \begin{cases} a_1a_2a_{12} &= 1 \\ a_{12}a_3a_{123} &= 1 \\ \cdots & \\ a_{1\cdots n-3}a_{n-2}a_{1\cdots n-2} &= 1 \\ a_{1\cdots n-2}a_{n-1}a_n &= -1. \end{cases} \tag{12}$$

Note that the commutation requirement between variables a_u and a_v in the original constraint is preserved, since they also need to satisfy the constraint of $a_ua_vy_{uv} = 1$. Denote the set of constraints in the modified BCS as $\mathcal{Q}_A$. Suppose the original BCS with size n consists of $|\tilde{\mathcal{Q}}_A|$ constraints. In correspondence with Eq. (10) in the main text, there are $|\mathcal{Q}| = 3|\mathcal{Q}_A|$ sets of questions in the modified BCS nonlocal game, with

$$\begin{aligned} |\mathcal{Q}_A| &= |\tilde{\mathcal{Q}}_A| + n - 3 \\ &= 2\binom{n}{2} + 14\binom{n}{4} + n - 2. \end{aligned} \tag{13}$$

V. MAGIC COMPUTATIONAL ADVANTAGE IN SHALLOW CIRCUITS

A. Outline

As shown in Theorem 3, the nonlocal game defined through the BCS in Eq. (9) separates the capabilities between a generic quantum world and the magic-free world to generate correlations. Now, we translate correlation generation into a computational task of a relation problem and show the magic advantage. As a reminder, the computational task is a single-user one. "Alice" and "Bob" in the nonlocal game now refer to parts of the circuit, which is merely for intuitive thinking. In particular, one should not consider the task as a distributed computation.

Briefly speaking, a relation problem randomly selects an input bit string z_{in} from a set and asks the computation to output a bit string z_{out}, such that z_{out} *always* satisfies a certain relation with respect to z_{in}. The high-level idea to analyze the shallow circuit capabilities is as follows: In a circuit comprising K-bounded fan-in gates, where each gate can act on at most K inputs, the value K mimics the light speed for information scrambling [47]. Furthermore, if the circuit is shallow, where the circuit depth is a constant independent of the problem size, it restricts the "time" for information scrambling; hence, many sites in the circuit are "space-like" separated from each other. If the relation problem is defined via a nonlocal game, where randomly chosen computing sites of "Alice" and "Bob" are required to generate nonlocal correlations, then the circuit must be capable of winning the game between "space-like" separated sites without communication. Suppose the underlying nonlocal game cannot be won perfectly without a particular resource. In that case, the players must communicate to exchange information and generate the desired correlation, which takes "time." Therefore, the shallow circuit should fail in the task. On the contrary, things become different if the nonlocal game can be won perfectly. Entanglement can be created and distributed between two arbitrary sites via entanglement swapping with bounded fan-in quantum gates in constant steps [28, 30], and quantum "pseudo-telepathy" completes the remaining task.

B. Relation problem separating $\mathsf{QNC}^0$and ClifNC^0

Given a nonlocal game with size n, we can define a relation problem labeled by n, R_N^n. In the following discussions, we focus on the relation problem R_N^8, namely the problem that embeds the BCS nonlocal game with size $n = 8$. Other values of n can be studied similarly. We describe the task by giving the quantum circuit that perfectly solves the computational problem. As shown in Fig. 5(b), consider a quantum circuit containing $2N$ computing sites labeling from 1 to $2N$. Imagine the circuit is divided into two parts, Alice and Bob, where Alice holds the odd-valued sites, and Bob holds the even-valued sites. Each site consists of a set of classical wires to receive the input of R_N^8 and quantum wires initialized in $|0\rangle$ for three qubits. Throughout this work, we denote the classical systems by double wires and quantum systems by single wires.

In the computation, Alice and Bob first prepare three pairs of the EPR state, $(|00\rangle + |11\rangle)/\sqrt{2}$, between their adjacent sites $(2i-1, 2i), i \in \mathbb{N}^+$, as shown by the blue boxes. Next, given an input instance (j, k, α, β), Alice and Bob perform three Bell-state measurements (BSM) between the three pairs of qubits on their adjacent sites $(2j, 2j+1), \cdots, (2k-2, 2k-1)$ in a concatenated manner, as shown by the white boxes. A BSM projects two qubits into one of the four orthogonal Bell states,

$$\begin{aligned}
|\Phi^+\rangle &= \frac{|00\rangle + |11\rangle}{\sqrt{2}}, \\
|\Phi^-\rangle &= \frac{|00\rangle - |11\rangle}{\sqrt{2}}, \\
|\Psi^+\rangle &= \frac{|01\rangle + |10\rangle}{\sqrt{2}}, \\
|\Psi^-\rangle &= \frac{|01\rangle - |10\rangle}{\sqrt{2}},
\end{aligned} \tag{14}$$

and the measurement can be realized by a CNOT gate with Pauli measurements. When the BSM is performed jointly on one qubit of two Bell states each, the remaining two qubits become one of the Bell states with equal probability conditioned on the measurement outcome, a phenomenon called entanglement swapping [48]. Afterward, Alice and Bob perform the perfect-winning strategy for the nonlocal game at sites $2j-1$ and $2k$ with respect to the questions α and β, respectively, as shown by the orange boxes.

To win the BCS nonlocal game, we hope the post-measurement state after entanglement swapping is $|\Phi^+\rangle^{\otimes 3}$, three pairs of the EPR state, such that $\langle\Phi^+|^{\otimes 3} A_\gamma \otimes A_\gamma^{\mathrm{T}} |\Phi^+\rangle^{\otimes 3} = 1$. However, a subtle issue is the so-called bit and phase flips in entanglement swapping. Due to the randomness in BSM, the post-measurement state may differ from the EPR state $|\Phi^+\rangle$, experiencing a rotation of a Pauli operator. Note that different from the case of Pauli measurements, where for any $|\psi\rangle \in \{|\Phi^+\rangle, |\Phi^-\rangle, |\Psi^+\rangle, |\Psi^-\rangle\}$ and any Pauli operator P, $\langle\psi| P \otimes P^{\mathrm{T}} |\psi\rangle = \pm 1$, such a Pauli error totally ruins the measurement statistics of Alice and Bob in the nonlocal game and results in random outcomes. To fix this issue, we compromise by embedding the circuit outcomes in these cases to the allowed relation for the computational problem while requiring the circuit to generate the desired nonlocal game statistics with a non-negligible probability. For the quantum circuit that takes the pseudo-telepathy as a sub-routine, the desired statistics can be generated with probability 1/64. On the contrary, any magic-free is incompetent to generate the desired statistics with any constant probability. We give the proof in SI Sec. IV.

With the above quantum circuit, we define the computational problem, as rigorously stated in Fig. 5(a). Strictly speaking, our problem not only requires the circuit to return an output that satisfies certain criteria but also to return one specific output with a non-negligible probability. This differs from the standard relation problem, where it suffices for the algorithm to return a valid output. A more accurate statement of our results can be given in terms of a sampling problem. Nevertheless, we shall keep using the term "a relation problem," which is more intuitive.

Building on the nonlocal games defined through Eq. (9), the following theorem illustrates the separation between $\mathsf{QNC}^0$and ClifNC^0circuits in solving the BCS relation computational problem. We provide the analysis details in SI Sec. IV.

Theorem 4. *Given the nonlocal game defined by the BCS in Eq. (9) with size $n \in 2\mathbb{N} + 6$, there is a relation problem R_N^n and a constant K_{th} independent of N, such that for any integer $K > K_{\mathrm{th}}$,*

- *R_N^n can be perfectly solved by a QNC^0circuit with K-bounded fan-in geometrically local gates, where some gates are non-Clifford operations.*
- *Any Clifford circuit with K-bounded fan-in gates that solves R_N^n with probability larger than $(1 + p_{\mathrm{Clif}})/2$ with p_{Clif} given in Eq. (10) must have a circuit depth at least increasing logarithmically with respect to the problem size N, where the gates can be non-geometrically local.*

By this, we prove the main result in Eq. (6). In the second part of the theorem, the logarithmic separation is tight. That is, a magic-free circuit with bounded fan-in gates can solve the problem, of which the depth grows logarithmically. For a straightforward solution, all the computing sites send their input to a fixed ancilla, which performs the nonlocal game calculation and sends back the result to the specified sites.

VI. DISCUSSIONS AND OUTLOOK

In summary, we discover a family of nonlocal games that require quantum magic to win perfectly and trans-

Input of R_N^8:
An instance of (j,k,α,β) defining

$$\alpha_i = \begin{cases} \alpha, & \text{if } i = j, \\ \perp, & \text{if } i \neq j, \end{cases}$$

$$\beta_i = \begin{cases} \beta, & \text{if } i = k, \\ \perp, & \text{if } i \neq k, \end{cases}$$

where $1 \leq j < k \leq N,\ \alpha \in \mathcal{Q}_A,\ \beta \in \mathcal{Q}_B$.

Valid outputs of R_N^8:
Bit strings $\{r_i^A(l)\}_i$ and $\{r_i^B(l)\}_i, l \in \{1,2,3\}$,
Case I: Long-range nonlocal game

$$\prod_{j<i\leq k} r_i^A(l) = +1, \forall l \in \{1,2,3\},$$
$$\prod_{j\leq i<k} r_i^B(l) = +1, \forall l \in \{1,2,3\},$$
$$(\mathbf{r}_j^A, \mathbf{r}_k^B) = f(\alpha,\beta),$$

where $\mathbf{r}_i^A = (r_i^A(1), r_i^A(2), r_i^A(3)) \in \{\pm 1\}^3$ and similar to $\mathbf{r}_i^B$, $f(\alpha,\beta)$ is the satisfying assignment in the nonlocal game.

Case II: Entanglement swapping flips
There exists $l \in \{1,2,3\}$, such that

$$\prod_{j<i\leq k} r_i^A(l) = -1, \quad \text{or} \quad \prod_{j\leq i<k} r_i^B(l) = -1.$$

Additional requirement:
Both cases occur with a non-negligible probability, for all (j,k,α,β)

FIG. 5: (a) Description of the shallow-circuit computation task R_N^8. (b) A quantum shallow circuit that realizes R_N^8.

late it into an unconditional proof of magic computational advantage. While not being the purpose of this work, by applying the “game gluing” technique [46, 49], one can combine games with different sizes in the family and construct a nonlocal game with a strict separation between the winning probabilities of classical, Clifford, and general quantum strategies. We consider this to be of independent interest to some research. In addition, we believe other nonlocal games exist that can demonstrate magic advantage. For instance, following the method of embedding a general group into a BCS in Ref. [43], one can obtain candidate BCS nonlocal games. In SI Sec. VA, we review the procedure. Combined with Theorem 1, one can efficiently check whether they have perfect-winning Clifford strategies.

To compute the relation problem in a realistic experiment, one shall further consider the noise. For this purpose, noise-tolerant methods, such as error correction and mitigation in a shallow circuit, need to be developed. With recent experimental progress, preparing magic states and implementing a few layers of non-Clifford gates are becoming easy [50, 51]. We expect that the computational task in this work can be faithfully realized on an upcoming early fault-tolerant quantum computing platform [52–54].

This work takes the first step in proving the computation necessity of quantum magic unconditioned on any complexity assumption. We hope our results can inspire further explorations in this direction, eventually going beyond the regime of shallow circuits and solidifying the “magic” of universal quantum computation.

ACKNOWLEDGMENTS

We acknowledge Zhengfeng Ji and Honghao Fu for the insightful discussions on the binary constraint systems and the group embedding results, Qi Zhao, Zhaohui Wei, and Yilei Chen for leading us to the consideration of non-Clifford quantum operations, Yu Cai for introducing to us the results in Ref. [46, 55], Yuwei Zhu, Boyang Chen, and Yuxuan Yan for helpful discussions on the group representation theory and quantum magic. We express special thanks to Tian Ye for his vital and generous help during early stages of this project in a weekly discussion. (Dated: May 20, 2024)

We prove the results presented in the main text in this Supplementary Information. In Sec. I, we present the necessary preliminaries for the notions in this work. In Sec. II, we analyze the new binary constraint system (BCS) proposed in this work along a group-theoretic approach. In Sec. III, we analyze the capabilities of Clifford strategies in the BCS-based nonlocal game. In Sec. IV, we introduce the relation problem based on the BCS nonlocal game, construct a shallow circuit solution that requires quantum magic, and prove the complexity hardness for magic-free circuits. In Sec. V, we review a group embedding result in Ref. [1] and provide an efficient algorithm to solve a linear BCS over the Pauli group.

I. PRELIMINARIES

In this section, we review preliminary concepts for this work. We assume readers are familiar with the basic notions of linear algebra, graph theory, and group theory, and the basic description of quantum systems. For completeness, we restate some basic notions that are listed in the main text.

In the Appendix, we overuse some letters such as n and i when expressing the total number of items or labelling the variables; nevertheless, their meaning can be specified from the context.

A. Quantum magic and non-Clifford operations

We first briefly review the concept of quantum magic and related notions. For simplicity, we only consider the n-qubit system based on the Pauli group. Nevertheless, the results can be easily generalized to systems with a prime dimension by using the Weyl-Heisenberg algebra. Readers who are interested in the topic may refer to the Ph.D. thesis of Gottesman [2] and its following works for a more in-depth discussion.

Let us start with the definition of the Pauli observables on a single qubit:

$$\mathbb{I} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \tag{1}$$

where $\mathbb{I}$ is the identity operator, and the other three observables σ_x, σ_y, and σ_z are always named nontrivial Pauli observables. The n-qubit Pauli group is defined as the set of operators

$$\mathbb{P}_n = \{\pm 1, \pm i\} \times \{\mathbb{I}, \sigma_x, \sigma_y, \sigma_z\}^{\otimes n}, \tag{2}$$

together with the operator multiplication. The Clifford group is defined as the normalizer of the Pauli group $\mathbb{P}_n$:

$$\mathbb{C}_n = \{C \in \mathbb{U}_n | \forall P \in \mathbb{P}_n, CPC^\dagger \in \mathbb{P}_n\}, \tag{3}$$

where $\mathbb{U}_n$ is the n-qubit unitary group. Operators in the Clifford group are called Clifford operations or gates. A highly related concept is the stabilizer state, which is generated by applying Clifford gates on the computational basis states, or equivalently the eigenstates of $\sigma_z^{\otimes n}$. If a state cannot be prepared in this way or by mixing stabilizer states, the state is said to contain quantum "magic" [3].

B. General binary constraint systems

In this section, we review the definition of a binary constraint system (BCS). A BCS consists of n binary variables $v_1, \cdots, v_n$ and m constraints $c_1, \cdots, c_m$, where each c_j is a Boolean equation with respect to a subset of v_i's, $v_i \in \mathcal{S}_j$. In later discussions, we shall specify a constraint by c_j. Note that BCS with general Boolean constrains can describe general systems of equations [4]. In a linear BCS, all the constraints are given by addition over $\mathbb{Z}_2$, or the parity operation over Boolean variables ranging in $\mathbb{Z}_2 = \{0, 1\}$. In the literature, such a BCS is also called a parity BCS. For convenience of a quantum generalization, it is equivalent to define the BCS over sign variables ranging in $\{+1, -1\}$. In this case, a Boolean function can be equivalently given by a multilinear function of a subset of variables on $\mathbb{R}$. For a linear BCS, the parity constraint becomes a product of the variables. In accordance with the notations in the main text, we mainly use the sign variables and denote each constraint c_j as a multilinear function of a set of variables $\{v_i : i \in \mathcal{S}_j\}$, namely in the form of $\prod_{i\in\mathcal{S}_j} v_i = c_j \in \{+1, -1\}$. Nevertheless, it is sometimes more convenient to use the Boolean variables to represent a BCS. In correspondence to the sign variables,

$$\begin{aligned} v_i v_j = +1 \Leftrightarrow v_i \oplus v_j = 0, \\ v_i v_j = -1 \Leftrightarrow v_i \oplus v_j = 1, \end{aligned} \tag{4}$$

where the LHS are the notations using sign variables and the RHS are the notations using Boolean variables. We shall specify the notations if we resort to the Boolean variables.

If a BCS has a satisfying assignment, namely a fixed assignment to the variables that satisfies all the constraint, we say it has a classical solution. Note that if all the constraints are $c_j = +1$, the BCS can be trivially satisfied by assigning all the variables to be $+1$. With respect to the BCS size, searching for a classical solution to a general BCS is NP-hard. On the other hand, the problem is in P for linear BCS, where one can apply Gaussian elimination or the replacement method to efficiently solve the system.

The quantum generalization of a BCS is an operator-valued constraint system. The variables v_j's are replaced with linear operators A_j's acting on a Hilbert space $\mathcal{H}$ with a finite dimension, such that

1. Each A_j is Hermitian with eigenvalues in $\{1, -1\}$, i.e., $A_j = A_j^\dagger$ and $A_j^2 = \mathbb{I}$ for all j.

2. A_j's satisfy all the constraints with c_i replaced with $c_i\mathbb{I}$, where $\mathbb{I}$ is the identity operator on $\mathcal{H}$.

3. If A_i and A_j appear in the same constraint, they commute with each other, i.e., $A_iA_j = A_jA_i$.

If there exists a Hilbert space $\mathcal{H}$ with dimension d and a set of linear operators following the above requirements, we say the BCS has a d-dimensional quantum satisfying assignment, or simply a quantum solution. As a side remark, the requirement that the operator variable acts on a finite-dimensional Hilbert space can be relaxed in several directions, including allowing an infinite dimension and limits of finite-dimensional systems. We do not discuss such generalizations and refer readers to Ref. [1, 5] for a more detailed definition.

If a BCS has a quantum solution, one can apply quantum measurements to realize it in an experiment, where they prepare independently and identically many copies of a quantum state and measure the observables in each constraint. For each constraint, the measurement results shall satisfy the relation in the fashion of classical variables. Note that the requirement for a quantum solution guarantees the validity of a joint measurement for each constraint. Due to the intrinsic randomness in quantum measurements, the same variable may take different values in different constraints. It is worth mentioning that measuring the set of observables on any state, including a maximally mixed state, generates the desired statistics for the constraints. The quantum satisfying assignment is also called a state-independent contextuality of the observables [6].

As the dimension can be arbitrary, searching for a quantum solution is undecidable [1, 7]. A helpful way of thinking is to regard the BCS as a group presentation statement [8, 9].

Definition 1 (Group presentation)**.** *Given a set $\mathcal{S}$, let $\mathcal{F}(\mathcal{S})$ be the free group on $\mathcal{S}$ and $\mathcal{R}$ a set of words on $\mathcal{S}$, and denote the quotient group of $\mathcal{F}(\mathcal{S})$ by the smallest normal subgroup containing each element in $\mathcal{R}$ as $\langle \mathcal{S} : \mathcal{R} \rangle$. A group G is said to have the presentation $\langle \mathcal{S} : \mathcal{R} \rangle$ if it is isomorphic to $\langle \mathcal{S} : \mathcal{R} \rangle$.*

In the group presentation, the elements in $\mathcal{S}$ are called generators, and the elements in $\mathcal{R}$ are called relators. Given a linear BCS, one can regard the constraints as a group presentation.

Definition 2 (Solution group of a linear BCS)**.** *Given a linear BCS with n binary variables $\{v_i\}$ and m constraints*

$\{c_j\}$, the solution group of the BCS is defined as the group with the following presentation:

$$\begin{aligned}\Gamma = \{\{J, g_i : i \in [n]\} : \{g_i^2 &= e, \forall i \in [n],\\ J^2 &= e,\\ \forall j \in [m], g_k g_l &= g_l g_k, \forall k, l \in \mathcal{S}_j,\\ J g_i &= g_i J, \forall i \in [n],\\ \prod_{i \in \mathcal{S}_j} g_i &= J^{\chi(c_j=-1)}, \forall j \in [m]\}\},\end{aligned} \tag{5}$$

where the group element J corresponds to -1 in the BCS, e defines the identity operator of the group, and $\chi(\cdot)$ is the indicator function that takes the value 1 if the argument is true and 0 if the argument is false.

Note that if $J = e$, the solution group is trivial, as the assignment of all the group elements to be e satisfies all the relators. On the contrary, should $J \neq e$, the solution group is non-trivial, and the group presentation corresponds to a valid operator-valued solution to the underlying BCS, as stated by the following lemma.

Lemma 1 ([9, 10])**.** *Given a linear BCS that defines a solution group with the group element J corresponding to -1, if J is non-trivial in some finite-dimensional representation of the solution group, then the BCS has a finite-dimensional quantum satisfying assignment. The converse is also true.*

The irreducible representation of the generators in the solution group determines the quantum realization [9, 11]. Here, a representation of the group refers to a group homomorphism of the group to a set of unitary operators on a Hilbert space, and an irreducible representation refers to a representation that does not have a non-trivial group-invariant subspace [12]. For a classical solution, it can be described by the Abelian group, where all the group elements commute with each other.

As an example of linear BCS, we review the Mermin-Peres BCS, also widely known as the "magic-square" system [13, 14]. Note that one should not mistake the name "magic" for the quantum resource of magic states. The Mermin-Peres BCS involves $n = 9$ variables and $m = 6$ constraints. In terms of sign variables ranging in $\{+1, -1\}$, the BCS is defined as follows:

$$\begin{aligned} v_1 v_2 v_3 &= 1,\\ v_4 v_5 v_6 &= 1,\\ v_7 v_8 v_9 &= 1,\\ v_1 v_4 v_7 &= 1,\\ v_2 v_5 v_8 &= 1,\\ v_3 v_6 v_9 &= -1.\end{aligned} \tag{6}$$

This BCS does not have a classical solution. On the other hand, it has a unique quantum solution over the Pauli group. We denote the operator that corresponds to v_i as A_i in accordance with the notations above. The quantum solution is given as follows [10, 15]:

$$\begin{aligned} A_1 &= \sigma_z \otimes \mathbb{I},\\ A_2 &= \mathbb{I} \otimes \sigma_z,\\ A_3 &= \sigma_z \otimes \sigma_z,\\ A_4 &= \mathbb{I} \otimes \sigma_x,\\ A_5 &= \sigma_x \otimes \mathbb{I},\\ A_6 &= \sigma_x \otimes \sigma_x,\\ A_7 &= \sigma_z \otimes \sigma_x,\\ A_8 &= \sigma_x \otimes \sigma_z,\\ A_9 &= \sigma_y \otimes \sigma_y,\end{aligned} \tag{7}$$

where $\otimes$ stands for the tensor product operation.

Given a BCS, one can define an associated nonlocal game [8]. In the nonlocal game, there are two cooperating players, Alice and Bob, who cannot communicate with each other once the game starts. With respect to a probability distribution, a referee randomly selects one constraint, c_s, and one variable, v_t, contained in the constraint. In our work, we always take the probability distribution to be uniform. The referee send s to Alice and t to Bob. Then, Alice returns an assignment to each variable v_i in c_s that satisfies the constraint and Bob returns an assignment to variable v_t. They win the game if and only if the assignments of Bob and Alice to v_t are the same. This type of nonlocal game extends the well-known Clauser-Horne-Shimony-Holt (CHSH) game [16], where the underlying BCS involves two binary variables and two multi-linear constraints,

$$\begin{aligned} v_1 v_2 &= 1, \\ v_1 v_2 &= -1. \end{aligned} \tag{8}$$

This BCS game is equivalent to the CHSH game in the sense of the probability distribution that Alice and Bob can achieve. Note that this BCS does not have either a classical solution or a quantum solution. Still, quantum strategies for the game can bring a higher winning probability than classical ones.

To maximize the winning probability, Alice and Bob can agree on a strategy for playing the game. We call a strategy is *perfect* if it wins with probability 1. We say Alice and Bob apply a classical strategy if they can access only shared and local randomness. In quantum theory, Alice and Bob can pre-share entanglement and apply local quantum operations. In general, when a BCS does not have a solution, it is possible that Alice assigns different values to the same variable upon different questions of constraint. However, it brings limited advantages. For classical strategies, using basic linear algebra analysis, it is not hard to prove that a BCS game has a perfect classical strategy if and only if the corresponding BCS has a solution. It follows that to decide whether a general BCS game has a perfect classical strategy is in NP-hard for general Boolean constraints and in P for linear constraints with respect to the BCS size. In the above examples, the CHSH game has a maximal winning probability of 3/4, and the Mermin-Peres game has a maximal winning probability of 8/9. In the quantum case, if the BCS does not have an operator-valued solution, then there does not exist a perfect winning strategy for the associated nonlocal game, and *vice versa*. This fact is first proved in Ref. [8]. If the BCS has a quantum solution, it is linked to a perfect quantum winning strategy in a one-to-one correspondence. Suppose the quantum solution to the BCS is given by observables $\{A_i\}_i$ acting on a d-dimensional system. Alice and Bob first share a maximally entangled state, $|\Phi^+\rangle = \sum_{i=0}^{d-1} |ii\rangle / \sqrt{d}$. When the nonlocal game starts, upon receiving the constraint c_s, Alice measures the observables A_i belonging to the constraint, and upon receiving the variable v_t, Bob measures the transpose of the observable A_t, denoted by A_t^{T}. The measurement statistics satisfy the winning condition.

For the well-known existing BCS that are solvable, it either has a classical solution, which corresponds to an Abelian group, or a quantum solution of Pauli strings as in the case of the Mermin-Peres magic square, which corresponds to the Pauli group. In Ref. [17], the author provides an efficient algorithm to determine perfect quantum solutions to a special type of linear BCS, where each variable shows up in exactly two constraints. Moreover, if such a BCS has a solution, the solution is necessarily given by Pauli strings, i.e., the solution is in the Pauli group. Following this result, it was conjectured that any linear BCS with an operator-valued satisfying assignment belongs to either of the two cases [17]. As mentioned in the main text, this conjecture has been suggested false [1, 7]. In the next section, we directly disprove this conjecture with a specific linear BCS.

II. GROUP-THEORETIC ANALYSIS OF THE BINARY CONSTRAINT SYSTEM

In this section, we apply group-theoretic tools to analyse the properties of the proposed linear BCS in the main text. We first review the BCS proposed in this work. Given an undirected complete graph $G = (V, E)$ with n vertices, it defines the following variables:

1. Each vertex $v \in V$ corresponds to one variable a_v.

2. Each undirected edge, denoted by $e = (u, v) \in E$, corresponds to three variables x_{uv}, y_{uv}, z_{uv}.

3. Every two disjoint edges, denoted by $e_1 = (u, v) \in E$ and $e_2 = (s, t) \in E$, where s, t, u, v are different vertices, correspond to

   (a) one variable $b_{uv|st} \equiv b_{st|uv}$, where $b_{e_1 e_2} = b_{e_2 e_1}$;

   (b) two variables $c_{e_1 e_2} \equiv c_{uv|st}$ and $c_{e_2 e_1} \equiv c_{st|uv}$, where $c_{e_1 e_2} \neq c_{e_2 e_1}$ in general.

Based on these variables, the BCS contains the following constraints,

$$\begin{aligned}
a_u a_v y_{uv} &= 1, \forall (u,v) \in E, \\
x_{uv} y_{uv} z_{uv} &= 1, \forall (u,v) \in E, \\
x_{uv} x_{st} b_{uv|st} &= 1, \forall (u,v),(s,t) \in E, \\
x_{uv} z_{st} c_{uv|st} &= 1, \forall (u,v),(s,t) \in E, \\
b_{uv|st} b_{vs|ut} b_{su|vt} &= 1, \forall (u,v),(s,t) \in E, \\
c_{uv|st} c_{vs|ut} c_{su|vt} &= 1, \forall (u,v),(s,t) \in E, \\
\prod_{v \in V} a_v &= -1.
\end{aligned} \tag{9}$$

For a nontrivial BCS, the system size is at least $n = 4$. If the BCS has a solution, then the other variables can be generated by a's and x's. For convenience, we label the vertices with natural numbers from 1 to n. For each vertex v and each edge $(u,v), u \neq v$, we can use transpositions between elements in the set $[2n]$ to represent the generators, where $a_v = (2v-1\ 2v)$ and $x_{uv} = (2u-1\ 2v-1)(2u\ 2v)$. Here, $(i\ j)$ represents a transposition between i and j. We have the following results for the BCS.

Theorem 1. *For any BCS of the above form with $n \in 2\mathbb{N}+5 = \{5,7,9,\cdots\}$, it has a classical solution.*

Proof. When $n \in 2\mathbb{N}+5$, the BCS can be satisfied by assigning all the variables a_v's to be -1 and all the other variables to be 1. □

Theorem 2. *When $n = 4$, this BCS has a two-qubit Pauli-string solution. On the other hand, the BCS does not have a classical solution or a single-qubit Pauli solution in this case.*

Proof. The BCS having no classical solution can be directly checked by solving the BCS on the binary field. By using the fact that there is no state-independent contextuality in a qubit system, one can prove that the BCS does not have a single-qubit Pauli solution either [18–20]. Later, we prove this statement under the context of linear BCS.

For the former statement, here is one construction of the two-qubit Pauli-string solution. We abbreviate the Pauli operators $\mathbb{I}, \sigma_x, \sigma_y, \sigma_z$ as I, X, Y, Z, respectively, and omit the tensor-product operator in the expressions.

TABLE I: A two-qubit Pauli-string solution for the BCS when $n = 4$.

□

Theorem 3 (A special case of the results in Ref. [18–20])**.** *If a linear BCS has a single-qubit operator-valued solution, then it has a classical solution.*

Proof. Two-dimensional matrices have such a special property: Suppose $A, B \in \mathbb{C}^{2\times 2}$ and $[A,B] = AB - BA = 0$. At least one of the following cases would happen (1) $A = c\mathbb{I}$ for some $c \in \mathbb{C}$; (2) $B = c\mathbb{I}$ for some $c \in \mathbb{C}$; (3) $A = cB$ for some $c \in \mathbb{C}$. Therefore, all two-dimensional matrices that are not proportional to the identity matrix $\mathbb{I}$ can be classified into different equivalence classes, with elements in a class proportional to each other.

Given a single-qubit operator-valued solution, denote the first equivalent class as $\{c_1 O, c_2 O, \cdots | c_1, c_2, \cdots = \pm 1\}$ where $O \neq \pm \mathbb{I}$ and $O^2 = \mathbb{I}$. Substituting $\{c_1 O, c_2 O, \cdots | c_1, c_2, \cdots = \pm 1\}$ with $\{c_1 \mathbb{I}, c_2 \mathbb{I}, \cdots | c_1, c_2, \cdots = \pm 1\}$ and not changing other variables also provides a solution. This is because (1) variables in different equivalent classes do not show up in the same constraint; (2) the constraints among the variables proportional to $\mathbb{I}$ and in the first equivalent class are not violated after the substitution. Similarly, we can set all variables proportional to $\mathbb{I}$ to give a solution. The proportional coefficient is a valid classical solution. □

Theorem 4. *For any BCS of the above form with $n \in 2\mathbb{N}+6 = \{6, 8, 10, \cdots\}$, it does not have a Pauli-string solution.*

Proof. Later we shall present a general method to determine whether a general linear BCS has a Pauli-string solution, where the current result can be regarded as a special case. Nevertheless, here we present a graph-based proof specific to this BCS, which is more illustrative.

We first specify the commutation properties of Pauli strings. The Pauli group elements are either anti-commuting, like $\{X, Z\} = XZ + ZX = 0$, or commuting, like $[X \otimes X, Z \otimes Z] = (X \otimes X)(Z \otimes Z) - (Z \otimes Z)(X \otimes X) = 0$. Therefore, if we swap any two operators in a multiplication of some Pauli-string operators, the operator value of the multiplication would at most differ with a sign.

Now we prove the theorem by contradiction. Assume the BCS described in the theorem has a Pauli-string solution. Without loss of generality, with respect to the correspondence between the BCS variables and vertices in a fully connected undirected graph, let us consider the sets of variables and constraints corresponding to a subgraph with five vertices, labeled with 1 through 5. For the quadrangle $\{1, 2, 4, 5\}$, we have the equation $b_{12|45} b_{24|15} b_{41|25} = \mathbb{I}$. Substituting all the b-type variables by $x_{uv} x_{st} b_{uv|st} = \mathbb{I}$, we have

$$x_{12} x_{45} x_{24} x_{15} x_{41} x_{25} = \mathbb{I}. \tag{10}$$

Similarly, for the quadrangles $\{1, 3, 4, 5\}$ and $\{2, 3, 4, 5\}$, we have the equations

$$x_{13} x_{45} x_{34} x_{15} x_{41} x_{35} = \mathbb{I}. \tag{11}$$

$$x_{23} x_{45} x_{34} x_{25} x_{42} x_{35} = \mathbb{I}. \tag{12}$$

Next, by multiplying the left and right sides of Eqs. (10)(11) and (12), respectively, swapping the order of the variables, and eliminating the adjacent two variables that are the same, we get

$$x_{12} x_{13} x_{23} x_{45} = \pm \mathbb{I}, \tag{13}$$

where "±" denotes that either case would happen. In this step, we have used the commutation properties of Pauli strings. In other words,

$$x_{45} \in \{\pm x_{12} x_{13} x_{23}\}. \tag{14}$$

As a reminder, x_{uv} and x_{vu} represent the same variable. Note that there is nothing special about the choice of x_{45} among the variables, and a similar result can be obtained with an arbitrary specification of a subgraph with five vertices. For instance, we can get

$$x_{46} \in \{\pm x_{12} x_{13} x_{23}\}. \tag{15}$$

Combining the above two equations, we have $x_{45} = \pm x_{46}$. For $n \geq 6$, following the above procedure and enumerating all such identities, one shall find that all the x-type variables differ from each other up to a sign, i.e., $x_{uv} \in \{\pm x\}$ for all $(u, v) \in E$. Thus we can assume that $x_{uv} = x'_{uv} x$ where $x'_{uv} \in \{\pm 1\}$.

Following the specification of the x-type variables, for any four distinct vertices $u, v, s, t \in V$, we have the following expressions:

$$\begin{aligned} b_{uv|st} &= x_{uv} x_{st} = x'_{uv} x'_{st} \mathbb{I}, \\ c_{uv|st} &= x_{uv} z_{st} = x_{uv} x_{st} y_{st} = x'_{uv} x'_{st} y_{st} = x'_{uv} x'_{st} a_s a_t. \end{aligned} \tag{16}$$

Consequently,

$$\begin{aligned} b_{uv|st} b_{vs|ut} b_{su|vt} &= x'_{uv} x'_{st} x'_{vs} x'_{ut} x'_{su} x'_{vt} = 1, \\ c_{uv|st} c_{vs|ut} c_{su|vt} &= x'_{uv} x'_{st} x'_{vs} x'_{ut} x'_{su} x'_{vt} a_s a_t a_u a_t a_v a_t = 1. \end{aligned} \tag{17}$$

Note that all the a-type variables commute with each other, since they simultaneously appear in the last equation of the BCS. We hence derive that $a_u a_v a_s a_t = 1$ for all four distinct vertices $u, v, s, t \in V$, which is equivalent to

$$a_u = a_v a_s a_t. \tag{18}$$

By applying a similar argument as for the x-type variables, we shall find that all the a-type variables are identical, i.e., $a_v \equiv a, \forall v \in V$. This contradicts the constraint $\prod_{v\in V} a_v = -1$ when n, the number of vertices, is even. Therefore, the BCS of the above form with $n \in 2\mathbb{N} + 6$ does not have a Pauli-string solution. □

Theorem 5. *For any BCS of the above form with $n \geq 4$, label the vertices from 1 to n. The BCS has a solution over the centralizer group of element $J = (1\ 2)(3\ 4)\cdots(2n-1\ 2n)$ in the permutation group S_{2n}.*

Proof. Consider $x_{(u,v)} = (2u-1\ 2v-1)(2u\ 2v)$, $a_v = (2v-1\ 2v)$, and all the other variables generated by them. One can easily check that the assignment satisfies the constraints. As J does not map to the identity element of the group, this is a non-trivial quantum solution following Lemma 1. The solution group corresponds to the centralizer of J in the permutation group, given by

$$C_J = S_n \ltimes \mathbb{Z}_2^n, \tag{19}$$

which is the semi-product of the permutation group S_n generated by $x_{(u,v)}$, and an Abelian group $\mathbb{Z}_2^n$ generated by a_v. □

Now we solve the irreducible representations of the solution, which gives the quantum realizations. We have the following theorem.

Theorem 6. *An irreducible representation of $S_n \ltimes \mathbb{Z}_2^n$ can be labeled by $\left(m, \theta^{(m)}, \rho^{(n-m)}\right)$ where m is an integer in $[0, n]$, $\theta^{(m)}$ and $\rho^{(n-m)}$ are two irreducible representations of permutation groups S_m and S_{n-m}, respectively. Given label $\left(m, \theta^{(m)}, \rho^{(n-m)}\right)$, we first get an irreducible representation of group $S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n$, which is given by*

$$\begin{aligned} &\phi^{(m,\theta,\rho)} : S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n \to M_{\dim\theta^{(m)}\times\dim\rho^{(n-m)}}(\mathbb{R}) \\ &x \in S_m, y \in S_{n-m}, z \in \mathbb{Z}_2^n, (x, y, z) \mapsto \theta^{(m)}(x) \otimes \rho^{(n-m)}(y) \otimes \varphi^{(m)}(z). \end{aligned} \tag{20}$$

Here, $\varphi^{(m)}$ is an irreducible representation of $\mathbb{Z}_2^n$ such that for any element $z = (z_1, z_2, \cdots, z_n) \in \mathbb{Z}_2^n$ where $\forall j, z_j \in \{0, 1\}$,

$$\varphi^{(m)}(z) = \prod_{j=1}^{m} (-1)^{z_j}. \tag{21}$$

The irreducible representation of $S_n \ltimes \mathbb{Z}_2^n$ labeled by $\left(m, \theta^{(m)}, \rho^{(n-m)}\right)$, denoted as $\Phi^{(m,\theta,\rho)}$, is the induced representation of $\phi^{(m,\theta,\rho)}$. Specifically, one first finds the left coset of $S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n$ in $S_n \ltimes \mathbb{Z}_2^n$, given by

$$\left\{g_1 S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n, g_2 S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n, \cdots, g_{\binom{n}{m}} S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n\right\}, \tag{22}$$

where $\left\{g_1, g_2, \cdots, g_{\binom{n}{n}}\right\}$ are representative elements and g_1 is the identity. Then, the induced representation $\Phi^{(m,\theta,\rho)}$ is defined on the bases $\left\{g_i \vec{e}_j | 1 \leq i \leq \binom{n}{m}, 1 \leq j \leq \dim\phi^{(m,\theta,\rho)}\right\}$ where $\vec{e}_j$ is a basis of the representation space of $\phi^{(m,\theta,\rho)}$. That is, for any element $g \in S_n \ltimes \mathbb{Z}_2^n$, suppose that $gg_i \in g_{\sigma(i)} S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n$ and set $h_i = g_{\sigma(i)}^{-1} g g_i$ where σ is a permutation on $\left\{1, 2, \cdots, \binom{n}{m}\right\}$, then

$$\Phi^{(m,\theta,\rho)}(g) = \left(\Pi_\sigma \otimes \mathbb{I}_{\dim\phi^{(m,\theta,\rho)}}\right) \left(\bigoplus_{i=1}^{n} \phi^{(m,\theta,\rho)}(h_i)\right). \tag{23}$$

Here, Π_σ is a permutation matrix defined on the computational basis $|1\rangle, |2\rangle, \cdots, \left|\binom{n}{m}\right\rangle$ and transforms $|i\rangle$ to $|\sigma(i)\rangle$.

Proof. This theorem is a direct corollary of Proposition 25 in [12]. To get an irreducible representation of $C_J = S_n \ltimes \mathbb{Z}_2^n$, we start from the irreducible representation of $\mathbb{Z}_2^n$. Note that $\mathbb{Z}_2^n = \langle a_1 \rangle \times \langle a_2 \rangle \times \cdots \times \langle a_n \rangle$ is generated by n two-order elements $a_1, a_2, \cdots, a_n$. Any irreducible representation of $\mathbb{Z}_2^n$ can be labeled by a vector with length n, like $(1, -1, \cdots, 1)$, denoting the values that n generators would be mapped to in the representation. Meanwhile, we call two irreducible representations equivalent if they can be mutually transformed via S_n. In other words, two irreducible representations are equivalent if and only if the corresponding vectors have the same number of -1. To obtain an irreducible representation of C_J, we only need to consider inequivalent irreducible representations of $\mathbb{Z}_2^n$ under the transformation of S_n. Without loss of generality, we choose these irreducible representations as $(1, 1, \cdots, 1)$, $(-1, 1, \cdots, 1)$, $(-1, -1, \cdots, 1)$, and $\cdots$, $(-1, -1, \cdots, -1)$ and label them with the number of -1, that is, $\{0, 1, \cdots, n\}$.

For a number $m \in \{0, 1, \cdots, n\}$, we get an irreducible representation of $\mathbb{Z}_2^n$, denoted as $\varphi^{(m)}$, mapping the generators a_i to $\varphi^{(m)}(a_i) = (-1)^{\mathbb{1}_{i \leq m}}$. Then, we consider a subgroup of S_n, such that any element h in this subgroup satisfies $\forall z \in \mathbb{Z}_2^n$,

$$\varphi^{(m)}(gzg^{-1}) = \varphi^{(m)}(z), \tag{24}$$

or equivalently, $1 \leq i \leq n$,

$$\varphi^{(m)}(ga_ig^{-1}) = \varphi^{(m)}(a_i). \tag{25}$$

Clearly, this subgroup must be $S_m \times S_{n-m}$. Then, one can define the irreducible representation of $S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n$ as

$$\begin{aligned} \phi^{(m,\theta,\rho)} &: S_m \times S_{n-m} \ltimes \mathbb{Z}_2^n \to M_{\dim \theta^{(m)} \times \dim \rho^{(n-m)}}(\mathbb{R}) \\ x \in S_m, y \in S_{n-m}, z \in \mathbb{Z}_2^n&, (x, y, z) \mapsto \theta^{(m)}(x) \otimes \rho^{(n-m)}(y) \otimes \varphi^{(m)}(z), \end{aligned} \tag{26}$$

where $\theta^{(m)}$ and $\rho^{(n-m)}$ are two irreducible representations of permutation groups S_m and S_{n-m}, respectively. Note that $\phi^{(m,\theta,\rho)}$ is a well-defined group homomorphism due to the condition of Eq. (24). Proposition 25 in [12] tells us that any irreducible representation of $S_n \ltimes \mathbb{Z}_2^n$ can be constructed by the induced representation of $\phi^{(m,\theta,\rho)}$ by traversing m, θ, and ρ. Proof is done. □

For a perfect strategy of the non-local game, the element J must be mapped to a non-identity element. Note that any element in C_J commutes with J. Via Theorem 6, one can obtain the following result:

$$\begin{aligned} \Phi^{(m,\theta,\rho)}(J) &= \varphi^{(m)}(J)\mathbb{I}_{\dim \Phi} \\ &= \varphi^{(m)}\left(\prod_{i=1}^{n} a_i\right)\mathbb{I}_{\dim \Phi} \\ &= \prod_{i=1}^{n} \varphi^{(m)}(a_i)\mathbb{I}_{\dim \Phi} \\ &= (-1)^{\text{mod}(m,2)}\mathbb{I}_{\dim \Phi}, \end{aligned} \tag{27}$$

where $\dim \Phi = \binom{n}{m} \dim \phi = \binom{n}{m} \dim \theta^{(m)} \dim \rho^{(n-m)} \geq \binom{n}{m}$. Thus, $\Phi^{(m,\theta,\rho)}(J)$ corresponds to a perfect measurement strategy if and only if m is odd. The smallest dimension of the quantum system for a perfect strategy is n when $m = 1$ or $m = n - 1$ and $\dim \theta^{(m)} = \dim \rho^{(n-m)} = 1$.

The quantum realization of the BCS in Eq. (9) is not unique. The underlying reason is that unlike the Pauli group, the permutation group has more than one inequivalent irreducible representations [12]. For $n = 8$, which is the smallest size for a non-trivial result where there is not a Pauli-string solution to the BCS, we consider the case where $m = 1$ and θ and ρ are both trivial representations, in which the dimension of the quantum system is 8. It implies that the corresponding non-local game can be realized with only 3 EPR pairs. The representations of the generators are given by the following:

$$a_1 = \begin{pmatrix} -1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{pmatrix}, a_2 = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & -1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{pmatrix}, \cdots, a_8 = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & -1 \end{pmatrix}, \tag{28}$$

$$x_{12} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 1 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{pmatrix}, x_{13} = \begin{pmatrix} 0 & 0 & 1 & \cdots & 0 \\ 0 & 1 & 0 & \cdots & 0 \\ 1 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{pmatrix}, \cdots, x_{18} = \begin{pmatrix} 0 & 0 & 0 & \cdots & 1 \\ 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & 0 & 0 & \cdots & 0 \end{pmatrix}. \tag{29}$$

The value of x_{uv} equals $x_{1u}x_{1v}x_{1u} = \mathbb{I}_8 - \mathbf{e}_{uu} - \mathbf{e}_{vv} + \mathbf{e}_{uv} + \mathbf{e}_{vu}$, where $\mathbb{I}_8$ is an eight-dimensional identity operator, and $\mathbf{e}_{ij}$ denotes an elementary matrix, of which the element in the i'th row and j'th column is one, and all the other elements are zero.

From the expression of the generators, we can see that the measurement observables do not belong to the Pauli group and need magic to realize. Following the same derivation, one can prove that the smallest non-trivial irreducible representation of the solution to the BCS defined over n vertices requires an n-dimensional system. Thus, we obtain an upper bound of the smallest number of qubits to win the non-local game.

Corollary 1. *The smallest number of qubits to win the associated nonlocal game of Eq. (9) is $O(\log n)$.*

III. CAPABILITIES OF CLIFFORD STRATEGIES IN THE NONLOCAL GAME

In proving the "magic" advantage in shallow circuit quantum computation, we need to specify the capabilities of Clifford strategies in the nonlocal BCS game. Thanks to the algebraic structure of BCS, we can use mature techniques from linear algebra to obtain quantitative results.

Suppose the players in a nonlocal game are restricted to Clifford operations only, or that they do not have access to quantum magic resources. In this case, the most general strategy they can apply to playing the nonlocal game is as follows:

- Before the nonlocal game starts:
  1. Alice and Bob prepares an n-qubit state and initialize it in $|0\rangle$.
  2. Alice and Bob apply joint Clifford operations and Pauli-string measurements to the state and evolve it into an entangled state ρ_{AB}, where the subscripts denote the subsystems they each will hold in the game.
- After the nonlocal game starts: Alice and Bob each applies Pauli-string measurements to their own quantum system.

In our discussions, we allow an arbitrarily large n. Using a convexity argument, we know that a mixed state does not bring any advantage to Alice and Bob in winning the nonlocal game, and we can hence take ρ_{AB} as a pure state $|\psi\rangle$ without loss of generality. By further applying the Schmidt decomposition result, a pure state can be written as

$$|\psi\rangle = \sum_{i=0}^{d-1} \alpha_i |ii\rangle , \tag{30}$$

where $\forall i, \alpha_i \geq 0$, and $\sum_{i=0}^{d-1} \alpha_i^2 = 1$. Note that the maximally entangled state, which is

$$\left|\Phi^+\right\rangle = \sum_{i=0}^{d-1} \frac{1}{\sqrt{d}} |ii\rangle , \tag{31}$$

can be prepared by applying control-NOT operations to $|0\rangle$, which is a Clifford operation. Therefore, a general bipartite entangled state $|\psi\rangle$ shared by Alice and Bob can only be linked with $|\Phi^+\rangle$ with a Clifford operation, i.e., $|\psi\rangle = U_C |\Phi^+\rangle$.

Based upon the above observations, we discuss the capabilities of Clifford operations in playing a parity BCS nonlocal game. In demonstrating the magic advantage, we are interested in the parity BCS that do not have a Pauli-string quantum satisfying assignment. We have the following result for these instances.

Theorem 7. *Suppose a parity BCS does not have a satisfying assignment with Pauli-string observables. Then, for any Clifford strategy, there exist a constraint labelled by c_s and a variable in it labelled by v_t, where the probability that the assignments of Alice and Bob to v_t under the constraint c_s are identical does not exceed $1/2$.*

Proof. In the first part of the proof, we prove the case where Alice and Bob initially share a maximally entangled state $|\Phi^+\rangle$ in Eq. (31) of an arbitrary dimension and then generalize the result to general Clifford strategies. In the BCS nonlocal game, without loss of generality, upon receiving the constraint labelled by s, Alice shall measure a set of commuting Pauli-string observables that return a satisfying assignment to the constraint, since a failure in satisfying the constraint results in a loss in the nonlocal game. On the other hand, the observables that she measures for the same variable, e.g., v_t, in different constraints can be different. To specify her strategy, we denote the observable Alice measures for vairable v_t in the constraint c_s as $A_t^{(s)}$. On Bob's side, we denote the observable he measures for variable v_t as B_t.

Now, suppose Alice and Bob initially share the maximally entangled state $|\Phi^+\rangle$. Assume there exists a Clifford strategy, such that $\forall s, t$,

$$\left\langle\Phi^+\right| A_t^{(s)} \otimes B_t \left|\Phi^+\right\rangle > 0. \tag{32}$$

Since Alice and Bob apply a Clifford strategy, $A_t^{(s)}$ and B_t are both Pauli strings, so is $A_t^{(s)} B_t^{\mathrm{T}}$. Using the property of $|\Phi^+\rangle$, the left-hand side of the above equation equals $\langle\Phi^+| A_t^{(s)} B_t^{\mathrm{T}} \otimes \mathbb{I} |\Phi^+\rangle = \mathrm{tr}\Big(A_t^{(s)} B_t^{\mathrm{T}}\Big)/d$, where d is the system dimension. Since $A_t^{(s)} B_t^{\mathrm{T}}$ is a Pauli string, we have $\mathrm{tr}\Big(A_t^{(s)} B_t^{\mathrm{T}}\Big)/d \in \{0, \pm 1\}$. According to our assumption, we conclude that $A_t^{(s)} = B_t^{\mathrm{T}}$ and $\langle\Phi^+| A_t^{(s)} \otimes B_t |\Phi^+\rangle = 1$ for all s, t. Besides,

$$\begin{aligned}
\left\langle\Phi^+\right| A_t^{(s_1)} A_t^{(s_2)} \otimes \mathbb{I} \left|\Phi^+\right\rangle &= \left\langle\Phi^+\right| (A_t^{(s_1)} \otimes \mathbb{I})(A_t^{(s_2)} \otimes \mathbb{I}) \left|\Phi^+\right\rangle \\
&= \left\langle\Phi^+\right| (A_t^{(s_1)} \otimes \mathbb{I})(A_t^{(s_2)} \otimes \mathbb{I}) \left|\Phi^+\right\rangle \left\langle\Phi^+\right| (\mathbb{I} \otimes B_t)(\mathbb{I} \otimes B_t) \left|\Phi^+\right\rangle \\
&\geq \left\langle\Phi^+\right| A_t^{(s_1)} \otimes B_t \left|\Phi^+\right\rangle \left\langle\Phi^+\right| A_t^{(s_2)} \otimes B_t \left|\Phi^+\right\rangle \\
&> 0,
\end{aligned} \tag{33}$$

which holds for all s_1, s_2 and t. In the third line, we apply the Cauchy-Schwarz inequality. The only value that the above equation can take is hence 1, indicating that $A_t^{(s_1)} = A_t^{(s_2)}$. Thus we can omit the superscript (s).

Since the linear BCS does not have a satisfying assignment with Pauli-string observables, we can use the commutation properties of Pauli operators and the substitution method and derive an expression $A_{t_1} A_{t_2} \cdots A_{t_m} = -\mathbb{I}$ for a set of variables that leads to a contradiction of $\mathbb{I} = -\mathbb{I}$. The proof of this statement shall be given in Corollary 2 in Appendix V B. Therefore, for any Clifford strategy, there exists a particular pair of inputs s, t such that $\langle\Phi^+| A_t^{(s)} \otimes B_t |\Phi^+\rangle \leq 0$. Consequently,

$$\Pr[\text{win} \mid s, t] = \frac{1}{2}\left(1 + \left\langle\Phi^+\right| A_t^{(s)} \otimes B_t \left|\Phi^+\right\rangle\right) \leq \frac{1}{2}. \tag{34}$$

Therefore, the average winning probability of the game is

$$\Pr[\text{win}] = \sum_{s',t'} \Pr[\text{win}|s', t'] \Pr[s', t'] \leq 1 - \frac{1}{2}\Pr[s, t]. \tag{35}$$

In the second part of the proof, we use the definition of Clifford operations that map a Pauli-string observable to a Pauli-string observable. For any initial state $|\psi\rangle$ that Alice and Bob may share in advance, it is linked with $|\Phi^+\rangle$ via a Clifford operation U_C. Then for any Pauli-string observables A_t, B_t,

$$\langle\psi| A_t \otimes B_t |\psi\rangle = \left\langle\Phi^+\right| U_C^\dagger (A_t \otimes B_t) U_C \left|\Phi^+\right\rangle \equiv \left\langle\Phi^+\right| A_t' \otimes B_t' \left|\Phi^+\right\rangle, \tag{36}$$

where A_t' and B_t' are also Pauli-string observables that adapt to the systems of Alice and Bob, respectively. Then, either $\{A_t'\}$ fails in yielding a satisfying assignment to one of the constraints, or the proof dates back to the first part. This finishes the proof. □

IV. 1D MAGIC BCS RELATION PROBLEM

In this part, we introduce the relation problem in detail by embedding the BCS nonlocal game into a one-dimensional grid. We will prove Theorem 4 in the main text, showing this problem can be solved by a generic constant-depth quantum circuit with only bounded fan-in gates, while any magic-free circuit requires a circuit depth that increases at least logarithmically to the input size. For simplicity, we consider the non-trivial BCS game with size $n = 8$. Three pairs of qubits suffice to realize the nonlocal game associated with this BCS, as shown in Section II. One can consider other values of n, where the proofs are similar.

In the shallow circuit computation, we apply the modified BCS given in Methods. That is, the constraint of $\prod_{v \in \mathcal{V}} a_v = -1$ is replaced with the set of constraints

$$\begin{cases}
a_1 a_2 a_{12} &= 1 \\
a_{12} a_3 a_{123} &= 1 \\
\cdots & \\
a_{1\cdots n-3} a_{n-2} a_{1\cdots n-2} &= 1 \\
a_{1\cdots n-2} a_{n-1} a_n &= -1.
\end{cases} \tag{37}$$

For the modified BCS with size $n = 8$, by applying Theorem 7, we have the following result.

Lemma 2. *In the modified BCS game with $n = 8$, suppose the questions are picked up uniformly at random. Then, the maximal winning probability for all Clifford strategies is upper-bounded by*

$$p_{\text{Clif}} \leq 1 - \frac{1}{6252}. \tag{38}$$

Now we introduce the relation problem R_N, which is labeled with a number N representing the problem size. One can assume that two players, Alice and Bob, collaborate with each other to solve R_N. The input and output of R_N are given as follows.

1. Input: in each round, Alice and Bob are given a question,
$$q = (\alpha_1, \beta_1, \cdots, \alpha_N, \beta_N), \alpha_i \in \mathcal{Q}^A \cup \{\perp\}, \beta_i \in \mathcal{Q}^B \cup \{\perp\}, \tag{39}$$
where q stands for "question", α_i is the input on Alice's side at site $i \in [N]$, and β_i is the input on Bob's side at site $i \in [N]$. $\mathcal{Q}^A$ consists of the set of constraints in the BCS, and $\mathcal{Q}^B$ consists of the set of variables in the BCS. Here, $\{\perp\}$ represents a null input.
2. Output: in each round, Alice and Bob need to return a reaction to the question,
$$r = (\mathbf{r}_1^A, \mathbf{r}_1^B, \cdots, \mathbf{r}_N^A, \mathbf{r}_N^B), \tag{40}$$
where r stands for "reaction", $\mathbf{r}_i^A = (r_i^A(1), r_i^A(2), r_i^A(3)) \in \{\pm 1\}^3$ is the output on Alice's side at site i, and similarly on Bob's side.

Now, we define the 1D magic BCS relation problem R_N. In the computation task, Alice and Bob are promised to receive an instance given by a tuple $(j, k, \alpha, \beta), 1 \leq j < k \leq N$, which defines the input as

$$\alpha_i = \begin{cases} \alpha, & \text{if } i = j, \\ \perp, & \text{if } i \neq j, \end{cases} \qquad \beta_i = \begin{cases} \beta, & \text{if } i = k, \\ \perp, & \text{if } i \neq k. \end{cases} \tag{41}$$

That is, we require the sites j on Alice's side and k on Bob's side to play the BCS nonlocal game with questions α and β, respectively. Alice and Bob are required to give an output satisfying either of the following requirements:

Case 1 For any $l \in \{1, 2, 3\}$,

$$\begin{aligned} \prod_{j < i \leq k} r_i^A(l) &= +1, \\ \prod_{j \leq i < k} r_i^B(l) &= +1, \end{aligned} \tag{42}$$

and

$$(\mathbf{r}_j^A, \mathbf{r}_k^B) = f(\alpha, \beta), \tag{43}$$

where f is the relation defined by the BCS nonlocal game.

Case 2 There exists $l \in \{1, 2, 3\}$ such that,

$$\prod_{j < i \leq k} r_i^A(l) = -1, \tag{44}$$

or

$$\prod_{j \leq i < k} r_i^B(l) = -1. \tag{45}$$

In addition, we require that **Case 1** occurs with a probability no smaller than a positive constant value $p \in (0, 1/64]$. By constant, we mean that p cannot be negligibly small, where there exists a sequence of positive values $\{p_1, \cdots, p_t, \cdots\}$ such that $p = \lim_{t \to \infty} p_t = 0^+$.

Below, we show that the 1D magic relation problem R_N can be solved by a QNC^0circuit but cannot be solved by any ClifNC^0circuit. We first show that there exists a shallow circuit with generic bounded fan-in quantum gates that perfectly completes this task. Now consider the following strategy:

1. Alice and Bob share $3N$ pairs of EPR states, $|\Phi^+\rangle^{\otimes 3N}$, where $|\Phi^+\rangle = (|00\rangle + |11\rangle)/\sqrt{2}$, and arrange them in three layers, denoted by $q_{2i-1}(l), q_{2i}(l), i \in [N], l \in \{1,2,3\}$, where qubits $q_{2i-1}(l)$ and $q_{2i}(l)$ reside in the state $|\Phi^+\rangle$. Alice holds the qubits $q_{2i-1}(l)$ and Bob holds the qubits $q_{2i}(l)$.

2. For any $j \leq i \leq k-1$, perform an entanglement swapping operation between pairs of EPRs with a BSM on qubits $q_{2i}(l)$ and $q_{2i+1}(l)$. Denote the Bell state measurement results on the pair of adjacent qubits $q_{2i}(l)$ and $q_{2i+1}(l)$ as $r_i^B(l)$ and $r_{i+1}^A(l)$, respectively.

3. On the three pairs of qubits $q_{2j-1}(l)$ and $q_{2k}(l)$, Alice and Bob perform the measurements corresponding to the winning strategy in the BCS nonlocal game and obtain outputs $(r_j^A(l), r_k^B(l))$.

4. Take an arbitrary measurement on the qubits that are not measured and record the measurement results with respect to the site indices.

Note that at the end of the entanglement swapping operations, qubits $q_{2j-1}(l)$ and $q_{2k}(l)$ reside in $|\Phi^+\rangle$ with probability $1/4$ for each $l \in \{1,2,3\}$. By construction, this strategy naturally meets the problem requirements, and the first requirement defined through Eq. (42) and (43) is met with probability $1/64$. One can also see the reason that we modify the underlying BCS game: Alice needs to output an assignment to all the variables that appear in the constraint. As Alice can only output 3 bits in the relation problem, we need to decompose the original n-variable constraint into smaller ones. Measuring the observables in the winning strategy of the BCS nonlocal game thus results in the desired statistics. Moreover, the above strategy can be realized in a constant depth with finite fan-in operations and a computational basis measurement. Nevertheless, there is a minimal fan-in size of the gates to realize the above strategy. The following theorem gives a sufficient gate fan-in size.

Theorem 8. *Suppose the quantum computation circuits act on qubits or bits. Then, the fan-in size $K = 14$ is sufficient for the above strategy.*

Proof. As counted in Methods, in the modified BCS nonlocal game for the relation problem R_N^8, the number of variables is $727 + 1 < 2^{10}$, and the number of constraints is $1042 + 1 < 2^{11}$, where we also need to consider the null input $\perp$. Thus, all possible inputs α_i, β_i at site $i \in [N]$ can be encoded as 11 bits.

Next, we prove that all the operations in the above strategy can be implemented by K-bounded fan-in gates with $K = 14$. Note that all constant input size boolean function can be computed in NC^0, so we only care about the classically controlled quantum gates [Fig. 1(b)] and quantum measurements [Fig. 1(c)]. We analyze the algorithm step by step:

1. EPR preparation: No classical bit is involved. The quantum circuit involves simply one or two-qubit quantum gates, hence $K \geq 0 + 2 = 2$ in this step.

2. BSM: First determine whether the input is $\perp$ through classical computing. Then perform BSM if it so and do nothing if not. This step requires $K \geq 1 + 2 = 3$.

3. Nonlocal game: 11 classical bits are needed to control 3-qubit quantum gates. This step requires $K \geq 11+3 = 14$.

Therefore, all the operations in the shallow-circuit strategy to solve the computational problem can be implemented using K bounded fan-in gates with $K = 14$. This finishes the proof. □

As a side remark, note that a classically controlled quantum gate with a constant number of classical control bits can be decomposed into compositions of single-bit classically controlled quantum gates within a constant depth where the quantum part acts on up to two qubits [21]. Thus, actually, $K = 3$ is sufficient, albeit a compromise of a few circuit layers.

Below, we prove the hardness of the problem for a ClifNC^0circuit with only bounded fan-in classical gates and Clifford gates, including classically controlled Clifford gates and constant-weight Pauli-string measurements. We illustrate these two types of bounded fan-in gates in Fig. 1. The bounded fan-in classically controlled quantum gates require the numbers of classical input bits and the controlled qubits to be both finite, and the controlled gate is Clifford in a ClifNC^0circuit. The circuit allows intermediate measurements, and the measurement results can be used to control subsequent quantum gates. The constant-weight Pauli measurement measures a Pauli observable on a constant number of qubits, where the POVM element is a stabilizer state. As a constant-weight Pauli measurement is equivalent to implementing a constant-depth Clifford gate followed by the computational basis measurement on the first qubit and implementing the inverse of the Clifford gate, we can take all measurements as computational basis measurements, or σ_z measurements.

Now, consider a magic-free circuit with depth D, and the gates within it have fan-in bounded by K, which means the total number of input classical bits and qubits of the gates is no larger than K. Denote the qubit or bit value at

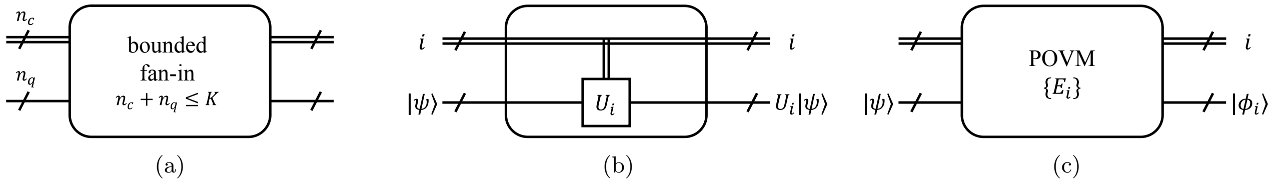

FIG. 1: (a) A general K-bounded fan-in gate acting on n_c bits and n_q qubits, with $n_c + n_q \le K$. There are two types of gates with $n_q > 0$: (b) Classically controlled quantum gates. The classical input i controls whether to apply the quantum gate U_i to the quantum input state $|\psi\rangle$; (c) Quantum measurement characterized by a positive operator-valued measure (POVM). The classical system acts as a register to record the measurement result. In a ClifNC^0circuit, U_i within the classically controlled gate is restricted to a Clifford operation. Meanwhile, in a ClifNC^0circuit, each measurement element E_i should be a mixture of stabilizer states. Equivalently, for a magic-free quantum input state $|\psi\rangle$, the post-measurement state $|\phi_i\rangle$ in a ClifNC^0circuit still does not contain quantum magic. In this work, we simply consider projective measurements. Both (b) and (c) are special cases of (a).

index v as i_v and suppose $\mathcal{E}_1$ is the gate of the first layer that contains i_v as an input. Then, $\mathrm{supp}(\mathcal{E}_1(i_v))$ determines a set of qubits and bits after the first layer of the circuit that may be affected by i_v. Similarly, we can consider the qubits and bits that may be affected in the next layer of the circuit. Denote the gates in each circuit layer are given by $\{\mathcal{E}_1, \mathcal{E}_2, \cdots, \mathcal{E}_D\}$. In the end, we call the set of qubits and bits

$$L_C^{\rightarrow}(i_v) = \mathrm{supp}(\mathcal{E}_D(\mathrm{supp}(\cdots \mathrm{supp}(\mathcal{E}_2(\mathrm{supp}(\mathcal{E}_1(i_v))))))) \tag{46}$$

the forward light cone of i_v.

The backward light cone of an output bit or qubit, o_w, at index b can be defined with the reverse of the forward light cone of the input and given by

$$L_C^{\leftarrow}(o_w) := \{i_v | o_w \in L_C^{\rightarrow}(i_v)\}. \tag{47}$$

The backward light cone of an output set, O, is defined as

$$L_C^{\leftarrow}(O) := \bigcup_{o \in O} L_C^{\leftarrow}(o). \tag{48}$$

Note that if a depth-D quantum circuit, $\mathcal{C}$, only comprises gates with fan-in bounded by K, then

$$|L_C^{\leftarrow}(o)| \le K^D, \tag{49}$$

and

$$|L_C^{\leftarrow}(O)| \le |O| K^D. \tag{50}$$

Note that the input of the relation problem R_N is classical and given by $q = (\alpha_1, \beta_1, \cdots, \alpha_N, \beta_N)$. Before acting gates, there are also an arbitrary number of classical ancillas with value 0 and quantum ancillas at state $|0\rangle$, which do not contain any input information. With the circuit's evolution, the input information will spread among classical bits and qubits via classically controlled quantum gates. Nonetheless, due to the gates being bounded fan-in and the circuit being at constant depth, the input information cannot spread a lot. The output of R_N can be read out from the classical bits after constant-depth circuit evolution. Without loss of generality, we can assume the output of R_N is read out from the first $6N$ bits at the last step of the circuit, which is $r = (\mathbf{r}_1^A, \mathbf{r}_1^B, \cdots, \mathbf{r}_N^A, \mathbf{r}_N^B)$ as mentioned above. We depict this procedure in Fig. 2(a).

Using the idea of information not spreading a lot, we will show that with high probability, an input value α_j (β_k) is independent of the output $\mathbf{r}_k^B$ ($\mathbf{r}_j^A$), as presented in Lemma 4. Before proving it, we first present the following lemma.

Lemma 3. *Let $\mathcal{C}$ be a depth-D circuit with classical inputs and an arbitrary number of quantum and classical ancillas, which comprises gates with fan-in upper bounded by K. The output of $\mathcal{C}$ is read out from the classical bits at the end of the circuit. Then, the following holds:*

Let O be a fixed subset of output bit indices, and suppose I is a randomly chosen subset of input bit indices such that for any input bit index v,

$$\Pr_I[v \in I] \le \eta. \tag{51}$$

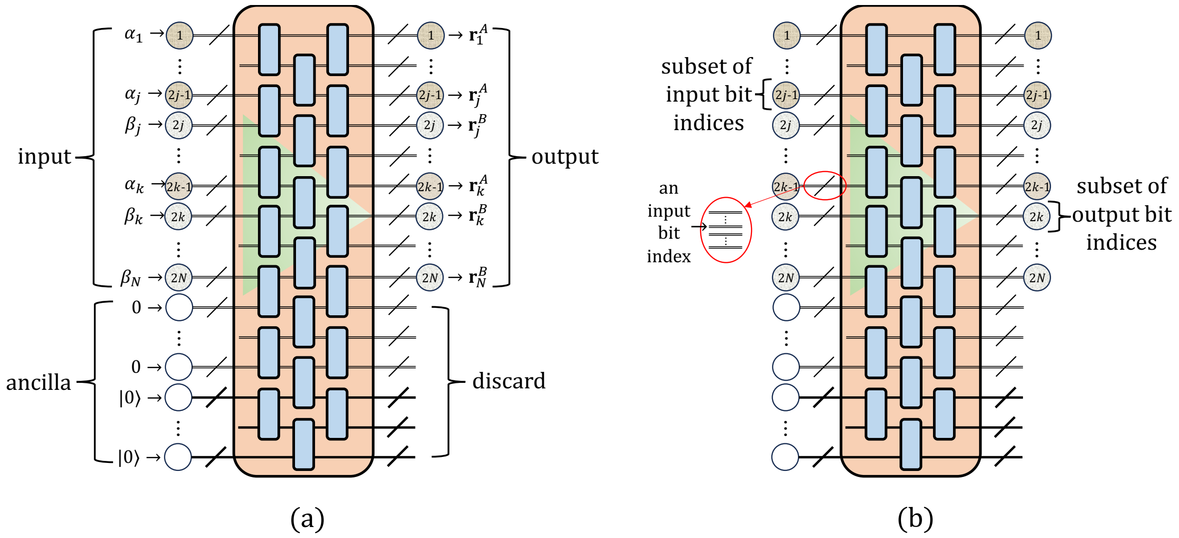

FIG. 2: (a) A circuit to solve relation problem R_N. The input comprises classical bits $(\alpha_1, \beta_1, \cdots, \alpha_N, \beta_N)$. Note that α_i takes value from $\mathcal{Q}^A \cup \{\perp\}$ and contains $\log\big(|\mathcal{Q}^A| + 1\big)$ bits. The case is similar for β_i. Besides, the circuit also has an arbitrary number of bits 0 and qubits $|0\rangle$ as ancillas. The output of the relation problem comprises classical bits $(\mathbf{r}_1^A, \mathbf{r}_1^B, \cdots, \mathbf{r}_N^A, \mathbf{r}_N^B)$. Each $\mathbf{r}_i^A$ or $\mathbf{r}_i^B$ contains three bits. Other qubits and bits within the circuit are discarded. (b) Diagram to label a subset of the input bits, a subset of the output bits, and an input bit. In Lemma 4, the subset of the input bits I is the set that takes value in $\mathcal{Q}^A$ or $\mathcal{Q}^B$ and does not take value of $\perp$. The subset of the output bits O is the set of bits outputting $\mathbf{r}_j^A$ or $\mathbf{r}_k^B$.

Then

$$\Pr_I[O \cap L_C^{\rightarrow}(I) \neq \emptyset] \leq \eta |O| 2^{|O|} K^D. \tag{52}$$

Proof.

$$\begin{aligned}
\Pr_I[O \cap L_C^{\rightarrow}(I) \neq \emptyset] &= \sum_{P \subseteq O, P \neq \emptyset} \Pr_I[O \cap L_C^{\rightarrow}(I) = P] \\
&\leq \sum_{P \subseteq O, P \neq \emptyset} \Pr_I[I \cap L_C^{\leftarrow}(P) \neq \emptyset] \\
&\leq \sum_{P \subseteq O, P \neq \emptyset} \sum_{v \in L_C^{\leftarrow}(P)} \Pr_I[v \in I] \\
&\leq \sum_{P \subseteq O, P \neq \emptyset} \sum_{v \in L_C^{\leftarrow}(P)} \eta \\
&\leq \sum_{P \subseteq O, P \neq \emptyset} |L_C^{\leftarrow}(P)| \eta \\
&\leq \sum_{P \subseteq O, P \neq \emptyset} |P| K^D \eta \\
&\leq 2^{|O|} |O| K^D \eta.
\end{aligned} \tag{53}$$

□

Lemma 4. *Consider a depth-D circuit composed of gates of fan-in at most K. The input of the circuit $q = (\alpha_1, \beta_1, \cdots, \alpha_N, \beta_N)$ is determined by a tuple (j, k, α, β) with $1 \leq j < k \leq N$ and given by Eq. (41). We denote the set of all possible inputs as S. The output of the circuit is given by $r = (\mathbf{r}_1^A, \mathbf{r}_1^B, \cdots, \mathbf{r}_N^A, \mathbf{r}_N^B)$. Define the event $E_\mathcal{C} \subset S$ in which the input parameters satisfy*

$$\mathrm{supp}(\mathbf{r}_j^A) \cap L_C^{\rightarrow}(\mathrm{supp}(\beta_k)) = \emptyset \text{ and } \mathrm{supp}(\mathbf{r}_k^B) \cap L_C^{\rightarrow}(\mathrm{supp}(\alpha_j)) = \emptyset. \tag{54}$$

Here, $\mathrm{supp}(x)$ *means the bits carrying on the value x. Under a uniform choice of input from S, the event $E_{\mathcal{C}}$ occurs with probability* $\Pr[E_{\mathcal{C}}] \geq 1 - \frac{48K^D}{N}$.

Proof. We consider a random input from the set S, which is constructed by a randomly generated tuple (j, k, α, β). Note that j and k are two different numbers uniformly and randomly picked from $\{1, 2, \cdots, N\}$ while α and β are randomly and uniformly picked from $\mathcal{Q}^A$ and $\mathcal{Q}^B$, respectively. Consider the input bit set as $I = \mathrm{supp}(\alpha_j)$ as the set that takes value in $\mathcal{Q}^A$ and does not take value of $\perp$ in Lemma 3 and suppose the input bit v is located at site j^*, as shown in Fig. 2(b). We have

$$\Pr_{\mathrm{supp}(\alpha_j)}[v \in \mathrm{supp}(\alpha_j)] = \Pr_{1 \leq j \leq N}[j = j^*] = \frac{1}{N}. \tag{55}$$

Meanwhile, consider the subset of the output bits O is the set of bits outputting $\mathbf{r}_k^B$, based on Lemma 3, we obtain

$$\Pr_{\mathrm{supp}(\alpha_j)}[\mathrm{supp}(\mathbf{r}_k^B) \cap L_C^{\rightarrow}(\mathrm{supp}(\alpha_j)) \neq \emptyset] \leq 2^{|\mathbf{r}_k^B|}|\mathbf{r}_k^B|K^D\frac{1}{N}. \tag{56}$$

Note that $\mathbf{r}_k^B$ only has 3 output bits, then

$$\Pr_{\mathrm{supp}(\alpha_j)}[\mathrm{supp}(\mathbf{r}_k^B) \cap L_C^{\rightarrow}(\mathrm{supp}(\alpha_j)) \neq \emptyset] \leq \frac{24K^D}{N}. \tag{57}$$

Similarly, we get

$$\Pr_{\mathrm{supp}(\beta_k)}[\mathrm{supp}(\mathbf{r}_j^A) \cap L_C^{\rightarrow}(\mathrm{supp}(\beta_k)) \neq \emptyset] \leq \frac{24K^D}{N}. \tag{58}$$

Thus,

$$\begin{aligned}\Pr_q[E_{\mathcal{C}}] &= \Pr_{\mathrm{supp}(\alpha_j),\mathrm{supp}(\beta_k)}[\mathbf{r}_j^A \cap L_C^{\rightarrow}(\beta_k) = \emptyset \cap \mathbf{r}_k^B \cap L_C^{\rightarrow}(\alpha_j) = \emptyset] \\ &= 1 - \Pr_{\mathrm{supp}(\alpha_j),\mathrm{supp}(\beta_k)}[\mathbf{r}_j^A \cap L_C^{\rightarrow}(\beta_k) \neq \emptyset \cup \mathbf{r}_k^B \cap L_C^{\rightarrow}(\alpha_j) \neq \emptyset] \\ &\geq 1 - \Pr_{\mathrm{supp}(\beta_k)}[\mathbf{r}_j^A \cap L_C^{\rightarrow}(\beta_k) \neq \emptyset] - \Pr_{\mathrm{supp}(\alpha_j)}[\mathbf{r}_k^B \cap L_C^{\rightarrow}(\alpha_j) \neq \emptyset] \\ &\geq 1 - \frac{48K^D}{N}.\end{aligned} \tag{59}$$

□

With Lemma 4, we are able to achieve our ultimate goal to prove the hardness of R_N for magic-free shallow circuits. The main idea is that with high probability, the event defined in Lemma 4 would happen, and if this event happens, the magic-free circuit cannot give a correct output as the nonlocal game requires magic to win with certainty.

Theorem 9. *Let $\mathcal{C}$ be a depth-D circuit with classical input values and classical and quantum ancillas, which only comprises magic-free operations with fan-in upper bounded by K. Now, consider the classical input $q = (\alpha_1, \beta_1, \cdots, \alpha_N, \beta_N)$ determined by Eq. (41) with α_j and β_k selected uniformly at random from $\mathcal{Q}^A$ and $\mathcal{Q}^B$. Then for any constant value $p \in (0, 1)$, the average probability that $\mathcal{C}$ outputs $r = (\mathbf{r}_1^A, \mathbf{r}_1^B, \cdots, \mathbf{r}_N^A, \mathbf{r}_N^B)$ such that*

(1) r and q satisfy the requirements in ***Case 1*** *and* ***Case 2****,*

(2) outputs ***Case 1*** *with probability no smaller than p,*

is at most $\frac{48K^D}{N} + p_{\mathrm{Clif}}$, with p_{Clif} given in Lemma 2. To meet the requirements with a success probability larger than $(1 + p_{\mathrm{Clif}})/2$, the circuit depth requirement is $\Theta(\log N)$.

Proof. The average success probability of $\mathcal{C}$ to output a correct relation between r and q is

$$\begin{aligned}
\Pr_q[\text{success}] =& \Pr_q[\textbf{Case 1}] \Pr_q[\text{success}|\textbf{Case 1}] + \Pr_q[\textbf{Case 2}] \Pr_q[\text{success}|\textbf{Case 2}] \\
=& \Pr_q[\textbf{Case 1}](\Pr_q[E_{\mathcal{C}}|\textbf{Case 1}] \Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}] + \Pr_q[E_{\mathcal{C}}^C|\textbf{Case 1}] \Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}^C]) \\
&+ \Pr_q[\textbf{Case 2}] \Pr_q[\text{success}|\textbf{Case 2}] \\
\leq& \Pr_q[\textbf{Case 1}](\Pr_q[E_{\mathcal{C}}|\textbf{Case 1}] \Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}] + 1 - \Pr_q[E_{\mathcal{C}}|\textbf{Case 1}]) + \Pr_q[\textbf{Case 2}] \\
=& 1 - \Pr_q[\textbf{Case 1}] \Pr_q[E_{\mathcal{C}}|\textbf{Case 1}](1 - \Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}]) \\
=& 1 - \Pr_q[E_{\mathcal{C}}](1 - \Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}]) \\
=& 1 - \Pr_q[E_{\mathcal{C}}] + \Pr_q[E_{\mathcal{C}}] \Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}] \\
\leq& \frac{48K^D}{N} + \Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}].
\end{aligned} \tag{60}$$

Here, $E_{\mathcal{C}}$ is the event defined in Lemma 4 and $E_{\mathcal{C}}^C$ is the complementary set of $E_{\mathcal{C}}$. From the above inequality, notice that the upper bound on the average success probability is irrelevant with the probability for **Case 1** to occur, i.e., the value of p. Now, we only need to investigate the value of $\Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}]$.

When **Case 1** happens, the success condition is making the inputs α_j and β_k and the outputs $\mathbf{r}_j^A$ and $\mathbf{r}_k^B$ satisfy the relation defined by the BCS game, i.e., Eq. (43). Also, when $E_{\mathcal{C}}$ happens, the output $\mathbf{r}_j^A$ only depends on α_j and does not depend on β_k. And the reverse is true for $\mathbf{r}_k^B$. It reduces to the case that Alice and Bob are trying to win the BCS non-local game without classical communication. As the circuit only comprises $|0\rangle$ as input quantum states, Clifford gates, and Pauli measurements, it means that Alice and Bob need to win this non-local game with Pauli measurements and magic-free states, whose winning probability is upper-bounded by p_{Clif}. That is, $\Pr_q[\text{success}|\textbf{Case 1}, E_{\mathcal{C}}] \leq p_{\text{Clif}}$. Then, we conclude that the average success probability of $\mathcal{C}$ to output a correct relation between r and q is

$$\Pr_q[\text{success}] \leq \frac{48K^D}{N} + p_{\text{Clif}}. \tag{61}$$

To output the correct relation with a success probability larger than $(1 + p_{\text{Clif}})/2$, the circuit depth D has a lower bound as below.

$$\frac{48K^D}{N} + p_{\text{Clif}} \geq \frac{1 + p_{\text{Clif}}}{2} \Leftrightarrow D \geq \frac{\log N + \log \frac{1-p_{\text{Clif}}}{96}}{\log K} = \Omega(\log N). \tag{62}$$

On the other hand, as stated in the main text, there is a classical circuit with circuit depth $O(\log N)$ that solves the problem. Therefore, the bound on the circuit depth for magic-free circuits to solve the problem is tight. This finishes the proof. □

V. FINDING POTENTIAL MAGIC-NECESSARY LINEAR BINARY CONSTRAINT SYSTEMS

In this section, we discuss finding other instances of linear BCS that require magic for a perfect quantum solution. It is challenging to develop a general procedure for this target. Instead, we provide a "guess-and-check" procedure: (1) First, obtain a potential BCS, and (2) Second, verify whether the BCS has a solution over the Pauli group. For the first step, one can use the group embedding results in Ref. [1]. Building on the group-theoretic results, including Ref. [8, 9], Ref. [1] provides an efficient procedure to embed a group into a BCS, which is a group homomorphism of the original group to a non-trivial BCS solution group; hence the procedure constructs a BCS that necessarily has a (quantum) solution. In particular, the output solution group inherits the representation properties of the original group. However, such a BCS may have a classical solution or a quantum solution over the Pauli group, where magic is absent. We develop an efficient classical algorithm for this issue to decide whether a linear BCS has a Pauli-string solution. Besides aiding the search for non-trivial linear BCS, we hope this result can help explore the decidability problems for general BCS and nonlocal games [5].

A. Slofstra's group embedding procedure

A group G is said to be embedded into group K if there exists an injective group homomorphism $\phi : G \to K$. One can pose additional requirements to the group embedding to guarantee the inheritance of group representation properties; see Definitions 10 and 14 in Ref. [1] for example. This is also one of the core issues in the group embedding procedure in Ref. [1]. For our purpose of finding magic-necessary BCS, some analysis on the group representation inheritance issue may be redundant. Nevertheless, we faithfully review the group embedding results of Ref. [1] here and leave the problem of simplifying the procedure to future work. For the convenience of stating the group embedding results, we use the Boolean variables and parity constraints instead of the sign variables and multilinear constraints in this subsection. The conversion between sign variables and Boolean variables is given in Eq. (4).

As we now use the Boolean variable notation, a BCS can be compactly written as $M\vec{v} = \vec{c}$, where M is an $m \times n$ Boolean matrix, $\vec{v} = (v_1, \cdots, v_n)^{\mathrm{T}}$ is the vector of variables, and $\vec{c} = (c_1, \cdots, c_m)^{\mathrm{T}}$ is the vector of constraints. The non-zero elements in the j'th row of M define the set of variables presented in the j'th constraint, $\mathcal{S}_j$. We first define several classes of groups, including a restatement of the BCS solution group with the current notations.

Definition 3 (Solution group of a linear BCS using Boolean variables)**.** *Given a linear BCS with n binary variables $\{v_i\}$ and m constraints $\{c_j\}$ specified by $M\vec{v} = \vec{c}$, the solution group of the BCS is defined as the group with the following presentation:*

$$\begin{aligned}\Gamma(M, \vec{c}) = \{\{J, g_i : i \in [n]\} : \{&g_i^2 = e, \forall i \in [n],\\ &J^2 = e,\\ \forall j \in [m], &g_k g_l = g_l g_k, \forall k, l \in \mathcal{S}_j,\\ &J g_i = g_i J, \forall i \in [n],\\ &\prod_{i \in \mathcal{S}_j} g_i = J^{c_j}, \forall j \in [m]\}\},\end{aligned} \tag{63}$$

where e defines the identity operator of the group. We take the convention that $J^0 = e$.

Definition 4 (Linear-plus-conjugacy group)**.** *Given a linear BCS with n binary variables $\{v_i\}$ and m constraints $\{c_j\}$ specified by $M\vec{v} = \vec{c}$, and $\mathcal{C} \subseteq [n] \times [n] \times [n]$ with $[n] = \{1, \cdots, n\}$, the linear-plus-conjugacy group $\Gamma(M, \vec{c}, \mathcal{C})$ is defined as*

$$\Gamma(M, \vec{c}, \mathcal{C}) \equiv \langle \Gamma(M, \vec{c}) : g_i g_j g_i = g_k, \forall (i, j, k) \in \mathcal{C} \rangle, \tag{64}$$

where the relators $g_i g_j g_i = g_k$ are additionally posed to the solution group $\Gamma(M, \vec{c})$.

Definition 5 (Homogeneous linear-plus-conjugacy group)**.** *Given an $m \times n$ Boolean matrix M where the set of non-zero elements in the j'th row is given by $\mathcal{S}_j$, and $\mathcal{C} \subseteq [n] \times [n] \times [n]$, the homogeneous linear-plus-conjugacy group $\Gamma_0(M, \mathcal{C})$ is defined as*

$$\begin{aligned}\Gamma_0(M, \mathcal{C}) = \{\{g_i : i \in [n]\} : \{&g_i^2 = e, \forall i \in [n],\\ \forall j \in [m], &g_k g_l = g_l g_k, \forall k, l \in \mathcal{S}_j,\\ &\prod_{i \in \mathcal{S}_j} g_i = e, \forall j \in [m],\\ &g_i g_j g_i = g_k, \forall (i, j, k) \in \mathcal{C}\}\}.\end{aligned} \tag{65}$$

Definition 6 (Extended homogeneous linear-plus-conjugacy group)**.** *Given an $m \times n$ Boolean matrix M, $\mathcal{C}_0 \subseteq [n] \times [n] \times [n]$, $\mathcal{C}_1 \subseteq [l] \times [n] \times [n]$, and L an $l \times l$ lower-triangular matrix with non-negative integer entries, the extended homogeneous linear-plus-conjugacy group $E\Gamma_0(M, \mathcal{C}_0, \mathcal{C}_1, L)$ is defined as*

$$\begin{aligned}E\Gamma_0(M, \mathcal{C}_0, \mathcal{C}_1, L) \equiv \langle \Gamma_0(M, \mathcal{C}_0), h_1, \cdots, h_l : &h_i g_j h_i^{-1} = g_k, \forall (i, j, k) \in \mathcal{C}_1,\\ &h_i h_j h_i^{-1} = h_j^{L_{ij}}, \forall i > j \wedge L_{ij} > 0\rangle,\end{aligned} \tag{66}$$

where L_{ij} refers to the element on the i'th row and j'column of matrix L.

With the above definition, Ref. [1] proves the following embedding results:

Theorem 10 ([1])**.** *Suppose a group G has a presentation in the form of an extended homogeneous linear-plus-conjugacy group given by $E\Gamma_0(M, \mathcal{C}_0, \mathcal{C}_1, L)$. Then there are the following group embedding results:*

1. *There exists a group embedding of $E\Gamma_0(M, \mathcal{C}_0, \mathcal{C}_1, L)$ into a homogeneous linear-plus-conjugacy group (Proposition 33 in Ref. [1]):*
$$E\Gamma_0(M, \mathcal{C}_0, \mathcal{C}_1, L) \to \Gamma_0(M', \mathcal{C}), \tag{67}$$
where $\Gamma_0(M', \mathcal{C})$ is a homogeneous linear-plus-conjugacy group.

2. *The extended $\Gamma_0(M', \mathcal{C})$ can be transformed into a linear-plus-conjugacy group (see the remark after Definition 31 in Ref. [1]):*
$$\Gamma_0(M', \mathcal{C}) \times \mathbb{Z}_2 = \Gamma(M', 0, \mathcal{C}). \tag{68}$$

3. *By adding relations with respect to one group element $J \in \Gamma(M', 0, \mathcal{C}), J \neq e$, which extends the matrix M' into N and adds non-homogeneous linear constraints that involve J, extend the linear-plus-conjugacy group:*
$$\Gamma(M', 0, \mathcal{C}) \to \Gamma(N, \vec{c}, \mathcal{C}'), \tag{69}$$
where $\vec{c} \neq 0$, with some entries equal to J.

4. *There exists a group embedding of $\Gamma(N, \vec{c}, \mathcal{C}')$ into a linear group (Proposition 27 in Ref. [1]):*
$$\Gamma(N, \vec{c}, \mathcal{C}) \to \Gamma(N', \vec{c}'), \tag{70}$$
which defines a BCS solution group that has a non-trivial group element $J \neq e$.

The proof is constructive, thus one can derive the concrete groups in each step. In brief, as long as a group can be presented in the form of Def. 6, which is an extended homogeneous linear-plus-conjugacy group, it can be converted into a BCS solution group after a series of group embeddings and a proper construction of non-trivial relators with respect to a group element $J \neq e$, which is set to correspond to -1 in the BCS. As promised by Lemma 1, the underlying BCS of the solution group has an (operator-valued) solution.

B. Efficient algorithm for finding perfect Pauli-string solutions to linear BCS

Next, we provide an efficient algorithm to determine the existence of a Pauli-string solution to a general linear BCS. Combined with Slofstra's group embedding procedure, one can guess and test BCS instances to search for a potential BCS that has a non-trivial solution group other than the Pauli group.

We first present some fundamental properties of Pauli-string observables.

Lemma 5. *Suppose $A_1, A_2, \cdots, A_n$ are Pauli-string observables. For $i, j \in [n]$, define $C_{ij} = A_iA_jA_iA_j$ as the commutator between A_i and A_j. Then, C_{ij}'s have the following properties:*

1. *$C_{ij} \in \{\pm\mathbb{I}\}$. Specifically, $C_{ij} = \mathbb{I}$ when $A_iA_j - A_jA_i = 0$, and $C_{ij} = -\mathbb{I}$ when $A_iA_j + A_jA_i = 0$;*
2. *$C_{ij} = C_{ji}$ and $C_{ii} = \mathbb{I}$;*
3. *$A_iA_j = C_{ij}A_jA_i$.*

The proof of Lemma 5 is straightforward, and we leave it to the readers as an exercise. According to the first property, C_{ij} is always proportional to $\mathbb{I}$ and thus commute with all the A_i's. We can treat C_{ij}'s as numbers ± 1 for simplicity. The second property shows that for a group of n A_i's, the number of independent commutators C_{ij}'s among them is at most $n(n-1)/2$. The third property shall be vital for our later discussions, as it allows us to swap two adjacent variables A_i and A_j in a product of Pauli strings up to an additional coefficient C_{ij}. Together with the first property, for a product of Pauli-string variables, we can arbitrarily rearrange their order up to a change in the sign.

Given a linear BCS, we first determine if it has a classical solution, i.e., $A_i \in \{\pm 1\}$ for all $i \in [n]$. This is equivalent to solving a system of linear equations over $\mathbb{Z}_2$, which can be done in poly(n) steps through, for example, the Gaussian elimination method. Going back to determine if the BCS has a Pauli-string solution, if we hope to apply a similar procedure, the only obstacle is that the variables might not commute with each other. Nevertheless, thanks to the nice properties of Pauli strings in Lemma 5, we can do the same thing as finding a classical solution with at most a difference in sign, which we record as a sign variable C_i. Should the BCS have a Pauli-string solution, at the end of the elimination, we can express each variable A_i as a product of some variables, which we term the "free variables," multiplied by a plus or minus sign $C_i \in \{\pm 1\}$. We use the terminology "free variables" as they are allowed to take any value, while the remaining variables depend on their values. Now we give the rigorous statement and prove it.

Lemma 6. *For a linear BCS with n variables $A_1, \cdots, A_n$ and m constraints, if it has a Pauli-string solution, then there exists a set of free variables $\{A_{i_k}\}_k$, such that each variable in the BCS can be represented in the form of $A_i = C_i A_{i_1} A_{i_2} \cdots A_{i_k} \cdots$, where $C_i \in \{\pm 1\}$ and A_{i_k}'s are arranged with the subscript k from small to large. This result can be obtained in* poly(n, m) *steps.*

Proof. When finding an operator-valued solution to a linear BCS, we require the variables in the same constraint to be compatible, as discussed in Appendix I B. Now we prove a stronger statement that does not rely on this requirement.

We prove the lemma by mathematical induction on m. The statement holds when $m = 1$, where $A_1 A_2 \cdots A_n = \pm 1$. Clearly, $A_1 = \pm A_2 \cdots A_n$, and we can take $A_2 \cdots A_n$ as free variables. We use the first property in Lemma 5 when there is a need to change the order of two variables, which finishes in poly(n) steps using a sorting algorithm. Now assume the statement holds for $m = k$. When $m = k + 1$, without loss of generality, suppose the first constraint is the added constraint with $A_1 A_2 \cdots A_l = \pm 1$. Thus, $A_1 = \pm A_2 \cdots A_l$. Substitute this expression into the other equations and simplify them using Lemma 5, which finishes in poly(n, m) steps using Gaussian elimination. Then, we get a set of k constraints. According to the induction hypothesis, every variable A_i can be represented as a product of free variables up to a sign. So we can plug the free variables into the added constraint $A_1 = \pm A_2 \cdots A_l$ and get the expression for A_1 in terms of free variables. Therefore, the statement holds for $m = k + 1$. □

Now, we get the expression for each variable in terms of a set of free variables, resulting in a linear BCS over A_i's and additional sign variables C_i's.

We further consider the conditions in the original linear BCS and eliminate all the non-free variable A_i's. Using Lemma 6, we find a set of free variables and use them to express all the other variables. Then, we substitute the expressions into the original BCS and obtain a new BCS containing the free variables and C_i's. By the definition of the free variable, every free variable occurs for an even number of times in each constraint of the new BCS by this step, otherwise, it is determined by the other variables through their commutators. By further applying Lemma 5, we can get rid of all the A_i variables and obtain a set of equations of C_i's and C_{kl}'s where k, l are the commutators of the free variables A_k and A_l. In addition, if A_i and A_j appear in the same constraint of the original BCS, they commute with each other, i.e., $A_i A_j A_i A_j = 1$. For each pair of A_i and A_j, by applying Lemma 6, replace them in the equation $A_i A_j A_i A_j = 1$ via their expressions in terms of the free variables and obtain the other equations of C_{kl}'s where k, l are indices of free variables. In the end, we convert the original linear BCS to an equivalent set of equations of C_i's ($i \in [n]$) and C_{kl}'s (k, l are indices of free variables), which is just a system of linear equations over $\mathbb{Z}_2$. Note that all the procedures are simply substitutions and the order swaps between variables, which finish in poly(n, m) steps. Should the original BCS have a Pauli-string solution, we can efficiently solve the newly derived linear equations and get a set of valid values for C_i's and C_{kl}'s.

Note that by this step, we have not finished solving the original BCS over the Pauli group, as we have not determined the operator values of A_i's. The following lemma gives a systematic method to assign legitimate Pauli-string values for all the free variables and, hence, all the variables in the original BCS.

Lemma 7. *For any given set of sign variables $\{C_{ij} = \pm 1\}_{1 \le i < j \le n}$, there exists a set of Pauli strings $\{A_i\}_{1 \le i \le n}$, such that for any $1 \le i < j \le n$, $A_i A_j A_i A_j = C_{ij}$. That is, the commutator between A_i and A_j is C_{ij}.*

Proof. We give an explicit construction. Suppose there are p sign variables equal to -1, given by $C_{i_1 j_1}, C_{i_2 j_2}, \cdots, C_{i_p j_p}$. Then, we can construct Pauli strings over p qubits according to the following rule: for every q'th qubit in each Pauli string, where $1 \le q \le p$, assign σ_x for A_{i_q} and σ_z for A_{j_q}; assign all the other qubits as $\mathbb{I}$. That is,

$$\text{the } q\text{'th qubit of } A_k = \begin{cases} \sigma_x, & \text{if } k = i_q, \\ \sigma_z, & \text{if } k = j_q, \\ \mathbb{I}, & \text{otherwise.} \end{cases} \tag{71}$$

It can be directly checked that this construction satisfies the requirements.

□

Later, we take the Mermin-Peres magic square BCS as an example to exhibit the entire procedure. As a side note, the correspondence between traceless symmetric matrices over $\mathbb{Z}_2^{n \times n}$ and Pauli strings was implicitly used in Lemma 7 in Ref. [4].

Now we summarize the results for determining the Pauli-string solution to a linear BCS.

Theorem 11. *For a linear BCS with n variables and m constraints, there exists a classical algorithm that determines whether it has a perfect quantum strategy on the Pauli group in* poly(n, m) *steps.*

The procedures can be summarized as follows:

1. Solve the BCS as if it is a classical one, with a recording of the commutator and sign changes in each step. Get an expression for each variable in terms of a set of free variables.
2. Substitute the expressions into the original BCS. Get a system of linear functions of C_i's and C_{kl}'s and solve them over $\mathbb{Z}_2$.
3. Assign a Pauli string to every free variable. Then derive the operator values of all the variables according to the expressions in step 1.

On the other hand, if there is not a Pauli-string solution to the linear BCS, we shall come to a contradiction somewhere in the procedures.

Corollary 2. *Suppose a linear BCS does not have a satisfying assignment with Pauli-string observables. On the one hand, we can use the substitution method of solving a BCS and obtain a relation for a subset of variables,*

$$A_{t_1}A_{t_2}\cdots A_{t_k} = -\mathbb{I}. \tag{72}$$

On the other hand, by posing the commutation properties of Pauli strings to the BCS variables, the left-hand side can be eliminated to $\mathbb{I}$, resulting in a contradiction.

The proof of this corollary is similar to Lemma 6. In brief, in the algorithm for finding Pauli-string solutions, we only use two operations throughout the process: (1) substitution of expressions and (2) swapping two variables in an expression according to Lemma 5. If the algorithm cannot find a Pauli-string solution, it must result in a contradiction. As we keep the right-hand side of each formula to be $\pm\mathbb{I}$, the contradiction is thus the form of the statement in the corollary.

As an example, we apply the algorithm to find a Pauli-string solution to the Mermin-Peres magic square BCS. The original BCS is given by

$$\begin{aligned} A_1A_2A_3 &= 1,\\ A_4A_5A_6 &= 1,\\ A_7A_8A_9 &= 1,\\ A_1A_4A_7 &= 1,\\ A_2A_5A_8 &= 1,\\ A_3A_6A_9 &= -1. \end{aligned} \tag{73}$$

After the first step, we find that the BCS variables can be determined by a set of free variables $\{A_5, A_6, A_8, A_9\}$:

$$\begin{aligned} A_1 &= C_1A_5A_6A_8A_9,\\ A_2 &= C_2A_5A_8,\\ A_3 &= C_3A_6A_9,\\ A_4 &= C_4A_5A_6,\\ A_7 &= C_7A_8A_9. \end{aligned} \tag{74}$$

Substituting these expressions into the original BCS, we obtain the set of equations

$$\begin{aligned} A_1A_2A_3 &= C_1C_2C_3C_{59}C_{56}C_{58}C_{69}C_{89} = 1,\\ A_4A_5A_6 &= C_4C_{56} = 1,\\ A_7A_8A_9 &= C_7C_{89} = 1,\\ A_1A_4A_7 &= C_1C_4C_7C_{59}C_{68}C_{56}C_{58}C_{69}C_{89} = 1,\\ A_2A_5A_8 &= C_2C_{58} = 1,\\ A_3A_6A_9 &= C_3C_{69} = -1. \end{aligned} \tag{75}$$

Using the commutation conditions between variables in the same constraint as the original BCS, we have the equations

$$\begin{aligned} A_1A_2A_1A_2 &= C_{69} = 1,\\ &\cdots\\ A_4A_7A_4A_7 &= C_{59}C_{68}C_{56}C_{58}C_{69}C_{89} = 1,\\ &\cdots\\ A_8A_9A_8A_9 &= C_{89} = 1. \end{aligned} \tag{76}$$

Solving Eq. (75) and (76) over $\mathbb{Z}_2$, we have

$$\begin{aligned} &C_1 = C_2 = C_4 = C_7 = 1, \\ &C_3 = -1, \\ &C_{56} = C_{58} = C_{69} = C_{89} = 1, \\ &C_{59} = C_{68} = -1. \end{aligned} \tag{77}$$

With respect to the commutators among the free variables, we obtain two commutators that are equal to -1. Assign the free variables as two-qubit Pauli strings,

$$\begin{aligned} A_5 &= \sigma_x \otimes \mathbb{I}, \\ A_6 &= \mathbb{I} \otimes \sigma_x, \\ A_8 &= \mathbb{I} \otimes \sigma_z, \\ A_9 &= \sigma_z \otimes \mathbb{I}, \end{aligned} \tag{78}$$

and the other variables are then determined as

$$\begin{aligned} A_1 &= -\sigma_y \otimes \sigma_y, \\ A_2 &= \sigma_x \otimes \sigma_z, \\ A_3 &= -\sigma_z \otimes \sigma_x, \\ A_4 &= \sigma_x \otimes \sigma_x, \\ A_7 &= \sigma_z \otimes \sigma_z. \end{aligned} \tag{79}$$

This solution is equivalent to the solution in Eq. (7) in the sense of a unitary transformation, or a relabelling of the variables.

Abstract. Quantum mechanics imposes limits on the statistics of certain observables. The most famous example is the uncertainty principle. Similar trade-offs exist for the simultaneous violation of multiple Bell inequalities. In the simplest case of three observers, violating one inequality precludes the violation of any other inequality, a property called monogamy of Bell violations. We show that the Bell-monogamy does not hold universally and the only monogamous situation exists only for three observers. Consequently, the nature of quantum nonlocality is truly polygamous. The identified polygamous inequalities are experimentally violated and may be exploited for quantum cryptography or simultaneous self-testing of multiple nodes in a quantum network.

Keywords: quantum correlations, Bell inequalities, Bell monogamy, self-testing, quantum network

1 Introduction

Quantum nonlocality is one of the most intriguing features of quantum theory. Starting from its beginnings and the famous EPR argument [1], through the first works of John Bell [2] to various experiments [3–12], it reveals the impossibility of a local-realistic description of quantum phenomena. Violation of a Bell inequality serves now not only as fundamental test for the statements about the nature of reality but also finds applications in many areas of modern quantum technologies [13–19]. One crucial concept in the study of quantum nonlocality is the monogamy principle, which states that it is impossible to simultaneously violate all k-partite ($k < N$) two-setting Bell inequalities among N different parties. After the early findings by Scarani and Gisin [20], and later by Toner and Verstraete [21] (see also [22, 23]), it became a fundamental result in the field and the subject of many extensive studies [24–38].

However, as shown here, the monogamy principle is not fundamental. Rather, it is a mere consequence of the specific mathematical structure of certain inequalities, which are not universal. To support our claim, we develop a systematic method to construct Bell inequalities among $N-1$ observers that do not adhere to the monogamy principle for all $N > 3$. Furthermore, we provide an interesting minimalistic polygamous scenario based only on bipartite correlations between all pairs of observers. We show that the simultaneous violation of all inequalities is possible if the number of parties is $N = 18$. Recognising the practical challenges associated with generating high-fidelity quantum states in experimental setups, we could still identify inequalities that are violated experimentally by noisy six-qubit Dicke states. The polygamous nature of quantum nonlocality is therefore proven theoretically and confirmed in experiments.

2 Three parties and strict monogamy

We begin by recalling the standard results on Bell monogamy between three observers. Consider a scenario in which party A tries to simultaneously violate the CHSH inequalities [39] with parties B and C using a three-qubit quantum state. We denote the value of the CHSH-Bell parameters by $\mathcal{B}_{AB}$ and $\mathcal{B}_{AC}$, respectively. Quantum mechanics predicts that these parameters obey the relation [20, 21]

$$\mathcal{B}_{AB}^2 + \mathcal{B}_{AC}^2 \leq 8. \tag{1}$$

Note that if one of the inequalities is violated, e.g. $\mathcal{B}_{AB} > 2$, then the other one cannot be violated, $\mathcal{B}_{AC} < 2$. This is the statement of monogamy of Bell inequality violations.

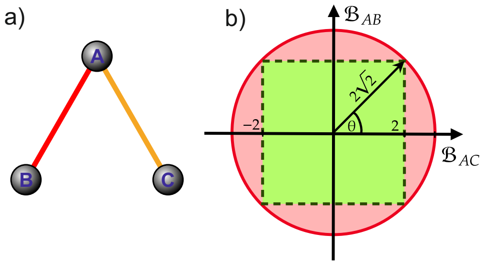

Figure 1: Visual representation of monogamy between CHSH inequality violations for three parties. *a*) Schematic of the arrangement where three observers (A, B, C) try to violate two inequalities (red and orange edges). *b*) Accessible values of Bell parameters $\mathcal{B}_{AB}$ and $\mathcal{B}_{AC}$ for parties AB and AC. According to local realistic models, the bound on each inequality is given by 2 and hence its predictions are confined to the square with a side length of 4. Quantum predictions lie within a circle of a radius $2\sqrt{2}$.

3 Polygamy of Bell violation

To demonstrate the polygamous nature of Bell nonlocality, we generalise the Toner-Verstraete scenario [21] to the case of N observers where each of them can perform measurements of two dichotomic observables $A_1^{(i)}, A_2^{(i)}$ $(i = 1, \ldots, N)$. Then, we analyze the simultaneous violation of Bell inequalities between $N-1$ observers in all possible N configurations. One strategy to find Bell inequalities that do not satisfy the monogamy principle is by imposing permutation symmetry. Let N observers share an N-qubit quantum state that is permutationally invariant, and they perform measurements of the same observables on it, i.e., $A_j^{(i)} = A_j^{(1)} (j = 1, 2; i = 2, ..., N)$. In such a situation, if we find a Bell inequality that is violated by the reduced state, it immediately implies that all inequalities under consideration are violated. This does not necessarily exclude correlation trade-offs, but it clearly rules out monogamy.

Polygamy of Mermin inequalities ($N \geq 5$). Let us now use this framework to show that the violation of multi-particle Mermin inequalities is polygamous. Let each of the N observers simultaneously measure a Mermin parameter $\mathcal{M}_{N-1}$ [40] involving $N-1$ parties. Correspondingly, there are N such parameters. The violation of all N $(N-1)$-qubit Mermin inequalities is the highest for the state $|\psi_{\max}\rangle = \frac{1}{\sqrt{2}}(|D_N^1\rangle + |1...1\rangle)$ and achieves the value equal to

$$\mathcal{M}_{N-1}^{\max} = \frac{2^{(N-2)/2}}{\sqrt{N}}. \quad (2)$$

Note that for $N = 3$ and $N = 4$ our result is consistent with [21] and [29], and we do not observe simultaneous violation of the Mermin inequalities. However, already from $N = 5$ onwards such a violation is possible and it increases exponentially with the number of qubits. Remarkably, in the limit of many particles, not only is there no monogamy of violations, but in fact every inequality is violated maximally.

Polygamy for four parties ($N = 4$). As shown in the previous section, it is not possible to violate all four three-qubit Mermin inequalities for observers (ABC, ABD, ACD, BCD) in a four-party system (A,B,C,D), where for simplicity $A^{(1)} \equiv A, A^{(2)} \equiv B$, etc. However, it is possible to find another set of two-setting Bell inequalities that have this feature.

Using an original method based on linear programming we found a three-qubit inequality $\langle I_{ABC}\rangle \leq 6$, where

$$\begin{aligned} I_{ABC} &= 2\ \mathrm{sym}[A_1] - \mathrm{sym}[A_1B_1] - \mathrm{sym}[A_1B_2] \quad (3)\\ &+ \mathrm{sym}[A_2B_2] + 2A_1B_1C_1 + \mathrm{sym}[A_2B_1C_1]\\ &- 2\ \mathrm{sym}[A_2B_2C_1] - A_2B_2C_2. \end{aligned}$$

We use here a compact notation for symmetrising over different observers

$$\mathrm{sym}[A_kB_lC_m] = \sum_{\pi(k,l,m)} A_kB_lC_m, \quad (4)$$

where the sum is over all permutations of (k, l, m), denoted as $\pi(k, l, m)$, assuming $A_0 = B_0 = C_0 = 1$, e.g., $\mathrm{sym}[A_1B_1] = A_1B_1 + A_1C_1 + B_1C_1$ being the permutations of $k = 1, l = 1, m = 0$. Analogous expressions can be formulated for I_{ABD}, I_{ACD}, I_{BCD} inequalities. It can be directly verified that all of them are simultaneously violated by the four-qubit state of the form $|\psi\rangle = \cos\theta|D_4^1\rangle + \sin\theta|1111\rangle$. The maximal violation of $6.154 > 6$ is observed for $\theta = 0.144$, and observables lying in the xz plane. We emphasise the relative simplicity, as every observer measures the same set of two observables. The above example shows that, already for a system of four particles, one can define inequalities involving three observers such that all of them are simultaneously violated.

Polygamy with two-body correlators. The violation of monogamy is by no means limited to the case of higher-order correlations. Here we focus on a minimalist scenario based on the measurements between each pair of observers. Again, we approach this problem through the linear programming technique described in Methods. As a result, the $(N-1)$-partite two-body Bell inequality was found to be $\langle I_{N-1}\rangle \geq 0$. The corresponding Bell operator is given as

$$\begin{aligned} I_{N-1} &= L + \alpha\,(\mathrm{sym}[A_1] + \mathrm{sym}[A_2]) \quad (5)\\ &+ \mathrm{sym}[A_1B_1] + 4\ \mathrm{sym}[A_1B_2] + \mathrm{sym}[A_2B_2], \end{aligned}$$

where L and α are defined by $L = 3((N-4)^2 + N - 2)$ and $\alpha = -3(N-4)$, respectively.

To determine the violation of (5) one has to minimize the Bell expression in (5) for the $(N-1)$-partite reduced state of some N-partite symmetric state, e.g., $|D_N^1\rangle$, using observables in the xz plane. By substituting $N = 18$ and plugging in the optimal observables we obtain

$$\langle I_{A_1A_2}\rangle_{\rho_2} = -\frac{4}{99}. \quad (6)$$

Therefore, the two-body Bell inequality (5) is clearly violated. This implies that the 18-qubit state $|D_{18}^1\rangle$ can simultaneously violate all 17-qubit two-body Bell inequalities and thus the monogamy principle does not hold. Note that here any exchange of information happens only between the pairs of observers.

Experimental demonstration of Bell polygamy. Although the polygamous character of Bell inequality violations is already present in four-qubit systems, an experimental demonstration of such phenomena would require an experiment with very low experimental errors. For this reason, we construct five-party inequalities for $N = 6$ observers with far less demanding visibility requirement and demonstrate in an optical experiment that they are violated in all six five-party subsystems. Again, by the linear programming method used before we arrive at the five-qubit inequality $\langle I_{ABCDE}\rangle \leq 6$ with

$$\begin{aligned} I_{ABCDE} &= -\,\mathrm{sym}[A_1B_1] - \mathrm{sym}[A_2B_2] \quad (7)\\ &+ \mathrm{sym}[A_1B_1C_1D_1] + \mathrm{sym}[A_1B_1C_1D_2]\\ &- \mathrm{sym}[A_1B_2C_2D_2] + \mathrm{sym}[A_2B_2C_2D_2]. \end{aligned}$$

It is worth noting that although these inequalities are defined for five qubits (they constitute the facet of a five-party Bell-Pitovsky polytope), they do not involve five-qubit correlations.

We experimentally demonstrate the existence of polygamous Bell-type correlations using five-party subsystems of a six-qubit Dicke state $|D_6^3\rangle$ prepared with polarisation entangled photons. A detailed description of the experimental setup can be found in Refs. [41, 42]. All six five-party Bell inequalities are simultaneously violated (see Table 1) by at least one standard deviation using the same settings. The observed average violation is $37.5787/6 > 6$.

Table 1: Experimental polygamy of nonlocality. Simultaneous violation of all six five-party Bell inequalities (7), with the local realistic bound of 6, where each observer measures the same settings in the xz plane. All inequalities are violated by at least one standard deviation.

Partition	Violation	Std. dev.
ABCDE	6.315	0.133
ABCDF	6.204	0.131
ABCEF	6.479	0.137
ABDEF	6.307	0.137
ACDEF	6.146	0.125
BCDEF	6.128	0.128

Figure 2 shows how the violation depends on the choice of measurement settings (the same for every observer) both for the theoretical prediction as well as for the experimentally prepared and measured state. A small, yet clearly visible, region of settings shows where the simultaneous violation of all inequalities is indeed possible.

The full manuscript is available at `https://arxiv.org/abs/2312.04373`.

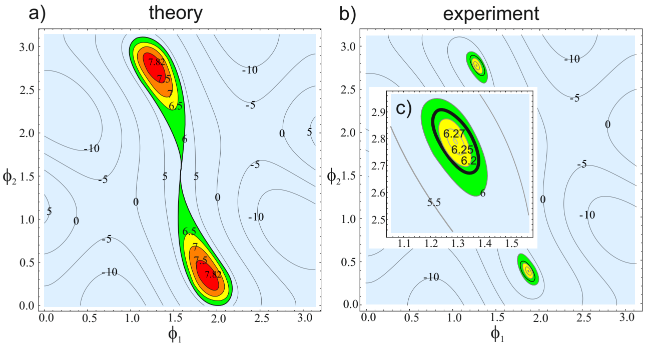

Figure 2: The average violation of inequalities (7) plotted as a function of measurement angles α and β. Panel *a*) shows the theoretical predictions arising from calculating the violation of inequalities using ideal state. Due to the symmetry of the six-qubit Dicke state, the average violation is equivalent to the violation obtained by any set of five parties. The average violation of all inequalities based on the experimental data is presented in panel *b*). Despite the apparent symmetry, due to the imperfections and statistics, not all inequalities are simultaneously violated in the coloured region. It is the area inside the bold line in panel *c*) where all six inequalities are violated simultaneously.

Abstract. The characterisation of rates of quantum information-theoretic tasks underlies the efficient use of quantum systems in information processing. Such tasks typically rely on the involved parties making a measurement and attempting to distinguish different states or communicated messages. Here we investigate a modified setting in which the parties are allowed an additional 'inconlusive' measurement outcome, which indicates that they do not make a guess, and the error probabilities are conditioned on conclusive attempts only. Such a scenario is equivalent to quantum information processing assisted by the resource of *postselection.*

We completely characterise two of the most important quantum information-theoretic tasks — quantum hypothesis testing and entanglement-assisted communication over quantum channels — in the postselected setting, giving exact solutions already in the single-shot cases and establishing computable, single-letter expressions for the asymptotic rates. Notably, we show that postselection considerably simplifies the framework of quantum information theory, resulting in markedly simplified solutions and properties. We prove in particular that the asymptotic error exponent of discriminating any two quantum states ρ and σ is given by the Hilbert projective metric $D_{\max}(\rho\|\sigma)+D_{\max}(\sigma\|\rho)$ in asymmetric hypothesis testing, and by the Thompson metric $\max\{D_{\max}(\rho\|\sigma), D_{\max}(\sigma\|\rho)\}$ in symmetric hypothesis testing. This endows these two quantities with fundamental operational interpretations in quantum state discrimination. Similarly, we show that the entanglement- and nonsignalling-assisted capacities of quantum channels are given by a variant of mutual information based on the Hilbert projective metric. Our hypothesis testing results extend to very general settings of composite hypotheses and channel discrimination, allowing for solutions to be obtained even in cases where the rates are not known in conventional quantum Shannon theory. Our achievability bounds for communication make use of a novel postselected teleportation-based protocol.

We thus obtain fundamental limits on the performance of quantum information processing even under the powerful resource of postselection. Joint submission of arXiv:2209.10550 and arXiv:2308.02583.

Keywords: Postselection; hypothesis testing; quantum state discrimination; quantum channel discrimination; entanglement-assisted communication; quantum channel capacity.

1 Background

The main aim of quantum information science is to understand how quantum physical resources can be used to enhance our ability to manipulate and transmit information. This study has been particularly fruitful in delineating the ultimate limits of such advantages: for instance, the standard approach of quantum Shannon theory is to study asymptotic transformation rates, which describe the limit where one has access to an unbounded number of quantum state or channel uses. Although idealised, such limits led to a substantial simplification of the evaluation of many operational quantities, while at the same time precisely characterising the extent of advantages that quantum resources can provide even under permissive assumptions. They have thus formed the foundation of quantum communication theory and are the bedrock of our understanding of quantum information processing. It was further realised that providing additional resources — for instance, allowing two communicating parties to share quantum entanglement [1, 2, 3] — not only can significantly enhance our ability to perform quantum information processing tasks, but also, again, drastically simplify the computation of the operational quantities, overcoming problems such as the (in)famous nonadditivity [4, 5] and superactivation [6, 7] phenomena which hinder the evaluation of quantum channel capacities.

It thus becomes a fundamental problem to understand two aspects of this question: on the one hand, how allowing additional resources can enhance quantum information processing, and on the other, how it can simplify the complex mathematical problems underlying its operational characterisation.

2 Summary

To gain insight into the limits of quantum advantages in communication and information processing, here we initiate the study of quantum Shannon theory enhanced by the resource of *postselection.* In its basic form, it simply corresponds to a situation where a party in a given task is allowed an additional 'inconclusive' measurement outcome — representing, for example, situations in which a given process does not conclusively distinguish between some states in consideration, resulting in no guess being made. Crucially, we only consider results conditioned on a conclusive outcome — that is, postselected — and do

*kj264@cornell.edu
†bartosz.regula@gmail.com
‡ludovico.lami@gmail.com
§wilde@cornell.edu

not penalise the parties for an inconclusive result.

Focusing on the tasks of quantum hypothesis testing as well as communication over quantum channels assisted by shared correlations, our main finding is the **exact evaluation of the optimal performance of these tasks in all relevant settings**. In particular: we obtain not only asymptotic results but also tightly characterise the one-shot and many-copy performance of the tasks; we characterise hypothesis testing error probabilities in both symmetric and asymmetric discrimination settings, for both quantum states and channels; we evaluate quantum channel capacities, both quantum and classical, in both one-shot and asymptotic cases, assisted by both entanglement and nonsignalling resources. The framework is shown to enjoy **remarkably simplified properties** compared to conventional quantum Shannon theory, allowing us to give **closed-form, single-letter, SDP-computable expressions for all considered quantities**. Our methods extend even to settings where results in conventional Shannon theory are not known: for instance, composite hypothesis testing, strong converse channel discrimination rates, or an exact one-shot characterisation of entanglement-assisted channel capacities and their equivalence with nonsignalling-assisted ones. Here we focus in particular on applications to communication, discussing achievable protocols in detail and devising a postselected teleportation-based coding scheme.

The price to pay in our approach is the need to allow one communicating party arbitrary access to postselection. Such a concession is known to significantly enhance the power of quantum mechanics in many contexts such as computation and metrology [8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19], even being equivalent to having access to postselected closed timelike curves [20, 21, 22]. However, due to the remarkable simplifications that follow, postselection can be very useful in understanding the ultimate power of quantum information processing, and it has already found use, e.g., as the conceptual foundation of the hardness arguments that underlie quantum supremacy experiments [23]. In a similar manner, we hope that our results can find use both in the formalisation of the foundations of quantum theory, as well as in the study of the limits of practical information processing protocols even in permissive settings.

3 Framework

Postselected hypothesis testing. Given a state that is promised to be either ρ or σ, the experimenter's goal is to guess which one the state actually is, with an additional option of making no guess. In this situation, the experimenter's strategy can in general be described by a three-outcome measurement $\{P, Q, \mathbb{1} - P - Q\}$, such that the first two outcomes correspond to guessing ρ and guessing σ, respectively, and the last outcome corresponds to being inconclusive. In the asymmetric setting, no prior probabilities of ρ or σ are assumed. The postselected type I error probability (for mistaking ρ as σ) is given by $\mathrm{Tr}[Q\rho]/\mathrm{Tr}[(P+Q)\rho]$, and the postselected type II error probability (for mistaking σ as ρ) is given by $\mathrm{Tr}[P\sigma]/\mathrm{Tr}[(P+Q)\sigma]$. The optimal type II error with constraints on the type I error is represented by the *postselected ε-hypothesis testing relative entropy*:

$$D^{\varepsilon}_{\mathrm{pH}}(\rho\|\sigma) :=$$
$$-\log_2 \inf_{P,Q\geq 0}\left\{\frac{\mathrm{Tr}[P\sigma]}{\mathrm{Tr}[(P+Q)\sigma]} : \frac{\mathrm{Tr}[Q\rho]}{\mathrm{Tr}[(P+Q)\rho]} \leq \varepsilon,\ P+Q \leq \mathbb{1}\right\}.$$

In the symmetric setting, the prior probabilities of ρ and σ are known to be p and $q \equiv 1-p$, respectively. Then the minimum postselected error probability is given by $\overline{p}_{\mathrm{err}}(\rho,\sigma|p,q) := \inf_{P,Q\geq 0}\left\{\frac{p\mathrm{Tr}[Q\rho]+q\mathrm{Tr}[P\sigma]}{\mathrm{Tr}[(P+Q)(p\rho+q\sigma)]} : P+Q\leq\mathbb{1}\right\}.$

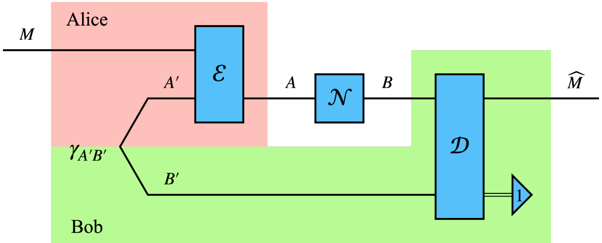

Figure 1: *Postselected entanglement-assisted (pEA) communication.*

Postselected entanglement-assisted (pEA) communication. In pEA communication, Alice (the sender) and Bob (the receiver) aim at transmitting a quantum or classical message from her system M to his system $\widehat{M} \cong M$ through a given quantum channel $\mathcal{N}_{A\to B}$. See Fig. 1. As in conventional entanglement-assisted communication [1, 24, 25], they are allowed to share an unbounded amount of entanglement to assist the transmission. What differs from the conventional setting is that we now assume that Bob's decoding operation has the additional option of being inconclusive about the message being transmitted. The postselected error probability of the transmission is then defined to be conditioned on him being conclusive. We define the *one-shot ε-error postselected entanglement-assisted (pEA) quantum capacity* and the *asymptotic pEA quantum capacity* of the channel $\mathcal{N}_{A\to B}$, respectively, as

$$Q^{\varepsilon}_{\mathrm{pEA}}(\mathcal{N}) := \sup_{\Theta\in\mathrm{pEA}} \left\{\log_2 d_M : P_{\mathrm{err}}(\Theta;\mathcal{N}) \leq \varepsilon\right\},$$
$$Q_{\mathrm{pEA}}(\mathcal{N}) := \inf_{\varepsilon\in(0,1)} \liminf_{n\to\infty} \frac{1}{n} Q^{\varepsilon}_{\mathrm{pEA}}(\mathcal{N}^{\otimes n}),$$

where, in the first equation, d_M is the dimensionality of the system M, $P_{\mathrm{err}}(\Theta;\mathcal{N})$ is the worst-case postselected error probability with respect to a protocol Θ over the channel $\mathcal{N}$, and the supremum is over all pEA protocols. If we only consider transmission of classical messages (i.e., if M is classical), the capacities similarly defined are called the *one-shot* and *asymptotic pEA classical capacities*, denoted by $C^{\varepsilon}_{\mathrm{pEA}}(\mathcal{N})$ and $C_{\mathrm{pEA}}(\mathcal{N})$, respectively.

Postselected nonsignalling-assisted (pNA) communication. The only difference with pEA communication is that now Alice and Bob can be assisted by general nonsignalling correlations, which is a broader class of correlations than shared entanglement. The resulting one-shot quantum and classical capacities are denoted by $Q^{\varepsilon}_{\mathrm{pNA}}(\mathcal{N})$ and $C^{\varepsilon}_{\mathrm{pNA}}(\mathcal{N})$, and the resulting asymptotic quantum and classical capacities are denoted by $Q_{\mathrm{pNA}}(\mathcal{N})$ and $C_{\mathrm{pNA}}(\mathcal{N})$. Nonsignalling-assisted communication was studied in the conventional (non-postselected) framework in [26, 27, 28].

4 Results

Our results are expressed in terms of the following information-theoretic measures. Denoting the max-relative entropy [29] between two states ρ and σ by $D_{\max}(\rho\|\sigma)$, the *Hilbert projective metric* [30, 17] between ρ and σ is defined as $D_\Omega(\rho\|\sigma) := D_{\max}(\rho\|\sigma) + D_{\max}(\sigma\|\rho)$, and the *Thompson metric* [31] between ρ and σ is defined as $D_\Xi(\rho\|\sigma) := \max\{D_{\max}(\rho\|\sigma), D_{\max}(\sigma\|\rho)\}$. We define the *projective mutual information* of a channel $\mathcal{N}_{A\to B}$ as

$$I_\Omega(\mathcal{N}) := \sup_{\rho_{RA}} I_\Omega(R;B)_{\mathcal{N}_{A\to B}[\rho_{RA}]},$$

where $I_\Omega(R;B)_{\omega_{RB}} := \inf_{\sigma_B} D_\Omega(\omega_{RB}\|\omega_R \otimes \sigma_B)$ is a variant of the mutual information of a bipartite state ω_{RB} derived from the Hilbert projective metric. We note that all the above measures can be evaluated using semidefinite programs (SDPs).

Postselected hypothesis testing. In the asymmetric setting, we show that the error exponent in postselected hypothesis testing can be precisely characterised in terms of the Hilbert projective metric:

$$D^\varepsilon_{\mathrm{pH}}(\rho\|\sigma) = \log_2\left(\tfrac{\varepsilon}{1-\varepsilon}2^{D_\Omega(\rho\|\sigma)} + 1\right) \quad \forall \varepsilon \in (0,1). \quad (1)$$

By the additivity of $D_\Omega(\rho\|\sigma)$, the one-shot characterisation readily gives rise to the counterpart of quantum Stein's lemma [32, 33] in the postselected framework: $\lim_{n\to\infty} \frac{1}{n} D^\varepsilon_{\mathrm{pH}}(\rho^{\otimes n}\|\sigma^{\otimes n}) = D_\Omega(\rho\|\sigma)$ $\forall \varepsilon \in (0,1)$. In the symmetric setting, we show that the minimum postselected error probability is precisely characterised by the Thompson metric: $\overline{p}_{\mathrm{err}}(\rho,\sigma|p,q) = (2^{D_\Xi(\rho\|\sigma)} + 1)^{-1}$. This helps establish the counterpart of the quantum Chernoff bound [34, 35] in the postselected framework: $\lim_{n\to\infty} -\frac{1}{n}\log_2 \overline{p}_{\mathrm{err}}(\rho^{\otimes n}, \sigma^{\otimes n}|p,q) = D_\Xi(\rho\|\sigma)$ $\forall p \equiv 1-q \in (0,1)$. These results in particular endow D_Ω and D_Ξ with explicit operational meanings in state discrimination.

It is noteworthy that in both the asymmetric and symmetric settings of postselected hypothesis testing, the one-shot results imply that the multi-shot postselected error probabilities contain no terms of order lower than linear in n, which strongly contrasts with the situation encountered in the conventional framework [36, 37].

Furthermore, all our results for postselected hypothesis testing are straightforwardly extended to more general settings such as composite hypothesis testing and strong converse channel hypothesis testing, contrasting with the extraordinary complications of similar settings in the conventional framework [38, 39, 40, 41, 42, 43, 44, 45]. In the discrimination of channels, we show in particular that parallel protocols are always optimal: both in non-asymptotic and asymptotic channel discrimination, no advantage can be gained by using adaptive or even more general discrimination schemes, such as those involving indefinite causal order.

Postselected entanglement & nonsignalling-assisted (pEA & pNA) communication. Our main results are tight upper and lower bounds on the one-shot ε-error quantum and classical capacities of any channel $\mathcal{N}_{A\to B}$ in both the pEA and pNA scenarios. Our bounds show that all these capacities are approximately characterised by an analytical expression in terms of the postselected error probability ε and the channel's projective mutual information $I_\Omega(\mathcal{N})$:

$$\begin{aligned} C^\varepsilon_{\mathrm{pEA}}(\mathcal{N}) &\approx C^\varepsilon_{\mathrm{pNA}}(\mathcal{N}) \approx 2Q^\varepsilon_{\mathrm{pEA}}(\mathcal{N}) \approx 2Q^\varepsilon_{\mathrm{pNA}}(\mathcal{N}) \\ &\approx \log_2\left(\tfrac{\varepsilon}{1-\varepsilon}2^{I_\Omega(\mathcal{N})} + 1\right) \quad \forall \varepsilon \in (0,1). \end{aligned} \quad (2)$$

Our proof technique is sketched as follows. First of all, we propose a postselected entanglement-assisted coding scheme based on probabilistic teleportation, and this constructively proves the lower bound on $Q^\varepsilon_{\mathrm{pEA}}(\mathcal{N})$. Diverging from typical coding schemes in the conventional framework, the postselected teleportation-based coding follows the idea of (1) teleporting the message entirely through the shared entangled systems and (2) encoding the classical information of whether the teleportation succeeded into the input system A of the channel $\mathcal{N}$. As Bob decodes this classical information, he would gain insight into whether the message was teleported successfully, and he makes a guess about the message only if he believes there was a success. We then prove a non-trivial connection between the optimal performance of this scheme and $I_\Omega(\mathcal{N})$. For the converse direction, we establish an upper bound on $C^\varepsilon_{\mathrm{pNA}}(\mathcal{N})$ based on the postselected hypothesis testing relative entropy, which, by invoking Eq. (1), is given by the rightmost terms in Eq. (2). By linking the one-shot quantum and classical capacities via superdense coding, we observe that the derived upper and lower bounds match, resulting in Eq. (2).

We then prove that the projective mutual information of channels is additive, using which our one-shot results give rise to a single-letter characterisation of the asymptotic capacities in both the pEA and pNA scenarios:

$$C_{\mathrm{pEA}}(\mathcal{N}) = C_{\mathrm{pNA}}(\mathcal{N}) = 2Q_{\mathrm{pEA}}(\mathcal{N}) = 2Q_{\mathrm{pNA}}(\mathcal{N}) = I_\Omega(\mathcal{N}).$$

The simplicity of our asymptotic results parallels that of Shannon's celebrated noisy-channel coding theorem for classical channels [46] and the entanglement-assisted capacity theorem for quantum channels in the conventional framework [1, 24], but the postselected results enjoy significantly simpler proofs. Furthermore, we find that the strong converses of all the capacities above are the same as the capacities themselves, and that feedback assistance does not provide any additional advantage in both the asymptotic and non-asymptotic regimes. Analogies of such findings are known for both classical channels [47, 48] and quantum channels in the conventional framework [2, 49, 50, 51, 52, 53], although they were much more difficult to establish there. In addition, the optimum rates of pEA and pNA communication feature only the capacity term and another $O(\frac{1}{n})$ term, which echoes the same property in postselected hypothesis testing and contrasts with the non-trivial second-order asymptotics in the conventional framework [54].

Abstract. Identification of possible transformations of quantum objects including quantum states and quantum operations is indispensable in developing quantum algorithms. Universal transformations, defined as input-independent transformations, appear in various quantum applications. Such is the case for universal transformations of unitary operations. However, extending these transformations to non-unitary operations is nontrivial and largely unresolved. Addressing this, we introduce *isometry adjointation* protocols that convert an input isometry operation into its adjoint operation, which include both unitary operation and quantum state transformations. The paper details the construction of parallel and sequential isometry adjointation protocols, derived from unitary inversion protocols using quantum combs, and achieving optimal approximation error. This error is shown to be independent of the output dimension of the isometry operation. In particular, we explicitly obtain an asymptotically optimal parallel protocol achieving an approximation error $\epsilon = \Theta(d^2/n)$, where d is the input dimension of the isometry operation and n is the number of calls of the isometry operation. The research also extends to isometry inversion and universal error detection, employing semidefinite programming to assess optimal performances. The findings suggest that the optimal performance of general protocols in isometry adjointation and universal error detection is not dependent on the output dimension, and that indefinite causal order protocols offer advantages over sequential ones in isometry inversion and universal error detection. The full paper of this work is on arXiv [1].

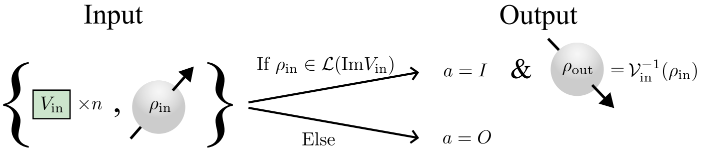
1 Problem setting and main results

Quantum protocols dealing with unknown quantum states have been extensively studied, such as state cloning [2]. Possibility and impossibility of such protocols have played an important role in implementing cryptographic protocols [3, 4]. Unknown quantum operations are also utilized in various quantum protocols, such as oracle quantum computation [5], unitary property testing [6], and higher-order quantum transformations [7]. In general, it is difficult to utilize unknown quantum states and operations in quantum protocols since we require an extra resource overhead to estimate their description via process tomography [8, 9]. Previous works have invented subroutines to deal with unknown quantum states or unitary operations such as swap test [10], amplitude amplification [11], and transformations of unknown unitary operations [12–19]. However, their extension to general quantum operations are not well investigated. One of the most important class of quantum operations are isometry operations, which represent encoding of quantum information into a higher-dimensional system. Mathematically, they include unitary operations and pure quantum states as special cases, namely, $\mathbb{V}_{\rm iso}(d,D) \simeq \mathbb{U}(d)$ for $D = d$ and $\mathbb{V}_{\rm iso}(d,D) \simeq \mathbb{C}^D$ for $d = 1$ hold, where $\mathbb{V}_{\rm iso}(d,D)$ is the set of isometry operators $V : \mathbb{C}^d \to \mathbb{C}^D$ and $\mathbb{U}(d)$ is the set of d-dimensional unitary operators. In this work, we define the task *isometry adjointation* given as follows.



Input
Output
$V_{\rm in}$ $\times n$
$\rho_{\rm in}$
If $\rho_{\rm in} \in \mathcal{L}(\mathrm{Im} V_{\rm in})$
$a = I$
&
$\rho_{\rm out} = \mathcal{V}_{\rm in}^{-1}(\rho_{\rm in})$
Else
$a = O$

Figure 1: Definition of the task isometry adjointation.

Definition 1 (Isometry adjointation)**.** *Given n calls of an unknown isometry operation $V_{\rm in} \in \mathbb{V}_{\rm iso}(d,D)$, the task is to implement a quantum instrument $\{\Phi_I, \Phi_O\}$*[1] *such that Φ_I approximates the adjoint operation $V_{\rm in}^{\dagger}$*[2]*.*

The adjoint operation can be written as $V_{\rm in}^{\dagger}\rho_{\rm in}V_{\rm in} = \mathcal{V}_{\rm in}^{-1}(\Pi_{\mathrm{Im}\, V_{\rm in}}\rho_{\rm in}\Pi_{\mathrm{Im}\, V_{\rm in}})$, where $\mathcal{V}_{\rm in}^{-1}$ is a CPTP map satisfying $\mathcal{V}_{\rm in}^{-1} \circ \mathcal{V}_{\rm in} = \mathbb{1}_d$, and $\Pi_{\mathrm{Im}\, V_{\rm in}}$ is an orthogonal projector onto the image $\mathrm{Im}\, V_{\rm in}$. Thus, an isometry adjointation protocol checks whether the input quantum state is within the subspace $\mathrm{Im}\, V_{\rm in}$ specified by the unknown isometry operation $V_{\rm in}$, and if the input state is in the subspace, it applies the

*satoshiyoshida.phys@gmail.com

[1] The measurement outcomes I and O stand for "in $\mathrm{Im}\, V_{\rm in}$" and "out of $\mathrm{Im}\, V_{\rm in}$", respectively (see also Fig. 1).

[2] We also demand that the one-side error condition $\Phi_O \circ \mathcal{V}_{\rm in} = 0$, i.e., when $\rho_{\rm in} \in \mathcal{L}(\mathrm{Im}\, V_{\rm in})$, we obtain the measurement outcome $a = I$ with a unit probability.

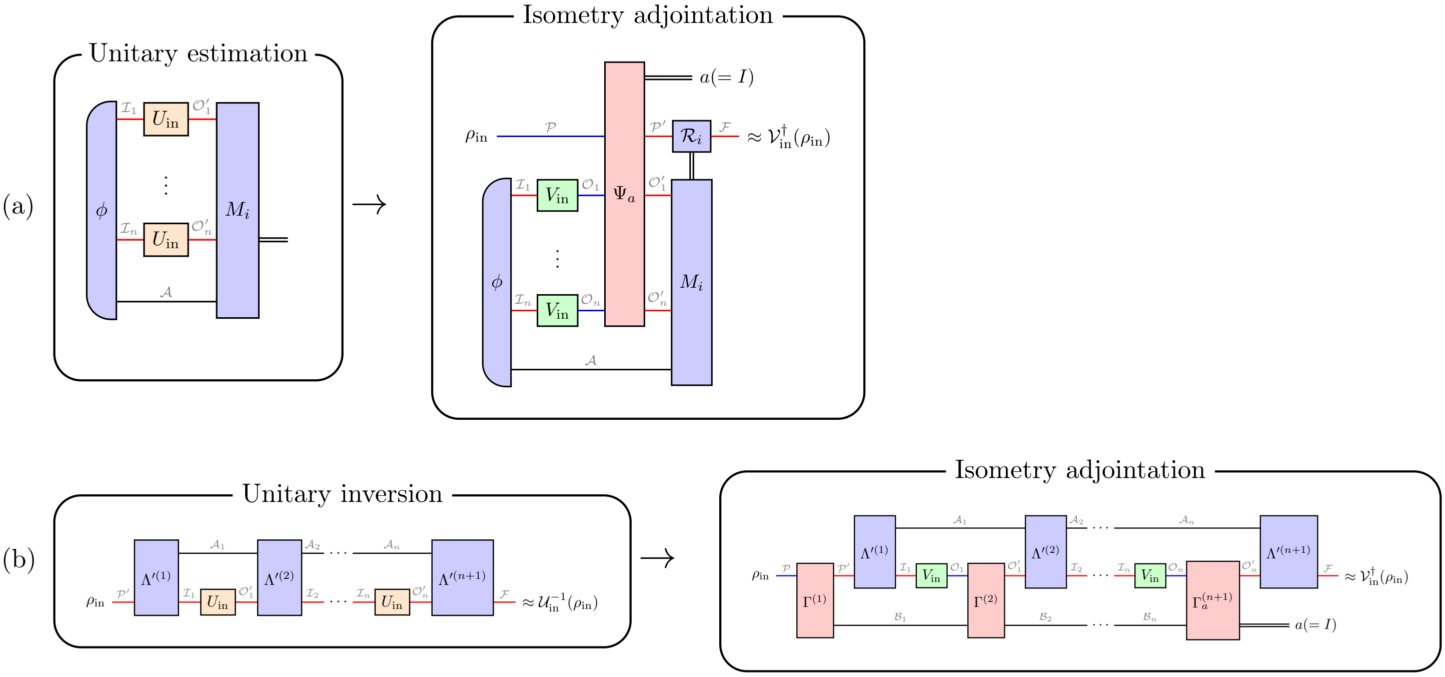


Figure 2: (a) Construction of a parallel isometry adjointation protocol from a covariant unitary estimation protocol. (b) Construction of a sequential isometry adjointation protocol from a unitary inversion protocol.

inverse operation $\mathcal{V}_{\rm in}^{-1}$ on the input state (Fig. 1). This task reduces to unitary inversion [15–19] ($U \in \mathbb{U}(d) \mapsto U^{-1}$) for $D = d$ and swap test [10], or programmable projective measurement [20] ($|\psi\rangle \in \mathbb{C}^D \mapsto \{|\psi\rangle\langle\psi|, \mathbb{1} - |\psi\rangle\langle\psi|\}$) for $d = 1$. We show two ways to construct isometry adjointation protocols, one of which utilizes the input isometry operations in parallel, and the other utilizes them in sequence. The parallel protocol is constructed from a unitary estimation protocol, and the sequential protocol is from a unitary inversion protocol (Fig. 2). Both of them achieve the optimal performances among all parallel or sequential protocols.

Theorem 2. *The parallel or sequential protocols shown in Fig. 2 implement the quantum instrument $\{\Phi_I, \Phi_O\}$ satisfying*

$$\begin{aligned}\Phi_I(\rho_{\rm in}) =&(1-p)V_{\rm in}^\dagger \rho_{\rm in} V_{\rm in}\\ &+ \frac{\mathbb{1}_d}{d}\operatorname{Tr}\{[p\Pi_{\operatorname{Im} V_{\rm in}} + \alpha(\mathbb{1}_D - \Pi_{\operatorname{Im} V_{\rm in}})]\rho_{\rm in}\}, \quad (1)\end{aligned}$$

where $p, \alpha \in [0,1]$ are obtained from the original unitary estimation or unitary inversion protocol. The worst-case diamond-distance error is given by $\epsilon = \frac{1}{2}\sup_{V_{\rm in}\in\mathbb{V}_{\rm iso}(d,D)} \|\Phi - \mathcal{V}_{\rm adjoint}\|_\diamond = \max\{\frac{1}{2}(1-d^{-2})p, \alpha\}$, where Φ and $\mathcal{V}_{\rm adjoint}$ are CPTP maps defined by $\Phi := \Phi_I \otimes |0\rangle\langle 0| + \Phi_O \otimes |1\rangle\langle 1|$ and $\mathcal{V}_{\rm adjoint} := \mathcal{V}^\dagger \otimes |0\rangle\langle 0| + \frac{\mathbb{1}_d}{d}\operatorname{Tr}[(\mathbb{1}_D - \Pi_{\operatorname{Im} V_{\rm in}})\cdot] \otimes |1\rangle\langle 1|$.

Theorem 3. *For given d, D, n, the protocols shown in Figs. 2 achieve the optimal worst-case diamond-distance error among all parallel or sequential protocols, respectively.*

In particular, p, α in (1) is given in Theorems 5 and 6 of the technical manuscript [1], which do not depend on the output dimension D of the isometry. Thus, we obtain the following Lemma.

Lemma 4. *The optimal approximation error ϵ of parallel or sequential isometry adjoinattion using n calls of the input isometry operation $V_{\rm in} \in \mathbb{V}_{\rm iso}(d, D)$ do not depend on D.*

2 Construction of parallel and sequential isometry adjointation protocols

We construct a quantum instrument $\{\Psi_a : \mathcal{L}(\mathbb{C}^D)^{\otimes n+1} \to \mathcal{L}(\mathbb{C}^d)^{\otimes n+1}\}_{a\in\{I,O\}}$ using the quantum Schur transform [21–24] satisfying the following equation [25]:

$$\begin{aligned}\Psi_I[\mathcal{V}_{\rm in}^{\otimes n}(\phi)\otimes\rho] = &\int_{\mathbb{U}(d)} \mathrm{d}U \mathcal{U}^{\otimes n}(\phi)\otimes(\mathcal{U}\circ\mathcal{V}_{\rm in}^\dagger)(\rho)\\ &+\operatorname{Tr}\left[(\mathbb{1}_D - \Pi_{\operatorname{Im} V_{\rm in}}))\rho\right]\Psi_I(\phi), \quad (2)\end{aligned}$$

where $\mathcal{V}_{\rm in}(\cdot) := V_{\rm in}\cdot V_{\rm in}^\dagger$, $\mathcal{U}(\cdot) := U \cdot U^\dagger$, $\mathrm{d}U$ is the Haar measure on $\mathbb{U}(d)$, and Ψ_I is a completely positive trace non-increasing (CPTNI) map. To cancel out $\mathcal{U}$ after $\mathcal{V}_{\rm in}^\dagger$ in (2), a unitary estimation protocol is combined as shown in Fig. 2 (a). The left panel of Fig. 2 (a) shows a parallel protocol for unitary inversion using a unitary estimation protocol. The input unitary operation $U_{\rm in}$ is estimated as $\hat{U}_i$ from the measurement outcome i of a POVM $\{M_i\}$ on the state $\mathcal{U}_{\rm in}^{\otimes n} \otimes \mathbb{1}(\phi)$. The inverse operation $R_i := \hat{U}_i^{-1}$ of the estimated operation is applied to the input quantum state $\rho_{\rm in}$. Assuming that the unitary estimation protocol is covariant, we can show that the quantum circuit shown in the right panel of Fig. 2 (a) implements a quantum operation (1) with $p = \frac{d^2}{d^2-1}(1 - F_{\mathrm{est}})$ and $\alpha = \operatorname{Tr} \Psi_I[\operatorname{Tr}_{\mathcal{A}}(\phi)]$ where F_{est} is the entanglement fidelity of unitary estimation and ϕ is shown in Fig. 2. From covariant unitary estimation protocols presented in Refs. [26–29], we show the isometry adjointation protocol achieving $p = O(d^4/n^2)$, $\alpha = O(d^2/n)$ in (1). Thus, for $n \gg d^2$, this protocol achieves $\epsilon = O(d^2/n)$, and in particular for the case of $d = 2$, this is given by $\epsilon = 6.2287/n + O(n^{-2})$. Therefore, we can achieve an approximation error ϵ by $n = O(d^2/\epsilon)$ calls of the input isometry operation. We also show that this scaling is optimal among all possible parallel protocols, i.e., $\inf_{\text{parallel protocol}} \epsilon = \Theta(d^2/n)$.

From a given sequential unitary inversion protocol, we construct an isometry adjointation protocol as shown in Fig. 2 (b). This construction is done by inserting the set of quantum operations $\Gamma^{(i)}$ (red one) to the unitary inversion protocol composed of $\Lambda'^{(i)}$ (blue one). The sequence of $\Lambda'^{(i)}$ transforms the action of n calls of $\mathcal{V}_{\mathrm{in}}$ to $\mathcal{V}_{\mathrm{in}}^\dagger$ and randomized unitary operation, similarly to (2). We can show that the resulting protocol implements a quantum operation (1) if the original unitary inversion protocol is covariant [25].

Our constructions of isometry adjointation protocols are transformations from the unitary inversion protocols. Since the unitary inversion protocols are transformations of quantum operations, or quantum supermaps [30], such transformations are called quantum supersupermaps. Using the idea of quantum supersupermaps, the problem to design an isometry adjointation protocol reduces to designing a unitary inversion protocol, which is extensively studied in previous works [15–19]. Note that a similar idea is used in Ref. [31], which presents transformation of the function applied on block-encoding unitary operation in quantum singular value transformations.

3 Reduction to isometry inversion, universal error detection, and programmable projective measurement

By discarding the measurement outcome of isometry adjointation protocols in Fig. 2, we can implement *isometry inversion* [32]. Isometry inversion is the task to implement the inverse operation $\mathcal{V}_{\mathrm{in}}^{-1}$ of the input isometry operation $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$, where the inverse operation is defined as a CPTP map such that $\mathcal{V}_{\mathrm{in}}^{-1} \circ \mathcal{V}_{\mathrm{in}} = \mathbb{1}_d$. We can show that the obtained isometry inversion protocol has the approximation error ϵ that is the same as the original unitary inversion protocol. Since d-dimensional unitary inversion with approximation error ϵ can be done using $n = O(\mathrm{poly}(d)\epsilon^{-1/2})$ (parallel) or $n = O(\mathrm{poly}(d) \log \epsilon^{-1})$ calls of the input unitary operation [17], we can construct the isometry inversion protocol with the same number of the input operations. In particular for the case of $d = 2$, our construction with the deterministic exact unitary inversion [19] gives deterministic and exact isometry inversion.

By discarding the output state of isometry adjointation protocols in Fig. 2, we can implement *universal error detection*, which is a task to implement the POVM $\{\Pi_{\operatorname{Im} V_{\mathrm{in}}}, \mathbb{1}_D - \operatorname{Im} V_{\mathrm{in}}\}$ approximately. In particular, it implements the POVM $\{\Pi_{\operatorname{Im} V_{\mathrm{in}}} + \alpha(\mathbb{1}_D - \Pi_{\operatorname{Im} V_{\mathrm{in}}}), (1 - \alpha)(\mathbb{1}_D - \Pi_{\operatorname{Im} V_{\mathrm{in}}})\}$, where α is given in (1), which quantifies the approximation error of the protocol. The minimal value of α among parallel protocols is explicitly given in Theorem 12 of the technical manuscript [1], which scales as $\inf_{\text{paralell protocol}} \alpha = \Theta(d^2/n)$. The special case $(d = 1)$ of universal error detection reduces to a programmable projective measurement [20], which transforms an input unknown pure state $|\psi_{\mathrm{in}}\rangle \in \mathbb{C}^D$ to the corresponding POVM $\{|\psi_{\mathrm{in}}\rangle\langle\psi_{\mathrm{in}}|, \mathbb{1}_D - |\psi_{\mathrm{in}}\rangle\langle\psi_{\mathrm{in}}|\}$. The optimal approximation error is obtained in Ref. [20], which corresponds to the $d = 1$ case of our explicit expression of α [25].

Identification of possible transformations of quantum objects including quantum states and quantum operations is indispensable in developing quantum algorithms. Universal transformations, defined as input-independent transformations, appear in various quantum applications. Such is the case for universal transformations of unitary operations. However, extending these transformations to non-unitary operations is nontrivial and largely unresolved. Addressing this, we introduce *isometry adjointation* protocols that convert an input isometry operation into its adjoint operation, which include both unitary operation and quantum state transformations. The paper details the construction of parallel and sequential isometry adjointation protocols, derived from unitary inversion protocols using quantum combs, and achieving optimal approximation error. This error is shown to be independent of the output dimension of the isometry operation. In particular, we explicitly obtain an asymptotically optimal parallel protocol achieving an approximation error $\epsilon = \Theta(d^2/n)$, where d is the input dimension of the isometry operation and n is the number of calls of the isometry operation. The research also extends to isometry inversion and universal error detection, employing semidefinite programming to assess optimal performances. The findings suggest that the optimal performance of general protocols in isometry adjointation and universal error detection is not dependent on the output dimension, and that indefinite causal order protocols offer advantages over sequential ones in isometry inversion and universal error detection.

1 Introduction

The possibility and impossibility of universal transformation of unknown quantum states have played a major role in quantum information and foundations (e.g., state cloning

[1], universal NOT [2], and swap test [3] or programmable projective measurement [4]). Recently, transformations of quantum operations, namely, *quantum supermaps*, have been investigated to aim for *higher-order quantum computataion* [5], which is a candidate for the quantum generalization of higher-order functions [6], as well as its connections to channel resource theory [7], quantum thermodynamics [8], and causal structure [9]. Since universal transformation of quantum operations can be utilized as an elementary operation in higher-order quantum computation, the full characterization of possible universal transformations of quantum operations is indispensable. Although universal transformations of unitary operations have been extensively studied [10–33], their generalization to non-unitary operations have not been well investigated except for a few examples (Ref. [34] for POVM measurements and Ref. [35] for isometry operations). In particular, isometry operations represent encoding of quantum information, and universal transformation of them would be useful as an elementary building block in higher-order quantum computation.

This work extends one of the most important task of universal transformation of unitary operations, called *unitary inversion* [10, 25–33], to isometry operations. Unitary inversion is a task to transform an unknown unitary operation $\mathcal{U}_{\text{in}}$ into its inverse operation $\mathcal{U}_{\text{in}}^{-1}$, where $\mathcal{U}_{\text{in}}$ is given by $\mathcal{U}_{\text{in}}(\cdot) := U_{\text{in}} \cdot U_{\text{in}}^\dagger$ for a unitary operator U_{in}. Since the inverse of a unitary operator U_{in} can be given by the adjoint operator $U_{\text{in}}^\dagger$, one natural extension of unitary inversion to isometry operations is given by *isometry adjointataion*. We consider an isometry operation $\mathcal{V}_{\text{in}}(\cdot) := V_{\text{in}} \cdot V_{\text{in}}^\dagger$, where $V_{\text{in}} : \mathbb{C}^d \to \mathbb{C}^D$ is an isometry operator satisfying $V_{\text{in}}^\dagger V_{\text{in}} = \mathbb{1}_d$ for the identity operator $\mathbb{1}_d$. We denote the set of isometry operators $V_{\text{in}} : \mathbb{C}^d \to \mathbb{C}^D$ by $\mathbb{V}_{\text{iso}}(d, D)$, and the set of d-dimensional unitary operators by $\mathbb{U}(d) = \mathbb{V}_{\text{iso}}(d, d)$. Isometry adjointation is a task to transform an unknown isometry operation $\mathcal{V}_{\text{in}}$ to a quantum instrument $\{\Phi_a\}_{a \in \{I,O\}}$[1] such that Φ_I approximates the adjoint operation $\mathcal{V}_{\text{in}}^\dagger$, where $\mathcal{V}_{\text{in}}^\dagger$ is given by $\mathcal{V}_{\text{in}}^\dagger(\cdot) := V_{\text{in}}^\dagger \cdot V_{\text{in}}$. The adjoint operation $\mathcal{V}_{\text{in}}^\dagger(\cdot)$ is given as

$$\mathcal{V}_{\text{in}}^\dagger(\rho_{\text{in}}) = \mathcal{V}_{\text{in}}^{-1}(\Pi_{\text{Im}V_{\text{in}}} \rho_{\text{in}} \Pi_{\text{Im}V_{\text{in}}}), \tag{1}$$

where $\mathcal{V}_{\text{in}}^{-1}$ is the inverse operation satisfying $\mathcal{V}_{\text{in}}^{-1} \circ \mathcal{V}_{\text{in}}(\rho) = \rho$ for all $\rho \in \mathcal{L}(\mathbb{C}^d)$, and $\Pi_{\text{Im}V_{\text{in}}}$ is the orthogonal projector onto $\text{Im}V_{\text{in}}$. It implements the projective measurement $\{\Pi_{\text{Im}V_{\text{in}}}, \mathbb{1} - \Pi_{\text{Im}V_{\text{in}}}\}$ and the inverse operation $\mathcal{V}_{\text{in}}^{-1}$ at the same time (see Fig. 1). Isometry adjointation can be reduced to two relevant tasks called *isometry inversion* [35] and *universal error detection*, where the former is the task to implement the inverse operation $\mathcal{V}_{\text{in}}^{-1}$, and the latter is the task to implement the projective merasurement $\{\Pi_{\text{Im}V_{\text{in}}}, \mathbb{1} - \Pi_{\text{Im}V_{\text{in}}}\}$, from an unknown isometry operation $\mathcal{V}_{\text{in}}$.

We construct parallel and sequential protocols for isometry adjointation by transforming the corresponding unitary inversion protocol (Fig. 2 and Theorems 6 and 5). Isometry inversion and universal error detection protocols are constructed by discarding the measurement outcome and output quantum state, respectively, from the isometry adjointation

[1] Measurement outcomes $a \in \{I, O\}$ stand for "in $\text{Im}V_{\text{in}}$" and "out of $\text{Im}V_{\text{in}}$."

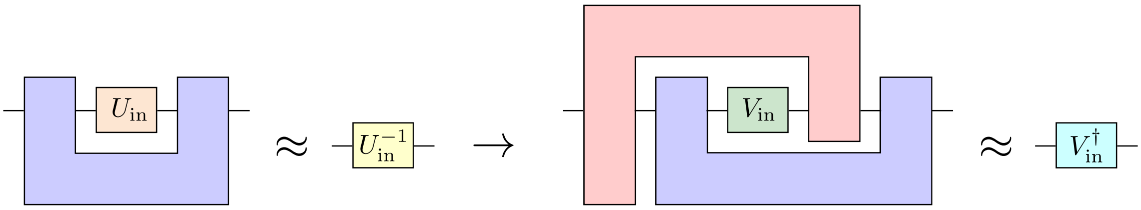

Figure 2: Left panel (unitary inversion): Transformation of a unitary operation U_{in} into its inverse operation U_{in}^{-1}. Right panel (isometry adjointation): Transformation of an isometry operation V_{in} into its adjoint operation $V_{\text{in}}^{\dagger}$. The isometry adjointation protocol is constructed by transforming the unitary inversion protocol (shown in blue) using a quantum comb shown in red.

protocol (Corollaries 7 and 8). We analyze the optimality of the constructed protocols, and we show the following properties:

- Our construction of parallel and sequential protocols gives the optimal performances among all parallel or sequential protocols (Theorem 10).
- Optimal parallel protocol for universal error detection is explicitly given (Theorem 12).
- A parallel protocol for isometry adjointation is given, which achieves an asymptotically optimal approximation error $\epsilon = \Theta(d^2 n^{-1})$ (Theorem 14).

We also give semidefinite programming (SDP) to obtain the optimal performances for these tasks using parallel, sequential, and general protocols including indefinite causal order [9, 36, 37] (Section 4.3).

The rest of this work is organized as follows. Section 2 defines the tasks isometry adjointation, isometry inversion, and universal error detection, and corresponding figures of merit. Section 3.1 introduces the technical details to obtain the main result of this paper (Theorem 5) in Section 3.2, constructing the isometry adjointation protocol. Section 3.3 constructs isometry inversion and universal error detection protocols from the isometry adjointation protocol. Section 4.1 introduces the Choi operator of the general quantum supermap and shows that the Choi operators corresponding to optimal protocols for isometry adjointation, isometry inversion, and universal error detection have the unitary group symmetry. Section 4.2 analyzes the optimal performances using analytical methods based on group theory. Section 4.3 numerically investigates the optimal performances using semidefinite programming. Section 5 concludes the work.

2 Problem setting

We consider the following tasks for the given unknown input state $\rho_{\text{in}} \in \mathcal{L}(\mathbb{C}^D)$ and the unknown isometry operation $\mathcal{V}(\cdot) \coloneqq V \cdot V^\dagger$ for $V \in \mathbb{V}_{\text{iso}}(d, D)$ (see Sections 2.1 – 2.3 for the detail):

- Probabilistic exact isometry inversion
  Promise: The input state ρ_{in} is within the code space $\mathcal{L}(\text{Im}V)$.
  Task: Output the quantum state $\mathcal{V}^{-1}(\rho_{\text{in}})$ with probability p.
- Deterministic isometry inversion
  Promise: The input state ρ_{in} is within the code space $\mathcal{L}(\text{Im}V)$.
  Task: Output a quantum state close to $\mathcal{V}^{-1}(\rho_{\text{in}})$.

- Universal error detection
  Task: Output the measurement outcome $a \in \{I, O\}$[2] with probability close to $\mathrm{Tr}(\Pi_{\mathrm{Im}V_{\mathrm{in}}}\rho_{\mathrm{in}})$ ($a = I$), and $\mathrm{Tr}[(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})\rho_{\mathrm{in}}]$ ($a = O$), where $\Pi_{\mathrm{Im}V_{\mathrm{in}}}$ is the orthogonal projectors onto the subspace $\mathrm{Im}V_{\mathrm{in}}$.

- Isometry adjointation
  Task: Output the quantum state probabilistically with the measurement outcome $a \in \{I, O\}$ with probability close to $\mathrm{Tr}(\Pi_{\mathrm{Im}V_{\mathrm{in}}}\rho_{\mathrm{in}})$ ($a = I$), and $\mathrm{Tr}[(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})\rho_{\mathrm{in}}]$ ($a = O$). When $\rho_{\mathrm{in}} \in \mathcal{L}(\mathrm{Im}V)$, the measurement outcome $a = I$ is obtained with a unit probability with an output quantum state close to $\mathcal{V}^{-1}(\rho_{\mathrm{in}})$. When the measurement outcome $a = O$ is obtained, an output quantum state is given by a fixed quantum state, e.g., the maximally mixed state.

We define the details of the task in the following subsections. To this, we introduce the notion of quantum supermaps, representing the transformations of quantum channels. We first consider a deterministic transformation from n quantum channels $\Phi_{\mathrm{in}}^{(i)} : \mathcal{L}(\mathcal{I}_i) \to \mathcal{L}(\mathcal{O}_i)$ for $i \in \{1, \cdots, n\}$ to a quantum channel $\Phi_{\mathrm{out}} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{F})$, where $\mathcal{I}_i$, $\mathcal{O}_i$, $\mathcal{P}$, and $\mathcal{F}$ are Hilbert spaces[3]. Such a transformation is represented as a linear supermap

$$\mathcal{C} : \bigotimes_{i=1}^{n} [\mathcal{L}(\mathcal{I}_i) \to \mathcal{L}(\mathcal{O}_i)] \to [\mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{F})], \tag{2}$$

where $[\mathcal{L}(\mathcal{H}_1) \to \mathcal{L}(\mathcal{H}_2)]$ is a set of linear maps from $\mathcal{L}(\mathcal{H}_1)$ to $\mathcal{L}(\mathcal{H}_2)$. A probabilistic transformation of quantum channels is represented as a set $\{\mathcal{C}_a\}_a$, where a corresponds to the classical outcome. We consider three classes of transformations, as shown below.

- Parallel protocol
  We call $\mathcal{C}$ is implemented by a parallel protocol when input operations are used in parallel as follows:

  $$\mathcal{C}\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right] = \Lambda^{(2)} \circ \left[\bigotimes_{i=1}^{n} \Phi_{\mathrm{in}}^{(i)} \otimes \mathbb{1}_{\mathcal{A}}\right] \circ \Lambda^{(1)}, \tag{3}$$

  where $\Lambda^{(1)} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{I}^n \otimes \mathcal{A})$ and $\Lambda^{(2)} : \mathcal{L}(\mathcal{O}^n \otimes \mathcal{A}) \to \mathcal{L}(\mathcal{F})$ are quantum channels, $\mathcal{A}$ is an auxiliary Hilbert space, and $\mathcal{I}^n$ and $\mathcal{O}^n$ are joint Hilbert spaces defined by $\mathcal{I}^n := \bigotimes_{i=1}^{n} \mathcal{I}_i$ and $\mathcal{O}^n := \bigotimes_{i=1}^{n} \mathcal{O}_i$, respectively. Similarly, we consider the implementation of a probabilistic transformation of $\{\mathcal{C}_a\}_a$ in a parallel protocol given by

  $$\mathcal{C}_a\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right] = \Lambda_a^{(2)} \circ \left[\bigotimes_{i=1}^{n} \Phi_{\mathrm{in}}^{(i)} \otimes \mathbb{1}_{\mathcal{A}}\right] \circ \Lambda^{(1)}, \tag{4}$$

  where $\{\Lambda_a^{(2)}\}_a$ is a quantum instrument[4]. We also consider a subclass of parallel protocols called parallel delayed input-state protocols, which are realized as

  $$\mathcal{C}\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right](\rho_{\mathrm{in}}) = \Lambda\left[\rho_{\mathrm{in}} \otimes \left(\bigotimes_{i=1}^{n} \Phi_{\mathrm{in}}^{(i)} \otimes \mathbb{1}_{\mathcal{A}}\right)(\phi)\right], \tag{5}$$

[2] I stands for "in ImV" and O stands for "out of ImV."

[3] $\mathcal{P}$ stands for "global past" and $\mathcal{F}$ stands for "global future."

[4] A quantum instrument is a set of completely-positive maps that sum up to a completely-positive and trace-preserving map [38].

where $\rho_{\mathrm{in}} \in \mathcal{L}(\mathcal{P})$ is an input quantum state and $\phi \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{A})$ is a quantum state. Similarly, we consider the parallel delayed input-state protocol of a probabilistic transformation given by

$$\mathcal{C}_a\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right](\rho_{\mathrm{in}}) = \Lambda_a\left[\rho_{\mathrm{in}} \otimes \left(\bigotimes_{i=1}^{n} \Phi_{\mathrm{in}}^{(i)} \otimes \mathbb{1}_{\mathcal{A}}\right)(\phi)\right]. \tag{6}$$

- Sequential protocol (quantum comb [39])
We call $\mathcal{C}$ is implemented by a sequential protocol or a quantum comb [39] when input operations are used sequentially as follows:

$$\mathcal{C}\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right] = \Lambda^{(n+1)} \circ \left[\Phi_{\mathrm{in}}^{(n)} \otimes \mathbb{1}_{\mathcal{A}_n}\right] \circ \Lambda^{(n)} \circ \cdots \circ \Lambda^{(2)} \circ \left[\Phi_{\mathrm{in}}^{(1)} \otimes \mathbb{1}_{\mathcal{A}_1}\right] \circ \Lambda^{(1)}, \tag{7}$$

where $\Lambda^{(1)} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{I}_1 \otimes \mathcal{A}_1), \Lambda^{(2)} : \mathcal{L}(\mathcal{O}_1 \otimes \mathcal{A}_1) \to \mathcal{L}(\mathcal{I}_2 \otimes \mathcal{A}_2), \cdots, \Lambda^{(n)} : \mathcal{L}(\mathcal{O}_{n-1} \otimes \mathcal{A}_{n-1}) \to \mathcal{L}(\mathcal{I}_n \otimes \mathcal{A}_n), \Lambda^{(n+1)} : \mathcal{L}(\mathcal{O}_n \otimes \mathcal{A}_n) \to \mathcal{L}(\mathcal{F})$ are quantum channels and $\mathcal{A}_1, \cdots, \mathcal{A}_n$ are auxiliary Hilbert spaces. Similarly, we consider the implementation of a probabilistic transformation of $\{\mathcal{C}_a\}_a$ in a sequential protocol given by

$$\mathcal{C}_a\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right] = \Lambda_a^{(n+1)} \circ \left[\Phi_{\mathrm{in}}^{(n)} \otimes \mathbb{1}_{\mathcal{A}_n}\right] \circ \Lambda^{(n)} \circ \cdots \circ \Lambda^{(2)} \circ \left[\Phi_{\mathrm{in}}^{(1)} \otimes \mathbb{1}_{\mathcal{A}_1}\right] \circ \Lambda^{(1)}, \tag{8}$$

where $\{\Lambda_a^{(n+1)}\}_a$ is a quantum instrument.

- General protocol
We consider the most general case, where $\mathcal{C}$ satisfies the following properties:

   1. Completely CP preserving: $(\mathcal{C} \otimes \mathbb{1})\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right]$ is completely positive (CP) for all CP maps $\Phi_{\mathrm{in}}^{(1)} : \mathcal{L}(\mathcal{I}_1 \otimes \mathcal{A}_1) \to \mathcal{L}(\mathcal{O}_1 \otimes \mathcal{B}_1), \cdots, \Phi_{\mathrm{in}}^{(n)} : \mathcal{L}(\mathcal{I}_n \otimes \mathcal{A}_n) \to \mathcal{L}(\mathcal{O}_n \otimes \mathcal{B}_n)$, where $\mathcal{A}_1, \cdots, \mathcal{A}_n$ and $\mathcal{B}_1, \cdots, \mathcal{B}_n$ are auxiliary Hilbert spaces and $\mathbb{1}$ is the identity supermap defined by $\mathbb{1}(\Phi) = \Phi$ for all $\Phi : \mathcal{L}\left[\bigotimes_{i=1}^n \mathcal{A}_i\right] \to \mathcal{L}\left[\bigotimes_{i=1}^n \mathcal{B}_i\right]$.
   2. TP preserving: $\mathcal{C}\left[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}\right]$ is trace preserving (TP) for all TP maps $\Phi_{\mathrm{in}}^{(1)} : \mathcal{L}(\mathcal{I}_1) \to \mathcal{L}(\mathcal{O}_1), \cdots, \Phi_{\mathrm{in}}^{(n)} : \mathcal{L}(\mathcal{I}_n) \to \mathcal{L}(\mathcal{O}_n)$.

We say that $\mathcal{C}$ is a *quantum superchannel* [39] if it satisfies the above conditions. For a probabilistic transformation, we consider the case when $\{\mathcal{C}_a\}_a$ is given by a *quantum superinstrument*, namely, $\mathcal{C}_a$ is completely CP preserving and $\sum_a \mathcal{C}_a$ is TP preserving. The classes of quantum superchannel and superinstrument include indefinite causal order [9, 36, 37], which is not realizable in a conventional quantum circuit model.

2.1 Isometry inversion

We consider a probabilistic exact or deterministic implementation of isometry inversion. For a probabilistic exact implementation, we require that the output state is $\mathcal{V}^{-1}(\rho_{\mathrm{in}})$ for all $\rho_{\mathrm{in}} \in \mathcal{L}(\mathrm{Im}V)$ with probability p. For a deterministic implementation, we require that the output state is obtained deterministically for all $\rho_{\mathrm{in}} \in \mathcal{L}(\mathrm{Im}V)$. We consider the worst-case channel fidelity defined by

$$F_{\mathrm{worst}} = \inf_{V \in \mathbb{V}_{\mathrm{iso}}(d,D)} F_{\mathrm{ch}}[\mathcal{C}[\mathcal{V}^{\otimes n}] \circ \mathcal{V}, \mathbb{1}_d], \tag{9}$$

where F_{ch} is the channel fidelity [40] and $\mathbb{1}_d$ is the identity operation. The channel fidelity between a quantum channel Λ on a d-dimensional system and a d-dimensional unitary operation $\mathcal{U}(\cdot) = U \cdot U^\dagger$ is given by

$$F_{\text{ch}}(\Lambda, \mathcal{U}) = \frac{1}{d^2} \operatorname{Tr}[J_\Lambda |U\rangle\!\rangle\langle\!\langle U|], \tag{10}$$

where J_Λ and $|U\rangle\!\rangle$ are the Choi operator of Λ and the Choi vector of U [41, 42], respectively, defined by

$$J_\Lambda \coloneqq \sum_{i,j} |i\rangle\langle j| \otimes \Lambda(|i\rangle\langle j|), \tag{11}$$

$$|U\rangle\!\rangle \coloneqq \sum_i |i\rangle \otimes U\,|i\rangle \tag{12}$$

using the computational basis $\{|i\rangle\}$ of the input system (see Section 3.1.1 for the detail of the Choi representation). Therefore, $F_{\text{ch}}(\Lambda, \mathcal{U})$ is linear with respect to Λ. The channel fidelity is invariant under the action of unitary operations, i.e.,

$$F_{\text{ch}}(\mathcal{U}' \circ \Lambda^{(1)} \circ \mathcal{U}, \mathcal{U}' \circ \Lambda^{(2)} \circ \mathcal{U}) = F_{\text{ch}}(\Lambda^{(1)}, \Lambda^{(2)}) \tag{13}$$

holds for any quantum channels $\Lambda^{(1)}$ and $\Lambda^{(2)}$ and unitary operations $\mathcal{U}$ and $\mathcal{U}'$. Therefore, when $D = d$, the definition (9) of the figure of merit for deterministic isometry inversion corresponds to the worst-case channel fidelity for deterministic unitary inversion introduced in Ref. [29] given by

$$F_{\text{worst}} = \inf_{U \in \mathbb{U}(d)} F_{\text{ch}}[\mathcal{C}(\mathcal{U}^{\otimes n}), \mathcal{U}^{-1}]. \tag{14}$$

We denote the optimal success probability of isometry inversion in parallel, sequential, and general protocols by $p_{\text{opt}}^{(x)}(d, D, n)$ for $x = \text{PAR}$ (parallel), $x = \text{SEQ}$ (sequential), and $x = \text{GEN}$ (general), respectively. Similarly, we denote the optimal fidelity of isometry inversion by $F_{\text{opt}}^{(x)}(d, D, n)$.

2.2 Universal error detection

We define the task to implement the POVM $\{\Pi_I, \Pi_O\}$ given by

$$\Pi_I = \Pi_{\operatorname{Im} V_{\text{in}}} + \alpha(\mathbb{1}_D - \Pi_{\operatorname{Im} V_{\text{in}}}), \tag{15}$$

$$\Pi_O = (1 - \alpha)(\mathbb{1}_D - \Pi_{\operatorname{Im} V_{\text{in}}}), \tag{16}$$

i.e., we require the one-sided error condition such that we obtain the measurement outcome $a = I$ with a unit probability when $\rho_{\text{in}} \in \mathcal{L}(\operatorname{Im} V_{\text{in}})$ holds. We denote the minimal value of α in parallel, sequential, and general protocols as $\alpha_{\text{opt}}^{(x)}(d, D, n)$ for $x = \text{PAR}$ (parallel), $x = \text{SEQ}$ (sequential), and $x = \text{GEN}$ (general), respectively.

2.3 Isometry adjointation

We demand the quantum superinstrument $\{\mathcal{C}_I, \mathcal{C}_O\}$ satisfies

$$\operatorname{Tr} \mathcal{C}_I[\mathcal{V}^{\otimes n}](\rho_{\text{in}}) = 1 \quad \forall \rho_{\text{in}} \in \mathcal{D}(\operatorname{Im} V), \tag{17}$$

which corresponds to the one-sided error condition in universal error detection. We define the quantum channels corresponding to the output quantum instrument and adjoint operation by

$$\mathcal{C}[\mathcal{V}^{\otimes n}](\cdot) := \mathcal{C}_I[\mathcal{V}^{\otimes n}](\cdot) \otimes |0\rangle\langle 0| + \mathcal{C}_O[\mathcal{V}^{\otimes n}](\cdot) \otimes |1\rangle\langle 1| \,, \tag{18}$$

$$\mathcal{V}_{\text{adjoint}}(\cdot) := V^\dagger \cdot V \otimes |0\rangle\langle 0| + \text{Tr}[(\mathbb{1}_D - \Pi_{\text{Im}V})\cdot]\frac{\mathbb{1}}{d} \otimes |1\rangle\langle 1| \,, \tag{19}$$

and define the figure of merit by the worst-case diamond-distance error:

$$\epsilon = \sup_{V \in \mathbb{V}_{\text{iso}}(d,D)} \frac{1}{2}\left\| \mathcal{C}[\mathcal{V}^{\otimes n}] - \mathcal{V}_{\text{adjoint}} \right\|_\diamond, \tag{20}$$

where $\|\cdot\|_\diamond$ is the diamond norm [43]. We denote the minimal value of ϵ in parallel, sequential, and general protocols by $\epsilon_{\text{opt}}^{(x)}(d, D, n)$ for $x = \text{PAR}$ (parallel), $x = \text{SEQ}$ (sequential), and $x = \text{GEN}$ (general), respectively.

3 Construction of isometry adjointation protocols and reduction to isometry inversion and universal error detection

In Section 3.1, we introduce the Choi representation to represent quantum channels and quantum supermaps. We also introduce the link product to represent their compositions. Then, we introduce the group theoretic technique called the Schur-Weyl duality. In Section 3.2, we construct isometry adjointation protocols by transforming unitary inversion protocols using the quantum comb derived from the Schur-Weyl duality. We also derive isometry inversion and universal error detection protocols from the isometry adjointation protocol.

In the following discussions, we suppose $\mathcal{I}_1 = \cdots \mathcal{I}_n = \mathcal{F} = \mathcal{O}'_1 = \cdots = \mathcal{O}'^n = \mathcal{P}' = \mathbb{C}^d$, $\mathcal{O}_1 = \cdots = \mathcal{O}_n = \mathcal{P} = \mathbb{C}^D$, and denote the joint Hilbert spaces by $\mathcal{I}^i := \bigotimes_{j=1}^i \mathcal{I}_j$, $\mathcal{O}'^i := \bigotimes_{j=1}^i \mathcal{O}'_j$, and $\mathcal{O}^i = \bigotimes_{j=1}^i \mathcal{O}_j$ for $j \in \{1, \cdots, n\}$. To illustrate the dimensions of the Hilbert spaces corresponding to the wires in the quantum circuits shown in this Section, we utilize the following color code of wires: a red wire corresponds to a d-dimensional Hilbert space, a blue wire corresponds to a D-dimensional Hilbert space, and a black wire corresponds to a Hilbert space with an arbitrary dimension. The dual wires in the quantum circuits represent classical information transmissions.

3.1 Preliminaries

3.1.1 Choi representation and link product

Any quantum channel $\Lambda : \mathcal{L}(\mathcal{I}) \to \mathcal{L}(\mathcal{O})$ can be represented by the Choi operator $J_\Lambda \in \mathcal{L}(\mathcal{I} \otimes \mathcal{O})$ defined by [41, 42]

$$J_\Lambda := \sum_{i,j} |i\rangle\langle j|_\mathcal{I} \otimes \Lambda(|i\rangle\langle j|)_\mathcal{O}, \tag{21}$$

where $\{|i\rangle\}$ is the computational basis of $\mathcal{I}$. In particular, the Choi operator $J_\mathcal{V}$ of an isometry operation $\mathcal{V}(\cdot) := V \cdot V^\dagger$ for an isometry operator $V : \mathcal{I} \to \mathcal{O}$ is represented as

$$J_\mathcal{V} = |V\rangle\rangle\langle\langle V|, \tag{22}$$

where $|V\rangle\rangle \in \mathcal{I} \otimes \mathcal{O}$ is the Choi vector of V defined by

$$|V\rangle\rangle := \sum_i |i\rangle_{\mathcal{I}} \otimes (V|i\rangle)_{\mathcal{O}}. \tag{23}$$

A composition of two quantum channels $\Lambda^{(1)} : \mathcal{L}(\mathcal{I}) \to \mathcal{L}(\mathcal{O}_1)$ and $\Lambda^{(2)} : \mathcal{L}(\mathcal{O}_1) \to \mathcal{L}(\mathcal{O}_2)$ can be represented in terms of the corresponding Choi operators as

$$J_{\Lambda^{(2)} \circ \Lambda^{(1)}} = J_{\Lambda^{(2)}} \star J_{\Lambda^{(1)}}, \tag{24}$$

where $\star$ is the link product [44] defined by

$$A \star B := \mathrm{Tr}_{\mathcal{B}}[(A^{T_{\mathcal{B}}} \otimes \mathbb{1}_{\mathcal{C}})(\mathbb{1}_{\mathcal{A}} \otimes B)] \tag{25}$$

for $A \in \mathcal{L}(\mathcal{A} \otimes \mathcal{B})$ and $B \in \mathcal{L}(\mathcal{B} \otimes \mathcal{C})$, and $A^{T_{\mathcal{B}}}$ is the partial transpose of A with respect to the subsystem $\mathcal{B}$. The link product satisfies the commutativity and associativity relations by definition, given as

$$A \star B = B \star A, \tag{26}$$

$$(A \star B) \star C = A \star (B \star C) \tag{27}$$

for $A \in \mathcal{L}(\mathcal{A} \otimes \mathcal{B})$, $B \in \mathcal{L}(\mathcal{B} \otimes \mathcal{C})$, and $C \in \mathcal{L}(\mathcal{C} \otimes \mathcal{D})$. If the two operators A and B does not have an overlap subsystem, i.e., $A \in \mathcal{L}(\mathcal{A})$ and $B \in \mathcal{L}(\mathcal{B})$ for $\mathcal{A} \neq \mathcal{B}$, the link product of A and B becomes the tensor product:

$$A \star B = A \otimes B. \tag{28}$$

Using the Choi operator and the link product, we can represent the quantum combs defined in Eq. (7). The Choi operator of the quantum channel shown in the right-hand side of Eq. (7) is given by

$$J_{\Lambda^{(n+1)}} \star J_{\Phi_{\mathrm{in}}^{(n)}} \star J_{\Lambda^{(n)}} \star \cdots \star J_{\Lambda^{(2)}} \star J_{\Phi_{\mathrm{in}}^{(1)}} \star J_{\Lambda^{(1)}}. \tag{29}$$

Using Eqs. (26)-(28), this can be rewritten as

$$C \star \bigotimes_{i=1}^{n} J_{\Phi_{\mathrm{in}}^{(i)}}, \tag{30}$$

where $C \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ is the Choi operator of the quantum comb $\mathcal{C}$ defined by

$$C := J_{\Lambda^{(n+1)}} \star J_{\Lambda^{(n)}} \star \cdots \star J_{\Lambda^{(1)}}. \tag{31}$$

Therefore, the action of a quantum comb $\mathcal{C}$ on input quantum operations $\{\Phi_{\mathrm{in}}^{(1)}, \cdots, \Phi_{\mathrm{in}}^{(n+1)}\}$ is given in the Choi representation by

$$J_{\mathcal{C}[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}]} = C \star \bigotimes_{i=1}^{n} J_{\Phi_{\mathrm{in}}^{(i)}}. \tag{32}$$

The following Theorem characterizes the set of Choi operators of quantum combs.

Theorem 1. [44, 45] *Suppose $\mathcal{P}, \mathcal{F}, \mathcal{I}_i, \mathcal{O}_i$ for $i \in \{1, \cdots, n\}$ are Hilbert spaces and define the joint Hilbert spaces by $\mathcal{I}^n := \bigotimes_{i=1}^n \mathcal{I}_i$ and $\mathcal{O}^n := \bigotimes_{i=1}^n \mathcal{O}_i$. The operator $C \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ can be written as Eq. (31) using quantum channels $\Lambda^{(1)} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{I}_1 \otimes \mathcal{A}_1), \Lambda^{(2)} : \mathcal{L}(\mathcal{O}_1 \otimes \mathcal{A}_1) \to \mathcal{L}(\mathcal{I}_2 \otimes \mathcal{A}_2), \cdots, \Lambda^{(n)} : \mathcal{L}(\mathcal{O}_{n-1} \otimes \mathcal{A}_{n-1}) \to \mathcal{L}(\mathcal{I}_n \otimes \mathcal{A}_n), \Lambda^{(n+1)} :$*

$\mathcal{L}(\mathcal{O}_n \otimes \mathcal{A}_n) \to \mathcal{L}(\mathcal{F})$ and auxiliary Hilbert spaces $\mathcal{A}_1, \cdots, \mathcal{A}_n$ if and only if C satisfies the following equations:

$$C \geq 0, \tag{33}$$

$$\operatorname{Tr}_{\mathcal{I}_i} C^{(i)} = C^{(i-1)} \otimes \mathbb{1}_{\mathcal{O}_{i-1}} \quad \forall i \in \{1, \cdots, n+1\}, \tag{34}$$

where $\mathcal{O}_0$ and $\mathcal{I}_{n+1}$ are defined by $\mathcal{O}_0 := \mathcal{P}$ and $\mathcal{I}_{n+1} := \mathcal{F}$, and $C^{(i)}$ for $i \in \{0, \cdots, n+1\}$ are defined by $C^{(n+1)} := C$, $C^{(i-1)} := \operatorname{Tr}_{\mathcal{O}_{i-1}\mathcal{I}_i} C^{(i)} / \dim \mathcal{O}_{i-1}$ and $C^{(0)} := 1$.

The probabilistic transformation $\{\mathcal{C}_a\}_a$ in a sequential protocol given by Eq. (8) can be similarly represented by

$$J_{\mathcal{C}_a[\Phi_{\text{in}}^{(1)} \otimes \cdots \otimes \Phi_{\text{in}}^{(n)}]} = C_a \star \bigotimes_{i=1}^{n} J_{\Phi_{\text{in}}^{(i)}}, \tag{35}$$

where C_a is the Choi operator of the probabilistic transformation $\{\mathcal{C}_a\}_a$ defined by

$$C_a := J_{\Lambda_a^{(n+1)}} \star J_{\Lambda^{(n)}} \star \cdots \star J_{\Lambda^{(1)}}. \tag{36}$$

The following Theorem characterizes the set of Choi operators of probabilistic transformations implemented in sequential protocols.

Theorem 2. [44, 45] *Suppose $\mathcal{P}, \mathcal{F}, \mathcal{I}_i, \mathcal{O}_i$ for $i \in \{1, \cdots, n\}$ are Hilbert spaces and define the joint Hilbert spaces by $\mathcal{I}^n := \bigotimes_{i=1}^n \mathcal{I}_i$ and $\mathcal{O}^n := \bigotimes_{i=1}^n \mathcal{O}_i$. The set of operators $\{C_a\}_a \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ can be written as Eq. (31) using quantum channels $\Lambda^{(1)} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{I}_1 \otimes \mathcal{A}_1), \Lambda^{(2)} : \mathcal{L}(\mathcal{O}_1 \otimes \mathcal{A}_1) \to \mathcal{L}(\mathcal{I}_2 \otimes \mathcal{A}_2), \cdots, \Lambda^{(n)} : \mathcal{L}(\mathcal{O}_{n-1} \otimes \mathcal{A}_{n-1}) \to \mathcal{L}(\mathcal{I}_n \otimes \mathcal{A}_n)$, a quantum instrument $\{\Lambda_a^{(n+1)}\}_a : \mathcal{L}(\mathcal{O}_n \otimes \mathcal{A}_n) \to \mathcal{L}(\mathcal{F})$ and auxiliary Hilbert spaces $\mathcal{A}_1, \cdots, \mathcal{A}_n$ if and only if C satisfies the following equations:*

$$C_a \geq 0, \tag{37}$$

$$\operatorname{Tr}_{\mathcal{I}_i} C^{(i)} = C^{(i-1)} \otimes \mathbb{1}_{\mathcal{O}_{i-1}} \quad \forall i \in \{1, \cdots, n+1\}, \tag{38}$$

where $\mathcal{O}_0$ and $\mathcal{I}_{n+1}$ are defined by $\mathcal{O}_0 := \mathcal{P}$ and $\mathcal{I}_{n+1} := \mathcal{F}$, and $C^{(i)}$ for $i \in \{0, \cdots, n+1\}$ are defined by $C^{(n+1)} := \sum_a C_a$, $C^{(i-1)} := \operatorname{Tr}_{\mathcal{O}_{i-1}\mathcal{I}_i} C^{(i)} / \dim \mathcal{O}_{i-1}$ and $C^{(0)} := 1$.

The link product also represents the composition of two quantum combs. We consider two quantum combs $\mathcal{C}'$ and $\mathcal{T}$ defined by

$$\mathcal{C}'\left[\Phi_{\text{in}}'^{(1)} \otimes \cdots \otimes \Phi_{\text{in}}'^{(n)}\right] := \Lambda'^{(n+1)} \circ (\Phi_{\text{in}}'^{(n)} \otimes \mathbb{1}_{\mathcal{A}_n}) \circ \cdots \circ \Lambda'^{(2)} \circ (\Phi_{\text{in}}'^{(1)} \otimes \mathbb{1}_{\mathcal{A}_1}) \circ \Lambda'^{(1)}, \tag{39}$$

$$\mathcal{T}\left[\Phi_{\text{in}}''^{(1)} \otimes \cdots \otimes \Phi_{\text{in}}''^{(n)}\right] := \Gamma^{(n+1)} \circ (\Phi_{\text{in}}''^{(n)} \otimes \mathbb{1}_{\mathcal{B}_n}) \circ \cdots \circ \Gamma^{(2)} \circ (\Phi_{\text{in}}''^{(1)} \otimes \mathbb{1}_{\mathcal{B}_1}) \circ \Gamma^{(1)}, \tag{40}$$

where $\mathcal{A}_i$ and $\mathcal{B}_i$ for $i \in \{1, \cdots, n\}$ are auxiliary Hilbert spaces and $\Lambda'^{(1)} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{I}_1 \otimes \mathcal{A}_1)$, $\Lambda'^{(i)} : \mathcal{L}(\mathcal{O}'_{i-1} \otimes \mathcal{A}_{i-1}) \to \mathcal{L}(\mathcal{I}_i \otimes \mathcal{A}_i)$ for $i \in \{2, \cdots, n\}$, $\Lambda'^{(n+1)} : \mathcal{L}(\mathcal{O}'_n \otimes \mathcal{A}_n) \to \mathcal{L}(\mathcal{F})$, $\Gamma^{(1)} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{P}' \otimes \mathcal{B}_1)$, $\Gamma^{(i)} : \mathcal{L}(\mathcal{O}_{i-1} \otimes \mathcal{B}_{i-1}) \to \mathcal{L}(\mathcal{O}'_{i-1} \otimes \mathcal{B}_i)$ for $i \in \{2, \cdots, n\}$, and $\Gamma^{(n+1)} : \mathcal{L}(\mathcal{O}_n \otimes \mathcal{B}_n) \to \mathcal{L}(\mathcal{O}'_n)$ are quantum channels. We define the composed quantum comb $\mathcal{C}$ by

$$\mathcal{C}\left[\Phi_{\text{in}}^{(1)}, \cdots, \Phi_{\text{in}}^{(n)}\right] := \Lambda^{(n+1)} \circ (\Phi_{\text{in}}^{(n)} \otimes \mathbb{1}_{\mathcal{A}_n\mathcal{B}_n}) \circ \cdots \circ \Lambda^{(2)} \circ (\Phi_{\text{in}}^{(1)} \otimes \mathbb{1}_{\mathcal{A}_1\mathcal{B}_1}) \circ \Lambda^{(1)}, \tag{41}$$

$$\Lambda^{(i)} := (\Lambda'^{(i)} \otimes \mathbb{1}_{\mathcal{B}_i}) \circ (\Gamma^{(i)} \otimes \mathbb{1}_{\mathcal{A}_{i-1}}) \quad \forall i \in \{1, \cdots, n+1\}. \tag{42}$$

In terms of the Choi operator, this composition can be written as

$$C = C' \star T, \tag{43}$$

where C', T, and C are Choi operators of $\mathcal{C}'$, $\mathcal{T}$, and $\mathcal{C}$, respectively.

3.1.2 Schur-Weyl duality

We introduce the Schur-Weyl duality as follows. We consider representations of the special unitary group $\mathbb{U}(d)$ and the permutation group $\mathfrak{S}_n$ on a n-fold Hilbert space $(\mathbb{C}^d)^{\otimes n}$ defined by

$$\mathbb{U}(d) \ni U \mapsto U^{\otimes n} \in \mathcal{L}(\mathbb{C}^d)^{\otimes n}, \tag{44}$$

$$\mathfrak{S}_n \ni \pi \mapsto P_\pi \in \mathcal{L}(\mathbb{C}^d)^{\otimes n}, \tag{45}$$

where P_π is a permutation operator on $(\mathbb{C}^d)^{\otimes n}$ defined by

$$P_\pi(|\psi_1\rangle \otimes \cdots \otimes |\psi_n\rangle) := \left|\psi_{\pi^{-1}(1)}\right\rangle \otimes \cdots \otimes \left|\psi_{\pi^{-1}(n)}\right\rangle \quad \forall |\psi_1\rangle, \cdots, |\psi_n\rangle \in \mathbb{C}^d. \tag{46}$$

The Schur-Weyl duality asserts a simultaneous irreducible decomposition of the two representations $U^{\otimes n}$ and P_π given by

$$(\mathbb{C}^d)^{\otimes n} = \bigoplus_{\mu \in \mathbb{Y}_n^d} \mathcal{U}_\mu^{(d)} \otimes \mathcal{S}_\mu, \tag{47}$$

$$U^{\otimes n} = \bigoplus_{\mu \in \mathbb{Y}_n^d} (U_\mu)_{\mathcal{U}_\mu^{(d)}} \otimes \mathbb{1}_{\mathcal{S}_\mu}, \tag{48}$$

$$P_\pi = \bigoplus_{\mu \in \mathbb{Y}_n^d} \mathbb{1}_{\mathcal{U}_\mu^{(d)}} \otimes (\pi_\mu)_{\mathcal{S}_\mu}, \tag{49}$$

where μ runs in the set of Young diagrams with n boxes whose depth is less than or equal to d, denoted by $\mathbb{Y}_n^d$, and U_μ and π_μ are irreducible representations of $\mathbb{U}(d)$ and $\mathfrak{S}_n$ on the linear spaces $\mathcal{U}_\mu^{(d)}$ and $\mathcal{S}_\mu$, respectively.[5] We denote the dimensions of the irreducible representation spaces $\mathcal{U}_\mu^{(d)}$ and $\mathcal{S}_\mu$ by $m_\mu^{(d)}$ and d_μ, respectively.[6] They are given by [46]

$$d_\mu = \frac{n!}{\mathrm{hook}(\mu)}, \tag{50}$$

$$m_\mu^{(d)} = \frac{\prod_{(i,j)\in\mu}(d+j-i)}{\mathrm{hook}(\mu)}, \tag{51}$$

where $\mathrm{hook}(\mu)$ for $\mu \in \mathbb{Y}_n^d$ is defined by

$$\mathrm{hook}(\mu) = \prod_{(i,j)\in\mu} (\mu_i + \mu'_j - i - j + 1), \tag{52}$$

and (i,j) is the coordinate of a box in the Young diagram μ such that i represents the row number running from bottom to top and j represents the column number running from left to right. The numbers μ_i and μ'_j are the numbers of boxes in the i-th row and the j-th column, respectively. The n-fold isometry operator $V^{\otimes n}$ for $V \in \mathbb{V}_{\mathrm{iso}}(d,D)$ can also be decomposed as

$$V^{\otimes n} = \bigoplus_{\mu \in \mathbb{Y}_n^d} (V_\mu)_{\mathcal{U}_\mu^{(d)} \to \mathcal{U}_\mu^{(D)}} \otimes \mathbb{1}_{\mathcal{S}_\mu}, \tag{53}$$

[5] The superscript d is put on $\mathcal{U}_\mu^{(d)}$ since the properties of the representation space $\mathcal{U}_\mu^{(d)}$, e.g., the dimension, depends on the local dimension d. On the other hand, we do not put the superscript d on $\mathcal{S}_\mu$ like $\mathcal{S}_\mu^{(d)}$ since the representation space $\mathcal{S}_\mu^{(d)}$ is automorphic to $\mathcal{S}_\mu^{(d')}$ for an arbitrary local dimension d'.

[6] The dimension of $\mathcal{U}_\mu^{(d)}$ is denoted by $m_\mu^{(d)}$ since $\mathcal{U}_\mu^{(d)}$ is the multiplicity space corresponding to the irreducible representation space $\mathcal{S}_\mu$ [see Eq. (47)].

where $V_\mu : \mathcal{U}_\mu^{(d)} \to \mathcal{U}_\mu^{(D)}$ is an isometry operator, as shown in Ref. [35].

Due to Schur's lemma, any operator commuting with $U^{\otimes n}$ for all $U \in \mathbb{U}(d)$ can be written as a linear combination of the operators $E_{ij}^{\mu,d}$ defined by

$$E_{ij}^{\mu,d} := \mathbb{1}_{\mathcal{U}_\mu^{(d)}} \otimes |\mu, i\rangle\langle\mu, j|_{\mathcal{S}_\mu} \tag{54}$$

for $i, j \in \{1, \cdots, d_\mu\}$, where $\{|\mu, i\rangle\}$ is an orthonormal basis of $\mathcal{S}_\mu$. Then, the following relation holds:

$$\operatorname{Tr} E_{ij}^{\mu,d} = m_\mu^{(d)} \delta_{ij}, \quad E_{ij}^{\mu,d} E_{kl}^{\nu,d} = \delta_{\mu\nu}\delta_{jk} E_{il}^{\mu,d}, \tag{55}$$

where δ_{ij} is Kronecker's delta defined by $\delta_{ii} = 1$ and $\delta_{ij} = 0$ for $i \neq j$. In particular, $\{m_\mu^{(d)-1/2} E_{ij}^{\mu,d}\}$ forms an orthonormal basis of the set of operators commuting with $U^{\otimes n}$ for all $U \in \mathbb{U}(d)$ under the Hilbert-Schmidt inner product $\langle X, Y\rangle := \operatorname{Tr}\left(X^\dagger Y\right)$. Thus, any operator ρ commuting with $U^{\otimes n}$ for all $U \in \mathbb{U}(d)$ can be represented as

$$\rho = \sum_{\mu \in \mathbb{Y}_n^d} \sum_{i,j=1}^{d_\mu} \frac{\operatorname{Tr}\left(E_{ji}^{\mu,d} \rho\right)}{m_\mu^{(d)}} E_{ij}^{\mu,d}. \tag{56}$$

Also, we define the Young projector Π_μ by

$$\Pi_\mu^{(d)} := \sum_{i=1}^{d_\mu} E_{ii}^{\mu,d}, \tag{57}$$

which is an orthonormal projector onto the subspace $\mathcal{U}_\mu^{(d)} \otimes \mathcal{S}_\mu$.

In particular, we consider the Schur basis of $(\mathbb{C}^d)^{\otimes n}$ defined by

$$|\mu, u, i\rangle := |\mu, u\rangle_{\mathcal{U}_\mu^{(d)}} \otimes |\mu, i\rangle_{\mathcal{S}_\mu}, \tag{58}$$

where $\{|\mu, u\rangle\}$ is the Gelfand-Zetlin basis of $\mathcal{U}_\mu^{(d)}$ and $\{|\mu, i\rangle\}$ is the Young-Yamanouchi basis of $\mathcal{S}_\mu$. The change of the basis from the computational basis to the Schur basis is called the quantum Schur transform [47–52], denoted by V_{Sch}. The standard tableaux with frame μ is indexed by $i \in \{1, \cdots, d_\mu\}$ and the i-th standard tableau is denoted by s_i^μ. Each element in the Young-Yamanouchi basis $\{|\mu, i\rangle\}$ is associated with the standard tableaux s_i^μ. We also define the set of operators $\{E_{ab}^{\lambda,d}\}$ on $(\mathbb{C}^d)^{\otimes n-1}$ for $\lambda \in \mathbb{Y}_{n-1}^d$ and $a, b \in \{1, \cdots, d_\lambda\}$. To express the relation between $\{E_{ij}^{\mu,d}\}$ and $\{E_{ab}^{\lambda,d}\}$, we introduce the following notations on the Young diagrams. We denote the set of Young diagrams obtained by adding (removing) a box to λ by $\lambda + \square$ ($\lambda - \square$), and the index of the standard tableau $s_{a_\mu^\lambda}^\mu$ obtained by adding a box $\boxed{n}$ to a standard tableau s_a^λ by a_μ^λ. Then, the following Lemma holds.

Lemma 3. [21, 30, 53, 54] *The tensor product $E_{ab}^{\lambda,d} \otimes \mathbb{1}_d$ and the partial trace of $E_{ij}^{\mu,d}$ in the last system for $\lambda \in \mathbb{Y}_{n-1}^d$ and $\mu \in \mathbb{Y}_n^d$ are given by*

$$E_{ab}^{\lambda,d} \otimes \mathbb{1}_d = \sum_{\mu \in \lambda + \square} E_{a_\mu^\lambda b_\mu^\lambda}^{\mu,d}, \quad \operatorname{Tr}_n E_{a_\mu^\lambda b_\mu^\kappa}^{\mu,d} = \delta_{\lambda\kappa} \frac{m_\mu^{(d)}}{m_\lambda^{(d)}} E_{ab}^{\lambda,d}. \tag{59}$$

3.2 Construction of isometry adjointation protocol

3.2.1 Transformation from unitary inversion to isometry inversion

In this section, we derive a probabilistic quantum comb $\{\mathcal{T}_I, \mathcal{T}_O\}$ transforming a unitary inversion protocol to an isometry adjointation protocol as

$$\begin{aligned} &C' \star |U_{\mathrm{in}}\rangle\!\rangle\langle\!\langle U_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n} \approx |U_{\mathrm{in}}^{-1}\rangle\!\rangle\langle\!\langle U_{\mathrm{in}}^{-1}|_{\mathcal{P}'\mathcal{F}} \quad \forall U_{\mathrm{in}} \in \mathbb{U}(d) \\ &\implies T_I \star C' \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \approx |V_{\mathrm{in}}^{\dagger}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^{\dagger}|_{\mathcal{P}\mathcal{F}} \quad \forall V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D), \end{aligned} \tag{60}$$

where C' is the Choi operator corresponding to a quantum comb implementing unitary inversion, and T_I is the Choi operator corresponding to $\mathcal{T}_I$.

We define $T_I, T_O \in \mathcal{L}(\mathcal{P}' \otimes \mathcal{O}'^n \otimes \mathcal{P} \otimes \mathcal{O}^n)$ using the operators $\{E^{\mu,d}_{ij}\}$ introduced in Section 3.1.2 by

$$T_I := \sum_{\mu \in \mathbb{Y}^d_{n+1}} \sum_{i,j=1}^{d_\mu} \frac{(E^{\mu,d}_{ij})_{\mathcal{P}'\mathcal{O}'^n} \otimes (E^{\mu,D}_{ij})_{\mathcal{P}\mathcal{O}^n}}{m^{(d)}_\mu}, \tag{61}$$

$$T_O := \sum_{t=d}^{n} \sum_{\substack{\mu_{n+1} \in \cdots \in \mu_t \\ \mu_t \in \mathbb{Y}^d_t, \mu_{t+1} \notin \mathbb{Y}^d_{t+1}}} \sum_{a,b=1}^{d_{\mu_t}} \frac{(E^{\mu_t,d}_{ab})_{\mathcal{P}'\mathcal{O}'^{t-1}} \otimes \mathbb{1}_{\mathcal{O}'_t \cdots \mathcal{O}'_n} \otimes (E^{\mu_i,D}_{a^{\mu_t}_{\mu_{t+1}\cdots\mu_{n+1}} b^{\mu_t}_{\mu_{t+1}\cdots\mu_{n+1}}})_{\mathcal{P}\mathcal{O}^n}}{d^{n+1-t} m^{(d)}_{\mu_t}}, \tag{62}$$

where $\mu_j \in \mu_{j+1}$ for $j = t, \cdots, n$ represents that μ_{j+1} is a Young diagram obtained by adding a box to μ_j, and $a^{\mu_t}_{\mu_{t+1}\cdots\mu_{n+1}}$ is defined by $a^{\mu_t}_{\mu_{t+1}\cdots\mu_{n+1}} := (\cdots(a^{\mu_t}_{\mu_{t+1}})^{\mu_{t+1}}_{\mu_{t+2}})\cdots)^{\mu_n}_{\mu_{n+1}}$, namely, the index of the standard tableau obtained by recursively adding a box $\boxed{j+1}$ to $s^{\mu_j}_a$ for $j = t, \cdots, n$. Then, $\{\mathcal{T}_I, \mathcal{T}_O\}$ satisfies the quantum comb condition as shown in the following Lemma.

Lemma 4. *The set of operators $\{T_I, T_O\}$ defined in Eqs. (61) and (62) satisfies*

$$T_I \geq 0, \quad T_O \geq 0, \tag{63}$$

$$\mathrm{Tr}_{\mathcal{O}'_{i-1}} T^{(i)} = T^{(i-1)} \otimes \mathbb{1}_{\mathcal{O}_{i-1}} \quad \forall i \in \{1, \cdots, n+1\}, \tag{64}$$

where $\mathcal{O}_0$ and $\mathcal{O}'_0$ are defined by $\mathcal{O}'_0 := \mathcal{P}'$ and $\mathcal{O}_0 := \mathcal{P}$, and $T^{(i)}$ are defined by $T^{(n+1)} := T_I + T_O$, $T^{(i)} := \mathrm{Tr}_{\mathcal{O}'_i\mathcal{O}_i} T^{(i+1)}/D$ for $i \in \{1, \cdots, n+1\}$, and $T^{(0)} := 1$.

Proof. See Appendix A.1 for the proof. □

Lemma 4 imply the existence of quantum channels $\Gamma^{(1)} : \mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{I}_1 \otimes \mathcal{B}_1), \Gamma^{(2)} : \mathcal{L}(\mathcal{O}_1 \otimes \mathcal{B}_1) \to \mathcal{L}(\mathcal{O}'_2 \otimes \mathcal{B}_2), \cdots, \Gamma^{(n)} : \mathcal{L}(\mathcal{O}_{n-1} \otimes \mathcal{B}_{n-1}) \to \mathcal{L}(\mathcal{O}'_n \otimes \mathcal{B}_n)$, a quantum instrument $\{\Gamma^{(n+1)}_I, \Gamma^{(n+1)}_O\} : \mathcal{L}(\mathcal{O}_n \otimes \mathcal{B}_n) \to \mathcal{L}(\mathcal{F})$ and auxiliary Hilbert spaces $\mathcal{B}_1, \cdots, \mathcal{B}_n$ such that (see Theorem 2)

$$T_a = J_{\Gamma^{(n+1)}_a} \star J_{\Gamma^{(n)}} \star \cdots \star J_{\Gamma^{(1)}} \quad \forall a \in \{I, O\}, \tag{65}$$

where J_Γ is the Choi operator of $\Gamma \in \{\Gamma^{(1)}, \cdots, \Gamma^{(n)}, \Gamma^{(n+1)}_a\}$.

We compose the probabilistic quantum comb $\{\mathcal{T}_I, \mathcal{T}_O\}$ with the unitary inversion protocol to implement isometry adjointation. Suppose a quantum comb $\mathcal{C}' : \bigotimes_{i=1}^n [\mathcal{L}(\mathcal{I}_i) \to \mathcal{L}(\mathcal{O}'_i)] \to [\mathcal{L}(\mathcal{P}') \to \mathcal{L}(\mathcal{F})]$ given by [see Fig. 3 (a-1)]

$$\mathcal{C}'\left[\Phi^{(1)}_{\mathrm{in}}, \cdots, \Phi^{(n)}_{\mathrm{in}}\right] := \Lambda'^{(n+1)} \circ (\Phi^{(n)}_{\mathrm{in}} \otimes \mathbb{1}_{\mathcal{A}_n}) \circ \cdots \circ \Lambda'^{(2)} \circ (\Phi^{(1)}_{\mathrm{in}} \otimes \mathbb{1}_{\mathcal{A}_1}) \circ \Lambda'^{(1)} \tag{66}$$

implements deterministic unitary inversion approximately:

$$\mathcal{C}'(\mathcal{U}_{\mathrm{in}}^{\otimes n}) \approx \mathcal{U}_{\mathrm{in}}^{-1} \quad \forall U_{\mathrm{in}} \in \mathbb{U}(d). \tag{67}$$

Reference [29] shows that the optimal worst-case channel fidelity of unitary inversion is achieved with the protocol whose Choi operator C' satisfies the $\mathbb{U}(d) \times \mathbb{U}(d)$ symmetry given by

$$[C', U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}'\mathcal{O}'^n}] = 0 \quad \forall U', U'' \in \mathbb{U}(d). \tag{68}$$

From the sequential unitary inversion protocol satisfying the $\mathbb{U}(d) \times \mathbb{U}(d)$ symmetry (68), we define a probabilistic transformation as follows [see Fig. 3 (b)]:

$$\mathcal{C}_a\left[\Phi_{\mathrm{in}}^{(1)}, \cdots, \Phi_{\mathrm{in}}^{(n)}\right] := \Lambda_a^{(n+1)} \circ (\Phi_{\mathrm{in}}^{(n)} \otimes \mathbb{1}_{\mathcal{A}_n\mathcal{B}_n}) \circ \cdots \circ \Lambda^{(2)} \circ (\Phi_{\mathrm{in}}^{(1)} \otimes \mathbb{1}_{\mathcal{A}_1\mathcal{B}_1}) \circ \Lambda^{(1)}, \tag{69}$$

$$\Lambda^{(i)} := (\Lambda'^{(i)} \otimes \mathbb{1}_{\mathcal{B}_i}) \circ (\Gamma^{(i)} \otimes \mathbb{1}_{\mathcal{A}_{i-1}}) \quad \forall i \in \{1, \cdots, n\}, \tag{70}$$

$$\Lambda_a^{(n+1)} := (\Lambda'^{(n+1)} \otimes \mathbb{1}_{\mathcal{B}_{n+1}}) \circ (\Gamma_a^{(n+1)} \otimes \mathbb{1}_{\mathcal{A}_n}), \tag{71}$$

where $\Gamma^{(1)}, \cdots, \Gamma^{(n)}$ and $\{\Gamma_a^{(n+1)}\}_a$ are quantum channels and a quantum instrument composing the quantum supersupermap $\{\mathcal{T}_a\}_a$ and $\Lambda'^{(1)}, \cdots, \Lambda'^{(n+1)}$ are quantum channels composing the unitary inversion quantum comb $\mathcal{C}'$ [see Eqs. (65) and (66)]. The supermap $\{\mathcal{C}_a\}_a$ implements isometry adjointation as shown in the following Theorem.

Theorem 5. *The sequential protocol shown in Fig. 3 (b) implements an isometry adjointation with the worst-case diamond-norm error given by*

$$\epsilon = \max\{\alpha_{C'}, 1 - F_{\mathrm{UI}}\}, \tag{72}$$

where $\alpha_{C'}$ is defined by

$$\alpha_{C'} := \mathrm{Tr}[\mathrm{Tr}_{\mathcal{F}}(C')\Sigma], \tag{73}$$

Σ is defined by

$$\Sigma := \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\mu \in \lambda + \square} \sum_{a,b=1}^{d_\lambda} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes \frac{(E_{a_\mu^\lambda b_\mu^\lambda}^{\mu,d})_{\mathcal{O}'^n\mathcal{P}'}}{m_\mu^{(d)}}, \tag{74}$$

and F_{UI} is the worst-case channel fidelity of the unitary inversion.

Proof sketch. We show that the probabilistic quantum comb $\{\mathcal{T}_I, \mathcal{T}_O\}$ derived in this section satisfies

$$T_I \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \approx \int_{\mathbb{U}(d)} \mathrm{d}U |UV_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle UV_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{P}'} \otimes |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n}, \tag{75}$$

where $\mathrm{d}U$ is the Haar measure of $\mathbb{U}(d)$. Then, Eq. (60) holds since

$$T_I \star C' \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \approx C' \star \int_{\mathbb{U}(d)} \mathrm{d}U |UV_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle UV_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{P}'} \otimes |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n} \tag{76}$$

$$\approx \int_{\mathbb{U}(d)} \mathrm{d}U |UV_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle UV_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{P}'} \star |U^{-1}\rangle\!\rangle\langle\!\langle U^{-1}|_{\mathcal{P}'\mathcal{F}} \tag{77}$$

$$= |V_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{F}}. \tag{78}$$

See Appendix A.2 for the detail. □

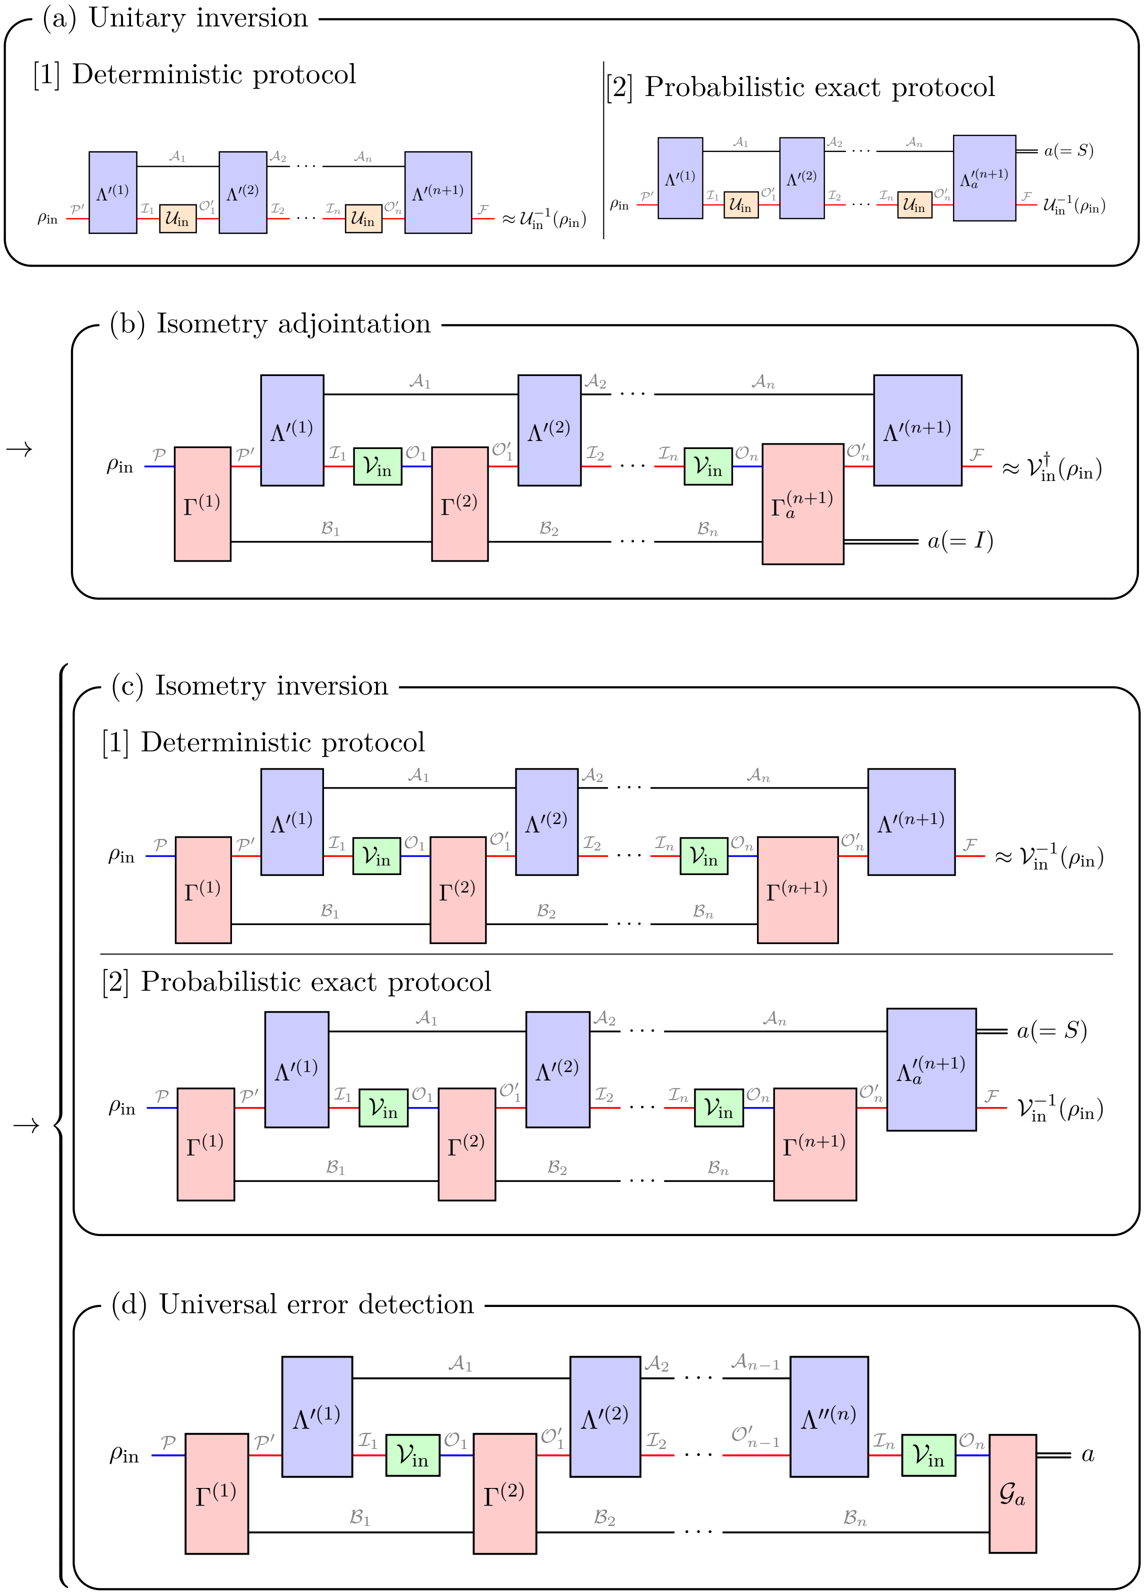

Figure 3: (a) Sequential protocols for deterministic and probabilistic exact unitary inversion. (b) A sequential isometry adjointation protocol is constructed by transforming the unitary inversion protocol using a quantum supersupermap. (c, d) Reduction to isometry inversion and universal error detection by discarding the measurement outcome and the output state of the isometry adjointation protocol, respectively.

3.2.2 Asymptotically optimal parallel protocol for isometry adjointation

We construct an asymptotically optimal parallel protocol for isometry adjointation by transforming the parallel protocol for unitary inversion. The optimal parallel protocol for deterministic unitary inversion is investigated in Ref. [29], which shows that the estimation-based protocol achieves the optimal worst-case channel fidelity among all parallel protocols. In the estimation-based unitary inversion protocol, one first estimates the input unitary operation U_{in} by applying U_{in} in parallel to a quantum state $\phi \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{A})$, and measure the output state by a POVM $\{M_i\} \subset \mathcal{L}(\mathcal{O}'^n \otimes \mathcal{A})$, where $\mathcal{A}$ is an auxiliary Hilbert space. We define the measurement channel $\{\mathcal{M}_i\}_i$ corresponding to the POVM $\{M_i\}$ defined by $\mathcal{M}_i(\cdot) \coloneqq \mathrm{Tr}(M_i \cdot)$. Then, one calculates the inverse operation $\mathcal{R}_i$ of the estimated unitary operation and applies $\mathcal{R}_i$ on the input quantum state ρ_{in}. This protocol can be expressed as [see Fig. 4 (a-1)]

$$\sum_i (\mathcal{R}_i \otimes \mathcal{M}_i)[\rho_{\text{in}} \otimes (\mathcal{U}_{\text{in}}^{\otimes n} \otimes \mathbb{1}_{\mathcal{A}})(\phi)] \approx \mathcal{U}_{\text{in}}^{-1}(\rho_{\text{in}}) \tag{79}$$

for all $U_{\text{in}} \in \mathbb{U}(d)$ and $\rho_{\text{in}} \in \mathcal{L}(\mathbb{C}^d)$. The worst-case channel fidelity of the unitary inversion is the same as the entanglement fidelity of the unitary estimation protocol given by

$$F_{\text{est}} \coloneqq \inf_{U_{\text{in}} \in \mathbb{U}(d)} F_{\text{ch}}[\mathcal{E}_{U_{\text{in}}}, \mathcal{U}_{\text{in}}]. \tag{80}$$

Here, $\mathcal{E}_{U_{\text{in}}}$ is the measure-and-prepare channel defined by

$$\mathcal{E}_{U_{\text{in}}} \coloneqq \sum_i p(\hat{U}_i | U_{\text{in}}) \hat{\mathcal{U}}_i, \tag{81}$$

where $p(\hat{U}_i | U_{\text{in}})$ is the probability to estimate the input unitary operation U_{in} as $\hat{U}_i$. The optimal estimation is shown to be done with the covariant protocol [55], satisfying

$$p(U' \hat{U}_i U'' | U' U_{\text{in}} U'') = p(\hat{U}_i | U_{\text{in}}) \quad \forall U', U'' \in \mathbb{U}(d). \tag{82}$$

By transforming the estimation-based protocol (79) using the covariant unitary estimation as shown in Eq. (60), we obtain an isometry adjointation protocol given by [see Fig. 4 (b)]

$$\mathcal{C}_a[\mathcal{V}_{\text{in}}^{\otimes n}](\rho_{\text{in}}) \coloneqq \sum_i (\mathcal{R}_i \otimes \mathcal{M}_i) \circ (\Psi_a \otimes \mathbb{1}_{\mathcal{A}})[\rho_{\text{in}} \otimes (\mathcal{V}_{\text{in}}^{\otimes n} \otimes \mathbb{1}_{\mathcal{A}})(\phi)] \tag{83}$$

for all $a \in \{I, O\}$, $V_{\text{in}} \in \mathbb{V}_{\text{iso}}(d, D)$ and $\rho_{\text{in}} \in \mathcal{L}(\mathbb{C}^D)$, where $\Psi_a : \mathcal{L}(\mathcal{O}^n \otimes \mathcal{P}) \to \mathcal{L}(\mathcal{O}'^n \otimes \mathcal{P}')$ is a quantum instrument implemented by Algorithm 1. The approximation error ϵ of isometry adjointation is given in the following Theorem.

Theorem 6. *The parallel protocol shown in Fig. 4 (b) implements an isometry adjointation with the worse-case diamond-norm error given by*

$$\epsilon = \max\{\alpha_\phi, 1 - F_{\text{est}}\}, \tag{84}$$

where α_ϕ is defined by

$$\alpha_\phi \coloneqq \sum_{\lambda \in \mathbb{Y}_n^d} \mathrm{Tr}\left[\mathrm{Tr}_{\mathcal{A}}(\phi) \Pi_\lambda^{(d)}\right] \sum_{\mu \in \lambda \cap \square \cap \mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)} \tag{85}$$

$$= \sum_{\lambda \in \mathbb{Y}_n^d} \mathrm{Tr}\left[\mathrm{Tr}_{\mathcal{A}}(\phi) \Pi_\lambda^{(d)}\right] \left[1 - \sum_{\mu \in \lambda + \square \setminus \mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)}\right], \tag{86}$$

$\mathrm{hook}(\mu)$ *is defined by Eq. (52), and F_{est} is the entanglement fidelity of the covariant unitary estimation.*

Algorithm 1 Implementation of the quantum instrument $\{\Psi_a\}_a$ utilized in the parallel protocol (83) for isometry adjointation.

```
Input: Quantum state $\rho_{\text{in}} \in \mathcal{L}(\mathbb{C}^D)^{\otimes n+1}$
Output: Quantum state $\rho_{\text{out}} \in \mathcal{L}(\mathbb{C}^d)^{\otimes n+1}$ with a measurement outcome $a \in \{I, O\}$
Apply the quantum Schur transform $V_{\text{Sch}}$ on the input quantum state $\rho_{\text{in}}$.
Measure the Young diagram register to obtain the measurement outcome $\mu$.
Trace out the unitary group register.
Let $\tau_\mu \in \mathcal{L}(\mathcal{S}_\mu)$ be the quantum state in the symmetric group register.
if $\mu \in \mathbb{Y}^d_{n+1}$ then
    $a \leftarrow I$.
    Prepare a quantum state $|\mu\rangle\langle\mu| \otimes \mathbb{1}_{\mathcal{U}^{(d)}_\mu}/m^{(d)}_\mu$.
    Apply the inverse quantum Schur transform $V^\dagger_{\text{Sch}}$ on the joint state $|\mu\rangle\langle\mu| \otimes \mathbb{1}_{\mathcal{U}^{(d)}_\mu}/m^{(d)}_\mu \otimes \tau_\mu$ to obtain the output quantum state $\rho_{\text{out}}$.
else
    $a \leftarrow O$.
    Trace out the quantum state $\tau_\mu \in \mathcal{L}(\mathcal{S}_\mu)$.
    $\rho_{\text{out}} \leftarrow \mathbb{1}_d^{\otimes n+1}/d^{n+1}$.
end if
return $\rho_{\text{out}}, a$
```

Proof. See Appendix A.3 for the proof. □

For $d = 2$, one can utilize the maximum-likelihood qubit-unitary estimation presented in Refs. [55–57] to achieve

$$\epsilon = \frac{6.2287}{n} + O(n^{-2}). \tag{87}$$

For a higher dimension $d > 2$, we can utilize the unitary estimation presented in Ref. [14] to achieve the following scaling:

$$\begin{aligned}\epsilon &= \frac{3\ln 2}{2}\frac{d^2}{n} + O(d^4 n^{-2}, dn^{-1}) &(88)\\ &= 1.0397\frac{d^2}{n} + O(d^4 n^{-2}, dn^{-1}). &(89)\end{aligned}$$

See Appendix B.3 for the details. As shown later (Theorem 14), these protocols achieve the asymptotically optimal worse-case diamond-norm error $\epsilon = \Theta(d^2/n)$.

3.3 Reduction to isometry inversion and universal error detection

By discarding the measurement outcome from the isometry adjointation protocols, we obtain deterministic isometry inversion protocols shown in Figs. 3 (c-1) and 4 (c-1), which are given by replacing $\Gamma_a^{(n+1)}$ and Ψ_a in the original isometry adjointation protocols with $\Gamma^{(n+1)} := \sum_a \Gamma_a^{(n+1)}$ and $\Psi := \sum_a \Psi_a$, respectively. The worst-case channel fidelity of the derived isometry inversion protocol is shown to be the same as the original unitary inversion protocol (see Appendix A.4.1). By replacing the original unitary inversion protocol with the probabilistic exact one, we obtain the probabilistic exact isometry inversion protocols as shown in Figs. 3 (c-2), 4 (c-2). The parallel protocol for probabilistic exact isometry inversion is the same as that shown in Ref. [35]. The derived protocols achieve the same

Figure 4: (a) [1] The estimation-based protocol using covariant unitary estimation achieves the optimal protocol for deterministic unitary inversion among all parallel protocols. [2] The delayed input-state protocol achieves the optimal protocol for probabilistic exact unitary inversion among parallel protocols. (b) A parallel isometry adjointation protocol is constructed by transforming the unitary inversion protocol using the quantum supersupermap. (c, d) Reduction to isometry inversion and universal error detection by discarding the measurement outcome and the output state of the isometry adjointation protocol, respectively.

success probability as the untiary inversion protocol (see Appendix A.4.2). In conclusion, we obtain the following Corollary.

Corollary 7. *Suppose there exists a parallel or sequential protocol for probabilistic exact (deterministic) d-dimensional unitary inversion achieving success probability p_{UI} (average-case channel fidelity F_{UI}) using n calls of $U_{\mathrm{in}} \in \mathbb{U}(d)$. Then, we can construct a parallel protocol for probabilistic exact (deterministic) isometry inversion for $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$ achieving success probability $p = p_{\mathrm{UI}}$ (worst-case channel fidelity $F = F_{\mathrm{UI}}$) using n calls of $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$.*

Reference [30] shows a deterministic exact sequential protocol for qubit-unitary inversion using four calls of the input qubit-unitary operation $U_{\mathrm{in}} \in \mathbb{U}(2)$. Combining this protocol with Theorem 7, we can construct a deterministic exact sequential protocol for qubit-encoding isometry inversion using four calls of the input qubit-encoding isometry operation $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(2, D)$ for any $D \geq 2$.

By discarding the output state from the isometry adjointation protocols, we obtain universal error detection protocols shown in Figs. 3 (d) and 4 (d). The sequential protocol shown in Fig. 3 (d) is obtained by discarding $\Lambda''^{(n+1)}$ in the original isometry adjointation protocol and replacing $\Gamma_a^{(n+1)}$ and $\Lambda'^{(n)}$ with the POVM measurement $\mathcal{G}_a := \mathrm{Tr} \circ \Gamma_a^{(n+1)}$ and the quantum channel $\Lambda''^{(n)} := \mathrm{Tr}_{\mathcal{A}_n} \circ \Lambda'^{(n)}$, respectively. The parallel protocol shown in Fig. 4 (d) is obtained by discarding $\mathcal{R}_i$ and M_i in the original isometry adjointation protocol, and replacing ϕ and Ψ_a with the quantum state $\phi' := \mathrm{Tr}_{\mathcal{A}}(\phi)$ and the POVM measurement $\mathcal{P}_a := \mathrm{Tr} \circ \Psi_a$, respectively. The approximation errors of the derived protocols are shown in the following Corollary (see Appendix A.4.3).

Corollary 8. *The sequential and parallel protocols shown in Figs. 3 (d) and 4 (d) implement a universal error detection with the approximation errors $\alpha^{(x)}$ for $x = \mathrm{SEQ}$ (sequential protocol) and $x = \mathrm{PAR}$ (parallel protocol) given by*

$$\alpha^{(\mathrm{SEQ})} = \mathrm{Tr}(C''\Sigma'), \tag{90}$$

$$\alpha^{(\mathrm{PAR})} = \sum_{\lambda \in \mathbb{Y}_n^d} \mathrm{Tr}\left(\phi' \Pi_\lambda^{(d)}\right) \sum_{\mu \in \lambda + \square \cap \mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)} \tag{91}$$

$$= \sum_{\lambda \in \mathbb{Y}_n^d} \mathrm{Tr}\left(\phi' \Pi_\lambda^{(d)}\right) \left[1 - \sum_{\mu \in \lambda + \square \setminus \mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)}\right], \tag{92}$$

where C'' is the Choi operator of the quantum comb given by $C'' := J_{\Lambda'(1)} \star J_{\Lambda'(2)} \star \cdots \star J_{\Lambda''(n)}$, Σ' is defined by $\Sigma' := \mathrm{Tr}_{\mathcal{O}_n'} \Sigma$ using Σ defined in Eq. (74), and ϕ' is a quantum state shown in the protocol 4 (d).

3.4 Relationship to programmable projective measurement

Reference [4] considers a task to construct a projective measurement $\{|\psi\rangle\langle\psi|, \mathbb{1} - |\psi\rangle\langle\psi|\}$ from n copies of an unknown quantum state $|\psi\rangle \in \mathbb{C}^D$. The task is to construct a measurement $\{\Pi_I, \Pi_O\}$ such that

$$\mathrm{Tr}(\Pi_I |\psi\rangle\langle\psi|) = 1, \tag{93}$$

$$\mathrm{Tr}\left(\Pi_I \left|\psi^\perp\right\rangle\left\langle\psi^\perp\right|\right) = \alpha \quad (\forall \left|\psi^\perp\right\rangle \perp |\psi\rangle). \tag{94}$$

This task can be considered as a special case ($d = 1$) of universal error detection. Reference [4] shows that the optimal failure probability is given by

$$\alpha = \frac{1}{n+1}. \tag{95}$$

The optimal success probability is achieved by a protocol shown in Fig. 5, where $\mathcal{M} = \{M_I, M_O\}$ is a POVM defined by $M_I = \Pi_{\mathrm{sym}}$ and $M_O = \mathbb{1} - \Pi_{\mathrm{sym}}$, where Π_{sym} is an orthonormal projector onto the totally symmetric subspace of $(\mathbb{C}^D)^{\otimes n+1}$. This protocol corresponds to the universal error detection protocol for $d = 1$. The universal error detection protocol is a generalization of programmable projective measurement for rank-d (destructive) projective measurement given by $\{\Pi_{\mathrm{Im}V_{\mathrm{in}}}, \mathbb{1} - \Pi_{\mathrm{Im}V_{\mathrm{in}}}\}$ using an isometry operator $V_{\mathrm{in}} : \mathbb{C}^d \to \mathbb{C}^D$. In particular, the parallel protocol shown in Fig. 4 (d) can be regarded as an implementation of the rank-d projective measurement using a program state $\mathcal{V}_{\mathrm{in}}^{\otimes n}(\phi')$.

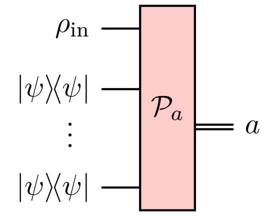

Figure 5: Optimal protocol for programmable projective measurement shown in Ref. [4].

4 Analysis of the optimal protocols

In Section 4.1, we reintroduce the Choi operator of the quantum supermap to describe the general superinstrument that is not implementable by the quantum circuit. We show that the optimal protocols for isometry adjointation, isometry inversion, and universal error detection can be found in the Choi operators satisfying the unitary group symmetry. We utilize the unitary group symmetry to investigate the optimal performances analytically in Section 4.2 and numerically in Section 4.3.

4.1 Choi representation of general superinstruments and $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry of the tasks

Similarly to Eq. (32) for a sequential protocol, a general superchannel $\mathcal{C} : \bigotimes_{i=1}^n [\mathcal{L}(\mathcal{I}_i) \to \mathcal{L}(\mathcal{O}_i)] \to [\mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{F})]$ can be represented in the Choi operator C satisfying

$$J_{\mathcal{C}[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}]} = C \star \bigotimes_{i=1}^{n} J_{\Phi_{\mathrm{in}}^{(i)}}, \tag{96}$$

where J_Φ is the Choi operator of a quantum channel Φ, and $C \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ is the Choi operator of $\mathcal{C}$. The set of superchannels implemented by parallel ($x = \mathrm{PAR}$) and sequential ($x = \mathrm{SEQ}$) protocols, and the set of general superchannel ($x = \mathrm{GEN}$) can be characterized by the positivity and linear conditions on C as

$$C \geq 0, \tag{97}$$

$$C \in \mathcal{W}^{(x)}, \tag{98}$$

where $\mathcal{W}^{(x)}$ is a linear subspace of $\mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ [see Appendix E.1 for the definition of $\mathcal{W}^{(x)}$]. The case $x = \mathrm{SEQ}$ corresponds to Theorem 1. A general superinstrument $\mathcal{C}_a : \bigotimes_{i=1}^n [\mathcal{L}(\mathcal{I}_i) \to \mathcal{L}(\mathcal{O}_i)] \to [\mathcal{L}(\mathcal{P}) \to \mathcal{L}(\mathcal{F})]$ can also be represented in the Choi operator C_a satisfying

$$J_{\mathcal{C}_a[\Phi_{\mathrm{in}}^{(1)} \otimes \cdots \otimes \Phi_{\mathrm{in}}^{(n)}]} = C_a \star \bigotimes_{i=1}^{n} J_{\Phi_{\mathrm{in}}^{(i)}}. \tag{99}$$

The set of superinstruments implemented by parallel ($x = \mathrm{PAR}$) and sequential ($x = \mathrm{SEQ}$) protocols, and the set of general superinstrument ($x = \mathrm{GEN}$) can be characterized by the positivity and linear conditions on $C := \sum_a C_a$ as

$$C_a \geq 0, \tag{100}$$

$$C := \sum_a C_a \in \mathcal{W}^{(x)}. \tag{101}$$

The case $x = \mathrm{SEQ}$ corresponds to Theorem 2.

The protocols for isometry inversion, universal error detection, and isometry adjointation can be represented by the Choi operators of the corresponding superchannel or superinstrument given by

$$\begin{cases} C \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}) & \text{(deterministic isometry inversion)} \\ \{C_S, C_F\} \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}) & \text{(probabilistic exact isometry inversion)} \\ \{C_I, C_O\} \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P}) & \text{(universal error detection)} \\ \{C_I, C_O\} \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}) & \text{(isometry adjointation)} \end{cases}. \tag{102}$$

The optimization of the Choi operators can be done under the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry as shown in the following Theorem.

Theorem 9. *The optimal performances of isometry inversion, universal error detection, and isometry adjointation can be searched within Choi operators satisfying*

$$\begin{cases} [C, U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 & & \text{(deterministic isometry inversion)} \\ [C_a, U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 & \forall a \in \{S, F\} & \text{(probabilistic exact isometry inversion)} \\ [C_a, U'^{\otimes n}_{\mathcal{I}^n} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 & \forall a \in \{I, O\} & \text{(universal error detection)} \\ [C_a, U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 & \forall a \in \{I, O\} & \text{(isometry adjointation)} \end{cases} \tag{103}$$

for all $U' \in \mathbb{U}(d)$ and $U'' \in \mathbb{U}(D)$.

Proof. See Appendix B.1 for the proof. □

4.2 Optimal construction of isometry inversion, universal error detection, and isometry adjointation protocols

We show that the construction of parallel or sequential protocols of isometry adjointation, isometry inversion, and universal error detection are the optimal, as shown in the following Theorem.

Theorem 10. *The parallel or sequential protocols for probabilistic exact isometry inversion, deterministic isometry inversion, universal error detection, and isometry adjointation shown in Theorems 5 and 6 and Corollaries 7 and 8 achieve the optimal performances among all parallel or sequential protocols, respectively.*

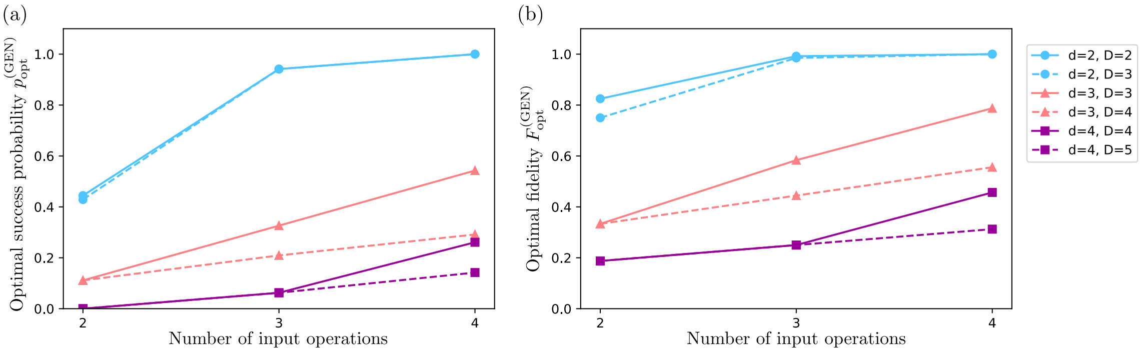

Figure 6: (a) Optimal success probability $p_{\rm opt}^{\rm (GEN)}$ and (b) optimal worst-case channel fidelity $F_{\rm opt}^{\rm (GEN)}$ of isometry inversion among general protocols including indefinite causal order. Solid lines represent the case $D = d$ (unitary inversion), and dashed lines represent the case $D = d+1$ for $d = 2$ (●), $d = 3$ (▲), and $d = 4$ (■). The optimal values shown here are obtained by numerical calculations, and numerical values are shown in Appendix D.

Proof. See Appendix C for the proof. □

Since the figure of merits shown in Theorems 5 and 6 and Corollaries 7 and 8 do not depend on D, we can show that the optimal performances do not depend on D.

Corollary 11. *For $D > d$ and $x \in \{\rm PAR, SEQ\}$, the following relations hold:*

$$\epsilon_{\rm opt}^{(x)}(d, D, n) = \epsilon_{\rm opt}^{(x)}(d, d+1, n), \tag{104}$$

$$F_{\rm opt}^{(x)}(d, D, n) = F_{\rm opt}^{(x)}(d, d, n), \tag{105}$$

$$p_{\rm opt}^{(x)}(d, D, n) = p_{\rm opt}^{(x)}(d, d, n), \tag{106}$$

$$\alpha_{\rm opt}^{(x)}(d, D, n) = \alpha_{\rm opt}^{(x)}(d, d+1, n). \tag{107}$$

Using Theorem 10, we analyze the optimal protocols for isometry inversion, universal error detection, and isometry adjointation in the following subsections.

4.2.1 Isometry inversion

The optimal success probability and fidelity of isometry inversion are given by those of unitary inversion when we use parallel or sequential protocols, as shown in Corollary 11. It is already shown in Ref. [35] for the parallel protocol, but the sequential protocol case is newly shown in this work, which is conjectured in Ref. [35].

To investigate the generalization of Corollary 11 for general protocols including indefinite causal order, we calculate the optimal probability or worst-case channel fidelity numerically (see Section 4.3 for the detail). Numerical results show that a similar equation does not hold for general protocols including indefinite causal order, i.e., $p_{\rm opt}^{\rm (GEN)}(d, D, n) < p_{\rm opt}^{\rm (GEN)}(d, d, n)$ or $F_{\rm opt}^{\rm (GEN)}(d, D, n) < F_{\rm opt}^{\rm (GEN)}(d, d, n)$ hold for some cases (see Fig. 6). This behavior is compatible with the fact that the composition of a general quantum supermap with a quantum comb does not yield a valid quantum supermap in general [58], so the construction of isometry inversion protocols shown in Fig. 3 (c) cannot be applied for general protocols.

4.2.2 Universal error detection

The optimal performance of parallel protocol $\alpha_{\rm opt}^{\rm (PAR)}(d, D, n)$ is given as follows.

Theorem 12.

$$\alpha_{\mathrm{opt}}^{(\mathrm{PAR})}(d,D,n) = \frac{1}{d+k+1}\left(d + \frac{d-l}{d+k-l}\right) = \frac{d^2}{n} + O(d^2 n^{-2}), \tag{108}$$

where k and l are given by $n = kd + l$ ($k \in \mathbb{Z}, 0 \leq l < d$).

Proof. See Appendix B.2 for the proof. □

From Theorem 12 and the result in Ref. [4], we can show the following property on the scaling of $\alpha_{\mathrm{opt}}^{(x)}(d,D,n)$ with respect to n.

Corollary 13.

$$\alpha_{\mathrm{opt}}^{(x)}(d,D,n) = \Theta(n^{-1}) \quad \forall D > d, \forall x \in \{\mathrm{PAR}, \mathrm{SEQ}, \mathrm{GEN}\} \tag{109}$$

holds for an arbitrary fixed value of d.

Proof. From Theorem 12, we obtain

$$\alpha_{\mathrm{opt}}^{(x)}(d,D,n) \leq \alpha_{\mathrm{opt}}^{(\mathrm{PAR})}(d,D,n) = O(n^{-1}). \tag{110}$$

The Hilbert space $\mathbb{C}^D$ can be embedded onto $\mathbb{V}_{\mathrm{iso}}(d,D)$ by identifying $|\psi\rangle \in \mathbb{C}^D$ with $V = |\psi\rangle\langle 0| + \sum_{i=1}^{d-1} |\psi_i\rangle\langle i| \in \mathbb{V}_{\mathrm{iso}}(d,D)$ for a set of orthonormal vectors $\{|\psi_i\rangle\}_{i=1}^{d-1}$ satisfying $\langle\psi_i|\psi\rangle = 0$ for all $i \in \{1,\cdots,d-1\}$. Therefore, a universal error detection protocol for $V \in \mathbb{V}_{\mathrm{iso}}(d,D)$ can simulate a programmable projective measurement for $|\psi\rangle \in \mathbb{C}^D$, which leads to

$$\alpha_{\mathrm{opt}}^{(x)}(d,D,n) \geq \frac{1}{n+1} = \Omega(n^{-1}). \tag{111}$$

Thus, we obtain $\alpha_{\mathrm{opt}}^{(x)}(d,D,n) = \Theta(n^{-1})$. □

4.2.3 Isometry adjointation

The optimal scaling of the approximation error of parallel isometry adjointation is given as follows.

Theorem 14.

$$\epsilon_{\mathrm{opt}}^{(\mathrm{PAR})}(d,D,n) = \Theta(d^2 n^{-1}). \tag{112}$$

Proof. First, $\epsilon_{\mathrm{opt}}^{(\mathrm{PAR})}(d,D,n) \geq \alpha_{\mathrm{opt}}^{(\mathrm{PAR})}$ holds since any isometry adjointation protocol can be transformed to an error detection protocol by discarding the output state of an isometry adjointation protocol. Thus, we obtain $\epsilon_{\mathrm{opt}}^{(\mathrm{PAR})}(d,D,n) = \Omega(d^2 n^{-1})$ from Theorem 12. On the other hand, from the construction shown in Section 3.2.2, we see that $\epsilon_{\mathrm{opt}}^{(\mathrm{PAR})}(d,D,n) = O(d^2 n^{-1})$ (see Appendix B.3). Thus, we obtain $\epsilon_{\mathrm{opt}}^{(\mathrm{PAR})}(d,D,n) = \Theta(d^2 n^{-1})$. □

4.3 Numerical results for the optimal protocols

From numerical calculations, we investigate the optimal protocols for isometry inversion, universal error detection, and isometry adjointation. We represent the protocols implementing isometry inversion, universal error detection, and isometry adjointation by their Choi operators and formulate the optimization of the figure of merits within the possible protocols as SDP. We utilize a $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry of the Choi operator (Theorem 9) to simplify the SDP, which is a similar technique presented in Ref. [30] (see also Ref. [59]). See Appendix E for the details of the derivation of the SDP. We calculate the derived SDP in MATLAB [60] using the interpreter CVX [61, 62] with the solvers SDPT3 [63–65], SeDuMi [66] and MOSEK [67]. Group-theoretic calculations to write down the SDP are done with SageMath [68]. See Appendix D for the numerical results. All codes are available at Ref. [69] under the MIT license [70].

The optimal performances for parallel or sequential protocols are calculated for the case of $D = d + 1$ since they do not depend on D (see Corollary 11), which is shown by the construction of protocols shown in Figs. 3 and 4. Although the same construction is impossible for general protocols including indefinite causal order, we also see that the optimal performances for general protocols do not depend on D as long as $D \geq d + 1$ holds by checking the values for $D = d + 1, \cdots, d + 10$. However, the maximum success probability (channel fidelity) of probabilistic exact (deterministic) isometry inversion for the case of $D = d$ (unitary inversion) is different from those for the case of $D = d + 1$ (isometry inversion), as shown in Tables 5 and 6 (corresponding to Fig. 6 in Section 4.2.1). We also see the advantage of indefinite causal order over sequential protocols in isometry inversion and universal error detection, but the advantage disappears in the case of isometry adjointation.

5 Conclusion

In this work, we investigate the universal transformation of isometry operations to explore the possible transformation in higher-order quantum computation. We define the task called isometry adjointation, which is to transform the isometry operation into its adjoint operation. The isometry adjointation protocol is constructed by transforming the unitary inversion protocol using the probabilistic quantum comb $\{\mathcal{T}_I, \mathcal{T}_O\}$. Using the idea of composition of quantum combs, the problem of designing isometry adjointation protocol reduces to designing a unitary inversion protocol, which is extensively studied in previous works [10, 25–33]. In special cases, the isometry adjointation reduces to unitary inversion (transformation of unitary operations) and programmable projective measurement (transformation of pure states). Due to such reducibility, isometry adjointation is a useful task to understand the difference between higher-order quantum computation and "lower-order" quantum computation (i.e., transformation of states), which are exhibited in several examples such as distinguishability [71] and superreplication [17, 18, 72], under a unified formulation. We also construct isometry inversion and universal error detection protocols by discarding measurement outcome and output quantum state, respectively. We show that our construction gives the optimal performances among all parallel or sequential protocols, which implies that the optimal performances among parallel or sequential protocols do not depend on the output dimension D of the isometry operation. We analyze the optimal performances of isometry adjointation and show that the optimal approximation error ϵ of the parallel isometry adjointation protocol is given by $\epsilon = \Theta(d^2 n^{-1})$, where d is the input dimension of the isometry operation, and n is the number of calls of the input operation.

To investigate the general protocols including indefinite causal order, we also provide the numerical results for the optimal performances of isometry adjointation, isometry inversion, and universal error detection using the semidefinite programming combined with the unitary group symmetry. The optimal performances of probabilistic exact (deterministic) unitary inversion ($D = d$) are different from those of isometry inversion ($D \geq d+1$), which is compatible with the impossibility of the composition of a general supermap with a quantum comb. However, numerical results also show that the optimal performances of isometry adjointation and universal error detection using the general protocol do not depend on D. We also see the advantage of indefinite causal order protocols over sequential protocols in isometry inversion and universal error detection, but the advantage disappears in isometry adjointation.

A Construction of isometry adjointation protocols

A.1 Proof of Lemma 4

By definition of $E_{ij}^{\mu,d}$ given in Eq. (54), T_I and T_O can be written as

$$T_I = \sum_{\mu_{n+1}\in\mathbb{Y}_{n+1}^d} \frac{\mathbb{1}_{\mathcal{U}_{\mu_{n+1}}^{(d)}} \otimes \mathbb{1}_{\mathcal{U}_{\mu_{n+1}}^{(D)}} \otimes |\phi_{\mu_{n+1}}\rangle\langle\phi_{\mu_{n+1}}|_{\mathcal{S}_{\mu_{n+1}}\mathcal{S}_{\mu_{n+1}}}}{m_{\mu_{n+1}}^{(d)}}, \tag{113}$$

$$T_O = \sum_{t=d}^{n} \sum_{\substack{\mu_{n+1}\in\cdots\in\mu_t \\ \mu_t\in\mathbb{Y}_t^d, \mu_{t+1}\notin\mathbb{Y}_{t+1}^d}} \frac{\mathbb{1}_{\mathcal{U}_{\mu_t}^{(d)}} \otimes \mathbb{1}_{\mathcal{O}'_t\cdots\mathcal{O}'_n} \otimes \mathbb{1}_{\mathcal{U}_{\mu_{n+1}}^{(D)}} \otimes |\phi_{\mu_{t+1}\cdots\mu_{n+1}}^{\mu_t}\rangle\langle\phi_{\mu_{t+1}\cdots\mu_{n+1}}^{\mu_t}|_{\mathcal{S}_{\mu_t}\mathcal{S}_{\mu_{n+1}}}}{d^{n+1-t} m_{\mu_t}^{(d)}}, \tag{114}$$

where $|\phi_{\mu_{n+1}}\rangle$ and $|\phi_{\mu_{t+1}\cdots\mu_{n+1}}^{\mu_t}\rangle$ are defined by

$$|\phi_{\mu_{n+1}}\rangle := \sum_{m=1}^{d_{\mu_{n+1}}} |\mu_{n+1}, m\rangle_{\mathcal{S}_{\mu_{n+1}}} \otimes |\mu_{n+1}, m\rangle_{\mathcal{S}_{\mu_{n+1}}}, \tag{115}$$

$$\left|\phi_{\mu_{t+1}\cdots\mu_{n+1}}^{\mu_t}\right\rangle := \sum_{a=1}^{d_{\mu_t}} |\mu_t, a\rangle_{\mathcal{S}_{\mu_t}} \otimes \left|\mu_{n+1}, a_{\mu_{t+1}\cdots\mu_{n+1}}^{\mu_t}\right\rangle_{\mathcal{S}_{\mu_{n+1}}}. \tag{116}$$

Therefore, $T_I \geq 0$ and $T_O \geq 0$ hold.

We next show Eq. (64) by redefining operators $T_I^{(i)}, T_O^{(i)} \in \mathcal{L}(\mathcal{P}' \otimes \mathcal{O}'^{i-1} \otimes \mathcal{P} \otimes \mathcal{O}^{i-1})$

for $i \in \{1, \cdots, n+1\}$ by

$$T_I^{(i)} := \sum_{\mu_i \in \mathbb{Y}_i^d} \sum_{m,n=1}^{d_{\mu_i}} \frac{(E_{mn}^{\mu_i,d})_{\mathcal{P}'\mathcal{O}'^{i-1}} \otimes (E_{mn}^{\mu_i,D})_{\mathcal{P}\mathcal{O}^{i-1}}}{m_{\mu_i}^{(d)}}, \tag{117}$$

$$T_O^{(i)} := \sum_{t=d}^{i-1} \sum_{\substack{\mu_i \in \cdots \in \mu_t \\ \mu_t \in \mathbb{Y}_t^d, \mu_{t+1} \notin \mathbb{Y}_{t+1}^d}} \sum_{a,b=1}^{d_{\mu_t}} \frac{(E_{ab}^{\mu_t,d})_{\mathcal{P}'\mathcal{O}'^{t-1}} \otimes \mathbb{1}_{\mathcal{O}'_t \cdots \mathcal{O}'_{i-1}} \otimes (E^{\mu_i,D}_{a^{\mu_t}_{\mu_{t+1}\cdots\mu_i} b^{\mu_t}_{\mu_{t+1}\cdots\mu_i}})_{\mathcal{P}\mathcal{O}^{i-1}}}{d^{i-t} m_{\mu_t}^{(d)}}, \tag{118}$$

which correspond to $T_I = T_O^{(n+1)}$ and $T_O = T_O^{(n+1)}$ for T_I, T_O defined in Eqs. (61) and (62). We show that $T_I^{(i)}, T_O^{(i)}$ defined in Eqs. (117) and (118) satisfy Eq. (64).

When $i = 1$, $T^{(1)}$ is given by

$$T^{(1)} = \frac{\mathbb{1}_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{P}'}}{d}. \tag{119}$$

Thus, $\mathrm{Tr}_{\mathcal{P}'} T^{(1)} = \mathbb{1}_{\mathcal{P}} = T^{(0)} \otimes \mathbb{1}_{\mathcal{P}}$ holds.

When $i > 1$, $T^{(i)}$ decomposes into three parts:

$$T^{(i)} = T_I^{(i)} + T_{t=i-1}^{(i)} + T_{d \leq t < i-1}^{(i)}, \tag{120}$$

where $T_{t=i-1}^{(i)}$ and $T_{d \leq t < i-1}^{(i)}$ are defined by

$$T_{t=i-1}^{(i)} := \sum_{\substack{\mu_i \in \mu_{i-1} \\ \mu_{i-1} \in \mathbb{Y}_{i-1}^d, \mu_i \notin \mathbb{Y}_i^d}} \sum_{a,b=1}^{d_{\mu_{i-1}}} \frac{(E_{ab}^{\mu_{i-1},d})_{\mathcal{P}'\mathcal{O}'^{i-2}} \otimes \mathbb{1}_{\mathcal{O}'_{i-1}} \otimes (E^{\mu_i,D}_{a^{\mu_{i-1}}_{\mu_i} b^{\mu_{i-1}}_{\mu_i}})_{\mathcal{P}\mathcal{O}^{i-2}}}{d m_{\mu_{i-1}}^{(d)}}, \tag{121}$$

$$\begin{aligned} &T_{d \leq t < i-1}^{(i)} \\ &:= \sum_{t=d}^{i-2} \sum_{\substack{\mu_i \in \cdots \in \mu_t \\ \mu_t \in \mathbb{Y}_t^d, \mu_{t+1} \notin \mathbb{Y}_{t+1}^d}} \sum_{a,b=1}^{d_{\mu_t}} \frac{(E_{ab}^{\mu_t,d})_{\mathcal{P}'\mathcal{O}'^{t-1}} \otimes \mathbb{1}_{\mathcal{O}'_t \cdots \mathcal{O}'_{i-1}} \otimes (E^{\mu_i,D}_{a^{\mu_t}_{\mu_{t+1}\cdots\mu_i} b^{\mu_t}_{\mu_{t+1}\cdots\mu_i}})_{\mathcal{P}\mathcal{O}^{i-1}}}{d^{i-t} m_{\mu_t}^{(d)}}. \end{aligned} \tag{122}$$

Partial traces of $T_I^{(i)}$, $T_{t=i-1}^{(i)}$ and $T_{d \leq t < i-1}^{(i)}$ over the subsystem $\mathcal{O}'_{i-1}$ are obtained as follows:

$$\mathrm{Tr}_{\mathcal{O}'_{i-1}} T_I^{(i)} = \sum_{\substack{\mu_i \in \mu_{i-1} \\ \mu_i \in \mathbb{Y}_i^d}} \sum_{a,b=1}^{d_{\mu_{i-1}}} \frac{(E_{ab}^{\mu_{i-1},d})_{\mathcal{P}'\mathcal{O}'^{i-2}} \otimes (E^{\mu_i,D}_{a^{\mu_{i-1}}_{\mu_i} b^{\mu_{i-1}}_{\mu_i}})_{\mathcal{P}\mathcal{O}^{i-1}}}{m_{\mu_{i-1}}^{(d)}}, \tag{123}$$

$$\mathrm{Tr}_{\mathcal{O}'_{i-1}} T_{t=i-1}^{(i)} = \sum_{\substack{\mu_i \in \mu_{i-1} \\ \mu_{i-1} \in \mathbb{Y}_{i-1}^d, \mu_i \notin \mathbb{Y}_i^d}} \sum_{a,b=1}^{d_{\mu_{i-1}}} \frac{(E_{ab}^{\mu_{i-1},d})_{\mathcal{P}'\mathcal{O}'^{i-2}} \otimes (E^{\mu_i,D}_{a^{\mu_{i-1}}_{\mu_i} b^{\mu_{i-1}}_{\mu_i}})_{\mathcal{P}\mathcal{O}^{i-2}}}{m_{\mu_{i-1}}^{(d)}}, \tag{124}$$

$$
\begin{aligned}
&\mathrm{Tr}_{\mathcal{O}'_{i-1}} T^{(i)}_{d\leq t<i-1}\\
&= \sum_{t=d}^{i-2} \sum_{\substack{\mu_{i-1}\in\cdots\in\mu_t\\ \mu_t\in\mathbb{Y}^d_t, \mu_{t+1}\notin\mathbb{Y}^d_{t+1}}} \sum_{a,b=1}^{d_{\mu_t}} \sum_{\mu_i\in\mu_{i-1}+\square} \frac{(E^{\mu_t,d}_{ab})_{\mathcal{P}'\mathcal{O}'^{t-1}} \otimes \mathbb{1}_{\mathcal{O}'_t\cdots\mathcal{O}'_{i-2}} \otimes (E^{\mu_i,D}_{a^{\mu_t}_{\mu_{t+1}\cdots\mu_i} b^{\mu_t}_{\mu_{t+1}\cdots\mu_i}})_{\mathcal{P}\mathcal{O}^{i-1}}}{d^{i-1-t} m^{(d)}_{\mu_t}}
\end{aligned}
\tag{125}
$$

$$
= \sum_{t=d}^{i-2} \sum_{\substack{\mu_{i-1}\in\cdots\in\mu_t\\ \mu_t\in\mathbb{Y}^d_t, \mu_{t+1}\notin\mathbb{Y}^d_{t+1}}} \sum_{a,b=1}^{d_{\mu_t}} \frac{(E^{\mu_t,d}_{ab})_{\mathcal{P}'\mathcal{O}'^{t-1}} \otimes \mathbb{1}_{\mathcal{O}'_t\cdots\mathcal{O}'_{i-2}} \otimes (E^{\mu_{i-1},D}_{a^{\mu_t}_{\mu_{t+1}\cdots\mu_{i-1}} b^{\mu_t}_{\mu_{t+1}\cdots\mu_{i-1}}})_{\mathcal{P}\mathcal{O}^{i-2}} \otimes \mathbb{1}_{\mathcal{O}_{i-1}}}{d^{i-1-t} m^{(d)}_{\mu_t}}
\tag{126}
$$

Therefore, one obtains

$$
\mathrm{Tr}_{\mathcal{O}'_{i-1}}[T^{(i)}_I + T^{(i)}_{t=i-1}] = \sum_{\mu_{i-1}\in\mathbb{Y}^d_{i-1}} \sum_{a,b=1}^{d_{\mu_{i-1}}} \sum_{\mu_i\in\mu_{i-1}+\square} \frac{(E^{\mu_{i-1},d}_{ab})_{\mathcal{P}'\mathcal{O}'^{i-2}} \otimes (E^{\mu_i,D}_{a^{\mu_{i-1}}_{\mu_i} b^{\mu_{i-1}}_{\mu_i}})_{\mathcal{P}\mathcal{O}^{i-1}}}{m^{(d)}_{\mu_{i-1}}}
\tag{127}
$$

$$
\begin{aligned}
&= \sum_{\mu_{i-1}\in\mathbb{Y}^d_{i-1}} \sum_{a,b=1}^{d_{\mu_{i-1}}} \frac{(E^{\mu_{i-1},d}_{ab})_{\mathcal{P}'\mathcal{O}'^{i-2}} \otimes (E^{\mu_{i-1},D}_{ab})_{\mathcal{P}\mathcal{O}^{i-2}} \otimes \mathbb{1}_{\mathcal{O}_{i-1}}}{m^{(d)}_{\mu_{i-1}}} && (128)\\
&= T^{(i-1)}_I \otimes \mathbb{1}_{\mathcal{O}_{i-1}}, && (129)\\
\mathrm{Tr}_{\mathcal{O}'_{i-1}} T^{(i)}_{d\leq t<i-1} &= T^{(i-1)}_O \otimes \mathbb{1}_{\mathcal{O}_{i-1}}. && (130)
\end{aligned}
$$

Thus, we obtain

$$
\begin{aligned}
\mathrm{Tr}_{\mathcal{O}'_{i-1}} T^{(i)} &= \mathrm{Tr}_{\mathcal{O}'_{i-1}}[T^{(i)}_I + T^{(i)}_{t=i-1} + T^{(i)}_{d\leq t<i-1}] && (131)\\
&= [T^{(i-1)}_I + T^{(i-1)}_O] \otimes \mathbb{1}_{\mathcal{O}_{i-1}}, && (132)\\
&= T^{(i-1)} \otimes \mathbb{1}_{\mathcal{O}_{i-1}}. && (133)
\end{aligned}
$$

A.2 Proof of Theorem 5: Construction of a sequential isometry adjointation protocol

First, we show that the probabilistic quantum comb $\{\mathcal{T}_I, \mathcal{T}_O\}$ satisfies

$$
T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} = \int_{\mathbb{U}(d)} \mathrm{d}U |UV^\dagger\rangle\!\rangle\langle\!\langle UV^\dagger|_{\mathcal{P}\mathcal{P}'} \otimes |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n} + (\mathbb{1}_D - \Pi_{\mathrm{Im}V})^T_{\mathcal{P}} \otimes \Sigma \tag{134}
$$

for all $V \in \mathbb{V}_{\mathrm{iso}}(d, D)$, where $\mathrm{d}U$ is the Haar measure on $\mathbb{U}(d)$ and Σ is defined in Eq. (74). By definition (61) of T_I, it satisfies

$$
[T_I, \mathbb{1}_{\mathcal{P}'\mathcal{O}'^n} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \quad \forall U' \in \mathbb{U}(D). \tag{135}
$$

Therefore,

$$
\begin{aligned}
T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} &= (\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n} \otimes \mathcal{U}'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n})(T_I) \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} && (136)\\
&= (\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n\mathcal{I}^n} \otimes \mathcal{U}'_{\mathcal{P}})(T_I \star |U'^T V\rangle\!\rangle\langle\!\langle U'^T V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}) && (137)
\end{aligned}
$$

Since $U'^T V = V$ holds for $U'^T = \mathbb{1}_{\mathrm{Im}V} \oplus U''_{(\mathrm{Im}V)^\perp}$ using $U'' \in \mathbb{U}(D-d)$, we obtain

$$
[T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}, \mathbb{1}_{\mathcal{P}'\mathcal{O}'^n\mathcal{I}^n} \otimes (\mathbb{1}_{\mathrm{Im}V} \oplus U''_{(\mathrm{Im}V)^\perp})^T_{\mathcal{P}}] = 0 \quad \forall U'' \in \mathbb{U}(D-d). \tag{138}
$$

Therefore, $T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}$ satisfies

$$\begin{aligned}T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} =& [\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n\mathcal{I}^n} \otimes (\Pi^T_{\mathrm{Im}V})_{\mathcal{P}}](T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})[\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n\mathcal{I}^n} \otimes (\Pi^T_{\mathrm{Im}V})_{\mathcal{P}}]\\ &+ (\mathbb{1}_D - \Pi_{\mathrm{Im}V})^T_{\mathcal{P}} \otimes \Sigma,\end{aligned} \tag{139}$$

where $\Sigma \in \mathcal{L}(\mathcal{P}'\mathcal{O}'^n\mathcal{I}^n)$ is given by

$$\Sigma = \frac{1}{D-d} T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \star (\mathbb{1}_D - \Pi_{\mathrm{Im}V})_{\mathcal{P}}. \tag{140}$$

Since $\Pi_{\mathrm{Im}V} = VV^\dagger$ holds, the first term in Eq. (137) can be evaluated as

$$\begin{aligned}&[\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n\mathcal{I}^n} \otimes (\Pi^T_{\mathrm{Im}V})_{\mathcal{P}}](T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})[\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n\mathcal{I}^n} \otimes (\Pi^T_{\mathrm{Im}V})_{\mathcal{P}}]\\
&= \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{i,j=1}^{d_\mu} \frac{(E^{\mu,d}_{ij})_{\mathcal{P}'\mathcal{O}'^n}}{m^{(d)}_\mu} \otimes (\mathbb{1}_{\mathcal{O}^n} \otimes \mathcal{V}^*_{\mathcal{P}''\to\mathcal{P}} \circ \mathcal{V}^T_{\mathcal{P}\to\mathcal{P}''})(E^{\mu,D}_{ij})_{\mathcal{P}\mathcal{O}^n} \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} &(141)\\
&= \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{i,j=1}^{d_\mu} \frac{(E^{\mu,d}_{ij})_{\mathcal{P}'\mathcal{O}'^n}}{m^{(d)}_\mu} \otimes (\mathbb{1}_{\mathcal{I}^n} \otimes \mathcal{V}^*_{\mathcal{P}''\to\mathcal{P}}) \circ \mathcal{V}^{T\otimes n+1}_{\mathcal{P}\mathcal{O}^n\to\mathcal{P}''\mathcal{I}^n}(E^{\mu,D}_{ij})_{\mathcal{P}\mathcal{O}^n} &(142)\\
&= \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{i,j=1}^{d_\mu} \frac{(E^{\mu,d}_{ij})_{\mathcal{P}'\mathcal{O}'^n}}{m^{(d)}_\mu} \otimes (\mathbb{1}_{\mathcal{I}^n} \otimes \mathcal{V}^*_{\mathcal{P}''\to\mathcal{P}})(E^{\mu,d}_{ij})_{\mathcal{P}''\mathcal{I}^n} &(143)\\
&= \int_{\mathbb{U}(d)} \mathrm{d}U (\mathbb{1}_{\mathcal{P}'} \otimes \mathcal{V}^*_{\mathcal{P}''\to\mathcal{P}})(|U\rangle\!\rangle\langle\!\langle U|_{\mathcal{P}''\mathcal{P}'}) \otimes |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n} &(144)\\
&= \int_{\mathbb{U}(d)} \mathrm{d}U |UV^\dagger\rangle\!\rangle\langle\!\langle UV^\dagger|_{\mathcal{P}\mathcal{P}'} \otimes |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n}, &(145)\end{aligned}$$

where $\mathcal{P}''$ is a Hilbert spaces given by $\mathcal{P}'' = \mathbb{C}^d$, $\mathrm{d}U$ is the Haar measure on $\mathbb{U}(d)$, and we have utilized the following relations:

$$V^{\dagger\otimes n+1} E^{\mu,D}_{ij} V^{\otimes n+1} = \begin{cases} E^{\mu,d}_{ij} & (\mu \in \mathbb{Y}^d_{n+1}) \\ 0 & (\mu \notin \mathbb{Y}^d_{n+1}) \end{cases}, \tag{146}$$

$$\int_{\mathbb{U}(d)} \mathrm{d}U |U\rangle\!\rangle\langle\!\langle U|^{\otimes n+1}_{\mathcal{P}''\mathcal{I}^n,\mathcal{P}'\mathcal{O}'^n} = \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{i,j=1}^{d_\mu} \frac{(E^{\mu,d}_{ij})_{\mathcal{P}'\mathcal{O}'^n} \otimes (E^{\mu,d}_{ij})_{\mathcal{P}''\mathcal{I}^n}}{m^{(d)}_\mu}, \tag{147}$$

the former of which follows from the decomposition of $V^{\otimes n+1}$ shown in Eq. (53) and the definition (54) of $E^{\mu,d}_{ij}$, and the latter of which is shown in Ref. [29]. The operator Σ defined in Eq. (140) is shown to be the same as Eq. (74) by the following calculation:

$$\begin{aligned}\Sigma &= \frac{1}{D-d} T_I \star |V\rangle\!\rangle\langle\!\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \star (\mathbb{1}_D - \Pi_{\mathrm{Im}V})_{\mathcal{P}}\\
&= \frac{1}{D-d}\left[(\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n\mathcal{P}} \otimes \mathcal{V}^{T\otimes n}_{\mathcal{O}^n\to\mathcal{I}^n})(\mathrm{Tr}_{\mathcal{P}}\, T_I) - \mathrm{Tr}_{\mathcal{P}''} \circ (\mathbb{1}_{\mathcal{P}'\mathcal{O}'^n} \otimes \mathcal{V}^{T\otimes n+1}_{\mathcal{P}\mathcal{O}^n\to\mathcal{P}''\mathcal{I}^n})(T_I)\right] &(148)\\
&= \frac{1}{D-d} \sum_{\lambda\in\mathbb{Y}^d_n} \sum_{\mu\in\lambda+\square} \sum_{a,b=1}^{d_\lambda} \left[\frac{m^{(D)}_\mu}{m^{(D)}_\lambda} - \frac{m^{(d)}_\mu}{m^{(d)}_\lambda}\right] (E^{\lambda,d}_{ab})_{\mathcal{I}^n} \otimes \frac{(E^{\mu,d}_{a^\lambda_\mu b^\lambda_\mu})_{\mathcal{O}'^n\mathcal{P}'}}{m^{(d)}_\mu}, &(149)\end{aligned}$$

where we have utilized Lemma 3 and Eq. (146). To calculate it further, we employ the dimension formula of the irreducible representation $\mathcal{U}^{(D)}_\mu$ of $\mathbb{U}(D)$ given by Eq. (51). In particular, for $\mu \in \lambda + \square$, the ratio of $m_\mu^{(d)}$ and $m_\lambda^{(d)}$ is given by

$$\frac{m_\mu^{(d)}}{m_\lambda^{(d)}} = (d + j - i)\frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)}, \tag{150}$$

where (i, j) is a coordinate of the box added to obtain μ from λ, i.e.,

$$\frac{m_\mu^{(D)}}{m_\lambda^{(D)}} - \frac{m_\mu^{(d)}}{m_\lambda^{(d)}} = (D - d)\frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)} \tag{151}$$

holds. Thus, we obtain Eq. (134).

We evaluate the Choi operator of $\mathcal{C}_a[\mathcal{V}_{\mathrm{in}}^{\otimes n}]$ given by

$$J_{\mathcal{C}_a[\mathcal{V}_{\mathrm{in}}^{\otimes n}]} = C' \star T_a \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \tag{152}$$

to show Theorem 5. From Eq. (134), it is given by

$$J_{\mathcal{C}_I[\mathcal{V}_{\mathrm{in}}^{\otimes n}]} = C' \star \int_{\mathbb{U}(d)} \mathrm{d}U |UV_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle UV_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{P}'} \otimes |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} + (\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})^T_{\mathcal{P}} \otimes C' \star \Sigma. \tag{153}$$

Since C' is the Choi operator of the covariant unitary inversion protocol, we obtain [29]

$$C' \star |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} = \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1} |U^{-1}\rangle\!\rangle\langle\!\langle U^{-1}|_{\mathcal{P}'\mathcal{F}} + \frac{d^2(1 - F_{\mathrm{UI}})}{d^2 - 1}\frac{\mathbb{1}_{\mathcal{F}}}{d} \otimes \mathbb{1}_{\mathcal{P}'}. \tag{154}$$

Thus, the first term in Eq. (153) is given by

$$\begin{aligned} &C' \star \int_{\mathbb{U}(d)} \mathrm{d}U |UV_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle UV_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{P}'} \otimes |U\rangle\!\rangle\langle\!\langle U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \\ &= \int_{\mathbb{U}(d)} \mathrm{d}U |UV_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle UV_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{P}'} \star \left[\frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1} |U^{-1}\rangle\!\rangle\langle\!\langle U^{-1}|_{\mathcal{P}'\mathcal{F}} + \frac{d^2(1 - F_{\mathrm{UI}})}{d^2 - 1}\frac{\mathbb{1}_{\mathcal{F}}}{d} \otimes \mathbb{1}_{\mathcal{P}'}\right] \quad (155) \\ &= \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1} |V_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{F}} + \frac{d^2(1 - F_{\mathrm{UI}})}{d^2 - 1}\frac{\mathbb{1}_{\mathcal{F}}}{d} \otimes (\Pi_{\mathrm{Im}V_{\mathrm{in}}}^T)_{\mathcal{P}}. \quad (156) \end{aligned}$$

Since C' and Σ satisfy the $\mathbb{U}(d)$ symmetry, namely,

$$[C', U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathbb{1}_{\mathcal{P}'\mathcal{O}'^n}] = 0, \tag{157}$$

$$[\Sigma, U'^{\otimes n+1}_{\mathcal{I}^n} \otimes \mathbb{1}_{\mathcal{P}'\mathcal{O}'^n}] = 0 \tag{158}$$

for all $U' \in \mathbb{U}(d)$, $C' \star \Sigma$ satisfies

$$[C' \star \Sigma, U'_{\mathcal{F}}] = 0 \tag{159}$$

for all $U' \in \mathbb{U}(d)$, i.e., it is proportional to the identity operator. Thus, the second term in Eq. (153) is given by

$$\begin{aligned} (\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})^T_{\mathcal{P}} \otimes C' \star \Sigma &= (\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})^T_{\mathcal{P}} \otimes \mathrm{Tr}[C' \star \Sigma]\frac{\mathbb{1}_{\mathcal{F}}}{d} \quad (160) \\ &= (\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})^T_{\mathcal{P}} \otimes \mathrm{Tr}[\mathrm{Tr}_{\mathcal{F}}(C')\Sigma]\frac{\mathbb{1}_{\mathcal{F}}}{d}, \quad (161) \end{aligned}$$

where we utilize the fact that $\Sigma = \Sigma^T$. Combining Eqs. (153), (156), and (161), we obtain

$$J_{\mathcal{C}_I[\mathcal{V}_{\mathrm{in}}^{\otimes n}]} = \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1} |V_{\mathrm{in}}^\dagger\rangle\rangle\langle\langle V_{\mathrm{in}}^\dagger|_{\mathcal{PF}} + \frac{\mathbb{1}_{\mathcal{F}}}{d} \otimes \left[\frac{d^2(1-F_{\mathrm{UI}})}{d^2-1} (\Pi^T_{\mathrm{Im} V_{\mathrm{in}}})_{\mathcal{P}} + \alpha_{C'} (\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}})^T_{\mathcal{P}} \right], \tag{162}$$

where $\alpha_{C'}$ is defined by

$$\alpha_{C'} \coloneqq \mathrm{Tr}[\mathrm{Tr}_{\mathcal{F}}(C')\Sigma]. \tag{163}$$

Therefore, we obtain

$$\mathcal{C}_I[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) = \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1} \mathcal{V}_{\mathrm{in}}^\dagger(\rho_{\mathrm{in}}) + \frac{\mathbb{1}_d}{d} \mathrm{Tr} \left\{ \left[\frac{d^2(1-F_{\mathrm{UI}})}{d^2-1} \Pi_{\mathrm{Im} V_{\mathrm{in}}} + \alpha_{C'} (\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}}) \right] \rho_{\mathrm{in}} \right\}. \tag{164}$$

Since $\mathcal{C}_I[V_{\mathrm{in}}^{\otimes n}] + \mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}]$ is a CPTP map and

$$\mathrm{Tr}\, \mathcal{C}_I[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) = \mathrm{Tr}\left\{ [\Pi_{\mathrm{Im} V_{\mathrm{in}}} + \alpha_{C'}(\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}})]\, \rho_{\mathrm{in}} \right\} \tag{165}$$

holds, $\mathrm{Tr}\, \mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) = (1 - \alpha_{C'})\, \mathrm{Tr}[(\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}})\rho_{\mathrm{in}}]$ holds. Since $\mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}]$ is a CP map, we obtain

$$\mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) = \mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\Pi_{(\mathrm{Im} V_{\mathrm{in}})^\perp} \rho_{\mathrm{in}} \Pi_{(\mathrm{Im} V_{\mathrm{in}})^\perp}). \tag{166}$$

Due to the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetries of C' and T_O,

$$[C' \star T_O, U'^{\otimes n+1}_{\mathcal{I}^n \mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \quad \forall U' \in \mathbb{U}(d), U'' \in \mathbb{U}(D) \tag{167}$$

holds. Thus, we obtain

$$\mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) = \mathcal{U}' \circ \mathcal{C}_O[(U'' V_{\mathrm{in}} U')^{\otimes n}] \circ \mathcal{U}''(\rho_{\mathrm{in}}) \quad \forall U' \in \mathbb{U}(d), U'' \in \mathbb{U}(D). \tag{168}$$

In particular, for all $U' \in \mathbb{U}(d)$, we take $U'' = U'''_{\mathrm{Im} V_{\mathrm{in}}} \oplus \mathbb{1}_{(\mathrm{Im} V_{\mathrm{in}})^\perp}$ for $U''' \in \mathbb{U}(d)$ such that $U'' V_{\mathrm{in}} U' = V_{\mathrm{in}}$. From Eqs. (166) and (168), we obtain

$$\mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) = \mathcal{U}' \circ \mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) \quad \forall U' \in \mathbb{U}(d), \tag{169}$$

thus, $\mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) \propto \frac{\mathbb{1}_d}{d}$. From Eq. (166), we obtain

$$\mathcal{C}_O[V_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}) = \frac{\mathbb{1}_d}{d} (1 - \alpha_{C'})\, \mathrm{Tr}[(\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}})\rho_{\mathrm{in}}]. \tag{170}$$

We evaluate the diamond norm $\|\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}] - \mathcal{V}_{\mathrm{adjoint}}\|_\diamond$ to complete the proof, where $\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}]$ and $\mathcal{V}_{\mathrm{adjoint}}$ are defined as

$$\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}](\cdot) \coloneqq \mathcal{C}_I[\mathcal{V}_{\mathrm{in}}^{\otimes n}](\cdot) \otimes |0\rangle\langle 0| + \mathcal{C}_O[\mathcal{V}_{\mathrm{in}}^{\otimes n}](\cdot) \otimes |1\rangle\langle 1|, \tag{171}$$

$$\mathcal{V}_{\mathrm{adjoint}}(\cdot) \coloneqq V_{\mathrm{in}}^\dagger \cdot V_{\mathrm{in}} \otimes |0\rangle\langle 0| + \mathrm{Tr}[(\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}}) \cdot] \frac{\mathbb{1}}{d} \otimes |1\rangle\langle 1|. \tag{172}$$

First, $\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}] - \mathcal{V}_{\mathrm{adjoint}}$ decomposes into two completely positive maps Φ_1 and Φ_2 as

$$\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}] - \mathcal{V}_{\mathrm{adjoint}} = \Phi_1 + \Phi_2, \tag{173}$$

$$\Phi_1(\rho_{\mathrm{in}}) \coloneqq -\frac{d^2(1-F_{\mathrm{UI}})}{d^2-1} [\mathcal{V}_{\mathrm{in}}^\dagger(\rho_{\mathrm{in}}) - \mathrm{Tr}(\Pi_{\mathrm{Im} V_{\mathrm{in}}} \rho_{\mathrm{in}})] \otimes |0\rangle\langle 0|, \tag{174}$$

$$\Phi_2(\rho_{\mathrm{in}}) \coloneqq \alpha_{C'}\, \mathrm{Tr}[(\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}})\rho_{\mathrm{in}}] \left(\frac{\mathbb{1}_d}{d} \otimes |0\rangle\langle 0| - \frac{\mathbb{1}_d}{d} \otimes |1\rangle\langle 1| \right), \tag{175}$$

whose kernels do not intersect, i.e., $\ker\Phi_1 \cap \ker\Phi_2 = \emptyset$. Since the diamond norm $\|\Phi_1+\Phi_2\|_\diamond$ is defined by

$$\|\Phi_1 + \Phi_2\|_\diamond := \sup_{\psi\in\mathcal{L}(\mathcal{P}\otimes\mathcal{A}), \|\psi\|_1\leq 1} \|(\Phi_1+\Phi_2)\otimes \mathbb{1}_{\mathcal{A}}(\psi)\|_1 \tag{176}$$

using an auxiliary Hilbert space $\mathcal{A}$ and the trace norm $\|\cdot\|_1$, it is given by

$$\begin{aligned}
&\|\Phi_1 + \Phi_2\|_\diamond \\
&= \sup_{\psi_i\in\ker\Phi_i\otimes\mathcal{L}(\mathcal{A}), \|\psi_1+\psi_2\|_1\leq 1} \|(\Phi_1+\Phi_2)\otimes \mathbb{1}_{\mathcal{A}}(\psi_1+\psi_2)\|_1 &(177)\\
&= \max_{0\leq x\leq 1}[x \sup_{\substack{\psi_1\in\ker\Phi_1\otimes\mathcal{L}(\mathcal{A})\\ \|\psi_1\|_1\leq 1}} \|\Phi_1\otimes \mathbb{1}_{\mathcal{A}}(\psi_1)\|_1 + (1-x) \sup_{\substack{\psi_2\in\ker\Phi_2\otimes\mathcal{L}(\mathcal{A})\\ \|\psi_2\|_1\leq 1}} \|\Phi_1\otimes \mathbb{1}_{\mathcal{A}}(\psi_2)\|_1] &(178)\\
&= \max\{\|\Phi_1\|_\diamond, \|\Phi_2\|_\diamond\}. &(179)
\end{aligned}$$

The diamond norm $\|\Phi_1\|_\diamond$ is given by

$$\begin{aligned}
\|\Phi_1\|_\diamond &= \|\Phi_1\circ\mathcal{V}_{\text{in}}\|_\diamond &(180)\\
&= \|\mathbb{1}_d - \mathcal{D}_q\|_\diamond &(181)\\
&= 2(1-F_{\text{UI}}), &(182)
\end{aligned}$$

where $\mathcal{D}_q$ is the depolarizing channel

$$\mathcal{D}_q(\rho) := (1-q)\rho + q\frac{\mathbb{1}_d}{d}\operatorname{Tr}(\rho), \tag{183}$$

q is given by $q := \frac{d^2}{d^2-1}(1-F_{\text{est}})$, and we utilize the fact that [73]

$$\|\mathbb{1}_d - \mathcal{D}_q\|_\diamond = \frac{2(d^2-1)}{d^2}q. \tag{184}$$

The diamond norm $\|\Phi_2\|_\diamond$ is given by

$$\begin{aligned}
&\|\Phi_2\|_\diamond \\
&= \sup_{\psi\in\mathcal{L}(\mathcal{P}\otimes\mathcal{A}), \|\psi\|_1\leq 1} \|\alpha_{C'}\operatorname{Tr}_{\mathcal{P}}[(\mathbb{1}_D - \Pi_{\operatorname{Im}V_{\text{in}}})\psi]\otimes(\frac{\mathbb{1}_d}{d}\otimes|0\rangle\langle 0| - \frac{\mathbb{1}_d}{d}\otimes|1\rangle\langle 1|)\|_1 &(185)\\
&= 2\alpha_\phi. &(186)
\end{aligned}$$

Thus, we obtain

$$\begin{aligned}
\epsilon &:= \frac{1}{2}\sup_{V_{\text{in}}\in\mathbb{V}_{\text{iso}}(d,D)} \|\mathcal{C}[\mathcal{V}_{\text{in}}^{\otimes n}] - \mathcal{V}_{\text{adjoint}}\|_\diamond &(187)\\
&= \max\{\alpha_{C'}, 1-F_{\text{UI}}\}. &(188)
\end{aligned}$$

A.3 Proof of Theorem 6: Construction of a parallel isometry adjointation protocol

The parallel protocol shown in Theorem 6 corresponds to the special case of the sequential protocol such that the Choi operator of the original untiary inversion protocol is given by

$$C' = \phi_{\mathcal{I}^n\mathcal{A}} \star \sum_i (M_i^T)_{\mathcal{O}'^n\mathcal{A}} \otimes (J_{\mathcal{R}_i})_{\mathcal{P}'\mathcal{F}}. \tag{189}$$

Since the Choi operator of a CPTP map $\mathcal{R}_i$ satisfies $\mathrm{Tr}_{\mathcal{F}}(J_{\mathcal{R}_i})_{\mathcal{P}'\mathcal{F}} = \mathbb{1}_{\mathcal{P}'}$, we obtain

$$\begin{aligned}
\mathrm{Tr}_{\mathcal{F}}(C') &= \phi_{\mathcal{I}^n\mathcal{A}} \star \sum_i (M_i^T)_{\mathcal{O}'^n\mathcal{A}} \otimes \mathbb{1}_{\mathcal{P}'} && (190)\\
&= \phi_{\mathcal{I}^n\mathcal{A}} \star \mathbb{1}_{\mathcal{O}'^n\mathcal{A}} \otimes \mathbb{1}_{\mathcal{P}'} && (191)\\
&= \mathrm{Tr}_{\mathcal{A}}(\phi) \otimes \mathbb{1}_{\mathcal{O}'^n\mathcal{P}'}. && (192)
\end{aligned}$$

Then, $\alpha_{C'}$ shown in Eq. (73) reduces to α_ϕ given by

$$\begin{aligned}
\alpha_\phi &:= \mathrm{Tr}[\mathrm{Tr}_{\mathcal{A}}(\phi)\, \mathrm{Tr}_{\mathcal{O}'^n\mathcal{P}'}(\Sigma)] && (193)\\
&= \sum_{\lambda\in\mathbb{Y}_n^d} \mathrm{Tr}\Big[\mathrm{Tr}_{\mathcal{A}}(\phi)\Pi_\lambda^{(d)}\Big] \sum_{\mu\in\lambda\cap\square\cap\mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)} && (194)\\
&= \sum_{\lambda\in\mathbb{Y}_n^d} \mathrm{Tr}\Big[\mathrm{Tr}_{\mathcal{A}}(\phi)\Pi_\lambda^{(d)}\Big] \left[1 - \sum_{\mu\in\lambda\backslash\square\cap\mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)}\right], && (195)
\end{aligned}$$

where we have utilized Lemma 3, Eq. (74), and the equality

$$\sum_{\nu\in\lambda+\square} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\nu)} = 1, \tag{196}$$

shown as follows. From Lemma 3,

$$E_{aa}^{\lambda,D} \otimes \mathbb{1}_D = \sum_{\mu\in\lambda+\square} E_{a_\mu^\lambda a_\mu^\lambda}^{\mu,D} \tag{197}$$

holds for $a \in \{1, \cdots, d_\lambda\}$. By taking the trace of the both-hand side, we obtain

$$Dm_\lambda^{(D)} = \sum_{\mu\in\lambda+\square} m_\mu^{(D)}. \tag{198}$$

By using Eqs. (51) and (198), we show Eq. (196) as

$$\begin{aligned}
\sum_{\nu\in\lambda+\square} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\nu)} &= \lim_{D\to\infty} \frac{\sum_{\nu\in\lambda+\square} m_\nu^{(D)}}{Dm_\lambda^{(D)}} && (199)\\
&= 1. && (200)
\end{aligned}$$

Thus, the approximation error of isometry adjointation is given by

$$\epsilon = \max\{\alpha_\phi, 1 - F_{\mathrm{est}}\}. \tag{201}$$

A.4 Reduction to isometry inversion and universal error detection

A.4.1 Deterministic isometry inversion

By discarding the measurement outcome of the isometry adjointation protocol shown in Eqs. (164) and (169), we obtain the following protocol:

$$\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}] = \mathcal{C}_I[\mathcal{V}_{\mathrm{in}}^{\otimes n}] + \mathcal{C}_O[\mathcal{V}_{\mathrm{in}}^{\otimes n}] \tag{202}$$

This protocol satisfies

$$\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}] \circ \mathcal{V}_{\mathrm{in}}(\rho_{\mathrm{in}}) = \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1}\rho_{\mathrm{in}} + \frac{\mathbb{1}_d}{d}\left(1 - \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1}\right)\mathrm{Tr}(\rho_{\mathrm{in}}). \tag{203}$$

Thus, the worst-case channel fidelity of isometry inversion is given by

$$F_{\mathrm{ch}}(\mathcal{C}[\mathcal{V}_{\mathrm{in}}^{\otimes n}] \circ \mathcal{V}_{\mathrm{in}}, \mathbb{1}_d) = F_{\mathrm{UI}}. \tag{204}$$

A.4.2 Probabilistic exact isometry inversion

The construction of deterministic exact unitary inversion protocol can be rewritten in terms of the Choi operator as

$$\begin{aligned}
&C' \star |U_{\mathrm{in}}\rangle\!\rangle\langle\!\langle U_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n} \approx |U_{\mathrm{in}}^{-1}\rangle\!\rangle\langle\!\langle U_{\mathrm{in}}^{-1}|_{\mathcal{P}'\mathcal{F}} \quad \forall U_{\mathrm{in}} \in \mathbb{U}(d)\\
&\Longrightarrow T \star C' \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|_{\mathcal{P}''\mathcal{P}}\\
&\quad = \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1} |\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|_{\mathcal{P}''\mathcal{F}} + \frac{\mathbb{1}_{\mathcal{P}''\mathcal{P}}}{d}\left(1 - \frac{d^2 F_{\mathrm{UI}} - 1}{d^2 - 1}\right) \quad \forall V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D), \qquad (205)
\end{aligned}$$

where $\mathcal{P}''$ is a Hilbert space given by $\mathcal{P}'' = \mathbb{C}^d$. By replacing C' with the probabilistic exact unitary inversion comb $\{C'_S, C'_F\}$ with the success probability p_{UI} satisfying

$$C'_S \star |U_{\mathrm{in}}\rangle\!\rangle\langle\!\langle U_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}'^n} = p_{\mathrm{UI}} |U_{\mathrm{in}}^{-1}\rangle\!\rangle\langle\!\langle U_{\mathrm{in}}^{-1}|_{\mathcal{P}'\mathcal{F}} \quad \forall U_{\mathrm{in}} \in \mathbb{U}(d), \qquad (206)$$

we obtain the probabilistic exact isometry inversion protocol given by

$$\begin{aligned}
T \star C'_S \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|_{\mathcal{P}''\mathcal{P}} = p_{\mathrm{UI}} |\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|_{\mathcal{P}''\mathcal{F}}&\\
\forall V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D).& \qquad (207)
\end{aligned}$$

A.4.3 Universal error detection

By discarding the output state of the isometry adjointation protocol shown in Eqs. (164) and (169), we obtain the following protocol:

$$\mathrm{Tr}(\Pi_a \rho_{\mathrm{in}}) = \mathrm{Tr} \circ \mathcal{C}_a[\mathcal{V}_{\mathrm{in}}^{\otimes n}](\rho_{\mathrm{in}}), \qquad (208)$$

This protocol satisfies

$$\Pi_I = \Pi_{\mathrm{Im} V_{\mathrm{in}}} + \alpha_{C'}(\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}}), \qquad (209)$$

$$\Pi_O = (1 - \alpha_{C'})(\mathbb{1}_D - \Pi_{\mathrm{Im} V_{\mathrm{in}}}). \qquad (210)$$

Since C' corresponds to $C' = C'' \otimes \frac{\mathbb{1}_{\mathcal{O}'_n\mathcal{F}}}{d}$ using C'' shown in Corollary 8, $\alpha_{C'}$ is given by

$$\alpha'_C = \mathrm{Tr}(C''\Sigma'). \qquad (211)$$

B Analysis on the optimal protocols

B.1 Proof of Theorem 9: $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry of the tasks

We show Theorem 9 using the idea of a twirling map [74] similarly to Refs. [27, 29]. Assume that the Choi operators (102) achieve the optimal performances in parallel, sequential or general protocols including indefinite causal order. We define the $\mathbb{U}(d) \times \mathbb{U}(D)$-twirled Choi operators by

$$\begin{cases}
C' := \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(C) & \text{(deterministic isometry inversion)}\\
C'_a := \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(C_a) & \text{(probabilistic exact isometry inversion)}\\
C'_a := \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}'^{\otimes n}_{\mathcal{I}^n} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(C_a) & \text{(universal error detection)}\\
C'_a := \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(C_a) & \text{(isometry adjointation)}
\end{cases},$$

$$(212)$$

where $\mathrm{d}U'$ and $\mathrm{d}U''$ are the Haar measures of $\mathbb{U}(d)$ and $\mathbb{U}(D)$, respectively. Then, these operators satisfy $C'_a \geq 0$ and $C' = \sum_a C'_a \in \mathcal{W}^{(x)}$, and the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry given by

$$\begin{cases} [C', U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 & \text{(deterministic isometry inversion)} \\ [C'_a, U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \quad \forall a \in \{S, F\} & \text{(probabilistic exact isometry inversion)} \\ [C'_a, U'^{\otimes n}_{\mathcal{I}^n} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \quad \forall a \in \{I, O\} & \text{(universal error detection)} \\ [C'_a, U'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \quad \forall a \in \{I, O\} & \text{(isometry adjointation)} \end{cases} \tag{213}$$

for all $U' \in \mathbb{U}(d)$ and $U'' \in \mathbb{U}(D)$. Then, we can show Theorem 9 by showing that the $\mathbb{U}(d) \times \mathbb{U}(D)$-twirling does not decrease performances of each task. We show this in the following subsections.

B.1.1 Deterministic isometry inversion

The worst-case fidelity F_worst is given using the Choi operator C of the quantum superchannel by

$$F_\text{worst} = \inf_{V_\text{in} \in \mathbb{V}_\text{iso}(d,D)} F_\text{ch}[\mathcal{C}(\mathcal{V}_\text{in}^{\otimes n}) \circ \mathcal{V}_\text{in}, \mathbb{1}_d] \tag{214}$$

$$= \frac{1}{d^2} \inf_{V_\text{in} \in \mathbb{V}_\text{iso}(d,D)} \mathrm{Tr}\Big[C \star (|V_\text{in}\rangle\!\rangle\langle\!\langle V_\text{in}|_{\mathcal{P}''\mathcal{P}} \otimes |V_\text{in}\rangle\!\rangle\langle\!\langle V_\text{in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}) |\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|_{\mathcal{P}''\mathcal{F}}\Big] \tag{215}$$

$$= \frac{1}{d^2} \inf_{V_\text{in} \in \mathbb{V}_\text{iso}(d,D)} \mathrm{Tr}\Big[C (|V^*_\text{in}\rangle\!\rangle\langle\!\langle V^*_\text{in}|_{\mathcal{F}\mathcal{P}} \otimes |V^*_\text{in}\rangle\!\rangle\langle\!\langle V^*_\text{in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})\Big]. \tag{216}$$

Then, the worst-case channel fidelity of the $\mathbb{U}(d) \times \mathbb{U}(D)$-twirled Choi operator is given by

$$F'_\text{worst} = \frac{1}{d^2} \inf_{V_\text{in} \in \mathbb{V}_\text{iso}(d,D)} \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U''$$

$$\mathrm{Tr}\Big[\mathcal{U}'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(C) (|V^*_\text{in}\rangle\!\rangle\langle\!\langle V^*_\text{in}|_{\mathcal{F}\mathcal{P}} \otimes |V^*_\text{in}\rangle\!\rangle\langle\!\langle V^*_\text{in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})\Big] \tag{217}$$

$$\geq \frac{1}{d^2} \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \inf_{V_\text{in} \in \mathbb{V}_\text{iso}(d,D)}$$

$$\mathrm{Tr}\Big[C\mathcal{U}'^{\dagger\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}''^{\dagger\otimes n+1}_{\mathcal{P}\mathcal{O}^n} (|V^*_\text{in}\rangle\!\rangle\langle\!\langle V^*_\text{in}|_{\mathcal{F}\mathcal{P}} \otimes |V^*_\text{in}\rangle\!\rangle\langle\!\langle V^*_\text{in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})\Big] \tag{218}$$

$$= \frac{1}{d^2} \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \inf_{V_\text{in} \in \mathbb{V}_\text{iso}(d,D)}$$

$$\mathrm{Tr}\Big[C (|U''^\dagger V^*_\text{in} U'^*\rangle\!\rangle\langle\!\langle U''^\dagger V^*_\text{in} U'^*|_{\mathcal{F}\mathcal{P}} \otimes |U''^\dagger V^*_\text{in} U'^*\rangle\!\rangle\langle\!\langle U''^\dagger V^*_\text{in} U'^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})\Big] \tag{219}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' F_\text{worst} \tag{220}$$

$$= F_\text{worst}. \tag{221}$$

B.1.2 Probabilistic exact isometry inversion

Suppose a Choi operator C_S satisfies

$$C_S \star (|V_\text{in}\rangle\!\rangle\langle\!\langle V_\text{in}|_{\mathcal{P}''\mathcal{P}} \otimes |V_\text{in}\rangle\!\rangle\langle\!\langle V_\text{in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}) = p|\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|_{\mathcal{P}''\mathcal{F}} \quad \forall V_\text{in} \in \mathbb{V}_\text{iso}(d, D). \tag{222}$$

Then, the $\mathbb{U}(d) \times \mathbb{U}(D)$-twirled Choi operator also satisfies

$$C'_S \star (|V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|_{\mathcal{P}''\mathcal{P}} \otimes |V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}'^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(C_S) \star (|V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|_{\mathcal{P}''\mathcal{P}} \otimes |V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}) \tag{223}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' C_S \star \mathcal{U}'^{T\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}''^{T\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(|V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|_{\mathcal{P}''\mathcal{P}} \otimes |V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}) \tag{224}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' C_S \star (|U''^T V_{\rm in} U'\rangle\!\rangle\langle\!\langle U''^T V_{\rm in} U'|_{\mathcal{P}''\mathcal{P}} \otimes |U''^T V_{\rm in} U'\rangle\!\rangle\langle\!\langle U''^T V_{\rm in} U'|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}) \tag{225}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' p|\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|_{\mathcal{P}''\mathcal{F}} \tag{226}$$

$$= p|\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|_{\mathcal{P}''\mathcal{F}}, \tag{227}$$

i.e., it implements isometry inversion with success probability p.

B.1.3 Universal error detection

Suppose a supermap $\mathcal{C}_I$ satisfies

$$\mathcal{C}_I[\mathcal{V}_{\rm in}^{\otimes n}](\rho) = \mathrm{Tr}[(\Pi_{\mathrm{Im}V_{\rm in}} + \alpha(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\rm in}}))\rho] \tag{228}$$

for all $V_{\rm in} \in \mathbb{V}_{\rm iso}(d, D)$. In terms of the Choi operator, this relation is given by

$$C_I \star |V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} = (\Pi^T_{\mathrm{Im}V_{\rm in}})_{\mathcal{P}} + \alpha(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\rm in}})^T_{\mathcal{P}}. \tag{229}$$

Then, the $\mathbb{U}(d) \times \mathbb{U}(D)$-twirlied Choi operator also satisfies

$$C'_I \star |V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}'^{\otimes n}_{\mathcal{I}^n} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(C_I) \star |V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \tag{230}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}''_{\mathcal{P}}[C_I \star \mathcal{U}'^{T\otimes n}_{\mathcal{I}^n} \otimes \mathcal{U}''^{T\otimes n}_{\mathcal{O}^n}(|V_{\rm in}\rangle\!\rangle\langle\!\langle V_{\rm in}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})] \tag{231}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}''_{\mathcal{P}}(C_I \star |U''^T V_{\rm in} U'\rangle\!\rangle\langle\!\langle U''^T V_{\rm in} U'|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}) \tag{232}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}''_{\mathcal{P}}[(\Pi^T_{\mathrm{Im}U''^T V_{\rm in} U'})_{\mathcal{P}} + \alpha(\mathbb{1}_D - \Pi_{\mathrm{Im}U''^T V_{\rm in} U'})^T_{\mathcal{P}}] \tag{233}$$

$$= \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}''_{\mathcal{P}} \circ \mathcal{U}''^{\dagger}_{\mathcal{P}}[(\Pi^T_{\mathrm{Im}V_{\rm in}})_{\mathcal{P}} + \alpha(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\rm in}})^T_{\mathcal{P}}] \tag{234}$$

$$= (\Pi^T_{\mathrm{Im}V_{\rm in}})_{\mathcal{P}} + \alpha(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\rm in}})^T_{\mathcal{P}}, \tag{235}$$

i.e., it implements a universal error detection with the same performance as C_I.

B.1.4 Isometry adjointation

We introduce the notation to represent the diamond norm of a quantum channel Φ in terms of its Choi operator J_Φ, i.e., we define $\mathfrak{D}[J_\Phi]$ by

$$\mathfrak{D}[J_\Phi] \coloneqq \|\Phi\|_\diamond. \tag{236}$$

Then, $\mathfrak{D}[J_\Phi]$ satisfies the following properties:

$$\mathfrak{D}[(U_\mathcal{I} \otimes U'_\mathcal{O}) J_\Phi (U_\mathcal{I} \otimes U'_\mathcal{O})^\dagger] = \mathfrak{D}[J_\Phi] \quad \forall U \in \mathbb{U}(\dim \mathcal{I}), U' \in \mathbb{U}(\dim \mathcal{O}), \tag{237}$$

$$\mathfrak{D}[aJ_{\Lambda^{(1)}} + bJ_{\Lambda^{(2)}}] \leq a\mathfrak{D}[J_{\Lambda^{(1)}}] + b\mathfrak{D}[J_{\Lambda^{(2)}}] \quad \forall a, b \geq 0, \tag{238}$$

which corresponds to the following properties of the diamond norm:

$$\|\mathcal{U}' \circ \Phi \circ \mathcal{U}\|_\diamond = \|\Phi\|_\diamond \quad \forall U \in \mathbb{U}(\dim \mathcal{I}), U' \in \mathbb{U}(\dim \mathcal{O}), \tag{239}$$

$$\|a\Lambda^{(1)} + b\Lambda^{(2)}\|_\diamond \leq a\|\Lambda^{(1)}\|_\diamond + b\|\Lambda^{(2)}\|_\diamond \quad \forall a, b \geq 0, \tag{240}$$

The worst-case diamond-norm error ϵ is given using the Choi operator C_I by

$$\epsilon = \inf_{V_\mathrm{in} \in \mathbb{V}_\mathrm{iso}(d,D)} \mathfrak{D}[C \star |V_\mathrm{in}\rangle\!\rangle\langle\!\langle V_\mathrm{in}|^{\otimes n}_{\mathcal{I}^n \mathcal{O}^n} \otimes |0\rangle\langle 0| - |V_\mathrm{in}^\dagger\rangle\!\rangle\langle\!\langle V_\mathrm{in}^\dagger|_{\mathcal{P}\mathcal{F}} \otimes |0\rangle\langle 0|_\mathcal{A} - \frac{\mathbb{1}_\mathcal{P} \otimes \mathbb{1}_\mathcal{F}}{d} \otimes |1\rangle\langle 1|_\mathcal{A}], \tag{241}$$

where $C' \coloneqq C_I \otimes |0\rangle\langle 0|_\mathcal{A} + C_O \otimes |1\rangle\langle 1|_\mathcal{A}$ and $\mathcal{A} = \mathbb{C}^2$. Thus, the worst-case diamond-norm error of the $\mathbb{U}(d) \times \mathbb{U}(D)$-twirled Choi operator is given by

$$\begin{aligned}
\epsilon' = & \inf_{V_\mathrm{in} \in \mathbb{V}_\mathrm{iso}(d,D)} \mathfrak{D}[\int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \mathcal{U}'^{\otimes n+1}_{\mathcal{I}^n \mathcal{F}} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n} \otimes \mathbb{1}_\mathcal{A}(C) \star |V_\mathrm{in}\rangle\!\rangle\langle\!\langle V_\mathrm{in}|^{\otimes n}_{\mathcal{I}^n \mathcal{O}^n} \\
& \qquad - |V_\mathrm{in}^\dagger\rangle\!\rangle\langle\!\langle V_\mathrm{in}^\dagger|_{\mathcal{P}\mathcal{F}} \otimes |0\rangle\langle 0|_\mathcal{A} - \frac{\mathbb{1}_\mathcal{P} \otimes \mathbb{1}_\mathcal{F}}{d} \otimes |1\rangle\langle 1|_\mathcal{A}] && (242)\\
\leq & \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \inf_{V_\mathrm{in} \in \mathbb{V}_\mathrm{iso}(d,D)} \mathfrak{D}[\mathcal{U}'^{\otimes n+1}_{\mathcal{I}^n \mathcal{F}} \otimes \mathcal{U}''^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n} \otimes \mathbb{1}_\mathcal{A}(C) \star |V_\mathrm{in}\rangle\!\rangle\langle\!\langle V_\mathrm{in}|^{\otimes n}_{\mathcal{I}^n \mathcal{O}^n} \\
& \qquad - |V_\mathrm{in}^\dagger\rangle\!\rangle\langle\!\langle V_\mathrm{in}^\dagger|_{\mathcal{P}\mathcal{F}} \otimes |0\rangle\langle 0|_\mathcal{A} - \frac{\mathbb{1}_\mathcal{P} \otimes \mathbb{1}_\mathcal{F}}{d} \otimes |1\rangle\langle 1|_\mathcal{A}] && (243)\\
= & \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \inf_{V_\mathrm{in} \in \mathbb{V}_\mathrm{iso}(d,D)} \mathfrak{D}[C \star \mathcal{U}'^{T \otimes n}_{\mathcal{I}^n} \otimes \mathcal{U}''^{T \otimes n}_{\mathcal{O}^n} (|V_\mathrm{in}\rangle\!\rangle\langle\!\langle V_\mathrm{in}|^{\otimes n}_{\mathcal{I}^n \mathcal{O}^n}) \\
& \qquad - \mathcal{U}'^\dagger_\mathcal{F} \otimes \mathcal{U}''^\dagger_\mathcal{P} \otimes \mathbb{1}_\mathcal{A} (|V_\mathrm{in}^\dagger\rangle\!\rangle\langle\!\langle V_\mathrm{in}^\dagger|_{\mathcal{P}\mathcal{F}} \otimes |0\rangle\langle 0|_\mathcal{A} + \frac{\mathbb{1}_\mathcal{P} \otimes \mathbb{1}_\mathcal{F}}{d} \otimes |1\rangle\langle 1|_\mathcal{A})] && (244)\\
= & \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \inf_{V_\mathrm{in} \in \mathbb{V}_\mathrm{iso}(d,D)} \mathfrak{D}[C \star (|U''^T V_\mathrm{in} U'\rangle\!\rangle\langle\!\langle U''^T V_\mathrm{in} U'|^{\otimes n}_{\mathcal{I}^n \mathcal{O}^n}) \\
& \qquad - |U'^\dagger V_\mathrm{in}^\dagger U''^*\rangle\!\rangle\langle\!\langle U'^\dagger V_\mathrm{in}^\dagger U''^*|_{\mathcal{P}\mathcal{F}} \otimes |0\rangle\langle 0|_\mathcal{A} - \frac{\mathbb{1}_\mathcal{P} \otimes \mathbb{1}_\mathcal{F}}{d} \otimes |1\rangle\langle 1|_\mathcal{A}] && (245)\\
= & \int_{\mathbb{U}(d)} \mathrm{d}U' \int_{\mathbb{U}(D)} \mathrm{d}U'' \epsilon && (246)\\
= & \epsilon, && (247)
\end{aligned}$$

i.e., it implements isometry adjointation with approximation error $\epsilon' \leq \epsilon$.

B.2 Proof of Theorem 12: Optimal parallel protocol for universal error detection

Due to Theorem 10, the optimal performance α of parallel error detection is given by minimizing α_ϕ shown in Theorem 8:

$$\alpha_\mathrm{opt}^{(\mathrm{PAR})} = \min_{\mathrm{Tr}(\phi)=1, \phi \geq 0} \sum_{\lambda \in \mathbb{Y}_n^d} \mathrm{Tr}(\phi \Pi_\lambda) \left[1 - \sum_{\mu \in \lambda + \square \setminus \mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)} \right]. \tag{248}$$

The right-hand side has the minimum value

$$\alpha_\mathrm{opt}^{(\mathrm{PAR})} = 1 - \max_{\lambda \in \mathbb{Y}_n^d} \sum_{\mu \in \lambda + \square \setminus \mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)} \tag{249}$$

at $\phi = \Pi_\lambda / \operatorname{Tr} \Pi_\lambda$, where λ is given by

$$\lambda = \arg\max_{\lambda \in \mathbb{Y}_n^d} \sum_{\mu \in \lambda + \square \setminus \mathbb{Y}_{n+1}^d} \frac{\operatorname{hook}(\lambda)}{\operatorname{hook}(\mu)}. \tag{250}$$

We define $f(\lambda)$ for $\lambda \in \mathbb{Y}_n^d$ by

$$f(\lambda) \coloneqq \sum_{\mu \in \lambda + \square \setminus \mathbb{Y}_{n+1}^d} \frac{\operatorname{hook}(\lambda)}{\operatorname{hook}(\mu)}, \tag{251}$$

and derive the maximum value of $f(\lambda)$. We denote the number of boxes in the i-th row of λ and μ by λ_i and μ_i, respectively. By definition of Young diagrams, λ_i satisfies $\lambda_1 \geq \cdots \lambda_d \geq 0$ and $\sum_i \lambda_i = n$. If $\lambda_d = 0$, any Young diagram in the set $\lambda + \square$ has depth smaller than or equal to d, i.e., $f(\lambda) = 0$. If $\lambda_1 \geq \cdots \lambda_d \geq 1$ holds, the set $\lambda + \square \setminus \mathbb{Y}_{n+1}^d$ is a one-point set whose element μ is given by $\mu_i = \lambda_i$ for $i \in \{1, \cdots, d\}$ and $\mu_{d+1} = 1$. Therefore, $f(\lambda)$ is given by

$$f(\lambda) = \frac{\operatorname{hook}(\lambda)}{\operatorname{hook}(\mu)} = \prod_{i=1}^{d} \frac{\lambda_i + d - i}{\lambda_i + d + 1 - i}. \tag{252}$$

We derive the maximum value of $f(\lambda)$ for $\lambda_1, \cdots, \lambda_d$ such that $\lambda_1 \geq \cdots \geq \lambda_d \geq 1$ and $\sum_i \lambda_i = n$. We show that λ giving the maximum value of $f(\lambda)$ should satisfy $|\lambda_{i_1} - \lambda_{i_2}| \leq 1$ for any $1 \leq i_1 < i_2 \leq d$ by contradiction. If there exists $1 \leq i_1 < i_2 \leq d$ such that $\lambda_{i_1} \geq \lambda_{i_2} + 2$, at least one of the following conditions holds:

1. There exists $i_1' \in \{1, \cdots, d\}$ such that $\lambda_{i_1'} \geq \lambda_{i_1'+1} + 2$
2. There exists $i_1', i_2' \in \{1, \cdots, d\}$ such that $i_1' + 1 \leq i_2' - 1$, $\lambda_{i_1'} \geq \lambda_{i_1'+1} + 1$ and $\lambda_{i_2'-1} \geq \lambda_{i_2'} + 1$

If the first condition holds, we define $i_2' \coloneqq i_1' + 1$. Then, $\kappa_1, \cdots, \kappa_d$ defined by

$$\kappa_i = \begin{cases} \kappa_i & (i \neq i_1', i_2') \\ \kappa_{i_1'} - 1 & (i = i_1') \\ \kappa_{i_2'} + 1 & (i = i_2') \end{cases} \tag{253}$$

satisfies $\kappa_1 \geq \cdots \geq \kappa_d$, $\sum_i \kappa_i = n$, and

$$\frac{f(\kappa)}{f(\lambda)} = \frac{\lambda_{i_1'} + d - i_i' - 1}{\lambda_{i_1'} + d - i_1' + 1} \frac{\lambda_{i_2'} + d - i_2' + 2}{\lambda_{i_2'} + d - i_2'} > 1, \tag{254}$$

i.e., λ cannot give the maximum value of $f(\lambda)$. Therefore, the Young diagram λ giving the maximal value of $f(\lambda)$ should satisfy $|\lambda_{i_1} - \lambda_{i_2}| \leq 1$ for any $1 \leq i_1 < i_2 \leq d$. Such a Young diagram is uniquely determined as

$$\lambda_i = \begin{cases} k + 1 & (i \in \{1, \cdots, l\}) \\ k & (i \in \{l + 1, \cdots, d\}) \end{cases}, \tag{255}$$

where $k \in \mathbb{Z}$ and $l \in \{0, \cdots, d - 1\}$ are defined by $n = kd + l$. Then, we obtain

$$\alpha_{\mathrm{opt}}^{(\mathrm{PAR})} = 1 - \max_{\lambda \in \mathbb{Y}_n^d} f(\lambda) = \frac{1}{d + k + 1} \left(d + \frac{d - l}{d + k - l} \right). \tag{256}$$

B.3 Proof of Theorem 14: Asymptotically optimal parallel protocol for isometry adjointation

For $d=2$, Refs. [55, 57] present the maximum-likelihood qubit-unitary estimation protocol achieving the entanglement fidelity $F_{\mathrm{est}} = 1 - O(n^{-2})$ using n calls of input unitary operation. Although Refs. [55, 57] do not present the explicit form of the probe state, one can utilize the resource state for entanglement-assisted alignment of the reference frames presented in Ref. [56] to achieve the same asymptotic scaling of the entanglement fidelity $F_{\mathrm{est}} = 1 - O(n^{-2})$. The resource state presented in Ref. [56] is given by

$$|\phi\rangle = \frac{2}{\sqrt{n+3}} \sum_{j=0(1/2)}^{n/2} \frac{1}{\sqrt{2j+1}} \sin\frac{(2j+1)\pi}{n+3} \sum_{m=-j}^{j} |jm\rangle_{\mathcal{I}^n} |jm\rangle_{\mathcal{A}}, \tag{257}$$

where j and m represents total angular momentum and z-component of total angular momentum of a n-qubit system. The summation of j starts from 0 if n is even and $1/2$ if n is odd. These values correspond to the Schur basis, where j corresponds to the Young diagram λ whose number of boxes in i-th row, denoted by λ_i ($i = 1, 2$), is determined by $j = (\lambda_1 - \lambda_2)/2$, and m corresponds to an element in $\mathcal{U}_\lambda^{(2)}$. Then, the value α_ϕ shown in Theorem 6 is calculated as

$$\alpha_\phi = \frac{4}{n+3} \sum_{j=0(1/2)}^{n/2} \sin^2\frac{(2j+1)\pi}{n+3} \left[1 - \frac{(\frac{n}{2}+j+1)(\frac{n}{2}-j)}{(\frac{n}{2}+j+2)(\frac{n}{2}-j+1)}\right]. \tag{258}$$

To evaluate α_ϕ in the asymptotic limit $n \to \infty$, we introduce the variable $x = \frac{2j}{n}$ and approximate the sum in Eq. (258) by the integral over x as

$$\begin{aligned} \alpha_\phi &= \frac{4}{n+3} \int_0^1 \mathrm{d}x \frac{n}{2} \sin^2\frac{(x+\frac{1}{n})\pi}{1+\frac{3}{n}} \left[1 - \frac{(1+x+\frac{2}{n})(1-x)}{(1+x+\frac{4}{n})(1-x+\frac{2}{n})}\right] + O(n^{-2}) && (259)\\ &= \frac{8}{n} \int_0^1 \mathrm{d}x \frac{\sin^2(x\pi)}{1-x^2} + O(n^{-2}) && (260)\\ &\approx \frac{6.2287}{n} + O(n^{-2}), && (261) \end{aligned}$$

where the integral is evaluated by Mathematica [75]. Thus, utilizing this estimation method to construct the parallel isometry adjointation protocol, one can achieve

$$\epsilon = \max\{\alpha_\phi, 1 - F_{\mathrm{est}}\} = \frac{6.2287}{n} + O(n^{-2}). \tag{262}$$

For a higher-dimension $d > 2$, Ref. [14] presents an asymptotically optimal unitary estimation protocol achieving the entanglement fidelity $F_{\mathrm{est}} = 1 - O(d^4 n^{-2})$. This protocol utilizes the probe state given by

$$|\phi\rangle = \sum_{\lambda \in \mathrm{S}_{\mathrm{young}}} \sqrt{\frac{q_\lambda}{d_\lambda m_\lambda^{(d)}}} \sum_{i=1}^{d_\lambda} \sum_{u=1}^{m_\lambda^{(d)}} (|\lambda, i\rangle_{\mathcal{S}_\lambda} \otimes |\lambda, u\rangle_{\mathcal{U}_\lambda^{(d)}})_{\mathcal{I}^n} \otimes (|\lambda, i\rangle_{\mathcal{S}_\lambda} \otimes |\lambda, u\rangle_{\mathcal{U}_\lambda^{(d)}})_{\mathcal{A}}, \tag{263}$$

where $\{q_\lambda\}$ is a probability distribution over the set $\mathrm{S}_{\mathrm{young}} \subset \mathbb{Y}_n^d$ defined by

$$\begin{aligned} \mathrm{S}_{\mathrm{young}} := \{\lambda \in \mathbb{Y}_n^d | \lambda_i = \mu_{0,i} + N(2d-3) + 1 - (N+1)(i-1) + \tilde{\lambda}_i \\ \forall i \leq d-1, \exists \tilde{\lambda} \in \{0, \cdots, N-1\}^{d-1}\}. \end{aligned} \tag{264}$$

Here, λ_i represents the number of boxes in the i-th row of λ, N is defined by $N := \lfloor \frac{1}{3d-2}(\frac{2n}{d-1} + d - 2)\rfloor$, $\mu_{0,i}$ is defined by $\mu_{0,i} := \lfloor \frac{n_0}{d} \rfloor + 1$ for $i \in \{1, \cdots, n_0 - \lfloor \frac{n_0}{d} \rfloor d\}$ and $\mu_{0,i} := \lfloor \frac{n_0}{d} \rfloor$ for $i \in \{n_0 - \lfloor \frac{n_0}{d} \rfloor d + 1, \cdots, d\}$, and n_0 is defined by $n_0 := n - \frac{((3d-2)N-d+2)(d-1)}{2}$. Then, the value α_ϕ shown in Theorem 6 is evaluated as

$$\alpha_\phi = \sum_{\lambda \in \mathbb{S}_{\mathrm{young}}} q_\lambda \left[1 - \sum_{\mu \in \lambda + \square \setminus \mathbb{Y}^d_{n+1}} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\mu)}\right] \tag{265}$$

$$= \sum_{\lambda \in \mathbb{S}_{\mathrm{young}}} q_\lambda \left[1 - \prod_{i=1}^{d} \frac{\lambda_i + d - i}{\lambda_i + d - i + 1}\right]. \tag{266}$$

We evaluate α_ϕ in the asymptotic limit $n \to \infty$. In this region, λ_i is given by

$$\lambda_i = \frac{4n}{3d} - \frac{2n}{3d^2}(i-1) + O(d, d^{-2}n). \tag{267}$$

Thus, α_ϕ is evaluated as follows.

$$\alpha_\phi = 1 - \prod_{i=1}^{d} \left[1 - \frac{3d}{2n} \frac{1 + O(d^2 n^{-1}, d^{-1})}{2 - \frac{i-1}{d}}\right] \tag{268}$$

$$= \frac{3d}{2n} \sum_{i=1}^{d} \frac{1}{2 - \frac{i-1}{d}} + O(d^4 n^{-2}, dn^{-1}). \tag{269}$$

$$= \frac{3d^2}{2n} \int_0^1 \frac{\mathrm{d}x}{2-x} + O(d^4 n^{-2}, dn^{-1}) \tag{270}$$

$$= \frac{3 \ln 2}{2} \frac{d^2}{n} + O(d^4 n^{-2}, dn^{-1}). \tag{271}$$

Thus, utilizing this estimation method to construct the parallel isometry adjointation protocol, one can achieve

$$\epsilon = \max\{\alpha_\phi, 1 - F_{\mathrm{est}}\} = \frac{3 \ln 2}{2} \frac{d^2}{n} + O(d^4 n^{-2}, dn^{-1}). \tag{272}$$

C Proof of Theorem 10: Optimal construction of isometry inversion, universal error detection, and isometry adjointation protocols

We show Theorem 10 by constructing the parallel or sequential protocol for isometry inversion, universal error detection, and isometry adjointation in the forms shown in Theorems 5 and 6 and Corollaries 7 and 8 achieving the optimal performances among parallel or sequential protocols. To this end, we utilize Theorem 9 to write down the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetric Choi operators of parallel or sequential protocols achieving the optimal performances. Then we construct the protocols in the forms shown in Theorems 5 and 6 and Corollaries 7 and 8 by constructing the corresponding Choi operators.

Suppose $\mathcal{I}_1 = \cdots = \mathcal{I}_n = \mathcal{F} = \mathbb{C}^d$, $\mathcal{O}_1 = \cdots = \mathcal{O}_n = \mathcal{P} = \mathbb{C}^D$, $\mathcal{O}'_1 = \cdots = \mathcal{O}'_n = \mathcal{P}' = \mathbb{C}^d$, and we define the joint Hilbert spaces $\mathcal{I}^n := \bigotimes_{i=1}^n \mathcal{I}_i$, $\mathcal{O}^n := \bigotimes_{i=1}^n \mathcal{O}_i$, and $\mathcal{O}'^n := \bigotimes_{i=1}^n \mathcal{O}'_i$. We assume that

$$C \in \begin{cases} \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}) & \text{(isometry inversion, isometry adjointation)} \\ \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P}) & \text{(universal error detection)} \end{cases} \tag{273}$$

is the Choi operator satisfying the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry (320), which can be written as Eqs. (321) or (322) using $\{C_{\mu\nu}\}$ or $\{C_{\lambda\nu}\}$. If C is the Choi operator of parallel or sequential protocol, i.e., $C \in \mathcal{W}^{(x)}$ for $x \in \{\mathrm{PAR}, \mathrm{SEQ}\}$, the Choi operator

$$C' \in \begin{cases} \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}'^n \otimes \mathcal{P}' \otimes \mathcal{F}) & \text{(isometry inversion, isometry adjointation)} \\ \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}'^n \otimes \mathcal{P}') & \text{(universal error detection)} \end{cases} \tag{274}$$

defined by

$$C' \coloneqq \sum_{\mu \in \mathbb{Y}_{n+1}^d} \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{i,j=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \frac{[C_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)} m_\nu^{(D)}} (E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}} \otimes (E_{kl}^{\nu,d})_{\mathcal{P}'\mathcal{O}'^n} \tag{275}$$

for isometry inversion or isometry adjointation, and

$$C' \coloneqq \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} \frac{[C_{\lambda\nu}]_{ak,bl}}{m_\lambda^{(d)} m_\nu^{(D)}} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,d})_{\mathcal{P}'\mathcal{O}'^n} \tag{276}$$

for universal error detection, satisfies $C' \in \mathcal{W}^{(x)}$ [see Eqs. (330) and (331)]. We utilize this fact to show the construction of the protocols in the forms shown in Theorems 5 and 6 and Corollaries 7 and 8.

C.1 Probabilistic exact isometry inversion

Assume that $\{C_S, C_F\} \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ is the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetric Choi operator of parallel ($x = \mathrm{PAR}$) or sequential ($x = \mathrm{SEQ}$) protocol achieving the optimal success probability $p_{\mathrm{opt}}^{(x)}(d, D, n)$ of isometry inversion, which can be written as Eqs. (403) and (404). Defining $\{C'_S, C'_F\} \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}'^n \otimes \mathcal{P}' \otimes \mathcal{F})$ by

$$C'_S = \sum_{\mu \in \mathbb{Y}_{n+1}^d} \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{i,j=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \frac{[S_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)} m_\nu^{(D)}} (E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}} \otimes (E_{kl}^{\nu,d})_{\mathcal{P}'\mathcal{O}'^n}, \tag{277}$$

$$C'_F = \sum_{\mu \in \mathbb{Y}_{n+1}^d} \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{i,j=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \frac{[F_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)} m_\nu^{(D)}} (E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}} \otimes (E_{kl}^{\nu,d})_{\mathcal{P}'\mathcal{O}'^n}, \tag{278}$$

$C'_S, C'_F \geq 0$ and $C' \coloneqq C'_S + C'_F \in \mathcal{W}^{(x)}$ holds. Thus, the corresponding supermap $\{\mathcal{C}_S, \mathcal{C}_F\}$ can be implemented in a parallel ($x = \mathrm{PAR}$) or sequential ($x = \mathrm{SEQ}$) protocol. In particular for the case $x = \mathrm{PAR}$, since its Choi operator satisfies the $\mathbb{U}(d) \times \mathbb{U}(d)$ symmetry, it can be implemented using a delayed input-state protocol [27, 28]. Since $\{C_S, C_F\}$ achieves the optimal success probability $p_{\mathrm{opt}}^{(x)}(d, D, n)$, it satisfies [see Eq. (402)]

$$\mathrm{Tr}(C_S \Omega) = p_{\mathrm{opt}}^{(x)}(d, D, n), \tag{279}$$

$$\mathrm{Tr}(C_S \Omega) = \mathrm{Tr}[C_S(\Xi \otimes \mathbb{1}_{\mathcal{F}})]. \tag{280}$$

Defining Ω' and Ξ' by replacing $\mathcal{P}\mathcal{O}^n$ and D in Eqs. (394) and (396) with $\mathcal{P}'\mathcal{O}'^n$ and d, respectively, $\{C'_S, C'_F\}$ satisfies

$$\mathrm{Tr}(C'_S \Omega') = p_{\mathrm{opt}}^{(x)}(d, D, n), \tag{281}$$

$$\mathrm{Tr}(C'_S \Omega') = \mathrm{Tr}[C'_S(\Xi' \otimes \mathbb{1}_{\mathcal{F}})], \tag{282}$$

which implies $\{C'_S, C'_F\}$ implements probabilistic exact d-dimensional unitary inversion with success probability $p_{\mathrm{opt}}^{(x)}(d, D, n)$. Therefore, we can construct a parallel or sequential protocol achieving the optimal success probability $p_{\mathrm{opt}}^{(x)}(d, D, n)$ of isometry inversion using the construction shown in Theorem 7.

C.2 Deterministic isometry inversion

Assume that $C \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ is the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetric Choi operator of parallel ($x = \text{PAR}$) or sequential ($x = \text{SEQ}$) protocol achieving the optimal worst-case channel fidelity $F_{\text{opt}}^{(x)}(d, D, n)$, which can be written as Eq. (321). Defining $C' \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}'^n \otimes \mathcal{P}' \otimes \mathcal{F})$ by Eq. (275), $C' \geq 0$ and $C' \in \mathcal{W}^{(x)}$ holds. Thus, the corresponding supermap $\mathcal{C}$ can be implemented in a parallel or sequential protocol. In particular for the case $x = \text{PAR}$, since its Choi operator satisfies the $\mathbb{U}(d) \times \mathbb{U}(d)$ symmetry, it can be implemented using an estimation-based protocol [29]. Since C achieves the optimal worst-case channel fidelity $F_{\text{opt}}^{(x)}(d, D, n)$, it satisfies [see Eq. (410)]

$$\operatorname{Tr}(C\Omega) = F_{\text{opt}}^{(x)}(d, D, n). \tag{283}$$

Defining Ω' by replacing $\mathcal{P}\mathcal{O}^n$ and D in Eq. (394) with $\mathcal{P}'\mathcal{O}'^n$ and d, respectively, C' satisfies

$$\operatorname{Tr}(C'\Omega') = F_{\text{opt}}^{(x)}(d, D, n), \tag{284}$$

which implies C' implements deterministic d-dimensional unitary inversion with worst-case channel fidelity $p_{\text{opt}}^{(x)}(d, D, n)$. Therefore, we can construct a parallel or sequential protocol achieving the optimal worst-case channel fidelity $F_{\text{opt}}^{(x)}(d, D, n)$ of isometry inversion using the construction shown in Theorem 7.

C.3 Universal error detection

Assume that $\{C_I, C_O\} \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P})$ is the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetric Choi operator of a parallel ($x = \text{PAR}$) or sequential ($x = \text{SEQ}$) protocol achieving the optimal error $\alpha_{\text{opt}}^{(x)}(d, D, n)$, which can be written as Eqs. (413) and (414). Defining $C'' \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}'^n \otimes \mathcal{P}')$ by Eq. (276) for $C_{\lambda\nu} := I_{\lambda\nu} + O_{\lambda\nu}$ for $\lambda \in \mathbb{Y}_n^d$ and $\nu \in \mathbb{Y}_{n+1}^d$, $C'' \geq 0$ and $C'' \in \mathcal{W}^{(x)}$ hold. Characterization of $\mathcal{W}^{(x)}$ shown in Eqs. (318) and (319) for the case $\mathcal{F} = \mathbb{C}$ (no global future) and the $\mathbb{U}(d) \times \mathbb{U}(d)$ symmetry of C'' implies that C'' can be written as

$$C'' = \begin{cases} \phi_{\mathcal{I}^n} \otimes \mathbb{1}_{\mathcal{P}'\mathcal{O}'^n} & (x = \text{PAR}), \\ C' \otimes \mathbb{1}_{\mathcal{O}_n} & (x = \text{SEQ}), \end{cases} \tag{285}$$

where $\phi \in \mathcal{L}(\mathcal{I}^n)$ is a quantum state and $C' \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}'^{n-1} \otimes \mathcal{P}')$ is the Choi operator of a $(n-1)$-slot sequential protocol. Since $\{C_I, C_O\}$ achieves the optimal error $\alpha_{\text{opt}}^{(x)}(d, D, n)$, it satisfies [see Eq.(412)]

$$\operatorname{Tr}(C_I\Sigma) = \alpha_{\text{opt}}^{(x)}(d, D, n), \tag{286}$$

$$\operatorname{Tr}(C_I\Xi) = 1. \tag{287}$$

Since Eq. (287) corresponds to the condition

$$\operatorname{Tr}\, \mathcal{C}_I(\mathcal{V}_{\text{in}}^{\otimes n})(\rho_{\text{in}}) = 1 \quad \forall \rho_{\text{in}} \in \mathcal{L}(\operatorname{Im} V_{\text{in}}), \tag{288}$$

it can be replaced with the equivalent condition

$$\operatorname{Tr}\, \mathcal{C}_O(\mathcal{V}_{\text{in}}^{\otimes n})(\rho_{\text{in}}) = 0 \quad \forall \rho_{\text{in}} \in \mathcal{L}(\operatorname{Im} V_{\text{in}}), \tag{289}$$

which can be represented as

$$\mathrm{Tr}(C_O \Xi) = 0. \tag{290}$$

Therefore, we obtain [see Eq. (396)]

$$0 = \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \mathbb{Y}_{n+1}^d} \mathrm{Tr}(O_{\lambda\nu} \Xi_{\lambda\nu}) \tag{291}$$

$$= \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{\lambda \in \nu - \square} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} \frac{m_\nu^{(d)}}{d m_\nu^{(D)} m_\lambda^{(d)}} [\pi_\nu]^*_{a_\nu^\lambda k} [\pi_\nu]_{l b_\nu^\lambda} [O_{\lambda\nu}]_{ba,lk}, \tag{292}$$

which leads to

$$\sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} [\pi_\nu]^*_{a_\nu^\lambda k} [\pi_\nu]_{l b_\nu^\lambda} [O_{\lambda\nu}]_{ba,lk} = 0 \quad \forall \nu \in \mathbb{Y}_{n+1}^d, \lambda \in \nu - \square. \tag{293}$$

Thus, we obtain [see Eq. (401)]

$$\mathrm{Tr}(O_{\lambda\nu} \Sigma_{\lambda\nu}) = 0 \quad \forall \nu \in \mathbb{Y}_{n+1}^d, \lambda \in \nu - \square. \tag{294}$$

Since Eq. (401) reduces to Σ defined in Eq. (74) by replacing $\mathcal{P}\mathcal{O}^n$ and D with $\mathcal{P}'\mathcal{O}'^n$ and d,

$$\mathrm{Tr}(C''\Sigma) = \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{\lambda \in \nu - \square} \mathrm{Tr}(C_{\lambda\nu} \Sigma_{\lambda\nu}) \tag{295}$$

$$= \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{\lambda \in \nu - \square} \mathrm{Tr}(I_{\lambda\nu} \Sigma_{\lambda\nu}) \tag{296}$$

$$\leq \mathrm{Tr}(C_I \Sigma) \tag{297}$$

$$= \alpha_{\mathrm{opt}}^{(x)} \tag{298}$$

holds. Substituting Eq. (285) for $x = \mathrm{PAR}, \mathrm{SEQ}$ to Eq. (298), we obtain

$$\alpha_{\mathrm{opt}}^{(\mathrm{PAR})} \geq \mathrm{Tr}(\phi \, \mathrm{Tr}_{\mathcal{P}'\mathcal{O}'^n}(\Sigma)) \tag{299}$$

$$= \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \lambda + \square \cap \mathbb{Y}_{n+1}^d} \mathrm{Tr}\left(\phi \Pi_\lambda^{(d)}\right) \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\nu)} \tag{300}$$

$$= \alpha_\phi, \tag{301}$$

$$\alpha_{\mathrm{opt}}^{(\mathrm{SEQ})} \geq \mathrm{Tr}(C' \, \mathrm{Tr}_{\mathcal{O}'_n}(\Sigma)) \tag{302}$$

$$= \mathrm{Tr}(C'\Sigma') \tag{303}$$

$$= \alpha_{C'}, \tag{304}$$

where α_ϕ and $\alpha_{C'}$ are defined in Theorem 8, respectively. Thus, the parallel and sequential protocols constructed in Theorem 8 achieves the optimal error $\alpha_{\mathrm{opt}}^{(x)}(d, D, n)$.

C.4 Isometry adjointation

Assume that $\{C_I, C_O\} \subset \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$ is the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetric Choi operator of parallel ($x = \mathrm{PAR}$) or sequential ($x = \mathrm{SEQ}$) protocol achieving the optimal worst-case diamond-norm error $\epsilon_{\mathrm{opt}}^{(x)}(d, D, n)$ of isometry adjointation, which can be written as

Eqs. (419) and (420). Defining $C' \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}'^n \otimes \mathcal{P}' \otimes \mathcal{F})$ by Eq. (275) for $C_{\mu\nu} := I_{\mu\nu} + O_{\mu\nu}$ for $\mu, \nu \in \mathbb{Y}_{n+1}^d$, $C' \geq 0$ and $C' \in \mathcal{W}^{(x)}$ hold. Thus, the corresponding supermap $\mathcal{C}''$ can be implemented by a parallel ($x = \mathrm{PAR}$) or sequential ($x = \mathrm{SEQ}$) protocol. In particular, for the case $x = \mathrm{PAR}$, since its Choi operator satisfies the $\mathbb{U}(d) \times \mathbb{U}(d)$ symmetry, it can be implemented using a covariant-estimation-based protocol as shown in Fig. 4 (a-1) [14, 29]. Since $\{C_I, C_O\}$ achieves the optimal worst-case diamond-norm error $\epsilon_{\mathrm{opt}}^{(x)}(d, D, n)$ of isometry adjointation, it satisfies [see Eq. (418)]

$$1 - \mathrm{Tr}(C_I \Omega) \leq \epsilon_{\mathrm{opt}}^{(x)}(d, D, n), \tag{305}$$

$$\mathrm{Tr}[C_I(\Sigma \otimes \mathbb{1}_{\mathcal{F}})] \leq \epsilon_{\mathrm{opt}}^{(x)}(d, D, n), \tag{306}$$

$$\mathrm{Tr}[C_I(\Xi \otimes \mathbb{1}_{\mathcal{F}})] = 1. \tag{307}$$

Similarly to Sections C.2 and C.3, defining Ω' by replacing $\mathcal{P}\mathcal{O}^n$ and D in Eq. (394) with $\mathcal{P}'\mathcal{O}'^n$ and d, we obtain

$$1 - \mathrm{Tr}(C' \Omega') \leq \epsilon_{\mathrm{opt}}^{(x)}(d, D, n), \tag{308}$$

$$\mathrm{Tr}[C'(\Sigma \otimes \mathbb{1}_{\mathcal{F}})] \leq \epsilon_{\mathrm{opt}}^{(x)}(d, D, n). \tag{309}$$

For the case $x = \mathrm{PAR}$, C' can be implemented by a covariant unitary-estimation protocol achieving the average fidelity $F_{\mathrm{est}} = \mathrm{Tr}(C'\Omega')$ [14, 29]. $\mathrm{Tr}[C'(\Sigma \otimes \mathbb{1}_{\mathcal{F}})]$ can be evaluated by the probe state $\phi \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{A})$ of the unitary estimation protocol as

$$\begin{aligned}
\mathrm{Tr}[C'(\Sigma \otimes \mathbb{1}_{\mathcal{F}})] &= \mathrm{Tr}[\mathrm{Tr}_{\mathcal{F}}(C)\Sigma] && (310)\\
&= \mathrm{Tr}(\mathrm{Tr}_{\mathcal{A}}(\phi)\, \mathrm{Tr}_{\mathcal{P}'\mathcal{O}'^n}(\Sigma)) && (311)\\
&= \sum_{\lambda \in \mathbb{Y}_n^d} \mathrm{Tr}\left[\mathrm{Tr}_{\mathcal{A}}(\phi) \Pi_\lambda^{(d)}\right] \left[1 - \sum_{\nu \in \lambda + \square \setminus \mathbb{Y}_{n+1}^d} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\nu)}\right] && (312)\\
&= \alpha_\phi, && (313)
\end{aligned}$$

where α_ϕ is defined in Theorem 6. Thus, the parallel protocol constructed in Theorem 6 achieves the optimal worst-case diamond-norm error $\epsilon_{\mathrm{opt}}^{(\mathrm{PAR})}(d, D, n)$.

For the case $x = \mathrm{SEQ}$, $\mathrm{Tr}(C'\Omega')$ represents the worst-case channel fidelity of d-dimensional unitary inversion, and $\mathrm{Tr}[C'(\Sigma \otimes \mathbb{1}_{\mathcal{F}})]$ can be evaluated as [see Eq. (319)]

$$\begin{aligned}
\mathrm{Tr}[C'(\Sigma \otimes \mathbb{1}_{\mathcal{F}})] &= \mathrm{Tr}[\mathrm{Tr}_{\mathcal{F}}(C')\Sigma] && (314)\\
&= \alpha_{C'}, && (315)
\end{aligned}$$

where $\alpha_{C'}$ is defined in Theorem 5. Thus, the sequential protocol constructed in Theorem 5 achieves the optimal worst-case diamond-norm error $\epsilon_{\mathrm{opt}}^{(\mathrm{SEQ})}(d, D, n)$.

D Numerical results

We show the numerical results on the optimal performances of probabilistic exact isometry inversion, deterministic isometry inversion, universal error detection, and isometry adjointation using n calls of an input isometry operation $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$ with parallel, sequential, or general protocols including indefinite causal order in Tables 1, 2, 3 and 4. The obtained values are compatible with the previous works [27, 29, 30, 35], where Ref. [27] shows the maximum success probability of unitary inversion for the cases of $d = 2, n \leq 3$

and $d = 3, n \leq 2$, Ref. [29] shows the maximum channel fidelity of unitary inversion for the cases of $d = 2, n \leq 3$ and $d = 3, n \leq 2$, Ref. [27] shows the maximum success probability of isometry inversion for the cases of $d = 2, n \leq 3$ and $d = 3, n \leq 2$, and Ref. [30] shows the maximum channel fidelity of unitary inversion for parallel and sequential protocols for the cases of $d \leq 6$ and $n \leq 5$.

E Semidefinite programming to obtain the optimal transformations of isometry operations with the $\mathbb{U}(d)\times\mathbb{U}(D)$ symmetry

As shown in Theorem 9, the optimal protocols for isometry inversion, universal error detection and isometry adjointation can be searched within the Choi operators having the $\mathbb{U}(d)\times\mathbb{U}(D)$ symmetry. To utilize this symmetry for a numerical search of the optimal protocols, we derive the characterization of the quantum superchannels and the conditions for isometry inversion, universal error detection, and isometry adjointation under the $\mathbb{U}(d)\times\mathbb{U}(D)$ symmetry. Then, we derive the SDPs giving the optimal performances of these tasks, which are shown below.

E.1 Choi representation of general superchannels and $\mathbb{U}(d)\times\mathbb{U}(D)$ symmetry

As shown in Section 4.1, the Choi operator C of a quantum superchannel $\mathcal{C}:\bigotimes_{i=1}^n[\mathcal{L}(\mathcal{I}_i)\to\mathcal{L}(\mathcal{O}_i)]\to[\mathcal{L}(\mathcal{P})\to\mathcal{L}(\mathcal{F})]$ implemented by parallel ($x=\mathrm{PAR}$) and sequential ($x=\mathrm{SEQ}$) protocols, and general superchannels ($x=\mathrm{GEN}$) can be represented by a Choi operator $C\in\mathcal{L}(\mathcal{I}^n\otimes\mathcal{O}^n\otimes\mathcal{P}\otimes\mathcal{F})$ satisfying

$$C\geq 0, \tag{316}$$

$$C\in\mathcal{W}^{(x)}. \tag{317}$$

The set $\mathcal{W}^{(x)}$ for $x\in\{\mathrm{PAR},\mathrm{SEQ}\}$ are given by [27, 44]

$$C\in\mathcal{W}^{(\mathrm{PAR})}\iff\begin{cases}\mathrm{Tr}_{\mathcal{F}}\,C=\mathrm{Tr}_{\mathcal{O}^n}\,C\otimes\mathbb{1}_{\mathcal{O}^n}/\dim\mathcal{O}^n\\ \mathrm{Tr}_{\mathcal{I}^n\mathcal{O}^n}\,C=\dim\mathcal{O}^n\mathbb{1}_{\mathcal{P}}\end{cases}, \tag{318}$$

$$C\in\mathcal{W}^{(\mathrm{SEQ})}\iff\mathrm{Tr}_{\mathcal{I}_i}\,C^{(i)}=C^{(i-1)}\otimes\mathbb{1}_{\mathcal{O}_{i-1}}\quad\forall i\in\{1,\cdots,n+1\}, \tag{319}$$

where $\mathcal{O}_0$ and $\mathcal{I}_{n+1}$ are defined by $\mathcal{O}_0:=\mathcal{P}$ and $\mathcal{I}_{n+1}:=\mathcal{F}$, and $C^{(i)}$ for $i\in\{0,\cdots,n+1\}$ are defined by $C^{(n+1)}:=C$, $C^{(i-1)}:=\mathrm{Tr}_{\mathcal{O}_{i-1}\mathcal{I}_i}\,C^{(i)}/\dim\mathcal{O}_{i-1}$ and $C^{(0)}:=1$. The characterization of the set $\mathcal{W}^{(\mathrm{GEN})}$ is shown in Ref. [76].

We consider the case $\mathcal{I}_1=\cdots=\mathcal{I}_n=\mathcal{F}=\mathbb{C}^d,\mathcal{P}=\mathcal{O}_1=\cdots=\mathcal{O}_n=\mathbb{C}^D$ (isometry inversion, isometry adjointation) and $\mathcal{I}_1=\cdots=\mathcal{I}_n=\mathbb{C}^d,\mathcal{P}=\mathcal{O}_1=\cdots=\mathcal{O}_n=\mathbb{C}^D,\mathcal{F}=\mathbb{C}$ (universal error detection), and characterize the Choi operator $C\in\mathcal{L}(\mathcal{I}^n\otimes\mathcal{O}^n\otimes\mathcal{P}\otimes\mathcal{F})$ under the $\mathbb{U}(d)\times\mathbb{U}(D)$ symmetry given by

$$\begin{cases}[C,U_{\mathcal{I}^n\mathcal{F}}^{\otimes n+1}\otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}]=0 & \text{(isometry inversion, isometry adjointation)}\\ [C,U_{\mathcal{I}^n}^{\otimes n}\otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}]=0 & \text{(universal error detection)}\end{cases} \tag{320}$$

for all $U\in\mathbb{U}(d)$ and $U'\in\mathbb{U}(D)$ (see Theorem 9). Due to this symmetry, the Choi operator C can be written using the operator $E_{ij}^{\mu,d}$ introduced in Eq. (54) as

$$C=\sum_{\mu\in\mathbb{Y}_{n+1}^d}\sum_{\nu\in\mathbb{Y}_{n+1}^D}\sum_{i,j=1}^{d_\mu}\sum_{k,l=1}^{d_\nu}\frac{[C_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)}m_\nu^{(D)}}(E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}}\otimes(E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n} \tag{321}$$

for isometry inversion or isometry adjointation, and

$$C=\sum_{\lambda\in\mathbb{Y}_n^d}\sum_{\nu\in\mathbb{Y}_{n+1}^D}\sum_{a,b=1}^{d_\lambda}\sum_{k,l=1}^{d_\nu}\frac{[C_{\lambda\nu}]_{ak,bl}}{m_\lambda^{(d)}m_\nu^{(D)}}(E_{ab}^{\lambda,d})_{\mathcal{I}^n}\otimes(E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n} \tag{322}$$

for universal error detection using a $d_\mu d_\nu$ ($d_\lambda d_\nu$)-dimensional square matrix $C_{\mu\nu}$ ($C_{\lambda\nu}$), where ik (ak) and jl (bl) are the indices for row and column numbers, respectively. The characterization of quantum superchannels is rewritten in terms of $C_{\mu\nu}$ or $C_{\lambda\nu}$ as follows. By definition of $E^{\mu,d}_{ij}$ in Eq. (54), the positivity of C is written as

$$\begin{cases} C_{\mu\nu} \geq 0 \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1} & \text{(isometry inversion, isometry adjointation)} \\ C_{\lambda\nu} \geq 0 \quad \forall \lambda \in \mathbb{Y}^d_n, \nu \in \mathbb{Y}^D_{n+1} & \text{(universal error detection)} \end{cases}. \tag{323}$$

Using Lemma 3, the condition $C \in \mathcal{W}^{(x)}$ for $x \in \{\mathrm{PAR}, \mathrm{SEQ}\}$ is given by

$$C \in \mathcal{W}^{(x)} \iff \begin{cases} \{C_{\mu\nu}\} \in \mathcal{W}^{(x)}_{\mathrm{sym}} & \text{(isometry inversion, isometry adjointation)} \\ \{C_{\lambda\nu}\} \in \mathcal{W}^{(x)}_{\mathrm{sym}} & \text{(universal error detection)} \end{cases}, \tag{324}$$

where $\mathcal{W}^{(x)}_{\mathrm{sym}}$ is given by

$$\{C_{\mu\nu}\} \in \mathcal{W}^{(\mathrm{PAR})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \displaystyle\sum_{\mu \in \lambda + \square} (X^\lambda_\mu \otimes \mathbb{1}_{d_\nu}) \frac{C_{\mu\nu}}{m^{(D)}_\nu} (X^\lambda_\mu \otimes \mathbb{1}_{d_\nu})^\dagger = D_\lambda \otimes \frac{\mathbb{1}_{d_\nu}}{D^{n+1}} \quad \forall \lambda \in \mathbb{Y}^d_n, \nu \in \mathbb{Y}^D_{n+1} \\ \displaystyle\sum_{\mu \in \mathbb{Y}^d_{n+1}} \sum_{\nu \in \mathbb{Y}^D_{n+1}} \mathrm{Tr}(C_{\mu\nu}) = D^{n+1} \end{cases}, \tag{325}$$

$$\{C_{\mu\nu}\} \in \mathcal{W}^{(\mathrm{SEQ})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \displaystyle\sum_{\lambda \in \gamma + \square} (X^\gamma_\lambda \otimes \mathbb{1}_{d_\kappa}) \frac{C^{(i)}_{\lambda\kappa}}{m^{(D)}_\kappa} (X^\gamma_\lambda \otimes \mathbb{1}_{d_\kappa})^\dagger = \sum_{\delta \in \kappa - \square} (\mathbb{1}_{d_\gamma} \otimes X^\delta_\kappa)^\dagger \frac{C^{(i-1)}_{\gamma\delta}}{m^{(D)}_\delta} (\mathbb{1}_{d_\gamma} \otimes X^\delta_\kappa) \\ \qquad\qquad\qquad\qquad\qquad\qquad \forall i \in \{1, \cdots, n+1\}, \gamma \in \mathbb{Y}^d_{i-1}, \kappa \in \mathbb{Y}^D_i \\ C^{(0)}_{\emptyset\emptyset} = 1 \end{cases} \tag{326}$$

for isometry inversion and isometry adjointation, where D_λ for $\lambda \in \mathbb{Y}^d_n$ are defined by

$$D_\lambda := \sum_{\mu \in \lambda + \square} \sum_{\nu \in \mathbb{Y}^D_{n+1}} \mathrm{Tr}_\nu[(X^\lambda_\mu \otimes \mathbb{1}_{d_\nu}) C_{\mu\nu} (X^\lambda_\mu \otimes \mathbb{1}_{d_\nu})^\dagger] \tag{327}$$

$C^{(i)}_{\lambda\kappa}$ for $\lambda \in \mathbb{Y}^d_i, \kappa \in \mathbb{Y}^D_i$ are defined by

$$C^{(i)}_{\lambda\kappa} := \begin{cases} C_{\lambda\kappa} & (i = n+1) \\ \frac{1}{D} \sum_{\mu \in \lambda + \square, \nu \in \kappa + \square} (X^\lambda_\mu \otimes X^\kappa_\nu) C^{(i+1)}_{\mu\nu} (X^\lambda_\mu \otimes X^\kappa_\nu)^\dagger & (0 \leq i \leq n) \end{cases}, \tag{328}$$

X^γ_λ for $\lambda \in \gamma + \square, \gamma \in \mathbb{Y}^d_{i-1}$ are $d_\gamma \times d_\lambda$ matrices defined by

$$[X^\gamma_\lambda]_{c,a} := \delta_{c^\gamma_\lambda, a}, \tag{329}$$

c^γ_λ is the index of the standard tableau $s^\lambda_{c^\gamma_\lambda}$ obtained by adding a box $\boxed{i}$ to the standard tableau s_c^γ, and $\emptyset$ represents the Young tableau with zero boxes. The set $\mathcal{W}_{\mathrm{sym}}^{(x)}$ is given by

$$\{C_{\lambda\nu}\} \in \mathcal{W}_{\mathrm{sym}}^{(\mathrm{PAR})} \iff$$
$$\begin{cases} \dfrac{C_{\lambda\nu}}{m_\nu^{(D)}} = D_\lambda \otimes \dfrac{\mathbb{1}_{d_\nu}}{D^{n+1}} \quad \forall\lambda \in \mathbb{Y}_n^d, \nu \in \mathbb{Y}_{n+1}^D \\ \displaystyle\sum_{\lambda\in\mathbb{Y}_{n+1}^d} \sum_{\nu\in\mathbb{Y}_{n+1}^D} \mathrm{Tr}(C_{\lambda\nu}) = D^n \end{cases}, \tag{330}$$

$$\{C_{\lambda\nu}\} \in \mathcal{W}_{\mathrm{sym}}^{(\mathrm{SEQ})} \iff$$
$$\begin{cases} \dfrac{C_{\lambda\nu}}{m_\nu^{(D)}} = \displaystyle\sum_{\kappa\in\nu-\square} (\mathbb{1}_{d_\lambda} \otimes X_\nu^\kappa)^\dagger \frac{C_{\lambda\kappa}^{(n)}}{m_\kappa^{(D)}} (\mathbb{1}_{d_\lambda} \otimes X_\nu^\kappa) \quad \forall\lambda \in \mathbb{Y}_n^d, \nu \in \mathbb{Y}_{n+1}^D \\ \displaystyle\sum_{\lambda\in\gamma+\square} (X_\lambda^\gamma \otimes \mathbb{1}_{d_\kappa}) \frac{C_{\lambda\kappa}^{(i)}}{m_\kappa^{(D)}} (X_\lambda^\gamma \otimes \mathbb{1}_{d_\kappa})^\dagger = \sum_{\delta\in\kappa-\square} (\mathbb{1}_{d_\nu} \otimes X_\kappa^\delta)^\dagger \frac{C_{\gamma\delta}^{(i-1)}}{m_\delta^{(D)}} (\mathbb{1}_{d_\nu} \otimes X_\kappa^\delta) \\ \qquad\qquad\qquad\qquad\qquad\qquad \forall i \in \{1, \cdots, n\}, \gamma \in \mathbb{Y}_{i-1}^d, \kappa \in \mathbb{Y}_i^D \\ C_{\emptyset\emptyset}^{(0)} = 1 \end{cases} \tag{331}$$

for universal error detection, where D_λ for $\lambda \in \mathbb{Y}_n^d$ are defined by

$$D_\lambda \coloneqq \sum_{\nu\in\mathbb{Y}_{n+1}^D} \mathrm{Tr}_\nu(C_{\lambda\nu}), \tag{332}$$

$C_{\lambda\kappa}^{(i)}$ for $\lambda \in \mathbb{Y}_i^d, \kappa \in \mathbb{Y}_i^D$ are defined by

$$C_{\lambda\kappa}^{(i)} \coloneqq \begin{cases} \frac{1}{D} \sum_{\nu\in\kappa+\square} (\mathbb{1}_{d_\lambda} \otimes X_\nu^\kappa) C_{\lambda\nu} (\mathbb{1}_{d_\lambda} \otimes X_\nu^\kappa)^\dagger & (i = n) \\ \frac{1}{D} \sum_{\mu\in\lambda+\square, \nu\in\kappa+\square} (X_\mu^\lambda \otimes X_\nu^\kappa) C_{\mu\nu}^{(i+1)} (X_\mu^\lambda \otimes X_\nu^\kappa)^\dagger & (0 \leq i \leq n-1) \end{cases}, \tag{333}$$

and X_λ^γ are defined in Eq. (329).

E.2 Conditions for isometry inversion, universal error detection, and isometry adjointation under the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry

We consider the action of a supermap $\mathcal{C}$ on n calls of an isometry operation $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$ when its Choi operator C satisfies the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry (320). Then, $\mathcal{C}(\mathcal{V}_{\mathrm{in}}^{\otimes n})$ is given in the following form.

Lemma 15. *If the Choi operator of a quantum supermap $\mathcal{C}$, denoted by C, satisfies the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry (320), then $\mathcal{C}(\mathcal{V}_{\mathrm{in}}^{\otimes n})$ for $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$ is given by*

$$\mathcal{C}(\mathcal{V}_{\mathrm{in}}^{\otimes n})(\rho_{\mathrm{in}}) = \begin{cases} x V_{\mathrm{in}}^\dagger \rho_{\mathrm{in}} V_{\mathrm{in}} + \dfrac{\mathbb{1}_{\mathcal{F}}}{d} \mathrm{Tr}[\rho_{\mathrm{in}}(y \Pi_{\mathrm{Im}V_{\mathrm{in}}} + z(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}}))] \\ \qquad\qquad\qquad\qquad (\text{isometry inversion, isometry adjointation}) \\ \mathrm{Tr}[\rho_{\mathrm{in}}(v \Pi_{\mathrm{Im}V_{\mathrm{in}}} + w(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}}))] \qquad (\text{universal error detection}) \end{cases} \tag{334}$$

for all $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$ and $\rho_{\mathrm{in}} \in \mathcal{L}(\mathbb{C}^d)$, where $\Pi_{\mathrm{Im}V_{\mathrm{in}}}$ and $(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})$ are orthogonal projectors onto the image $\mathrm{Im}V_{\mathrm{in}}$ of V_{in} and its complement $(\mathrm{Im}V_{\mathrm{in}})^\perp$, and $x, y, z, v, w \in \mathbb{C}$ are constant numbers given by

$$x \coloneqq \frac{1}{d^2 - 1} \mathrm{Tr}\Big[C(d^2\Omega - \Xi \otimes \mathbb{1}_{\mathcal{F}})\Big], \tag{335}$$

$$y \coloneqq \frac{d^2}{d^2 - 1} \mathrm{Tr}[C(\Xi \otimes \mathbb{1}_{\mathcal{F}} - \Omega)], \tag{336}$$

$$z \coloneqq \mathrm{Tr}[C(\Sigma \otimes \mathbb{1}_{\mathcal{F}})], \tag{337}$$

for isometry inversion and isometry adjointation, and

$$v := \mathrm{Tr}(C\Xi), \tag{338}$$

$$w := \mathrm{Tr}(C\Sigma), \tag{339}$$

for universal error detection, Ω, Ξ, Σ are defined by

$$\Omega := \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{i,j,k,l=1}^{d_\mu} [\Omega_\mu]_{ik,jl} (E^{\mu,d}_{ij})_{\mathcal{I}^n\mathcal{F}} \otimes (E^{\mu,D}_{kl})_{\mathcal{P}\mathcal{O}^n}, \tag{340}$$

$$\Xi := \sum_{\lambda\in\mathbb{Y}^d_n} \sum_{\nu\in\lambda+\square\cap\mathbb{Y}^d_{n+1}} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} [\Xi_{\lambda\nu}]_{ak,bl} (E^{\lambda,d}_{ab})_{\mathcal{I}^n} \otimes (E^{\nu,D}_{kl})_{\mathcal{P}\mathcal{O}^n} \tag{341}$$

$$\Sigma := \sum_{\lambda\in\mathbb{Y}^d_n} \sum_{\nu\in\lambda+\square} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} [\Sigma_{\lambda\nu}]_{ak,bl} (E^{\lambda,d}_{ab})_{\mathcal{I}^n} \otimes (E^{\nu,D}_{kl})_{\mathcal{P}\mathcal{O}^n}, \tag{342}$$

and $\Omega_\mu \in \mathcal{L}(\mathbb{C}^{d_\mu} \otimes \mathbb{C}^{d_\mu})$ and $\Xi_{\lambda\nu}, \Sigma_{\lambda\nu} \in \mathcal{L}(\mathbb{C}^{d_\lambda} \otimes \mathbb{C}^{d_\nu})$ are defined by

$$[\Omega_\mu]_{ik,jl} := \frac{[\pi_\mu]^*_{ik}[\pi_\mu]_{lj}}{d^2 m^{(D)}_\mu}, \tag{343}$$

$$[\Xi_{\lambda\nu}]_{ak,bl} := \frac{m^{(d)}_\nu}{d m^{(D)}_\nu m^{(d)}_\lambda} [\pi_\nu]^*_{a^\lambda_\nu k} [\pi_\nu]_{l b^\lambda_\nu}, \tag{344}$$

$$[\Sigma_{\lambda\nu}]_{ak,bl} := \frac{1}{D-d}\left[\frac{1}{m^{(D)}_\lambda} - \delta_{\nu\in\mathbb{Y}^D_{n+1}} \frac{m^{(d)}_\nu}{m^{(D)}_\nu m^{(d)}_\lambda}\right] [\pi_\nu]^*_{a^\lambda_\nu k} [\pi_\nu]_{l b^\lambda_\nu}, \tag{345}$$

where $[\pi_\mu]_{ij}$ are matrix elements of the irreducible representation π_μ for $\pi := (12\cdots n+1) \in \mathfrak{S}_{n+1}$ shown in Eq. (49) defined by $[\pi_\mu]_{ij} := \langle \mu, i| \pi_\mu |\mu, j\rangle$, $\delta_{\nu\in\mathbb{Y}^D_{n+1}}$ is defined by $\delta_{\nu\in\mathbb{Y}^D_{n+1}} = 1$ for $\nu \in \mathbb{Y}^D_{n+1}$ and $\delta_{\nu\in\mathbb{Y}^D_{n+1}} = 0$ for $\nu \notin \mathbb{Y}^d_{n+1}$, and a^λ_ν is the index of the standard tableau $s^\nu_{a^\lambda_\nu}$ obtained by adding a box $\boxed{n+1}$ to the standard tableau s^λ_a.

Proof. First, we consider the Choi operator C satisfying

$$[C, U^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \tag{346}$$

for all $U \in \mathbb{U}(d)$ and $U' \in \mathbb{U}(D)$. Then, $C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}$ for $V_{\mathrm{in}} \in \mathbb{V}_{\mathrm{iso}}(d, D)$ satisfies

$$C \star |U' V_{\mathrm{in}} U\rangle\!\rangle\langle\!\langle U' V_{\mathrm{in}} U|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}$$

$$= C \star (U^{T\otimes n}_{\mathcal{I}^n} \otimes U'^{\otimes n}_{\mathcal{O}^n}) |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} (U^{T\otimes n}_{\mathcal{I}^n} \otimes U'^{\otimes n}_{\mathcal{O}^n})^\dagger \tag{347}$$

$$= (U^{T\otimes n}_{\mathcal{I}^n} \otimes \mathbb{1}_{\mathcal{F}} \otimes \mathbb{1}_{\mathcal{P}} \otimes U'^{\otimes n}_{\mathcal{O}^n})^T C (U^{T\otimes n}_{\mathcal{I}^n} \otimes \mathbb{1}_{\mathcal{F}} \otimes \mathbb{1}_{\mathcal{P}} \otimes U'^{\otimes n}_{\mathcal{O}^n})^* \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \tag{348}$$

$$= (\mathbb{1}_{\mathcal{I}^n} \otimes U^\dagger_{\mathcal{F}} \otimes U'^*_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{O}^n}) C (\mathbb{1}_{\mathcal{I}^n} \otimes U^\dagger_{\mathcal{F}} \otimes U'^*_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{O}^n})^\dagger \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \tag{349}$$

$$= (U'^*_{\mathcal{P}} \otimes U^\dagger_{\mathcal{F}}) [C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}] (U'^*_{\mathcal{P}} \otimes U^\dagger_{\mathcal{F}})^\dagger \tag{350}$$

for all $U \in \mathbb{U}(d)$ and $U' \in \mathbb{U}(D)$. For $U \in \mathbb{U}(d)$ and $U'' \in \mathbb{U}[(\mathrm{Im} V_{\mathrm{in}})^\perp]$, $U' := V_{\mathrm{in}} U V^\dagger_{\mathrm{in}} + U''$ is a unitary operator and $U' V_{\mathrm{in}} U = V_{\mathrm{in}}$ holds. By substituting U and $U' = V_{\mathrm{in}} U V^\dagger_{\mathrm{in}} + U''$ to Eq. (350), we obtain

$$[(V_{\mathrm{in}} U V^\dagger_{\mathrm{in}} + U'')^*_{\mathcal{P}} \otimes U^\dagger_{\mathcal{F}}] [C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}] [(V_{\mathrm{in}} U V^\dagger_{\mathrm{in}} + U'')^*_{\mathcal{P}} \otimes U^\dagger_{\mathcal{F}}]^\dagger = C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}. \tag{351}$$

Decomposing $C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}$ as

$$C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} = (V_{\mathrm{in}}^* \otimes \mathbb{1}_{\mathcal{F}})P(V_{\mathrm{in}}^* \otimes \mathbb{1}_{\mathcal{F}})^\dagger + (V_{\mathrm{in}}^* \otimes \mathbb{1}_{\mathcal{F}})Q + R(V_{\mathrm{in}}^* \otimes \mathbb{1}_{\mathcal{F}})^\dagger + S \tag{352}$$

using linear operators $P \in \mathcal{L}(\mathbb{C}^d \otimes \mathcal{F})$, $Q : (\mathrm{Im}V_{\mathrm{in}})^\perp \otimes \mathcal{F} \to \mathbb{C}^d \otimes \mathcal{F}$, $R : \mathbb{C}^d \otimes \mathcal{F} \to (\mathrm{Im}V_{\mathrm{in}})^\perp \otimes \mathcal{F}$, and $S \in \mathcal{L}((\mathrm{Im}V_{\mathrm{in}})^\perp \otimes \mathcal{F})$, Eq. (351) is written as

$$(U^* \otimes U)A(U^* \otimes U)^\dagger = A, \tag{353}$$

$$(U^* \otimes U)B(U''^T \otimes U)^\dagger = B, \tag{354}$$

$$(U''^T \otimes U)C(U^* \otimes U)^\dagger = C, \tag{355}$$

$$(U''^T \otimes U)D(U''^T \otimes U)^\dagger = D. \tag{356}$$

Therefore, P is written as a linear combination of $|\mathbb{1}_d\rangle\!\rangle\langle\!\langle\mathbb{1}_d|$ and $\mathbb{1}_d \otimes \mathbb{1}_d$, $Q = 0$, $R = 0$, and S is proportional to $\mathbb{1}_{(\mathrm{Im}V_{\mathrm{in}})^\perp} \otimes \mathbb{1}_{\mathcal{F}}$. Therefore, $C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n}$ can be expressed by three parameters $x_{V_{\mathrm{in}}}$, $y_{V_{\mathrm{in}}}$, and $z_{V_{\mathrm{in}}}$ as

$$C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} = x_{V_{\mathrm{in}}}|V_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{F}} + y_{V_{\mathrm{in}}}(\Pi^T_{\mathrm{Im}V_{\mathrm{in}}})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} + z_{V_{\mathrm{in}}}(\Pi^T_{(\mathrm{Im}V_{\mathrm{in}})^\perp})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}. \tag{357}$$

From Eq. (350), we obtain

$$\begin{aligned}
&x_{U'V_{\mathrm{in}}U}|(U'V_{\mathrm{in}}U)^\dagger\rangle\!\rangle\langle\!\langle(U'V_{\mathrm{in}}U)^\dagger|_{\mathcal{P}\mathcal{F}} + y_{U'V_{\mathrm{in}}U}(\Pi^T_{\mathrm{Im}(U'V_{\mathrm{in}}U)})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} + z_{U'V_{\mathrm{in}}U}(\Pi^T_{(\mathrm{Im}(U'V_{\mathrm{in}}U))^\perp})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}\\
&= (U'^*_{\mathcal{P}} \otimes U^\dagger_{\mathcal{F}})[x_{V_{\mathrm{in}}}|V_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{F}} + y_{V_{\mathrm{in}}}(\Pi^T_{\mathrm{Im}V_{\mathrm{in}}})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} + z_{V_{\mathrm{in}}}(\Pi^T_{(\mathrm{Im}V_{\mathrm{in}})^\perp})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}](U'^*_{\mathcal{P}} \otimes U^\dagger_{\mathcal{F}})^\dagger \qquad (358)\\
&= x_{V_{\mathrm{in}}}|(U'V_{\mathrm{in}}U)^\dagger\rangle\!\rangle\langle\!\langle(U'V_{\mathrm{in}}U)^\dagger|_{\mathcal{P}\mathcal{F}} + y_{V_{\mathrm{in}}}(\Pi^T_{\mathrm{Im}(U'V_{\mathrm{in}}U)})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} + z_{V_{\mathrm{in}}}(\Pi^T_{(\mathrm{Im}(U'V_{\mathrm{in}}U))^\perp})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}, \qquad (359)
\end{aligned}$$

thus, $x_{V_{\mathrm{in}}}$, $y_{V_{\mathrm{in}}}$ and $z_{V_{\mathrm{in}}}$ does not depend on V_{in}. By rewriting $x_{V_{\mathrm{in}}} = x$, $y_{V_{\mathrm{in}}} = y$ and $z_{V_{\mathrm{in}}} = z$, we obtain

$$C \star |V_{\mathrm{in}}\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} = x|V_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{F}} + y(\Pi^T_{\mathrm{Im}V_{\mathrm{in}}})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} + z(\Pi^T_{(\mathrm{Im}V_{\mathrm{in}})^\perp})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}. \tag{360}$$

This Choi operator corresponds to the map

$$\mathcal{C}(\mathcal{V}_{\mathrm{in}}^{\otimes n})(\rho_{\mathrm{in}}) = xV_{\mathrm{in}}^\dagger \rho_{\mathrm{in}} V_{\mathrm{in}} + \frac{\mathbb{1}_{\mathcal{F}}}{d}\mathrm{Tr}[\rho_{\mathrm{in}}(y\Pi_{\mathrm{Im}V_{\mathrm{in}}} + z(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}}))]. \tag{361}$$

We calculate x, y and z as follows. Equation (360) is written as

$$\begin{aligned}
&\mathrm{Tr}_{\mathcal{I}^n\mathcal{O}^n}[C(\mathbb{1}_{\mathcal{P}\mathcal{F}} \otimes |V_{\mathrm{in}}^*\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})]\\
&= x|V_{\mathrm{in}}^\dagger\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^\dagger|_{\mathcal{P}\mathcal{F}} + y(\Pi^T_{\mathrm{Im}V_{\mathrm{in}}})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} + z(\Pi^T_{(\mathrm{Im}V_{\mathrm{in}})^\perp})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}.
\end{aligned} \tag{362}$$

Taking the Hilbert-Schmidt inner product with $|V_{\mathrm{in}}^*\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^*|_{\mathcal{F}\mathcal{P}}$, $(\Pi_{\mathrm{Im}V_{\mathrm{in}}})^*_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{F}}$ and $((\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}}))^*_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{F}}$, we obtain

$$\mathrm{Tr}\Big[C|V_{\mathrm{in}}^*\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes |V_{\mathrm{in}}^*\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^*|_{\mathcal{F}\mathcal{P}}\Big] = d^2x + y, \tag{363}$$

$$\mathrm{Tr}\Big[C|V_{\mathrm{in}}^*\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes (\Pi_{\mathrm{Im}V_{\mathrm{in}}})^*_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{F}}\Big] = d(x + y), \tag{364}$$

$$\mathrm{Tr}\Big[C|V_{\mathrm{in}}^*\rangle\!\rangle\langle\!\langle V_{\mathrm{in}}^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes ((\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}}))^*_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{F}}\Big] = (D - d)z. \tag{365}$$

Taking the Haar integral $\mathrm{d}V_{\mathrm{in}}$ on $\mathbb{V}_{\mathrm{iso}}(d,D)$, we obtain

$$\mathrm{Tr}(C\Omega) = x + \frac{y}{d^2}, \tag{366}$$

$$\mathrm{Tr}[C(\Xi \otimes \mathbb{1}_{\mathcal{F}})] = x + y, \tag{367}$$

$$\mathrm{Tr}[C(\Sigma \otimes \mathbb{1}_{\mathcal{F}})] = z, \tag{368}$$

where Ω, Ξ and Σ are defined by

$$\Omega := \frac{1}{d^2}\int_{\mathbb{V}_{\mathrm{iso}}(d,D)} \mathrm{d}V |V\rangle\rangle\langle\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes |V\rangle\rangle\langle\langle V|_{\mathcal{F}\mathcal{P}}, \tag{369}$$

$$\Xi := \frac{1}{d}\int_{\mathbb{V}_{\mathrm{iso}}(d,D)} \mathrm{d}V |V\rangle\rangle\langle\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes (\Pi_{\mathrm{Im}V})_{\mathcal{P}}, \tag{370}$$

$$\Sigma := \frac{1}{D-d}\int_{\mathbb{V}_{\mathrm{iso}}(d,D)} \mathrm{d}V |V\rangle\rangle\langle\langle V|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes ((\mathbb{1}_D - \Pi_{\mathrm{Im}V}))_{\mathcal{P}}. \tag{371}$$

Therefore, x, y and z are given by

$$x = \frac{1}{d^2-1}\mathrm{Tr}\Big[C(d^2\Omega - \Xi \otimes \mathbb{1}_{\mathcal{F}})\Big], \tag{372}$$

$$y = \frac{d^2}{d^2-1}\mathrm{Tr}[C(\Xi \otimes \mathbb{1}_{\mathcal{F}} - \Omega)], \tag{373}$$

$$z = \mathrm{Tr}[C(\Sigma \otimes \mathbb{1}_{\mathcal{F}})]. \tag{374}$$

Next, we consider the Choi operator C satisfying

$$[C, U^{\otimes n}_{\mathcal{I}^n} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \tag{375}$$

for all $U \in \mathbb{U}(d)$ and $U' \in \mathbb{U}(D)$. Defining $C' := C \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}$, C' satisfies

$$[C', U^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \tag{376}$$

for all $U \in \mathbb{U}(d)$ and $U' \in \mathbb{U}(D)$. Therefore, we can show that there exist constant numbers u, v, and w such that

$$\begin{aligned} &C \star |V_{\mathrm{in}}\rangle\rangle\langle\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} \\ &= C' \star |V_{\mathrm{in}}\rangle\rangle\langle\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} && (377) \\ &= u|V_{\mathrm{in}}^{\dagger}\rangle\rangle\langle\langle V_{\mathrm{in}}^{\dagger}|_{\mathcal{P}\mathcal{F}} + v(\Pi^T_{\mathrm{Im}V_{\mathrm{in}}})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d} + w(\Pi^T_{(\mathrm{Im}V_{\mathrm{in}})^{\perp}})_{\mathcal{P}} \otimes \frac{\mathbb{1}_{\mathcal{F}}}{d}, && (378) \end{aligned}$$

i.e., $u = 0$ and

$$C \star |V_{\mathrm{in}}\rangle\rangle\langle\langle V_{\mathrm{in}}|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} = v(\Pi^T_{\mathrm{Im}V_{\mathrm{in}}})_{\mathcal{P}} + w(\Pi^T_{(\mathrm{Im}V_{\mathrm{in}})^{\perp}})_{\mathcal{P}} \tag{379}$$

holds. We calculate v and w as follows. Equation (379) is written as

$$\mathrm{Tr}_{\mathcal{I}^n\mathcal{O}^n}[C(\mathbb{1}_{\mathcal{P}} \otimes |V_{\mathrm{in}}^*\rangle\rangle\langle\langle V_{\mathrm{in}}^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n})] = v(\Pi^T_{\mathrm{Im}V_{\mathrm{in}}})_{\mathcal{P}} + w(\Pi^T_{(\mathrm{Im}V_{\mathrm{in}})^{\perp}})_{\mathcal{P}}. \tag{380}$$

Taking the Hilbert-Schmidt inner product with $\Pi^*_{\mathrm{Im}V_{\mathrm{in}}}$ and $(\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}})^*$, we obtain

$$\mathrm{Tr}\Big[C|V_{\mathrm{in}}^*\rangle\rangle\langle\langle V_{\mathrm{in}}^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes (\Pi_{\mathrm{Im}V_{\mathrm{in}}})^*_{\mathcal{P}}\Big] = dv, \tag{381}$$

$$\mathrm{Tr}\Big[C|V_{\mathrm{in}}^*\rangle\rangle\langle\langle V_{\mathrm{in}}^*|^{\otimes n}_{\mathcal{I}^n\mathcal{O}^n} \otimes ((\mathbb{1}_D - \Pi_{\mathrm{Im}V_{\mathrm{in}}}))^*_{\mathcal{P}}\Big] = (D-d)w. \tag{382}$$

Taking the Haar integral $\mathrm{d}V_{\mathrm{in}}$ on $\mathbb{V}_{\mathrm{iso}}(d,D)$, we obtain

$$\mathrm{Tr}(C\Xi) = v, \tag{383}$$

$$\mathrm{Tr}(C\Sigma) = w. \tag{384}$$

We calculate Ω, Ξ and Σ as follows. First, due to the left- and right-invariance of the Haar measure $\mathrm{d}V$ given by $\mathrm{d}V = \mathrm{d}(U'VU)$ for all $U \in \mathbb{U}(d)$ and $U' \in \mathbb{U}(D)$, Ω and Ξ satisfies the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry given by

$$[\Omega, U^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \tag{385}$$

for all $U \in \mathbb{U}(d)$ and $U' \in \mathbb{U}(D)$. Thus, they can be written as

$$\Omega = \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{\nu\in\mathbb{Y}^D_{n+1}} \sum_{i,j=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \Omega^{\mu\nu}_{ijkl} (E^{\mu,d}_{ij})_{\mathcal{I}^n\mathcal{F}} \otimes (E^{\nu,D}_{kl})_{\mathcal{P}\mathcal{O}^n}, \tag{386}$$

using complex coefficients $\Omega^{\mu\nu}_{ijkl} \in \mathbb{C}$. The coefficients can be calculated as

$$\begin{aligned}
&\Omega^{\mu\nu}_{ijkl}\\
&= \frac{1}{m^{(d)}_\mu m^{(D)}_\nu} \mathrm{Tr}\left[\Omega (E^{\mu,d}_{ji})_{\mathcal{I}^n\mathcal{F}} \otimes (E^{\nu,D}_{lk})_{\mathcal{P}\mathcal{O}^n}\right] && (387)\\
&= \frac{1}{m^{(d)}_\mu m^{(D)}_\nu} \mathrm{Tr}\left[\Omega (E^{\mu,d}_{ji})_{\mathcal{I}^n\mathcal{F}} \otimes (P_\pi^\dagger E^{\nu,D}_{lk} P_\pi)_{\mathcal{O}^n\mathcal{P}}\right] && (388)\\
&= \frac{1}{m^{(d)}_\mu m^{(D)}_\nu} \sum_{k',l'=1}^{d_\nu} \frac{1}{d^2} \int_{\mathbb{V}_{\mathrm{iso}}(d,D)} \mathrm{d}V\, \mathrm{Tr}\left[|V\rangle\!\rangle\langle\!\langle V|^{\otimes n+1}_{\mathcal{I}^n\mathcal{F},\mathcal{O}^n\mathcal{P}} (E^{\mu,d}_{ji})_{\mathcal{I}^n\mathcal{F}} \otimes [\pi_\nu]_{ll'} (E^{\nu,D}_{l'k'})_{\mathcal{O}^n\mathcal{P}} [\pi_\nu]^*_{k'k}\right]\\
& && (389)\\
&= \frac{1}{m^{(d)}_\mu m^{(D)}_\nu} \sum_{k',l'=1}^{d_\nu} \frac{1}{d^2} \int_{\mathbb{V}_{\mathrm{iso}}(d,D)} \mathrm{d}V\, \mathrm{Tr}\left[|\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|^{\otimes n+1} (E^{\mu,d}_{ji}) \otimes [\pi_\nu]_{ll'} V^{\dagger\otimes n+1} (E^{\nu,D}_{l'k'}) V^{\otimes n+1} [\pi_\nu]^*_{k'k}\right],\\
& && (390)
\end{aligned}$$

where P_π is the permutation of Hilbert spaces defined in Eq. (49) for $\pi = (12\cdots n+1) \in \mathfrak{S}_{n+1}$, $[\pi_\mu]_{ij}$ are matrix elements of the irreducible representation π_μ defined by $[\pi_\mu]_{ij} \coloneqq \langle \mu, i|\, \pi_\mu\, |\mu, j\rangle$. As shown in Eq. (146) in Appendix A.2, $V^{\dagger\otimes n+1}(E^{\nu,D}_{l'k'})V^{\otimes n+1}$ is given by $(E^{\nu,d}_{l'k'})\delta_{\nu\in\mathbb{Y}^D_{n+1}}$. We consider the Schur basis introduced in Section 3.1.2. Since the quantum Schur transform is a real matrix, the maximally entangled state in the Schur basis is the same as that in the Schur basis, i.e.,

$$|\mathbb{1}_d\rangle\!\rangle^{\otimes n+1} = \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{u=1}^{m^{(d)}_\mu} \sum_{i=1}^{d_\mu} |\mu, u\rangle_{\mathcal{U}^{(d)}_\mu} \otimes |\mu, i\rangle_{\mathcal{S}_\mu} \otimes |\mu, u\rangle_{\mathcal{U}^{(d)}_\mu} \otimes |\mu, i\rangle_{\mathcal{S}_\mu}. \tag{391}$$

Thus, $\Omega^{\mu\nu}_{ijkl}$ is further calculated as

$$\begin{aligned}
\Omega^{\mu\nu}_{ijkl} &= \frac{\delta_{\nu\in\mathbb{Y}^D_{n+1}}}{m^{(d)}_\mu m^{(D)}_\nu} \sum_{k',l'=1}^{d_\nu} \frac{1}{d^2} \mathrm{Tr}\left[|\mathbb{1}_d\rangle\!\rangle\langle\!\langle \mathbb{1}_d|^{\otimes n+1} (E^{\mu,d}_{ji}) \otimes [\pi_\nu]_{ll'} (E^{\nu,d}_{l'k'}) [\pi_\nu]^*_{k'k}\right] && (392)\\
&= \frac{\delta_{\mu\nu}[\pi_\mu]^*_{ik}[\pi_\mu]_{lj}}{d^2 m^{(D)}_\mu}, && (393)
\end{aligned}$$

Therefore, Ω is given by

$$\Omega = \sum_{\mu \in \mathbb{Y}_{n+1}^d} \sum_{i,j,k,l=1}^{d_\mu} \frac{[\pi_\mu]_{ik}^* [\pi_\mu]_{lj}}{d^2 m_\mu^{(D)}} (E_{ij}^{\mu,d})_{\mathcal{I}^n \mathcal{F}} \otimes (E_{kl}^{\mu,D})_{\mathcal{P}\mathcal{O}^n}. \tag{394}$$

Since $(\Pi_{\mathrm{Im}V})_{\mathcal{P}} = \mathrm{Tr}_{\mathcal{F}} |V\rangle\!\rangle\langle\!\langle V|_{\mathcal{F}\mathcal{P}}$ holds, Ξ is calculated using Lemma 3 as

$$\Xi = d\, \mathrm{Tr}_{\mathcal{F}}\, \Omega \tag{395}$$

$$= \sum_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{\lambda \in \nu - \square} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} \frac{m_\nu^{(d)}}{d m_\nu^{(D)} m_\lambda^{(d)}} [\pi_\nu]_{a_\nu^\lambda k}^* [\pi_\nu]_{l b_\nu^\lambda} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}. \tag{396}$$

Since $((\mathbb{1}_D - \Pi_{\mathrm{Im}V}))_{\mathcal{P}} = \mathbb{1}_{\mathcal{P}} - (\Pi_{\mathrm{Im}V})_{\mathcal{P}}$ holds, Σ is calculated using Lemma 3 as

$$\Sigma = \frac{1}{D-d} \left[\int \mathrm{d}V |V\rangle\!\rangle\langle\!\langle V|_{\mathcal{I}^n \mathcal{O}^n}^{\otimes n} \otimes \mathbb{1}_{\mathcal{P}} - d\Xi \right] \tag{397}$$

$$= \frac{1}{D-d} \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{a,b=1}^{d_\lambda} \left[\frac{(E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{ab}^{\lambda,D})_{\mathcal{O}^n}}{m_\lambda^{(D)}} \otimes \mathbb{1}_{\mathcal{P}} \right.$$

$$\left. - \sum_{\nu \in \lambda + \square \cap \mathbb{Y}_{n+1}^d} \sum_{k,l=1}^{d_\nu} \frac{m_\nu^{(d)}}{m_\nu^{(D)} m_\lambda^{(d)}} [\pi_\mu]_{a_\nu^\lambda k}^* [\pi_\mu]_{l b_\nu^\lambda} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n} \right] \tag{398}$$

$$= \frac{1}{D-d} \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{a,b=1}^{d_\lambda} \sum_{\nu \in \lambda + \square} \left[\frac{(E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (P_\pi^\dagger E_{a_\nu^\lambda b_\nu^\lambda}^{\nu,D} P_\pi)_{\mathcal{P}\mathcal{O}^n}}{m_\lambda^{(D)}} \right.$$

$$\left. - \delta_{\nu \in \mathbb{Y}_{n+1}^d} \sum_{k,l=1}^{d_\nu} \frac{m_\nu^{(d)}}{m_\nu^{(D)} m_\lambda^{(d)}} [\pi_\nu]_{a_\nu^\lambda k}^* [\pi_\nu]_{l b_\nu^\lambda} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n} \right] \tag{399}$$

$$= \frac{1}{D-d} \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \lambda + \square} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} \left[\frac{1}{m_\lambda^{(D)}} - \delta_{\nu \in \mathbb{Y}_{n+1}^d} \frac{m_\nu^{(d)}}{m_\nu^{(D)} m_\lambda^{(d)}} \right] [\pi_\nu]_{a_\nu^\lambda k}^* [\pi_\nu]_{l b_\nu^\lambda} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n} \tag{400}$$

$$= \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \lambda + \square} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} \frac{1}{m_\nu^{(D)}} \frac{\mathrm{hook}(\lambda)}{\mathrm{hook}(\nu)} [\pi_\nu]_{a_\nu^\lambda k}^* [\pi_\nu]_{l b_\nu^\lambda} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}. \tag{401}$$

□

The parameters x, y, z, v, w in Lemma 15 are related to the constraints and the figure of merit of each task considered in this work as follows:

- Probabilistic exact isometry inversion: $x = p$ and $y = 0$.
- Deterministic isometry inversion: $x + y/d^2 = F_{\mathrm{worst}}$.
- Universal error detection: $v = 1$, $w = \alpha$.
- Isometry adjointation: $x + y = 1$, $\max\{1 - x - y/d^2, z\} = \epsilon$.

Using this property, we derive the SDP to obtain the optimal transformations of isometry operations in the next section.

E.3 Derivation of the SDP to obtain optimal transformation of isometry operations

E.3.1 Probabilistic exact isometry inversion

From Theorem 9 and Appendix E.2, the optimization problem of the success probability for isometry inversion is formulated as follows:

$$\begin{aligned}
&\max \operatorname{Tr}(C_S\Omega)\\
\text{s.t. } &0 \leq C_S, C_F \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}),\\
&C := C_S + C_F \in \mathcal{W}^{(x)},\\
&\operatorname{Tr}(C_S\Omega) = \operatorname{Tr}[C_S(\Xi \otimes \mathbb{1}_{\mathcal{F}})],\\
&[C_a, U_{\mathcal{I}^n\mathcal{F}}^{\otimes n+1} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 \quad \forall U \in \mathbb{U}(d), U' \in \mathbb{U}(D), a \in \{S, F\}.
\end{aligned} \tag{402}$$

Using the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry of $\{C_S, C_F\}$, we write $\{C_S, C_F\}$ similarly to Eq. (321) as

$$C_S = \sum_{\mu\in\mathbb{Y}_{n+1}^d} \sum_{\nu\in\mathbb{Y}_{n+1}^D} \sum_{i,j=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \frac{[S_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)} m_\nu^{(D)}} (E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}, \tag{403}$$

$$C_F = \sum_{\mu\in\mathbb{Y}_{n+1}^d} \sum_{\nu\in\mathbb{Y}_{n+1}^D} \sum_{i,j=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \frac{[F_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)} m_\nu^{(D)}} (E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}. \tag{404}$$

Then, $\operatorname{Tr}(C_S\Omega)$ and $\operatorname{Tr}[C_S(\Xi\otimes\mathbb{1}_{\mathcal{F}})]$ are given by

$$\operatorname{Tr}(C_S\Omega) = \sum_{\mu\in\mathbb{Y}_{n+1}^d} \operatorname{Tr}(S_{\mu\mu}\Omega_\mu), \tag{405}$$

$$\operatorname{Tr}[C_S(\Xi\otimes\mathbb{1}_{\mathcal{F}})] = \operatorname{Tr}[\operatorname{Tr}_{\mathcal{F}}(C_S)\Xi] \tag{406}$$

$$= \sum_{\lambda\in\mathbb{Y}_n^d} \sum_{\mu\in\lambda+\square} \sum_{\nu\in\mathbb{Y}_{n+1}^D} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} \frac{[S_{\mu\nu}]_{a_\mu^\lambda k, b_\mu^\lambda l}}{m_\mu^{(d)} m_\nu^{(D)}} \operatorname{Tr}\Big[(E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}\Xi\Big] \tag{407}$$

$$= \sum_{\lambda\in\mathbb{Y}_n^d} \sum_{\mu\in\lambda+\square} \sum_{\nu\in\mathbb{Y}_{n+1}^d} \operatorname{Tr}\Big[(X_\mu^\lambda \otimes \mathbb{1}_{d_\nu}) S_{\mu\nu} (X_\mu^\lambda \otimes \mathbb{1}_{d_\nu})^\dagger \Xi_{\lambda\nu}\Big], \tag{408}$$

where X_μ^λ is defined in Eq. (329) and a_μ^λ is the index of the standard tableau $s^\mu_{a_\mu^\lambda}$ obtained by adding a box $\boxed{n+1}$ to the standard tableau s_a^λ. Therefore, the SDP (402) is written as

$$\begin{aligned}
&\max \sum_{\mu\in\mathbb{Y}_{n+1}^d} \operatorname{Tr}(S_{\mu\mu}\Omega_\mu)\\
\text{s.t. } &0 \leq S_{\mu\nu}, F_{\mu\nu} \in \mathcal{L}(\mathbb{C}^{d_\mu} \otimes \mathbb{C}^{d_\nu}) \quad \forall \mu \in \mathbb{Y}_{n+1}^d, \nu \in \mathbb{Y}_{n+1}^D,\\
&\{C_{\mu\nu}\} := \{S_{\mu\nu} + F_{\mu\nu}\} \in \mathcal{W}_{\text{sym}}^{(x)},\\
&\sum_{\mu\in\mathbb{Y}_{n+1}^d} \operatorname{Tr}(S_{\mu\mu}\Omega_\mu) = \sum_{\lambda\in\mathbb{Y}_n^d} \sum_{\mu\in\lambda+\square} \sum_{\nu\in\mathbb{Y}_{n+1}^d} \operatorname{Tr}\Big[(X_\mu^\lambda \otimes \mathbb{1}_{d_\nu}) S_{\mu\nu} (X_\mu^\lambda \otimes \mathbb{1}_{d_\nu})^\dagger \Xi_{\lambda\nu}\Big].
\end{aligned} \tag{409}$$

E.3.2 Deterministic isometry inversion

From Theorem 9 and Appendix E.2, the optimization problem of the fidelity of deterministic isometry inversion is formulated as follows:

$$\begin{aligned} &\max \operatorname{Tr}(C\Omega)\\ \text{s.t. } &0 \leq C \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}),\\ &C \in \mathcal{W}^{(x)},\\ &[C, U_{\mathcal{I}^n\mathcal{F}}^{\otimes n+1} \otimes U_{\mathcal{P}\mathcal{O}^n}'^{\otimes n+1}] = 0 \quad \forall U \in \mathbb{U}(d), U' \in \mathbb{U}(D). \end{aligned} \tag{410}$$

Similarly to probabilistic isometry inversion, this SDP can be rewritten as follows:

$$\begin{aligned} &\max \sum_{\mu \in \mathbb{Y}_{n+1}^d} \operatorname{Tr}(C_{\mu\mu}\Omega_\mu)\\ \text{s.t. } &0 \leq C_{\mu\nu} \in \mathcal{L}(\mathbb{C}^{d_\mu} \otimes \mathbb{C}^{d_\nu}) \quad \forall \mu \in \mathbb{Y}_{n+1}^d, \nu \in \mathbb{Y}_{n+1}^D,\\ &\{C_{\mu\nu}\} \in \mathcal{W}_{\text{sym}}^{(x)}. \end{aligned} \tag{411}$$

E.3.3 Universal error detection

From Theorem 9 and Appendix E.2, the optimization problem of λ of universal error detection is formulated as follows:

$$\begin{aligned} &\min \operatorname{Tr}(C_I\Sigma)\\ \text{s.t. } &0 \leq C_I, C_O \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P}),\\ &C := C_I + C_O \in \mathcal{W}^{(x)},\\ &\operatorname{Tr}(C_I\Xi) = 1,\\ &[C_a, U_{\mathcal{I}^n}^{\otimes n} \otimes U_{\mathcal{P}\mathcal{O}^n}'^{\otimes n+1}] = 0 \quad \forall U \in \mathbb{U}(d), U' \in \mathbb{U}(D), a \in \{I, O\}. \end{aligned} \tag{412}$$

Using the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry of $\{C_I, C_O\}$, we write $\{C_I, C_O\}$ similarly to Eq. (322) as

$$C_I = \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \mathbb{Y}_{n+1}^D} \sum_{a,b=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \frac{[I_{\lambda\nu}]_{ak,bl}}{m_\lambda^{(d)} m_\nu^{(D)}} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}, \tag{413}$$

$$C_O = \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \mathbb{Y}_{n+1}^D} \sum_{a,b=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} \frac{[O_{\lambda\nu}]_{ak,bl}}{m_\lambda^{(d)} m_\nu^{(D)}} (E_{ab}^{\lambda,d})_{\mathcal{I}^n} \otimes (E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}. \tag{414}$$

Then, $\operatorname{Tr}(C_I\Sigma)$ and $\operatorname{Tr}(C_I\Xi)$ are given by

$$\operatorname{Tr}(C_I\Sigma) = \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \mathbb{Y}_{n+1}^D} \operatorname{Tr}(I_{\lambda\nu}\Sigma_{\lambda\nu}), \tag{415}$$

$$\operatorname{Tr}(C_I\Xi) = \sum_{\lambda \in \mathbb{Y}_n^d} \sum_{\nu \in \mathbb{Y}_{n+1}^d} \operatorname{Tr}(I_{\lambda\nu}\Xi_{\lambda\nu}). \tag{416}$$

Therefore, the SDP (412) is written as

$$\begin{aligned}
&\min \sum_{\lambda\in\mathbb{Y}_n^d}\sum_{\nu\in\mathbb{Y}_{n+1}^D} \mathrm{Tr}(I_{\lambda\nu}\Sigma_{\lambda\nu})\\
\text{s.t. } & 0\leq I_{\lambda\nu}, O_{\lambda\nu}\in\mathcal{L}(\mathbb{C}^{d_\lambda}\otimes\mathbb{C}^{d_\nu}) \quad \forall\lambda\in\mathbb{Y}_n^d, \nu\in\mathbb{Y}_{n+1}^D,\\
&\{C_{\lambda\nu}\} := \{I_{\lambda\nu}+O_{\lambda\nu}\}\in\mathcal{W}_{\mathrm{sym}}^{(x)},\\
&\sum_{\lambda\in\mathbb{Y}_n^d}\sum_{\nu\in\mathbb{Y}_{n+1}^d} \mathrm{Tr}(I_{\lambda\nu}\Xi_{\lambda\nu}) = 1.
\end{aligned} \tag{417}$$

E.3.4 Isometry adjointation

From Theorem 9 and Appendix E.2, the optimization problem of ϵ of isometry adjointation is formulated as follows:

$$\begin{aligned}
&\min\max\{1-\mathrm{Tr}(C_I\Omega), \mathrm{Tr}[C_I(\Sigma\otimes\mathbb{1}_{\mathcal{F}})]\}\\
\text{s.t. } & 0\leq C_I, C_O\in\mathcal{L}(\mathcal{I}^n\otimes\mathcal{O}^n\otimes\mathcal{P}\otimes\mathcal{F}),\\
&C := C_I + C_O \in \mathcal{W}^{(x)},\\
&\mathrm{Tr}[C_I(\Xi\otimes\mathbb{1}_{\mathcal{F}})] = 1,\\
&[C_a, U_{\mathcal{I}^n\mathcal{F}}^{\otimes n+1}\otimes U_{\mathcal{P}\mathcal{O}^n}^{\prime\otimes n+1}] = 0 \quad \forall U\in\mathbb{U}(d), U'\in\mathbb{U}(D), a\in\{I,O\}.
\end{aligned} \tag{418}$$

Using the $\mathbb{U}(d)\times\mathbb{U}(D)$ symmetry of $\{C_I, C_O\}$, we write $\{C_I, C_O\}$ similarly to Eq. (321) as

$$C_I = \sum_{\mu\in\mathbb{Y}_{n+1}^d}\sum_{\nu\in\mathbb{Y}_{n+1}^D}\sum_{i,j=1}^{d_\mu}\sum_{k,l=1}^{d_\nu}\frac{[I_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)}m_\nu^{(D)}}(E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}}\otimes(E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}, \tag{419}$$

$$C_O = \sum_{\mu\in\mathbb{Y}_{n+1}^d}\sum_{\nu\in\mathbb{Y}_{n+1}^D}\sum_{i,j=1}^{d_\mu}\sum_{k,l=1}^{d_\nu}\frac{[O_{\mu\nu}]_{ik,jl}}{m_\mu^{(d)}m_\nu^{(D)}}(E_{ij}^{\mu,d})_{\mathcal{I}^n\mathcal{F}}\otimes(E_{kl}^{\nu,D})_{\mathcal{P}\mathcal{O}^n}. \tag{420}$$

Then, similarly for the case of probabilistic exact isometry inversion, the SDP (418) as follows:

$$\begin{aligned}
&\min\max\left\{1-\sum_{\mu\in\mathbb{Y}_{n+1}^d}\mathrm{Tr}(I_{\mu\mu}\Omega_\mu), \sum_{\lambda\in\mathbb{Y}_n^d}\sum_{\mu\in\lambda+\square}\sum_{\nu\in\mathbb{Y}_{n+1}^D}\mathrm{Tr}\Big[(X_\mu^\lambda\otimes\mathbb{1}_{d_\nu})I_{\mu\nu}(X_\mu^\lambda\otimes\mathbb{1}_{d_\nu})^\dagger\Sigma_{\lambda\nu}\Big]\right\}\\
\text{s.t. } & 0\leq I_{\mu\nu}, O_{\mu\nu}\in\mathcal{L}(\mathbb{C}^{d_\mu}\otimes\mathbb{C}^{d_\nu}) \quad \forall\mu\in\mathbb{Y}_{n+1}^d, \nu\in\mathbb{Y}_{n+1}^D,\\
&\{C_{\mu\nu}\} := \{I_{\mu\nu}+O_{\mu\nu}\}\in\mathcal{W}_{\mathrm{sym}}^{(x)},\\
&\sum_{\lambda\in\mathbb{Y}_n^d}\sum_{\mu\in\lambda+\square}\sum_{\nu\in\mathbb{Y}_{n+1}^d}\mathrm{Tr}\Big[(X_\mu^\lambda\otimes\mathbb{1}_{d_\nu})I_{\mu\nu}(X_\mu^\lambda\otimes\mathbb{1}_{d_\nu})^\dagger\Xi_{\lambda\nu}\Big] = 1.
\end{aligned} \tag{421}$$

E.4 Derivation of the dual problems

We derive the dual problems of the SDPs to obtain the optimal transformations of isometry operations. Due to the strong duality, the dual problems gives the same optimal value as the corresponding primal problems. To this end, we first introduce the dual set of the Choi operators of quantum superchannels. Then, we derive the dual problems using the dual set. Finally, we simplify the derived dual problems using the $\mathbb{U}(d)\times\mathbb{U}(D)$ symmetry.

E.4.1 Characterization of the dual processes

We define the dual set $\overline{\mathcal{W}}^{(x)}$ of $\mathcal{W}^{(x)}$ for $x \in \{\mathrm{PAR}, \mathrm{SEQ}, \mathrm{GEN}\}$ by

$$\overline{C} \in \overline{\mathcal{W}}^{(x)} \iff \mathrm{Tr}\Big(C\overline{C}\Big) = 1 \quad \forall C \in \mathcal{W}^{(x)}. \tag{422}$$

Introducing the basis $\{\overline{C}_j\}$ of $\overline{\mathcal{W}}^{(x)}$, this relation leads to

$$\overline{C} \in \overline{\mathcal{W}}^{(x)} \iff \mathrm{Tr}\Big(C\overline{C}_j\Big) = 1 \quad \forall j. \tag{423}$$

As shown in Ref. [77], $\overline{\mathcal{W}}^{(x)}$ are given by

$$\overline{C} \in \overline{\mathcal{W}}^{(\mathrm{PAR})} \iff \begin{cases} \overline{C} = W \otimes \mathbb{1}_{\mathcal{F}} \\ \mathrm{Tr}_{\mathcal{O}^n} W = \mathrm{Tr}_{\mathcal{I}^n\mathcal{O}^n} W \otimes \mathbb{1}_{\mathcal{I}^n} / \dim \mathcal{I}^n \\ \mathrm{Tr}\, W = \dim \mathcal{I}^n \end{cases}, \tag{424}$$

$$\overline{C} \in \overline{\mathcal{W}}^{(\mathrm{SEQ})} \iff \begin{cases} \overline{C} = W \otimes \mathbb{1}_{\mathcal{F}} \\ \mathrm{Tr}_{\mathcal{O}_i} W^{(i)} = \mathbb{1}_{\mathcal{I}_i} \otimes W^{(i-1)}, \quad \forall i \in \{1, \cdots, n\} \\ \mathrm{Tr}\, W = \dim \mathcal{I}^n \end{cases}, \tag{425}$$

$$\overline{C} \in \overline{\mathcal{W}}^{(\mathrm{GEN})} \iff \begin{cases} \overline{C} = W \otimes \mathbb{1}_{\mathcal{F}} \\ \mathrm{Tr}_{\mathcal{O}_i} W = \mathrm{Tr}_{\mathcal{I}_i\mathcal{O}_i} W \otimes \mathbb{1}_{\mathcal{I}_i} / \dim \mathcal{I}_i \quad \forall i \in \{1, \cdots, n\} \\ \mathrm{Tr}\, W = \dim \mathcal{I}^n \end{cases}, \tag{426}$$

where $W^{(i)}$ are defined by

$$W^{(i)} := \begin{cases} W & (i = n) \\ \mathrm{Tr}_{\mathcal{I}_{i+1}\mathcal{O}_{i+1}} W^{(i+1)} / \dim \mathcal{I}_{i+1} \quad \forall i \in \{0, \cdots, n\} & (i \in \{0, \cdots, n-1\}) \end{cases}. \tag{427}$$

We also introduce the set $\mathrm{Cone}[\overline{\mathcal{W}}^{(x)}]$ of the dual sets $\overline{\mathcal{W}}^{(x)}$ defined by

$$\mathrm{Cone}[\overline{\mathcal{W}}^{(x)}] = \{\lambda \overline{C} | \lambda \in \mathbb{C}, \overline{C} \in \overline{\mathcal{W}}^{(x)}\}. \tag{428}$$

E.4.2 Probabilistic exact isometry inversion

We write down the dual problem of the SDP (402). To this end, we note that the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry does not change the optimal value of the SDP (402), so we can remove it when we consider the dual problem. Then, the SDP (402) corresponds to the following optimization problem:

$$\begin{aligned} &\max \mathrm{Tr}(C_S \Omega) \\ \text{s.t. } &0 \leq C_S, C_F \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}), \\ &\mathrm{Tr}(C_S \Omega) = \mathrm{Tr}[C_S(\Xi \otimes \mathbb{1}_{\mathcal{F}})], \\ &\mathrm{Tr}\Big[(C_S + C_F)\overline{C}_j\Big] = 1, \quad \forall j. \end{aligned} \tag{429}$$

By introducing the Lagrange multipliers $\omega, \lambda_j \in \mathbb{R}$ and $0 \leq \Gamma_S, \Gamma_F \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$, we can write down the corresponding Lagrangian

$$\begin{aligned} L &= \mathrm{Tr}(C_S\Omega) + [\mathrm{Tr}[C_S(\Xi \otimes \mathbb{1}_{\mathcal{F}})] - \mathrm{Tr}(C_S\Omega)]\omega + \mathrm{Tr}(C_S\Gamma_S) + \mathrm{Tr}(C_F\Gamma_F) \\ &\quad + \sum_j [1 - \mathrm{Tr}\left[(C_S + C_F)\overline{C}_j\right]]\lambda_j \qquad (430) \\ &= \sum_j \lambda_j + \mathrm{Tr}\left[C_S(\Omega - \omega\Omega + \omega\Xi \otimes \mathbb{1}_{\mathcal{F}} + \Gamma_S - \sum_j \lambda_j \overline{C}_j)\right] + \mathrm{Tr}\left[F(\Gamma_F - \sum_j \lambda_j \overline{C}_j)\right], \qquad (431) \end{aligned}$$

which gives the SDP (429) as the following optimization:

$$\max_{C_S, C_F \geq 0} \min_{\omega, \lambda_j \in \mathbb{R}, \Gamma_S, \Gamma_F \geq 0} L. \qquad (432)$$

This optimization problem corresponds to the following dual problem:

$$\begin{aligned} &\min \sum_j \lambda_j \\ \text{s.t. } &\omega, \lambda_j \in \mathbb{R}, 0 \leq \Gamma_S, \Gamma_F \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}), \\ &(1-\omega)\Omega + \omega\Xi \otimes \mathbb{1}_{\mathcal{F}} + \Gamma_S - \sum_j \lambda_j \overline{C}_j = 0, \\ &\Gamma_F - \sum_j \lambda_j \overline{C}_j = 0. \end{aligned} \qquad (433)$$

The variables Γ_S, Γ_F can be removed, and the variables λ_j and $\overline{C}_j$ can be replaced with $\overline{C} := \sum_j \lambda_j \overline{C}_j$. Since $\mathrm{Tr}\,\overline{C}_j = d^{n+1}$ holds for $\overline{C}_j \in \overline{\mathcal{W}}^{(x)}$, $\sum_j \lambda_j$ can be replaced with $\mathrm{Tr}\,\overline{C}/d^{n+1}$, which gives the following dual problem:

$$\begin{aligned} &\min \mathrm{Tr}\,\overline{C}/d^{n+1} \\ \text{s.t. } &\omega \in \mathbb{R}, 0 \leq \overline{C} \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}), \\ &\overline{C} \in \mathrm{Cone}[\overline{\mathcal{W}}^{(x)}], \\ &\overline{C} \geq (1-\omega)\Omega + \omega\Xi \otimes \mathbb{1}_{\mathcal{F}}. \end{aligned} \qquad (434)$$

E.4.3 Deterministic isometry inversion

Similarly to the case of probabilistic isometry inversion, the SDP (410) can be rewritten as the following optimization problem:

$$\begin{aligned} &\max \mathrm{Tr}(C\Omega) \\ \text{s.t. } &0 \leq C \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}), \\ &\mathrm{Tr}\left[C\overline{C}_j\right] = 1, \quad \forall j. \end{aligned} \qquad (435)$$

By introducing the Lagrange multipliers $\lambda_j \in \mathbb{R}$ and $0 \leq \Gamma \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$, we can write down the corresponding Lagrangian

$$\begin{aligned} L &= \mathrm{Tr}(C\Omega) + \mathrm{Tr}(C\Gamma) + \sum_j [1 - \mathrm{Tr}\left[C\overline{C}_j\right]]\lambda_j \qquad (436) \\ &= \sum_j \lambda_j + \mathrm{Tr}\left[C(\Omega + \Gamma - \sum_j \lambda_j \overline{C}_j)\right], \qquad (437) \end{aligned}$$

which gives the SDP (410) as the following optimization:

$$\max_{C\geq 0}\min_{\lambda_j\in\mathbb{R},\Gamma\geq 0} L. \tag{438}$$

This optimization problem corresponds to the following dual problem:

$$\begin{aligned}
&\min \sum_j \lambda_j\\
\text{s.t. } &\lambda_j\in\mathbb{R}, 0\leq\Gamma\in\mathcal{L}(\mathcal{I}^n\otimes\mathcal{O}^n\otimes\mathcal{P}\otimes\mathcal{F}),\\
&\Omega+\Gamma-\sum_j\lambda_j\overline{C}_j=0.
\end{aligned}\tag{439}$$

The variable Γ can be removed, and the variables λ_j and $\overline{C}_j$ can be replaced with $\overline{C}:=\sum_j\lambda_j\overline{C}_j$ as

$$\begin{aligned}
&\min \operatorname{Tr}\overline{C}/d^{n+1}\\
\text{s.t. } &\overline{C}\in\mathcal{L}(\mathcal{I}^n\otimes\mathcal{O}^n\otimes\mathcal{P}\otimes\mathcal{F}),\\
&\overline{C}\in\mathrm{Cone}[\overline{\mathcal{W}}^{(x)}],\\
&\overline{C}\geq\Omega.
\end{aligned}\tag{440}$$

E.4.4 Universal error detection

Similarly to the case of probabilistic isometry inversion, the SDP (412) can be rewritten as the following optimization problem:

$$\begin{aligned}
&\min \operatorname{Tr}(C_I\Sigma)\\
\text{s.t. } &0\leq C_I, C_O\in\mathcal{L}(\mathcal{I}^n\otimes\mathcal{O}^n\otimes\mathcal{P}),\\
&\operatorname{Tr}(C_I\Xi)=1,\\
&\operatorname{Tr}\Big[(C_I+C_O)\overline{C}_j\Big]=1\quad\forall j.
\end{aligned}\tag{441}$$

By introducing the Lagrange multipliers $\xi,\lambda_j\in\mathbb{R}$ and $0\leq\Gamma_I,\Gamma_O\in\mathcal{L}(\mathcal{I}^n\otimes\mathcal{O}^n\otimes\mathcal{P})$, the corresponding Lagrangian is given by

$$L=\operatorname{Tr}(C_I\Sigma)-\operatorname{Tr}(C_I\Gamma_I)-\operatorname{Tr}(C_O\Gamma_O)+[1-\operatorname{Tr}(C_I\Xi)]\xi+\sum_j[1-\operatorname{Tr}\Big[(C_I+C_O)\overline{C}_j\Big]]\lambda_j \tag{442}$$

$$=\sum_j\lambda_j+\xi+\operatorname{Tr}\left[C_I\Big(\Sigma-\Gamma_I-\xi\Xi-\sum_j\lambda_j\overline{C}_j\Big)\right]+\operatorname{Tr}\left[C_O(-\Gamma_O-\sum_j\lambda_j\overline{C}_j)\right], \tag{443}$$

which gives the SDP (412) as the following optimization:

$$\min_{C_I,C_O\geq 0}\max_{\xi,\lambda_j\in\mathbb{R},\Gamma_I,\Gamma_O\geq 0} L. \tag{444}$$

The corresponding dual problem is given by

$$\begin{aligned}
&\max\sum_j\lambda_j+\xi\\
\text{s.t. } &\Sigma-\Gamma_I-\xi\Xi-\sum_j\lambda_j\overline{C}_j=0,\\
&-\Gamma_O-\sum_j\lambda_j\overline{C}_j=0.
\end{aligned}\tag{445}$$

The variable Γ can be removed, and the variables λ_j and $\overline{C}_j$ can be replaced with $\overline{C} := -\sum_j \lambda_j \overline{C}_j$ as

$$\begin{aligned} &\max \xi - \operatorname{Tr} \overline{C}/d^n \\ \text{s.t. } &\xi \in \mathbb{R}, 0 \leq \overline{C} \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P}), \\ &\overline{C} \in \mathrm{Cone}[\overline{\mathcal{W}}^{(x)}], \\ &\overline{C} \geq \xi \Xi - \Sigma. \end{aligned} \tag{446}$$

E.4.5 Isometry adjointation

Similarly to the case of probabilistic isometry inversion, the SDP (418) can be rewritten as the following optimization problem:

$$\begin{aligned} &\min p \\ \text{s.t. } &0 \leq C_I, C_O \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}), \\ &1 - \operatorname{Tr}(C_I \Omega) \leq p, \\ &\operatorname{Tr}[C_I(\Sigma \otimes \mathbb{1}_{\mathcal{F}})] \leq p \\ &\operatorname{Tr}[C_I(\Xi \otimes \mathbb{1}_{\mathcal{F}})] = 1, \\ &\operatorname{Tr}\Big[(C_I + C_O)\overline{C}_j\Big] = 1 \quad \forall j. \end{aligned} \tag{447}$$

By introducing the Lagrange multipliers $\omega, \sigma \in \mathbb{R}_{\geq 0}$, $\xi, \lambda_j \in \mathbb{R}$ and $0 \leq \Gamma_I, \Gamma_O \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F})$, the corresponding Lagrangian is given by

$$\begin{aligned} L =& p - \operatorname{Tr}(C_I\Gamma_I) - \operatorname{Tr}(C_O\Gamma_O) + [1 - \operatorname{Tr}(C_I\Omega) - p]\omega + [\operatorname{Tr}[C_I(\Sigma \otimes \mathbb{1}_{\mathcal{F}})] - p]\sigma \\ &+ [1 - \operatorname{Tr}[C_I(\Xi \otimes \mathbb{1}_{\mathcal{F}})]]\xi + \sum_j [1 - \operatorname{Tr}\Big[(C_I + C_O)\overline{C}_j\Big]]\lambda_j \end{aligned} \tag{448}$$

$$\begin{aligned} =& \sum_j \lambda_j + \omega + \xi + p(1 - \omega - \sigma) + \operatorname{Tr}\left[C_I(-\Gamma_I - \omega\Omega + \sigma\Sigma \otimes \mathbb{1}_{\mathcal{F}} - \xi\Xi \otimes \mathbb{1}_{\mathcal{F}} - \sum_j \lambda_j \overline{C}_j)\right] \\ &+ \operatorname{Tr}\left[F(-\Gamma_O - \sum_j \lambda_j \overline{C}_j)\right]. \end{aligned} \tag{449}$$

The corresponding dual problem is given by

$$\begin{aligned} &\max \sum_j \lambda_j + \omega + \xi \\ \text{s.t. } &\omega + \sigma = 1, \\ &-\Gamma_I - \omega\Omega + \sigma\Sigma \otimes \mathbb{1}_{\mathcal{F}} - \xi\Xi \otimes \mathbb{1}_{\mathcal{F}} - \sum_j \lambda_j \overline{C}_j = 0, \\ &-\Gamma_O - \sum_j \lambda_j \overline{C}_j = 0. \end{aligned} \tag{450}$$

The variables $\Gamma_I, \Gamma_O, \sigma$ can be removed, and the variables λ_j and $\overline{C}_j$ can be replaced with $\overline{C} := -\sum_j \lambda_j \overline{C}_j$ as

$$\begin{aligned} &\max \omega + \xi - \operatorname{Tr} \overline{C}/d^{n+1} \\ \text{s.t. } &\xi \in \mathbb{R}, 0 \leq \omega \leq 1, 0 \leq \overline{C} \in \mathcal{L}(\mathcal{I}^n \otimes \mathcal{O}^n \otimes \mathcal{P} \otimes \mathcal{F}) \\ &\overline{C} \in \mathrm{Cone}[\overline{\mathcal{W}}^{(x)}], \\ &\overline{C} \geq \omega\Omega + \xi\Xi \otimes \mathbb{1}_{\mathcal{F}} - (1 - \omega)\Sigma \otimes \mathbb{1}_{\mathcal{F}}. \end{aligned} \tag{451}$$

E.4.6 Simplification of the dual problems using $\mathbb{U}(d) \times \mathbb{U}(D)$ and permutation symmetry

In the dual SDPs (434), (440), (446) and (451), we can impose the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry given by

$$\begin{cases} [\overline{C}, U^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 & \text{(isometry inversion, universal error detection)} \\ [\overline{C}, U^{\otimes n}_{\mathcal{I}^n} \otimes U'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}] = 0 & \text{(isometry adjointation)} \end{cases} \tag{452}$$

for all $U \in \mathbb{U}(d)$ and $U' \in \mathbb{U}(D)$, since for the optimal $\overline{C}_{\mathrm{opt}}$, the $\mathbb{U}(d) \times \mathbb{U}(D)$-twirled operator $\overline{C}'_{\mathrm{opt}}$ given by

$$\overline{C}'_{\mathrm{opt}} := \begin{cases} \int_{\mathbb{U}(d)} \mathrm{d}U \mathcal{U}^{\otimes n+1}_{\mathcal{I}^n\mathcal{F}} \otimes \mathcal{U}'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(\overline{C}) & \text{(isometry inversion, universal error detection)} \\ \int_{\mathbb{U}(d)} \mathrm{d}U \mathcal{U}^{\otimes n}_{\mathcal{I}^n} \otimes \mathcal{U}'^{\otimes n+1}_{\mathcal{P}\mathcal{O}^n}(\overline{C}) & \text{(isometry adjointation)} \end{cases} \tag{453}$$

also gives the optimal values of the dual SDPs. For the case of $x = \mathrm{GEN}$, we can also impose the permutation symmetry given by

$$\begin{cases} [\overline{C}, (P_\pi)_{\mathcal{I}^n} \otimes (P_\pi)_{\mathcal{O}^n} \otimes \mathbb{1}_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{F}}] = 0 & \text{(isometry inversion, universal error detection)} \\ [\overline{C}, (P_\pi)_{\mathcal{I}^n} \otimes (P_\pi)_{\mathcal{O}^n} \otimes \mathbb{1}_{\mathcal{P}}] = 0 & \text{(isometry adjointation)} \end{cases} \tag{454}$$

for all $\pi \in \mathfrak{S}_n$ and P_π is given in Eq. (49) since the $\mathfrak{S}_n$-twirled operator $\overline{C}''_{\mathrm{opt}}$ given by

$$\overline{C}''_{\mathrm{opt}} := \begin{cases} \sum_{\pi \in \mathfrak{S}_n} (\mathcal{P}_\pi)_{\mathcal{I}^n} \otimes (\mathcal{P}_\pi)_{\mathcal{O}^n} \otimes \mathbb{1}_{\mathcal{P}} \otimes \mathbb{1}_{\mathcal{F}}(\overline{C}) & \text{(isometry inversion, universal error detection)} \\ \sum_{\pi \in \mathfrak{S}_n} (\mathcal{P}_\pi)_{\mathcal{I}^n} \otimes (\mathcal{P}_\pi)_{\mathcal{O}^n} \otimes \mathbb{1}_{\mathcal{P}}(\overline{C}) & \text{(isometry adjointation)} \end{cases} \tag{455}$$

also gives the optimal values of the dual SDPs.

We characterize the set $\overline{\mathcal{W}}^{(x)}$ under the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry (452) [and the permutation symmetry (454) for $x = \mathrm{GEN}$]. Using the $\mathbb{U}(d) \times \mathbb{U}(D)$ symmetry (452), we write $\overline{C}$ using the operator $E^{\mu,d}_{ij}$ introduced in Eq. (54) as

$$\overline{C} = \sum_{\mu \in \mathbb{Y}^d_{n+1}} \sum_{\nu \in \mathbb{Y}^D_{n+1}} \sum_{i,j=1}^{d_\mu} \sum_{k,l=1}^{d_\nu} [\overline{C}_{\mu\nu}]_{ik,jl} (E^{\mu,d}_{ij})_{\mathcal{I}^n\mathcal{F}} \otimes (E^{\nu,D}_{kl})_{\mathcal{P}\mathcal{O}^n} \tag{456}$$

for isometry inversion or isometry adjointation, and

$$\overline{C} = \sum_{\lambda \in \mathbb{Y}^d_n} \sum_{\nu \in \mathbb{Y}^D_{n+1}} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} [\overline{C}_{\lambda\nu}]_{ak,bl} (E^{\lambda,d}_{ab})_{\mathcal{I}^n} \otimes (E^{\nu,D}_{kl})_{\mathcal{P}\mathcal{O}^n} \tag{457}$$

for universal error detection using a $d_\mu d_\nu$ $(d_\lambda d_\nu)$-dimensional square matrix $\overline{C}_{\mu\nu}$ $(\overline{C}_{\lambda\nu})$, where ik (ak) and jl (bl) are the indices for row and column numbers, respectively. We also write W and $W^{(i)}$ appearing in the characterization of $\overline{\mathcal{W}}^{(x)}$ as

$$W = \sum_{\lambda \in \mathbb{Y}^d_n} \sum_{\nu \in \mathbb{Y}^D_{n+1}} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} [W_{\lambda\nu}]_{ak,bl} (E^{\lambda}_{ab})_{\mathcal{I}^n} \otimes (E^{\nu}_{kl})_{\mathcal{P}\mathcal{O}^n}, \tag{458}$$

$$W^{(i)} = \sum_{\lambda \in \mathbb{Y}^d_i} \sum_{\nu \in \mathbb{Y}^D_{i+1}} \sum_{a,b=1}^{d_\lambda} \sum_{k,l=1}^{d_\nu} [W^{(i)}_{\lambda\nu}]_{ak,bl} (E^{\lambda}_{ab})_{\mathcal{I}^i} \otimes (E^{\nu}_{kl})_{\mathcal{P}\mathcal{O}^i}. \tag{459}$$

Using Lemma 3, the condition $\overline{C} \in \overline{\mathcal{W}}^{(x)}$ for $x \in \{\mathrm{PAR}, \mathrm{SEQ}, \mathrm{GEN}\}$ are given by

$$\overline{C} \in \overline{\mathcal{W}}^{(x)} \iff \begin{cases} \{\overline{C}_{\mu\nu}\} \in \overline{\mathcal{W}}^{(x)}_{\mathrm{sym}} & (\text{isometry inversion, isometry adjointation}) \\ \{\overline{C}_{\lambda\nu}\} \in \overline{\mathcal{W}}^{(x)}_{\mathrm{sym}} & (\text{universal error detection}) \end{cases}, \tag{460}$$

where $\overline{\mathcal{W}}^{(x)}_{\mathrm{sym}}$ is given by

$$\{\overline{C}_{\mu\nu}\} \in \overline{\mathcal{W}}^{(\mathrm{PAR})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \overline{C}_{\mu\nu} = \displaystyle\sum_{\lambda \in \mu - \square} (X^{\mu}_{\lambda} \otimes \mathbb{1}_{d_\nu}) W_{\lambda\nu} (X^{\mu}_{\lambda} \otimes \mathbb{1}_{d_\nu})^\dagger \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1} \\ \displaystyle\sum_{\nu \in \mathbb{Y}^D_{n+1}} m^{(D)}_{\nu} \operatorname{Tr}_\nu (W_{\lambda\nu}) = \mathbb{1}_{d_\lambda} \quad \forall \lambda \in \mathbb{Y}^d_n \end{cases}, \tag{461}$$

$$\{\overline{C}_{\mu\nu}\} \in \overline{\mathcal{W}}^{(\mathrm{SEQ})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \overline{C}_{\mu\nu} = \displaystyle\sum_{\lambda \in \mu - \square} (X^{\mu}_{\lambda} \otimes \mathbb{1}_{d_\nu}) W_{\lambda\nu} (X^{\mu}_{\lambda} \otimes \mathbb{1}_{d_\nu})^\dagger \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1} \\ \displaystyle\sum_{\nu \in \kappa + \square} m^{(D)}_{\nu} (\mathbb{1}_{d_\lambda} \otimes X^{\kappa}_{\nu}) W^{(i)}_{\lambda\nu} (\mathbb{1}_{d_\lambda} \otimes X^{\kappa}_{\nu})^\dagger = \displaystyle\sum_{\gamma \in \lambda - \square} m^{(D)}_{\kappa} (X^{\lambda}_{\gamma} \otimes \mathbb{1}_{d_\kappa}) W^{(i-1)}_{\gamma\kappa} (X^{\lambda}_{\gamma} \otimes \mathbb{1}_{d_\kappa})^\dagger \\ \qquad\qquad \forall i \in \{1, \cdots, n\}, \lambda \in \mathbb{Y}^d_i, \kappa \in \mathbb{Y}^D_i \\ W^{(0)}_{\emptyset\square} = \dfrac{1}{D} \end{cases}, \tag{462}$$

$$\{\overline{C}_{\mu\nu}\} \in \overline{\mathcal{W}}^{(\mathrm{GEN})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \overline{C}_{\mu\nu} = \displaystyle\sum_{\lambda \in \mu - \square} (X^{\mu}_{\lambda} \otimes \mathbb{1}_{d_\nu}) W_{\lambda\nu} (X^{\mu}_{\lambda} \otimes \mathbb{1}_{d_\nu})^\dagger \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1} \\ [W_{\lambda\nu}, \pi_\lambda \otimes \pi'_\nu] = 0 \quad \forall \pi \in \mathfrak{S}_n, \\ \displaystyle\sum_{\nu \in \kappa + \square} m^{(D)}_{\nu} (\mathbb{1}_{d_\lambda} \otimes X^{\kappa}_{\nu}) W_{\lambda\nu} (\mathbb{1}_{d_\lambda} \otimes X^{\kappa}_{\nu})^\dagger = \displaystyle\sum_{\gamma \in \lambda - \square} m^{(D)}_{\kappa} (X^{\lambda}_{\gamma} \otimes \mathbb{1}_{d_\kappa}) W^{(n-1)}_{\gamma\kappa} (X^{\lambda}_{\gamma} \otimes \mathbb{1}_{d_\kappa})^\dagger \\ \qquad\qquad \forall \lambda \in \mathbb{Y}^d_n, \kappa \in \mathbb{Y}^D_n \\ \displaystyle\sum_{\lambda \in \mathbb{Y}^d_n} \sum_{\nu \in \mathbb{Y}^D_{n+1}} m^{(d)}_{\lambda} m^{(D)}_{\nu} \operatorname{Tr}(W_{\lambda\nu}) = d^n \end{cases} \tag{463}$$

for isometry inversion and isometry adjointation, where $W^{(i)}_{\gamma\kappa}$ for $\gamma \in \mathbb{Y}^d_i$ and $\kappa \in \mathbb{Y}^D_{i+1}$ are defined by

$$W^{(i)}_{\gamma\kappa} := \begin{cases} W_{\gamma\kappa} & (i = n) \\ \frac{1}{d} \sum_{\lambda \in \gamma + \square} \sum_{\nu \in \kappa + \square} \frac{m^{(d)}_{\lambda} m^{(D)}_{\nu}}{m^{(d)}_{\gamma} m^{(D)}_{\kappa}} (X^{\gamma}_{\lambda} \otimes X^{\kappa}_{\nu}) W^{(i+1)}_{\lambda\nu} (X^{\gamma}_{\lambda} \otimes X^{\kappa}_{\nu})^\dagger & (i \in \{0, \cdots, n-1\}) \end{cases}, \tag{464}$$

π_λ is the irreducible representation of π given in Eq. (49), and π'_ν is the irreducible representation of π' defined by $\pi'(1) = 1$ and $\pi'(i+1) = \pi(i) + 1$ for $i \in \{1, \cdots, n\}$. The set

$\overline{\mathcal{W}}^{(x)}_{\mathrm{sym}}$ is given by

$$\{\overline{C}_{\lambda\nu}\} \in \overline{\mathcal{W}}^{(\mathrm{PAR})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \overline{C}_{\lambda\nu} = W_{\lambda\nu} \quad \forall \lambda \in \mathbb{Y}^d_n, \nu \in \mathbb{Y}^D_{n+1} \\ \displaystyle\sum_{\nu\in\mathbb{Y}^D_{n+1}} m^{(D)}_\nu \operatorname{Tr}_\nu(W_{\lambda\nu}) = \mathbb{1}_{d_\lambda} \quad \forall \lambda \in \mathbb{Y}^d_n \end{cases}, \tag{465}$$

$$\{\overline{C}_{\lambda\nu}\} \in \overline{\mathcal{W}}^{(\mathrm{SEQ})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \overline{C}_{\lambda\nu} = W_{\lambda\nu} \quad \forall \lambda \in \mathbb{Y}^d_n, \nu \in \mathbb{Y}^D_{n+1} \\ \displaystyle\sum_{\nu\in\kappa+\square} m^{(D)}_\nu (\mathbb{1}_{d_\lambda} \otimes X^\kappa_\nu) W^{(i)}_{\lambda\nu} (\mathbb{1}_{d_\lambda} \otimes X^\kappa_\nu)^\dagger = \sum_{\gamma\in\lambda-\square} m^{(D)}_\kappa (X^\lambda_\gamma \otimes \mathbb{1}_{d_\kappa}) W^{(i-1)}_{\gamma\kappa} (X^\lambda_\gamma \otimes \mathbb{1}_{d_\kappa})^\dagger \\ \hfill \forall i \in \{1, \cdots, n\}, \lambda \in \mathbb{Y}^d_i, \kappa \in \mathbb{Y}^D_i \\ W^{(0)}_{\emptyset\square} = \dfrac{1}{D} \end{cases}, \tag{466}$$

$$\{\overline{C}_{\lambda\nu}\} \in \overline{\mathcal{W}}^{(\mathrm{GEN})}_{\mathrm{sym}} \iff$$
$$\begin{cases} \overline{C}_{\lambda\nu} = W_{\lambda\nu} \quad \forall \lambda \in \mathbb{Y}^d_n, \nu \in \mathbb{Y}^D_{n+1} \\ [W_{\lambda\nu}, \pi_\lambda \otimes \pi'_\nu] = 0 \quad \forall \pi \in \mathfrak{S}_n, \\ \displaystyle\sum_{\nu\in\kappa+\square} m^{(D)}_\nu (\mathbb{1}_{d_\lambda} \otimes X^\kappa_\nu) W_{\lambda\nu} (\mathbb{1}_{d_\lambda} \otimes X^\kappa_\nu)^\dagger = \sum_{\gamma\in\lambda-\square} m^{(D)}_\kappa (X^\lambda_\gamma \otimes \mathbb{1}_{d_\kappa}) W^{(n-1)}_{\gamma\kappa} (X^\lambda_\gamma \otimes \mathbb{1}_{d_\kappa})^\dagger \\ \hfill \forall \lambda \in \mathbb{Y}^d_n, \kappa \in \mathbb{Y}^D_n \\ \displaystyle\sum_{\lambda\in\mathbb{Y}^d_n} \sum_{\nu\in\mathbb{Y}^D_{n+1}} m^{(d)}_\lambda m^{(D)}_\nu \operatorname{Tr}(W_{\lambda\nu}) = d^n \end{cases} \tag{467}$$

for universal error detection. Using this characterization of $\overline{\mathcal{W}}^{(x)}$ with the $\mathbb{U}(d) \times \mathbb{U}(D)$ and permutation symmetry, the dual SDPs (434), (440), (446) and (451) can be simplified as follows:

- Probabilistic exact isometry inversion

$$\begin{aligned} \min \ & \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{\nu\in\mathbb{Y}^D_{n+1}} \operatorname{Tr} \overline{C}_{\mu\nu}/d^{n+1} \\ \text{s.t. } & \omega \in \mathbb{R}, 0 \leq \overline{C}_{\mu\nu} \in \mathcal{L}(\mathbb{C}^{d_\mu} \otimes \mathbb{C}^{d_\nu}) \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1}, \\ & \{\overline{C}_{\mu\nu}\} \in \mathrm{Cone}[\overline{\mathcal{W}}^{(x)}_{\mathrm{sym}}], \\ & \overline{C}_{\mu\nu} \geq \delta_{\mu\nu}(1-\omega)\Omega_\mu + \omega \sum_{\lambda\in\mu-\square} (X^\lambda_\mu \otimes \mathbb{1}_{d_\mu})^\dagger \Xi_{\lambda\nu} (X^\lambda_\mu \otimes \mathbb{1}_{d_\mu}) \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1}. \end{aligned} \tag{468}$$

- Deterministic isometry inversion

$$\begin{aligned} \min \ & \sum_{\mu\in\mathbb{Y}^d_{n+1}} \sum_{\nu\in\mathbb{Y}^D_{n+1}} \operatorname{Tr} \overline{C}_{\mu\nu}/d^{n+1} \\ \text{s.t. } & \omega \in \mathbb{R}, 0 \leq \overline{C}_{\mu\nu} \in \mathcal{L}(\mathbb{C}^{d_\mu} \otimes \mathbb{C}^{d_\nu}) \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1}, \\ & \{\overline{C}_{\mu\nu}\} \in \mathrm{Cone}[\overline{\mathcal{W}}^{(x)}_{\mathrm{sym}}], \\ & \overline{C}_{\mu\mu} \geq \Omega_\mu \quad \forall \mu \in \mathbb{Y}^d_{n+1}. \end{aligned} \tag{469}$$

- Universal error detection

$$\begin{aligned}
&\max \xi - \sum_{\lambda \in \mathbb{Y}^d_n} \sum_{\nu \in \mathbb{Y}^D_{n+1}} \operatorname{Tr} \overline{C}_{\lambda\nu}/d^n \\
\text{s.t. } &\xi \in \mathbb{R}, 0 \leq \overline{C}_{\lambda\nu} \in \mathcal{L}(\mathbb{C}^{d_\lambda} \otimes \mathbb{C}^{d_\nu}) \quad \forall \lambda \in \mathbb{Y}^d_n, \nu \in \mathbb{Y}^D_{n+1}, \\
&\{\overline{C}_{\lambda\nu}\} \in \operatorname{Cone}[\overline{\mathcal{W}}^{(x)}_{\text{sym}}], \\
&\overline{C}_{\lambda\nu} \geq \xi \Xi_{\lambda\nu} - \Sigma_{\lambda\nu} \quad \forall \lambda \in \mathbb{Y}^d_n, \nu \in \mathbb{Y}^D_{n+1}.
\end{aligned} \tag{470}$$

- Isometry adjointation

$$\begin{aligned}
&\max \omega + \xi - \sum_{\mu \in \mathbb{Y}^d_{n+1}} \sum_{\nu \in \mathbb{Y}^D_{n+1}} \operatorname{Tr} \overline{C}_{\mu\nu}/d^{n+1} \\
\text{s.t. } &\xi \in \mathbb{R}, 0 \leq \omega \leq 1, 0 \leq \overline{C}_{\mu\nu} \in \mathcal{L}(\mathbb{C}^{d_\mu} \otimes \mathbb{C}^{d_\nu}) \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1}, \\
&\{\overline{C}_{\mu\nu}\} \in \operatorname{Cone}[\overline{\mathcal{W}}^{(x)}_{\text{sym}}], \\
&\overline{C}_{\mu\nu} \geq \delta_{\mu\nu} \omega \Omega + \sum_{\lambda \in \mu - \square} (X^\lambda_\mu \otimes \mathbb{1}_{d_\nu})^\dagger [\xi \Xi_{\lambda\nu} - (1-\omega)\Sigma_{\lambda\nu}](X^\lambda_\mu \otimes \mathbb{1}_{d_\nu}) \quad \forall \mu \in \mathbb{Y}^d_{n+1}, \nu \in \mathbb{Y}^D_{n+1}.
\end{aligned} \tag{471}$$

Abstract. The experimental realization of increasingly complex quantum states underscores the pressing need for new methods of state testing and learning. We show that any algorithm capable of testing if a state is a possibly mixed free-fermionic states or not would inevitably be inefficient, but we then present an efficient algorithm for testing low-rank free-fermionic states. We also prove improved bounds on the sample complexity for tomography of pure free-fermionic states, and we also generalize the algorithm to the mixed-scenario and to the case of states prepared by free-fermionic evolutions doped with a few fermionic magic gates.

Keywords: Quantum Learning, Tomography, Testing, Magic, Perturbation bounds, Fermions

1 Introduction

Note: This submission is based on this work recently posted on ArXiv [1] and also on another work that we will post shortly [2].

Ubiquitous in various domains of physics, from condensed matter theory to quantum chemistry, free-fermionic states, also known as fermionic Gaussian states or states prepared by matchgates circuits, are unique for quantum computation because they belong to a nontrivial class of efficiently classically simulable states [3, 4]. While these states may be considered ineffective for advantageous quantum computation, they serve as an essential milestone in the ongoing construction of fault-tolerant quantum devices: their efficiency in classical simulation provides a powerful tool for classical benchmarking quantum computation to ensure the correct functionality of quantum chips. However, before implementing any quantum benchmarking protocol based on free-fermionic states, experimentalists must verify that the state prepared on a quantum device is indeed close to a free-fermionic state. Addressing this concern, we formalize the problem as a property testing problem, aiming to distinguish situations where a given state (generally mixed) is close to the set of free-fermionic states from those where it is far. In the same fashion, given access to an unknown free-fermionic state, experimentalists must be able to learn a classical description of the state – a problem formalized as quantum state tomography. Our work comprehensively addresses the problem of testing and tomography of free-fermionic states, providing scenarios with provable efficiency guarantees and ruling out situations in which the aforementioned tasks are hard to perform. We also extend the learning and testing problem to the scenario of states prepared by arbitrary many free-fermionic evolutions and at most t local non-free evolutions, that we call t-doped fermionic Gaussian states (or t-doped free-fermionic/matchgates states). By Jordan-Wigner mapping, this also includes n-qubit states prepared by nearest-neighbour matchgate circuits with at most t SWAP-gates. The workhorse of our results is provided by new insights into free-fermionic states: Specifically, we show lower and upper bound on the minimum trace distance between a state and the set of free-fermionic states, which also serve as efficiently computable measures of 'non-Gaussianity' for the state. We derive useful bounds on the trace distance between two possibly mixed free-fermionic states in terms of the norm difference of their correlation matrices. Furthermore, we show that all the 'magic' in a t-doped free-fermionic state can be compressed via a free-fermionic unitary to a localized region of the system.

2 Fundamental insights

Imagine one aims to prepare a pure free-fermionic state on a quantum processor. In practice, an imperfect, non-Gaussian, yet close version of the state is actually prepared. The task of quantum state certification is to verify the almost correct preparation of the target state based on the operational distance between the two, i.e., the trace distance. However, since the distance between a theoretical quantum state ψ and a quantum state ρ is generally hard to measure, we aim to understand how the trace distance between two "close" quantum states is controlled by their respective correlation matrices, which can be efficiently measured in practical scenarios. Below, we upper bound the trace distance between a perfect pure free-fermionic state ψ and a non-Gaussian (possibly mixed) imperfect realization ρ through their respective covariance matrices.

Proposition 1 *Let ψ be a free fermionic pure state and ρ be a arbitrary quantum state with correlation matrices*

*bittel@fu-berlin.de
†jense@fu-berlin.de
‡yaroslav@cwi.nl
§lorenzo.leone@fu-berlin.de
¶a.mele@fu-berlin.de

$\Gamma(\psi), \Gamma(\rho)$ *respectively. Then:*

$$\|\psi-\rho\|_1 \leq \sqrt{\|\Gamma(\psi)-\Gamma(\rho)\|_1}. \tag{1}$$

Given that the correlation matrix $\Gamma(\psi)$ is known and efficiently classically encoded, Eq. (1) offers an efficient and direct method to verify the accurate preparation of ψ within a marginal error ε, as it is sufficient to measure $\Gamma(\rho)$ up to $O(\varepsilon^2)$ precision that require $\mathrm{poly}(n, 1/\varepsilon)$ resources.

Next, we introduce two perturbation bounds for the trace distance between two free-fermionic states in relation to the distance between their covariance matrices.

Theorem 2 (Trace distance bounds)

- *Let* $|\psi\rangle, |\phi\rangle$ *be two pure free-fermionic states, then:* $\|\psi-\phi\|_1 \leq \frac{1}{2}\|\Gamma(\psi)-\Gamma(\phi)\|_2$,
- *Let* ρ, σ *be two mixed free-fermionic states, then:* $$\|\rho-\sigma\|_1 \leq \sqrt{\|\Gamma(\rho)-\Gamma(\sigma)\|_1 + \tfrac{1}{2}\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2}\,.$$

In our technical manuscript, we also lower bound the quantity $\mathcal{M}(\rho) = \min_{\sigma\in\mathcal{G}} \|\rho-\sigma\|_1$, where $\mathcal{G}$ is the set of free-fermionic states (pure or mixed), in terms of the correlation matrix of the state ρ. This also serve as an efficient to estimate measure of non-Gaussianity for the given state.

We moreover establish a property of states prepared by arbitrary many free-fermionic evolutions (also called matchgates or Gaussian gates) and at most t local non free-fermionic gates (e.g., SWAP gates), that we denote as t-doped free-fermionic states (or, t-doped fermionic Gaussian state).

Theorem 3 (Magic compression) *For any t-doped free-fermionic state $|\psi\rangle$, there exists a Gaussian operation G such that*

$$G|\psi\rangle = |\phi\rangle \otimes |0^{n-\kappa t}\rangle, \tag{2}$$

where $|\phi\rangle$ is a state supported exclusively on κt qubits and κ is a constant.

Besides being fundamental for the efficiency of subsequent testing and tomography algorithms, we expect that these results have extensive applicability in the context of free fermions, in both theoretical and experimental realms. For example, the latter theorem sheds light also on the efficient circuit compilation of this class of states.

3 Testing free-fermionic states

Given copies of an unknown quantum state ρ, how to understand if it close or far from the set of free fermionic states? Our goal is to identify scenarios in which addressing the aforementioned question is feasible in terms of resources, to provide algorithms with provable efficiency guarantees, and to delineate situations in which answering the question is challenging. First of all, let us formulate the problem in a rigorous fashion.

Problem 1 Let $\varepsilon_B > \varepsilon_A \geq 0$. Given N copies of an unknown quantum state ρ with the promise that it falls into one of two distinct situations:

- **Case A:** There exists a free-fermionic state $\sigma \in \mathcal{G}$ such that $\|\rho-\sigma\|_1 \leq \varepsilon_A$.
- **Case B:** ρ is ε_B-far from all free-fermionic states σ, indicating $\min_{\sigma\in\mathcal{G}} \|\rho-\sigma\|_1 > \varepsilon_B$.

Determine whether the state is in Case A or Case B through measurements performed on the provided N state copies. Further specifications regarding the rank of the state ρ and the set of free-fermionic states $\mathcal{G} \equiv \mathcal{G}_{\mathrm{pure}}$, $\mathcal{G}_{\mathrm{mixed}}$, $\mathcal{G}_R$ (being pure, mixed and bounded rank R free-fermionic states respectively) must be provided.

When no prior assumptions on the state ρ and no restrictions on the set of free-fermionic states $\mathcal{G}$ are provided, we establish the general hardness for Problem 1, demonstrating that $N = \Omega(2^n)$ copies of the state ρ are necessary. Below, we present a more refined version of the mentioned no-go result.

Theorem 4 (Hardness of testing) *Let $\varepsilon_B > 0$. Let ρ denote the unknown state and $\mathcal{G}$ the set of free fermionic states considered. To solve Problem 1, with at least a $2/3$ probability of success, $N = \Omega(R/\varepsilon_B^2)$ copies are necessary if either of the following hypotheses is assumed:*

- *ρ is such that* $\mathrm{rank}(\rho) \leq R$,
- $\mathcal{G} \equiv \mathcal{G}_R$.

In particular, for $R = \exp(\Omega(n))$ the sample complexity grows exponentially in the number of modes n.

Given this hardness results, Theorem 4 prompts the natural question of whether an algorithm exists that scales polynomially with the rank R, which solve the property testing problem under the assumption that ρ has a rank at most R or when restricting to the set $\mathcal{G}_R$. In response to this, we present the following theorem.

Theorem 5 (Efficient free-fermionic testing)) *Problem 1 can be solved with $N = \mathrm{poly}(n, R)$ copies of ρ in the following scenarios:*

1. *the given state ρ is such that* $\mathrm{rank}(\rho) \leq R$;
2. *the set of Gaussian states is restricted to $\mathcal{G}_R$.*

We provide algorithms for case (i) and (ii) that use N samples and $\mathrm{poly}(n, R)$ computational resources.

Let us summarize our findings. In its full generality, that is, without rank assumptions on the state ρ and considering $\mathcal{G} \equiv \mathcal{G}_{\mathrm{mixed}}$, Problem 1 requires $N = \Omega(2^n)$ samples of the state to be solved. However, as claimed in Theorem 5, we have established that Problem 1 can be efficiently addressed both sample-wise and computationally under two specific scenarios: (i) when the given state ρ has a rank R that scales polynomially with the number of modes n, or (ii) when the focus is solely on quantifying closeness to the set of Gaussian states with polynomially bounded rank $\mathcal{G}_R$.

4 Learning free-fermionic states

We present a simple algorithm for efficiently learning a unknown n-qubit free-fermionic state either pure or mixed. More rigorously, we are concerned with the following problem: let $\rho \in \mathcal{G}$, with $\mathcal{G} = \mathcal{G}_{\text{mixed}}, \mathcal{G}_{\text{pure}}$, be a unknown (either pure or mixed) free-fermionic state, design a computationally efficient quantum learning algorithm that consumes N copies of ρ and output a classical description $\hat{\rho}$ that is ε-close in trace distance to ρ with failure probability of at most δ. Some earlier works [6, 5, 7] have already tackled this problem, but their analyses have been limited to the specific case of ρ being a pure free fermionic state. We first provide a better sample complexity upper bound limited to the case of pure states that significantly improves upon previous work. What is more, our approach extends to the more realistic mixed state scenario, significantly broadening the scope of such result. This extension, as well as the improved algorithm for pure state case, heavily rely on the toolkit developed and discussed in this paper, in particular Theorem 2.

Theorem 6 (Pure Gaussian states tomography) *Let ψ be a pure free-fermionic quantum state. For $\varepsilon, \delta \in (0, 1)$, there exist a learning algorithm that utilizes $N = O((n^3/\varepsilon^2)\log(n^2/\delta))$ copies of the state and only single-copies measurements to learn an efficient classical representation of the state $\hat{\psi}$ obeying $\|\psi - \hat{\psi}\|_1 \leq \varepsilon$, with a success probability of at least $1 - \delta$.*

Thus, our scaling $O(n^3/\varepsilon^2)$ improves upon the previous best scaling of Ref. [7] that was $O(n^3 m^2/\varepsilon^4)$ (where m represents the fixed number of particles of the fermionic state). We now present the theorem for the mixed case scenario.

Theorem 7 (Mixed Gaussian states tomography) *Let ρ be a mixed free-fermionic quantum state. For $\varepsilon, \delta \in (0, 1)$, there exist a learning algorithm that, utilizing $N = O((n^5/\varepsilon^4)\log(n^2/\delta))$ copies of the state ρ and single-copies measurements, learns a classical representation $\hat{\rho}$ of the state ρ obeying $\|\hat{\rho} - \rho\|_1 \leq \varepsilon$, with a success probability of at least $1 - \delta$.*

5 Learning and testing magical fermions

As in the case of Clifford circuits, for which the introduction of magic gates, such as T-gates, allows to reach universal quantum computation, also for the case of Gaussian (i.e., free-fermionic or matchgates) circuits the inclusion of certain magic gates, for example SWAP gates [8], allows to reach universality. If the number t of T-gates in a Clifford circuit is low, the resulting states can still be efficiently simulated classically [9]; it has also been recently demonstrated that such states, termed as t-doped stabilizer states, are still efficiently learnable [10, 11, 12]. Similarly, in the past year, it has been shown that matchgates circuits with a few magic gates are also classically simulable [13, 14, 15]. However, the learnability of such "t-doped fermionic states" remains unknown and this motivates the question: Can we efficiently learn states prepared by Gaussian operations (e.g. matchgates) and a few magic gates?

We answer it by proposing a sample and time efficient quantum learning algorithm of polynomial time and sample complexity that uses only single-copy measurements and learns a classical description of a t-doped fermionic Gaussian state; the learned state is guaranteed to be close to the true state in trace distance.

Theorem 8 (t-doped tomography) *Let $|\psi\rangle$ be a t-doped Gaussian state, and $\varepsilon, \delta \in (0, 1]$. Utilizing $O(\mathrm{poly}(n, 2^t))$ single-copy measurements and computational time, there exists an algorithm which outputs a classical representation of a state which is guaranteed to be at least ε close in trace distance to $|\psi\rangle$, with probability $\geq 1 - \delta$.*

Our learning algorithm may also be feasible to implement in near-term fermionic analog quantum simulators, like cold atoms in optical lattices, since we only utilize time evolutions of simple few-body fermionic Hamiltonians. The core of our algorithm relies on Theorem 3. Informally, it says that all the magic of such states can be *compressed* to a few qubits via a free-fermionic operation. The proof of this compression theorem is constructive, which has implications for the circuit complexity of $|\psi\rangle$ and for improved preparation of doped fermionic Gaussian states. The high level idea of the learning algorithm is to first learn a Gaussian unitary which *compresses* the magic, apply it to the state, and then perform full state state tomography on the first few qubits alone. Our learning algorithm is efficient for $t = \mathcal{O}(\log(n))$ and no longer efficient if the number of non-Gaussian gates is larger. However, we show that any algorithm to learn such states doped with a *slightly* more than than logarithmic number of non-Gaussian gates, must be necessarily inefficient, based on common cryptographic assumptions [16].

Theorem 9 (Time-complexity lower bound) *Under a common cryptographic assumption, there is no time efficient algorithm to learn a general $\tilde{\omega}(\log(n))$-doped Gaussian state.*

To obtain this result, we exploit the theory of pseudorandom-quantum states [17, 18], so far considered only for qubit-based systems, by bringing it into the fermionic realm.

Furthermore, our algorithm extends to all compressible states, i.e., those which can be written as $|\psi\rangle = G|\phi\rangle \otimes |0^{n-t}\rangle$, where G is a Gaussian unitary and $|\phi\rangle$ an arbitrary state supported solely on t-qubits (or fermionic modes). We also propose an efficient method to *test* if a given state is close or far from the set of compressible states, by showing an efficiently estimatable quantity that lower bounds the distance to this set.

Testing whether a quantum state is far from a classically efficiently tractable set of states is a fundamental task in quantum information. A physically relevant instance of such a set of states is given by free-fermionic states, also known as fermionic Gaussian states or states prepared by matchgate circuits. In this study, we analyze property testing of free-fermionic states, specifically the task of determining, through measurements, whether an unknown state is close to or far from the set of free-fermionic states. We first show that any algorithm capable of testing possibly mixed free-fermionic states would inevitably be inefficient. However, we then turn to presenting an efficient algorithm to test low-rank free-fermionic states. We prove improved bounds on the sample complexity for tomography of pure free-fermionic states, and we also generalize the algorithm to the mixed-scenario. The workhorse of our results is provided by new insights into fermionic Gaussian states: Specifically, we show lower and upper bound on the minimum trace distance between a state and the set of free-fermionic states, which also serve as efficiently computable measures of 'non-Gaussianity' for the state. Furthermore, we derive useful bounds on the trace distance between two possibly mixed free-fermionic states in terms of the norm difference of their correlation matrices.

I. Introduction

As the construction of quantum devices such as quantum computers and simulators progresses, there is a growing emphasis on developing efficient learning schemes to extract key diagnostic information from quantum systems. The tasks of quantum certification [1] and benchmarking [2] are crucial in any effort that aims are manipulating or preparing quantum states to utmost precision – and hence to achieve predictive power of a sort. Extracting information from quantum systems is generally a challenging task, marred by obstructions in sample and computational complexity, but real-world scenarios often defy general no-go results. States prepared on current quantum devices commonly feature a lot of structure; they possess specific properties and symmetries, diverging from general states which oftentimes can be seen largely as abstractions. Within the realm of fermionic quantum computation, free-fermionic [3] (or Gaussian) quantum states play a crucial role. Ubiquitous in various domains of physics, ranging from condensed matter theory [4] – then often referred to as arising in "non-interacting" settings – over the study of analog quantum simulators with ultra-cold fermionic atoms [5, 6] to quantum chemistry [7] what makes free-fermionic states unique for quantum computation is that they belong to a non-trivial class of efficiently classically simulable states [8–10]. While these states may be considered ineffective for advantageous quantum computation, they serve as an essential milestone in the ongoing construction of fault-tolerant quantum devices: Their efficiency in classical simulation provides a powerful tool for classical benchmarking quantum computation to ensure the correct functionality of quantum chips. This situation is not dissimilar from that of Clifford circuits and stabilizer states in the quantum computing domain.

However, before implementing any quantum benchmarking protocol based on free-fermionic states, experimentalists must usually verify that the state prepared on a quantum device is indeed close to a free-fermionic state in the first place. Addressing this concern, we formalize the problem as a *property testing problem*, aiming to distinguish situations where a given state (generally mixed) is close to the set of free-fermionic states from those where it is far. We not only provide a meticulous analysis, identifying scenarios for which it can be efficiently executed while ruling out cases in which it is computationally hard, but also provide polynomial-time algorithms to test

- (i) whether a general state is close to or far from the set of free-fermionic low-rank states and
- (ii) whether a low-rank state is close of far to the full set of free-fermionic states. Although seemingly similar, the two approaches differ significantly both conceptually and operationally. Ultimately, the choice between them rests entirely with the user and on the amount of prior knowledge that she has on the state, which we carefully discuss below. Moreover, these algorithms employ single-copy measurements, making them executable on near-term devices in a noise-resilient fashion.
- (iii) Furthermore, we present information-theoretic bounds that hold independent interest from both theoretical and experimental perspectives. In particular, we offer efficiently computable and experimentally measurable lower bounds for the minimum distance between a given state and the set of free-fermionic states. These bounds effectively probe the degree of non-Gaussianity (or magic) of a given state.
- (iv) Moreover, for general mixed free-fermionic states, we demonstrate that the maximal information-theoretic difference (trace distance) between two states is, at most, as large as the distance quantified by their respective correlation matrices, encoding two-body Majorana correlation functions. This relation is rigorously established with a *optimal perturbation bound* between

[*] {l.bittel, a.mele, jense, lorenzo.leone}@fu-berlin.de

the (Uhlmann) fidelity between two free-fermionic states and the operator norm difference between the respective correlation matrices. Beyond contributing to our testing algorithms, this result has significant implications for experimental perspectives, as Majorana correlations are easily measurable with single-copy Pauli measurements.

(v) Confining our analysis to pure states, we enhance this bound by offering an optimal perturbation bound for the overlap between two pure free-fermionic states. This is expressed in terms of the Hilbert-Schmidt norm difference between the correlation matrices of the states. Remarkably, the two bounds for pure and mixed states respectively are optimal in their respective domains, and they differ, making their effective merging unattainable. As an additional consequence of these perturbation bounds result, we develop a straightforward tomography algorithm that extends beyond and significantly improve previous known results [11], which were focused on pure and particle-preserving Gaussian states. In particular, for pure states, we significantly enhance the scaling compared to Ref. [11], and we extend the tomography algorithm for completely general mixed free-fermionic states.

A. Setup, preliminaries and definitions

In this section, we briefly provide the basic definitions necessary for the main results of this work, which are presented later on. We consider systems of n fermionic modes (or qubits, by virtue of the Jordan-Wigner representation). Majorana operators are defined, through standard Pauli single qubit operators $\{X_i, Z_i, Y_i, I\}$, as

$$\gamma_{2k-1} := (\prod_{j=1}^{k-1} Z_j)X_k \,, \qquad \gamma_{2k} := (\prod_{j=1}^{k-1} Z_j)Y_k \tag{1}$$

for $k \in [n]$, where $[n] := \{1, \dots, n\}$. Given a quantum state ρ, its *correlation matrix* (or covariance matrix) $\Gamma(\rho)$ is a $2n \times 2n$ matrix with elements

$$[\Gamma(\rho)]_{j,k} = -\frac{i}{2}\operatorname{Tr}\left([\gamma_j, \gamma_k]\,\rho\right), \tag{2}$$

where $j, k \in [2n]$. Correlation matrices are real and anti-symmetric, with eigenvalues in absolute value contained in the interval $[0, 1]$.

Let $O(2n)$ denote the orthogonal group on a $2n$-dimensional vector space. There is bijection between $O(2n)$ and *free-fermionic unitaries* (or Gaussian) acting a on n qubits system: For any orthogonal matrix $Q \in \mathrm{O}(2n)$, a free-fermionic unitary U_Q is a unitary satisfying

$$U_Q^\dagger \gamma_\mu U_Q = \sum_{\nu=1}^{2n} Q_{\mu,\nu}\gamma_\nu \tag{3}$$

for any $\mu \in [2n]$. This is a mild generalization of the $\mathrm{SO}(2n)$ case, which is associated with physical parity preserving Gaussian unitaries. For the sake of generality, we always present our results in the context of $\mathrm{O}(2n)$. Under free fermionic unitaries U_Q with associated orthogonal matrix $Q \in O(2n)$, correlation matrices transform simply as

$$\Gamma(U_Q \rho U_Q^\dagger) = Q\Gamma(\rho)Q^T. \tag{4}$$

A free fermionic state ρ is a state which can be expressed as

$$\rho = U_Q \bigotimes_{j=1}^{n} \left(\frac{I + \lambda_j Z_j}{2}\right) U_Q^\dagger, \tag{5}$$

for U_Q being the free-fermionic unitary associated with $Q \in \mathrm{O}(2n)$ and $\{\lambda_j\}_{j=1}^n$, dubbed as *normal eigenvalues*, being real numbers with $|\lambda_j| \leq 1$. For more details, refer to Section II. In the remainder of this work, we frequently employ the Schatten p-norms as matrix norms, defined as $\|A\|_p := \mathrm{tr}(|A|^p)^{1/p}$, for $|A| := \sqrt{A^\dagger A}$. From this, the *trace distance* between two quantum states ρ and σ is the distance in the 1-norm and is defined as

$$\|\rho - \sigma\|_1 := \mathrm{tr}\big(\sqrt{\rho - \sigma}\big). \tag{6}$$

The trace distance has a nice operational significance: it is the maximum probability of distinguishing two states via generalized quantum measurements. Related to the trace distance, there is the *fidelity* that quantifies the closeness of two quantum states and is defined as

$$\mathcal{F}(\rho, \sigma) := \operatorname{Tr}\left(\sqrt{\sqrt{\sigma}\rho\sqrt{\sigma}}\right)^2. \tag{7}$$

Notice that for ρ, σ being pure, it reduces to the square overlap between the state vectors. The trace distance and the fidelity are related by the *Fuchs van de Graaf* inequality [12]

$$1 - \sqrt{\mathcal{F}(\rho, \sigma)} \leq \frac{1}{2}\|\rho - \sigma\|_1 \leq \sqrt{1 - \mathcal{F}(\rho, \sigma)}. \tag{8}$$

Before concluding the section, let us introduce the set of free-fermionic states. In particular, in the rest of this work, two sets of free-fermionic states are considered: $\mathcal{G}_{\mathrm{mixed}}$, comprising all free-fermionic quantum states, and $\mathcal{G}_R$, encompassing free-fermionic states with a rank at most $R = 2^r$, where $r \in [n]$. We denote $\mathcal{G}_{\mathrm{pure}}$ the set $\mathcal{G}_R$ for $R = 1$. As a matter of fact, we have $\mathcal{G}_{\mathrm{pure}} \subset \mathcal{G}_R \subset \mathcal{G}_{\mathrm{mixed}}$ for $1 < r < n$.

B. Overview of the main results

In this section, we present the main results of this work in a relatively informal fashion, omitting their proofs. As mentioned earlier, the primary motivation behind this work is to provide a robust method for testing free-fermionic states. In achieving this goal, we have derived novel and optimal information-theoretic bounds between the trace distance and covariance matrices associated with fermionic states. These bounds are of independent interest and are instrumental for the main algorithms of this work, namely property testing and tomography of Gaussian states. Therefore, we first present the information-theoretic bounds below and briefly comment on their potential usage in other contexts beyond the scope of this work. Later on, we informally discuss the testing algorithm and the tomography algorithm in their simplest version. For a more detailed treatment and formal proofs, the interested reader is then referred to the more technical part of this work in Sections II, III, IV and V for detailed derivations.

A bound for optimal free-fermionic state certification. Imagine one aims to prepare a pure free-fermionic state on a quantum processor. In practice, an imperfect, non-Gaussian, yet close version of the state is actually prepared. The task of quantum state certification [1] is to verify the almost correct preparation of the target state based on the operational distance between the two, i.e., the trace distance. However, since the distance between a theoretical quantum state ψ and a quantum state ρ is generally hard to measure, we aim to understand how the trace distance between two "close" quantum states is controlled by their respective correlation matrices, which can be efficiently measured in practical scenarios. Below, we upper bound the trace distance between a perfect pure free-fermionic state ψ and a non-Gaussian (possibly mixed) imperfect realization ρ through their respective covariance matrices.

Lemma 1 (Closeness of quantum states in terms of correlation matrices). *Let $\psi \in \mathcal{G}_{\text{pure}}$ be a free fermionic pure state and ρ be an arbitrary (possibly non-Gaussian) quantum state. Then*

$$\|\psi - \rho\|_1 \leq \sqrt{\|\Gamma(\psi) - \Gamma(\rho)\|_1}, \tag{9}$$

further discussed and proved in Section III. Therefore, given that the correlation matrix $\Gamma(\psi)$ is known and efficiently classically encoded, Eq. (9) offers an efficient and direct method to verify the accurate preparation of ψ within a marginal error ε, as it is sufficient to measure $\Gamma(\rho)$ up to $O(\epsilon^2)$ precision that require $\text{poly}(n)$ resources.

Optimal perturbation bounds for free-fermionic states. Next, we introduce two perturbation bounds for the fidelity of two close free-fermionic states in relation to the distance between their covariance matrices.

Theorem 1 (Optimal perturbation bounds for free-fermionic states). *Let $|\psi\rangle, |\phi\rangle \in \mathcal{G}_{\text{pure}}$ two pure free-fermionic state vectors, then*

$$1 - |\langle\psi|\phi\rangle|^2 \leq \frac{1}{16}\|\Gamma(\psi) - \Gamma(\phi)\|_2^2, \tag{10}$$

while for $\rho, \sigma \in \mathcal{G}_{\text{mixed}}$ being two mixed free fermionic states, we find

$$1 - \mathcal{F}(\rho,\sigma) \leq \frac{1}{4}\|\Gamma(\rho) - \Gamma(\sigma)\|_1 + \frac{1}{8}\|\Gamma(\rho) - \Gamma(\sigma)\|_2^2. \tag{11}$$

The proof has to be found in Section III. Both inequalities (10) and (11) are optimal, i.e., they are saturated for pure and mixed states respectively. Indeed the pure bound is tight (exact) for all two mode Gaussian states of the the same parity, while the the mixed state bound is tight for general 1 mode Gaussian states.

Besides being fundamental for the efficiency of subsequent testing and tomography algorithms, we anticipate Theorem 1's inequality to have extensive applicability in the context of free fermions, in both theoretical and experimental realms. It operationally quantifies the closeness between two Gaussian states using their correlation matrices, which can be efficiently measured and computed with polynomial efforts.

Distance from the set of free-fermionic states: computable measures of non-Gaussianity. Given a quantum state ρ, the minimal distance from the set of free-fermionic states provides an operational measure of non-Gaussianity for fermionic systems. We recall that the minimal trace distance from a given set of free states constitutes a universally valid measure that respects all the desired properties of resource monotones [13]. However, the problem with such a measure is that it is neither computable, involving a minimization procedure, nor experimentally measurable. Here, we present lower bounds on the trace distance between a quantum state ρ and the set of free-fermionic states, that allow for the efficient estimation of non-Gaussianity in practical and experimental settings.

Lemma 2 (Lower bounds to trace distances). *Let ρ be an arbitrary quantum state and let λ_{r+1} be the $(r+1)$-th smallest normal eigenvalue of its correlation matrix $\Gamma(\rho)$, then*

$$\min_{\sigma \in \mathcal{G}_R} \|\rho - \sigma\|_1 \geq 1 - \lambda_{r+1}, \tag{12}$$

where the extremum is taken over $\mathcal{G}_R$. Conversely, if ρ is a arbitrary quantum state with $\text{rank}(\rho) \leq 2^r$ for $r \in [n]$, then

$$\min_{\sigma \in \mathcal{G}_{\text{mixed}}} \|\rho - \sigma\|_1 \geq \frac{(1-\lambda_{r+1})^{r+1}}{1 + (r+1)(1-\lambda_{r+1})^r}. \tag{13}$$

Note that Eq. (12) requires no assumption on the state ρ, and it lower bounds the distance from the set $\mathcal{G}_R$. Conversely, with the promise that ρ has a rank at most $R := 2^r$ with $r \in [n]$, Eq. (13) establishes a lower bound on the distance from the set of all free-fermionic states $\mathcal{G}_{\text{mixed}}$. The proof for the above results can be found in Section III A.

As discussed in Section II, estimating the normal eigenvalues of the correlation matrix of a quantum state can be done efficiently by employing single-qubit Pauli measurements. Thus, the above inequalities provide an efficient procedure to quantify how far a state is from the set of free-fermionic states in practical scenarios. Additionally, in Section III A, we observe that if we randomly sample a state from certain distributions (e.g., 2-design distributions [14] like states prepared by random quantum circuits of polynomial size or Haar random states), the aforementioned lower bounds are significantly larger than zero with high probability. This implies the detectability of the proposed quantity for most states in such distributions. Also, using such inequalities, we rigorously show that most of pure states are far from being free-fermionic.

Property testing for free-fermionic states. The question that stands behind the main motivation of our work is the following.

Given an unknown quantum state ρ, is it close to or far from the set of free fermionic states?

Specifically, our goal is to identify scenarios in which addressing the aforementioned question is feasible in terms of resources, to provide algorithms with provable efficiency guarantees, and to delineate situations in which answering the question is challenging. First of all, let us formulate the problem in a rigorous fashion.

Problem 1 (Property testing of free-fermionic states)**.** *Let $\varepsilon_B > \varepsilon_A \geq 0$. Given N copies of an unknown quantum state ρ with the promise that it falls into one of two distinct situations:*

- ***Case A:** There exists a free-fermionic state $\sigma \in \mathcal{G}$ such that $\|\rho - \sigma\|_1 \leq \varepsilon_A$.*
- ***Case B:** The state ρ is ε_B-far from all free-fermionic states σ, indicating $\min_{\sigma\in\mathcal{G}} \|\rho - \sigma\|_1 > \varepsilon_B$.*

Determine whether the state is in Case A or Case B through measurements performed on the provided N state copies. Further specifications regarding the rank of the state ρ and the set of free-fermionic states $\mathcal{G} \equiv \mathcal{G}_{\mathrm{pure}}, \mathcal{G}_{\mathrm{mixed}}, \mathcal{G}_R$ must be provided.

While we show that solving Problem 1 in its full generality requires an exponential amount of resources, rendering it unfeasible for practical purposes, we present algorithms capable of efficiently solving it under certain assumptions about the state under examination or by restricting the set of considered Gaussian states.

When no prior assumptions on the state ρ and no restrictions on the set of free-fermionic states $\mathcal{G}$ are provided, we establish the general hardness for Problem 1, demonstrating that $N = \Omega(2^n)$ copies of the state ρ are necessary. Below, we present a more refined version of the mentioned no-go result.

Theorem 2 (Hardness of testing bounded rank free-fermionic states)**.** *Let $\varepsilon_B > 0$ and $r \in [n]$. Let ρ denote the unknown state and $\mathcal{G}$ the set of free fermionic states considered. To solve Problem 1, with at least a $2/3$ probability of success, $N = \Omega(2^r/\varepsilon_B^2)$ copies are necessary if either of the following hypotheses is assumed:*

- *ρ is such that $\mathrm{rank}(\rho) \leq 2^r$ with $r \in [n]$,*
- *$\mathcal{G} \equiv \mathcal{G}_R$ with $R \leq 2^r$.*

In particular, for $r = \Omega(n)$ the sample complexity grows exponentially in the number of modes n.

While the formal proof has to be found Section IV B, the general idea at core of this complexity arises from recognizing that the maximally mixed state is free-fermionic. This fact allows us to leverage the hardness of distinguishing whether the underlying state is the maximally mixed state or far from it in trace distance, which is a notoriously hard problem [15]. The above theorem establishes necessary conditions on the samples N to be spent to solve Problem 1 given assumptions either on ρ or on $\mathcal{G}$. Given these results, Theorem 2 prompts the natural question of whether an algorithm exists that scales exponentially with r (polynomially with the rank), which solve the property testing problem under the assumption that ρ has a rank at most $R = 2^r$ or when restricting to the set $\mathcal{G}_R$. In response to this, we propose two learning algorithms that scale as $O(\mathrm{poly}(n, 2^r))$, and summarize our findings in the following informal theorem.

Theorem 3 (Efficient free-fermionic testing - Informal version of Theorems 16 and 17)**.** *Problem 1 can be solved with $N = \mathrm{poly}(n, 2^r)$ copies of ρ in the following scenarios:*

(i) The given state ρ is such that $\mathrm{rank}(\rho) \leq 2^r$.

(ii) The set of Gaussian states is restricted to $\mathcal{G}_R$ with $R \leq 2^r$.

We provide algorithms for case (i) and (ii) that use N samples and $\mathrm{poly}(n, 2^r)$ computational resources.

The core idea behind the efficiency of low-rank free-fermionic states lies in the fact that any free-fermionic state, up to a free-fermionic unitary, is equivalent to a product state. Thus, the algorithm first identifies this free-fermionic unitary to factorize the state. This reduction allows the problem to be simplified to testing whether the underlying state is a (free-fermionic) product state or not. This can be solved with a complexity that scales polynomially with the rank of the state 2^r. For instance, this can be achieved by employing full state tomography on only $r + 1$ qubits. Additional details, including assumptions on ε_A and ε_B, the algorithms presented in a pseudocode fashion, as well as the sample and computational analyses have to be found in Section IV.

Let us summarize our findings. In its full generality, that is, without rank assumptions on the state ρ and considering $\mathcal{G} \equiv \mathcal{G}_{\mathrm{mixed}}$, Problem 1 requires $N = \Omega(2^n)$ samples of the state to be solved. However, as claimed in Theorem 3, we have established that Problem 1 can be efficiently addressed both sample-wise and computationally under two specific scenarios: (i) when the given state ρ has a rank that scales polynomially with the number of modes n, or (ii) when the focus is solely on quantifying closeness to the set of Gaussian states with polynomially bounded rank.

Although these two approaches share similarities in principle, they differ significantly both conceptually and operationally. Ultimately, the choice between them rests entirely with the user. Specifically, if they possesses guarantees that the prepared state predominantly occupies a relatively small subspace of the Hilbert space, then we provided provable guarantees in probing the distance concerning all Gaussian states $\mathcal{G}_{\mathrm{mixed}}$. Conversely, if an experimentalist lacks a clear understanding of the nature of the state due to imprecisions or noise, they only have reliable assurances in determining whether the state is close to or far from the set of Gaussian states with polynomially bounded rank. Although seemingly less satisfactory, the latter approach is more general and applicable in completely agnostic situations.

Efficient tomography of free-fermionic states. We conclude this work by presenting a simple algorithm for efficiently learning a unknown n-qubit free-fermionic state either pure or mixed. More rigorously, we are concerned with the following problem: let $\rho \in \mathcal{G}$, with $\mathcal{G} = \mathcal{G}_{\mathrm{mixed}}, \mathcal{G}_{\mathrm{pure}}$, be a unknown free-fermionic state, design a computationally efficient quantum learning algorithm that consumes N copies of ρ and output a classical description $\hat{\rho}$ that is ε-close in trace distance to ρ with failure probability of at most δ. Some earlier works [11, 16, 17] have already tackled this problem, but their analysis has been limited to the specific case of ρ being a pure free fermionic state. We first provide an algorithm limited to the case of pure states that significantly improves upon previous work. What's more, our approach extends to the more realistic mixed state scenario, significantly broadening the scope of such result. This extension, as well as the improved algorithm for pure state case, heavily rely on the toolkit developed and discussed in the first part of this work, in particular Theorem 1.

Proposition 1 (Tomography of pure free-fermionic states). *Let ψ be a pure free-fermionic quantum state. For $\varepsilon \in (0,1)$ and $\delta \in (0,1]$ there exist a learning algorithm that utilize $N = 32(n^3/\varepsilon^2)\log\big(4n^2/\delta\big)$ copies of the state and only single-copies measurements to learn an efficient classical representation of the state $\hat{\psi}$ obeying $\|\psi - \hat{\psi}\|_1 \leq \varepsilon$.*

Therefore the overall scaling can be enhanced from $O(n^3m^2/\varepsilon^4)$ (where m represents the fixed number of particles) to $O(n^3/\varepsilon^2)$ significantly improving over the results of Ref. [11]. A more detailed analysis is conducted in Section V. The following theorem is a direct consequence of Theorem 1.

Theorem 4 (Tomography of mixed free-fermionic states). *Let $\varepsilon \in (0,1)$ and $\delta \in (0,1]$ and $\rho \in \mathcal{G}_{\mathrm{mixed}}$. There exists a computationally efficient quantum algorithm that, employing $N = O\left((n^5/\varepsilon^4)\log\big(n^2/\delta\big)\right)$ copies of the state ρ and single-copies Gaussian measurements, learns a classical representation $\hat{\rho}$ of the state ρ obeying $\|\hat{\rho} - \rho\|_1 \leq \varepsilon$, with a success probability of at least $1 - \delta$.*

In fact, we can even strengthen this result under specific assumptions on the input state ρ. Under the assumption that the underlying state is an n-modes fermionic state with a *fixed number of particles* m, the sample complexity of the protocol can be similarly demonstrated to be $O(n^3m^2)$.

C. Related work

The main motivation behind this work is to provide practical and efficient quantum algorithms for free-fermionic state testing. However, we also consider the task of quantum state tomography for free-fermionic states. In this section, we discuss previous work and position our algorithms in the current literature. Addressing the testing of specific properties in quantum states spans various contexts. A property tester for a quantum state class C involves taking copies of a state ρ as input and determining either A) whether ρ belongs to C or B) if ρ is ϵ-far in trace distance from all states in C, provided that one of these scenarios is true. The property testing problem is particularly intriguing due to its potential experimental applicability. Indeed, under relatively weak assumptions, it provides a direct means to experimentally verify if a given property holds.

In Ref. [15], the identity testing problem was explored with the goal of distinguishing whether the underlying state belongs to the class C of states close to maximally mixed states or is far from it. The problem, in its full generality, was shown to require a sample complexity scaling exponentially with the number of qubits, i.e., $\Omega(2^n)$. Simultaneously, an algorithm performing identity testing using $O(2^n)$ samples was demonstrated, thus showing optimality. Building on this hardness, product state testing has been examined in Ref. [18], focusing on the class C being the one of product states. Given the significance of testing genuine multipartite entanglement in quantum states, it is crucial to determine whether the underlying state is a product state or not. In Ref. [18], the authors have established a lower bound on the sample complexity of $\Omega(2^n)$, as well as an algorithm achieving the task using $O(2^n)$ copies by using entangled measurements over many specimens or "copies" and $O(4^n)$ unentangled (single-copy) measurements.

In a similar spirit to our work, there exists another relevant class of non-trivial classically simulatable states known as stabilizer states [19]. Stabilizer states are eigenstates of n independent and mutually commuting Pauli operators. In Ref. [20], considering the class C as the set of pure stabilizer states, a property testing algorithm was demonstrated that requires only $O(1)$ samples of the state. This remarkable efficiency is ultimately attributed to the use of entangling (Bell) measurements and techniques known as *Bell difference sampling*. In a slightly more general and practically applicable problem considered in Ref. [21], where the class C consists of states ε-close in trace distance to pure stabilizer states, it was shown that $O(1)$ copies of the state are sufficient for the testing algorithm to succeed. Similar settings in the free-bosonic realm have also been considered [22].

Quantum state tomography is the other learning problem addressed in this work. Given N copies of an unknown quantum state ρ, the aim of quantum state tomography is, through arbitrary measurements, to produce a classical description $\hat{\rho}$ of the state that is ε-close in trace distance to ρ with a failure probability of at most δ. In Ref. [23], a sample-optimal quantum state tomography algorithm has been introduced. Specifically, it has been shown that $\Omega(4^n)$ copies of the state are necessary for any quantum tomography algorithm to succeed. They have presented a sample-optimal algorithm scaling as $O(n4^n)$, thereby matching the lower bound up to a linear scaling factor in the number of qubits (modes) n.

Given the intrinsic inefficiency of quantum state tomography algorithm for general states, a natural question is whether if one restricts the class of input quantum states, whether quantum state tomography can be conducted both sample and computationally efficiently. In this regard, a number of insightful work has been produced that demonstrates sample and computational efficiency for specific class of states, which include: Pure stabilizer states [24], t-doped stabilizer states [25? , 26] (states obtained by at most t non-Clifford gates), matrix product states [27–31], quantum phase states [?] and more. Relevant for the current work is the recent efficient learning algorithm for n free-fermionic states with fixed particle number m presented in Ref. [11], which we significantly improve in scope and efficiency. The algorithm presented in Ref. [11] focuses only on learning *pure* free-fermionic states with fixed particle number m, with a scaling $O(n^3m^2\varepsilon^{-4})$. In this work, we not only improve the scaling from $O(n^3m^2\varepsilon^{-4})$ to $O(n^3\varepsilon^{-2})$, but we broaden the scope of the tomography algorithm to more practical scenarios and consider the case of mixed free-fermionic states. Notably, the analogous problem of learning mixed Gaussian states was previously unresolved also in the bosonic context. However, in a parallel work [32], together with other coauthors, we fill this gap in the bosonic literature.

D. Discussion and open questions

In this work, we have demonstrated an efficient method for discerning whether a quantum state is free-fermionic or not, utilizing experimentally feasible measurements. Additionally, we have introduced lower bounds, that can be efficiently estimated, on the distance of a state from the set of free-fermionic states. These bounds offer valuable insights into quantifying the extent of non-free fermionic features present in a quantum system. Furthermore, we have formally extended a series of algorithms algorithms previously proposed for learning free-fermionic pure states to the more complex mixed-state scenario. We posit that the findings presented in this work can serve as a valuable resource for designing and conducting quantum simulation experiments.

Furthermore, while our analysis comprehensively addresses the literature on testing and tomography of free-fermionic states, providing scenarios with provable efficiency guarantees and ruling out situations in which the aforementioned tasks are hard to perform, there remain several open questions related to the topics discussed in this paper.

- As discussed above, one particularly relevant class of classically simulatable states is the class of stabilizer states. While testing whether a given pure state is close or far in trace distance to the set of *pure* stabilizer states has been addressed, provable efficiency guarantees, as well as sample complexity lower bounds, are still missing for the more general and practical case of mixed states. Exploring this avenue would be interesting, especially in light of the algorithms discussed and developed in the manuscript.

- Within the class of classically simulatable states, there are subclasses representing "small" deviations from the sets of free-fermionic states or stabilizer states. Typically, such "small" deviations can be characterized by various notions related to the non-Gaussianity or non-stabilizerness of the given states, such as Gaussian rank (resp. stabilizer rank), doping the states with non-Gaussian (resp. non-Clifford) operations, or Gaussian extent (resp. stabilizer extent). Exploring these more general scenarios is therefore essential for both testing problems and quantum state tomography problems.

- The technical aspect of our work heavily relies on novel matrix inequalities proven here. In particular, Theorem 1 presents two optimal bounds relating the fidelity and the norm distance between the correlation matrices of pure and mixed Gaussian states, respectively. However, as also noted below Theorem 1, the two bounds cannot be merged. However, if we transfer the perturbation bound through the Fuchs-van de Graaf inequality to the trace distance, from Eq.(11) we obtain different results for the pure and mixed cases, respectively,

  $$\|\psi-\phi\|_1 \leq 4^{-1}\|\Gamma(\psi)-\Gamma(\phi)\|_2, \quad \text{pure states,}$$
  $$\|\rho-\sigma\|_1 \lesssim 2^{-1}\sqrt{\|\Gamma(\rho)-\Gamma(\sigma)\|_1}, \quad \text{mixed states.}$$

  Moreover, for the restrictive case in which $[\rho,\sigma]=0$, in Theorem 15, we can tighten Eq. (11) to

  $$\|\rho-\sigma\|_1 \leq 2^{-1}\|\Gamma(\rho)-\Gamma(\sigma)\|_1. \tag{14}$$

  Therefore, we conclude that it should be plausible that, for the trace-distance bound, there should be a universal bound for the pure and mixed cases that goes as

  $$|\rho-\sigma| \lesssim \alpha\|\Gamma(\rho)-\Gamma(\sigma)\|_1, \quad \text{(universal bound?)}$$

  with $\alpha=\Theta(1)$. Finding such a bound would guarantee optimal perturbation bounds for the trace norm difference as well and will be a matter of exciting future investigation.

II. Preliminaries

A. Notation and basic definitions

We use the following notation throughout our work. We denote with $\mathbb{C}^{d\times d}$ the set of $d \times d$ complex matrices, with $d \in \mathbb{N}$. The notation $[d]$ denotes the set of integers from 1 to d, i.e., $[d] := \{1, \dots, d\}$. We denote as I the identity operator, with a subscript specifying the dimension when necessary for clarity. The *Schatten p-norm* of a matrix $A \in \mathbb{C}^{d\times d}$, with $p \in [1, \infty]$, is given by

$$\|A\|_p := \mathrm{Tr}((\sqrt{A^\dagger A})^p)^{1/p}, \tag{S15}$$

which corresponds to the p-norm of the vector of singular values of A. The *operator norm* of a matrix $A \in \mathbb{C}^d$ is equal to its largest singular value. We denote the *Hilbert-Schmidt scalar product* as $\langle A, B\rangle_{HS} := \mathrm{Tr}\left(A^\dagger B\right)$. We denote as $\mathrm{O}(2n)$ the group of real orthogonal $2n \times 2n$ matrices. We denote the n-qubits Pauli operators as the elements of the set $\{I, X, Y, Z\}^{\otimes n}$, where I, X, Y, Z represent the standard single qubits Pauli. Pauli operators are traceless, Hermitian, square to the identity and form an orthogonal basis with respect the Hilbert-Schmidt scalar product for the space of linear operators. We define the set of quantum states as $\mathcal{S}\left(\mathbb{C}^d\right) := \{\rho \in \mathbb{C}^{d\times d} \,:\, \rho \geq 0,\ \mathrm{Tr}(\rho) = 1\}$. A state ρ is pure if and only if $\rho^2 = \rho$.

B. Free-fermionic states

In this subsection we provide definitions and Lemmas on free-fermionic states, which are useful for deriving our results. While we define these concepts in terms of qubits, it is worth noting that they can also be directly expressed in terms of fermions via the Jordan-Wigner mapping. In the following we consider an n-qubits system (or equivalently, n fermionic modes). Throughout this discussion, we focus on an n-qubit system. To begin, we introduce the definition of Majorana operators in relation to Pauli matrices.

Definition 1 (Majorana operators). *For each $k \in [n]$, Majorana operators can be defined as*

$$\gamma_{2k-1} := \left(\prod_{j=1}^{k-1} Z_j\right) X_k, \quad \gamma_{2k} := \left(\prod_{j=1}^{k-1} Z_k\right) Y_k. \tag{S16}$$

As can be readily verified, Majorana operators are Hermitian, traceless, and they square to the identity

$$\gamma_\mu = \gamma_\mu^\dagger, \quad \mathrm{Tr}(\gamma_\mu) = 0, \quad \gamma_\mu^2 = I \tag{S17}$$

for all $\mu \in [2n]$. Moreover, they anti-commute and are orthogonal with respect to the Hilbert-Schmidt inner product

$$\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu,\nu} I, \quad \langle \gamma_\mu, \gamma_\nu \rangle_{HS} = 0 \tag{S18}$$

for all $\mu, \nu \in [2n]$. As such, operators defined by Jordan-Wigner transformation conforms with the Majorana anti-commutation relations. A useful and easy to verify identity is $iZ_j = \gamma_{2j-1}\gamma_{2j}$.

Definition 2 (Majorana products). *Let S be the set $S := \{\mu_1, \ldots, \mu_{|S|}\} \subseteq [2n]$ with $1 \leq \mu_1 < \cdots < \mu_{|S|} \leq 2n$. We define*

$$\gamma_S := \gamma_{\mu_1} \cdots \gamma_{\mu_{|S|}}$$

if $S \neq \emptyset$ and $\gamma_\emptyset = I$ otherwise.

It is worth noting that the number of different sets $S \in [2n]$ and hence Majorana products is 4^n. For any set $S, S' \subseteq [2n]$, Majorana products are orthogonal

$$\langle \gamma_S, \gamma_{S'} \rangle_{HS} = 2^n \delta_{S,S'}.$$

Hence, they form a basis for $\mathbb{C}^{d \times d}$.

Definition 3 (Free-fermionic unitary). *For any orthogonal matrix $Q \in \mathrm{O}(2n)$, a free-fermionic unitary U_Q (also known as Gaussian unitary) is a unitary which satisfies*

$$U_Q^\dagger \gamma_\mu U_Q = \sum_{\nu=1}^{2n} Q_{\mu,\nu} \gamma_\nu \tag{S19}$$

for any $\mu \in [2n]$.

From this definition, it follows that $U_Q^\dagger = U_{Q^T}$. Since product of Majorana operators γ_μ with $\mu \in [2n]$ form a basis for the linear operators $\mathbb{C}^{d \times d}$, it suffices to specify how a unitary acts on the $2n$ Majorana operators γ_μ with $\mu \in [2n]$ to uniquely specify the unitary up to a phase. Specifically, for a given orthogonal matrix, there exists a known exact implementation of the associated free-fermionic unitary, which can be achieved using either $O(n^2)$ local 2-qubit gates [33] or $O(n^2)$ local 2-modes free-fermionic unitary Majorana evolutions [34]. From the previous definition, it follows the following.

Lemma 3 (Adjoint action of Gaussian unitary on a Majorana product). *For any $S \subseteq [2n]$ and U_Q free-fermionic unitary with $Q \in \mathrm{O}(2n)$, we have*

$$U_Q^\dagger \gamma_S U_Q = \sum_{S' \subseteq \binom{[2n]}{|S|}} \det(Q|_{S,S'}) \gamma_{S'} \tag{S20}$$

where $\binom{[2n]}{|S|}$ is defined as the set of subsets of $[2n]$ of cardinality $|S|$, while $Q|_{S,S'}$ is the restriction of the matrix Q to rows and columns indexed by S and S' respectively.

Proof. See Ref. [35] for a proof. □

We now give the definition of free-fermionic states (also known as fermionic Gaussian states).

Definition 4 (Free-fermionic states). *A free-fermionic state (also known as Gaussian state) in the Jordan-Wigner mapping can be defined as*

$$\rho = U_Q \rho_0 U_Q^\dagger, \quad \textit{with} \quad \rho_0 := \bigotimes_{j=1}^{n} \left(\frac{I + \lambda_j Z_j}{2}\right) \tag{S21}$$

where $\lambda_j \in [0,1]$ for each $j \in [n]$ and U_Q is the free-fermionic unitary associated to the orthogonal matrix $Q \in \mathrm{O}(2n)$.

This definition is slightly more general than defining a free-fermionic state like a state of the form $\exp(-\beta H)/\operatorname{Tr}(\exp(-\beta H)))$, where $\beta \in \mathbb{R}$ and H is a quadratic Hamiltonian in the Majorana operators. From the previous definition, it follows that ρ is pure if and only if $\lambda_j \in \{-1, 1\}$ for each $j \in [n]$. In such pure case, the state will be $U_Q |x\rangle$, where $|x\rangle := \bigotimes_{i=1}^{n} |x_i\rangle$ is a computational basis state with $x_i := (1 - \lambda_i)/2$. Since X_1 and $\{X_j X_{j+1}\}_{j=1}^{n} = \{-i\gamma_{2j}\gamma_{2j+1}\}_{j=1}^{n}$ are fermionic Gaussian unitaries, and the product of Gaussian unitaries is Gaussian, it follows that $\{X_j\}_{j=1}^{n}$ are Gaussian unitaries. Thus, without loss of generality, any pure fermionic Gaussian state can be written as $U_Q |0^n\rangle$, which is uniquely specified by an orthogonal matrix $Q \in \mathrm{O}(2n)$.

We can define now the correlation matrix of any (possibly non-free-fermionic) state.

Definition 5 (Correlation matrix)**.** *Given a (general) state ρ, we define its correlation matrix $\Gamma(\rho)$ as:*

$$[\Gamma(\rho)]_{j,k} := -\frac{i}{2} \operatorname{Tr}\left([\gamma_j, \gamma_k]\, \rho\right), \tag{S22}$$

where $j, k \in [2n]$.

The correlation matrix of any state is real and anti-symmetric, thus it has eigenvalues in pairs of the form $\pm i\lambda_j$ for $j \in [2n]$, where λ_j are real numbers such that $|\lambda_j| \leq 1$. Under free-fermionic unitaries, the correlation matrix of any quantum state changes by the adjoint action with the associated orthogonal matrix, as expressed in the following proposition.

Lemma 4 (Transformation of the correlation matrix under free-fermionic unitary)**.** *For any state ρ, we have*

$$\Gamma(U_Q \rho U_Q^\dagger) = Q\Gamma(\rho)Q^T, \tag{S23}$$

for any free-fermionic unitary U_Q associated to an orthogonal matrix $Q \in \mathrm{O}(2n)$.

This is easily verified by the definition of correlation matrix and free-fermionic unitary. We denote as Λ the correlation matrix of the $|0^n\rangle$ state vector, namely

$$\Lambda := \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = \bigoplus_{j=1}^{n} (iY). \tag{S24}$$

The correlation matrix of a computational basis state $|x\rangle$ with $x \in \{0,1\}^n$ is $\Gamma(|x\rangle) = \bigoplus_{j=1}^{n} (-1)^{x_i} (iY)$. It turns out that any real anti-symmetric matrix can be diagonalized with an orthogonal matrix, in particular we have the following result.

Lemma 5 (Normal decomposition of real anti-symmetric matrices [3])**.** *Any real anti-symmetric matrix Γ can be decomposed in the so-called* normal *form*

$$\Gamma = Q \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} Q^T, \tag{S25}$$

for an orthogonal matrix $Q \in \mathrm{O}(2n)$ and $\{\lambda_j\}_{j=1}^{n} \in \mathbb{R}$ real numbers ordered in increasing order. Thus, the eigenvalues of Γ are $\pm i\lambda_j$ for any $j \in [n]$. We denote $\{\lambda_j\}_{j=1}^{n}$ as normal eigenvalues.

The decomposition in Lemma 5 can be always performed in such a way that the orthogonal matrix $Q \in \mathrm{SO}(2n)$ (i.e., its determinant is one). In fact, if that is not the case, then we can write $Q = Q'\operatorname{diag}(-1, 1, \ldots, 1)$, for a matrix $Q' \in \mathrm{SO}(2n)$ (note that this matrix Q' exists because the product of two orthogonal matrix is an orthogonal matrix and because of the Cauchy–Binet formula of the determinant).

Using Lemma 5, we can show that the correlation matrix of any state ρ has normal eigenvalues less than one (and thus also the absolute values of its eigenvalues). In fact, let $\Gamma(\rho) = Q(\bigoplus_{j=1}^{n} i\lambda_j Y)Q^T$ be the correlation matrix expressed in its normal form. Then, we have

$$\lambda_j = (Q^T \Gamma(\rho) Q)_{2j-1,2j} = (\Gamma(U_Q^\dagger \rho U_Q))_{2j-1,2j} = \operatorname{Tr}\Big(U_Q^\dagger \rho U_Q Z_j\Big). \tag{S26}$$

Thus, because of Holder inequality we have $|\lambda_j| \leq \|U_Q^\dagger \rho U_Q\|_1 \|Z_j\|_\infty = 1$

Furthermore, by using Lemma 5, we establish a bijection between the set of free-fermionic states and the set of real-anti-symmetric matrices with eigenvalues smaller than one in absolute value.

Lemma 6 (Bijection between free-fermionic states and correlation matrices). *Given a free-fermionic state of the form*

$$\rho = U_Q \rho_0 U_Q^\dagger, \qquad \textit{with} \quad \rho_0 := \bigotimes_{j=1}^{n} \left(\frac{I + \lambda_j Z_j}{2} \right) \tag{S27}$$

where $\lambda_j \in [-1,1]$ for each $j \in [n]$ and U_Q is the free-fermionic unitary associated to the orthogonal matrix $Q \in \mathrm{O}(2n)$, then its correlation matrix is

$$\Gamma = Q \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} Q^T, \tag{S28}$$

which is a real and anti-symmetric matrix, with eigenvalues $\pm i\lambda_j$ in pairs such that $\lambda_j \in [-1,1]$ for any $j \in [n]$. Conversely, given a real, anti-symmetric matrix Γ, it can be decomposed as in Eq. (S28), in particular, its eigenvalues are of the form $\pm i\lambda_j$ in pairs. If $\lambda_j \in [-1,1]$, then Γ uniquely defines a state ρ of the form of Eq. (S27).

The previous theorem ensures that by specifying a valid correlation matrix (i.e., real, anti-symmetric, with eigenvalues smaller than one), we uniquely specify a free-fermionic state. Vice versa, having a free-fermionic state, it uniquely defines a correlation matrix. In particular, any pure free-fermionic state $|\psi\rangle = U_Q |0^n\rangle$ is specified by an orthogonal matrix $Q \in \mathrm{O}(2n)$, and its correlation matrix will be $\Gamma(\psi) = Q\Lambda Q^T$, where Λ is defined in Eq. (S24). From this, it follows:

Remark 1. *The correlation matrix $\Gamma(\psi)$ of a pure free-fermionic state ψ satisfies $\det(\Gamma(\psi)) = 1$, is an orthogonal matrix and its normal eigenvalues are all equal to one in absolute value.*

Moreover, we also have that the rank of a mixed free-fermionic state is related to the number of normal eigenvalues strictly smaller than one in absolute value, as it follows by Lemma 6.

Remark 2 (Relation between rank and normal eigenvalues of a free-fermionic state). *Let ρ be a free-fermionic state, expressed as $\rho = U_Q \left(\bigotimes_{j=1}^{n} (I + \lambda_j Z_j)/2 \right) U_Q^\dagger$, where $\{\lambda_j\}_{j=1}^{n} \subseteq [-1,1]$ and U_Q is a free-fermionic unitary. Let m be the number of elements in $\{\lambda_1, \ldots, \lambda_n\}$ that are in absolute value smaller than one. We then have $\mathrm{rank}(\rho) = 2^m$.*

In our analysis the notion of *Pfaffian* will be useful.

Definition 6 (Pfaffian of a matrix). *Let C be a $2n \times 2n$ anti-symmetric matrix. Its Pfaffian is defined as*

$$\mathrm{Pf}(C) = \frac{1}{2^n n!} \sum_{\sigma \in S_{2n}} \mathrm{sgn}(\sigma) \prod_{i=1}^{n} C_{\sigma(2i-1),\sigma(2i)}, \tag{S29}$$

where S_{2n} is the symmetric group of order $(2n)!$ and $\mathrm{sgn}(\sigma)$ is the signature of σ. The Pfaffian of an $m \times m$ antisymmetric matrix with m odd is defined to be zero.

Well-known properties are the following. For any matrix B, we have $\mathrm{Pf}(BCB^T) = \det(B)\,\mathrm{Pf}(C)$ and $\mathrm{Pf}(\lambda C) = \lambda^n\,\mathrm{Pf}(C)$, where C is a $2n \times 2n$ anti-symmetric matrix and $\lambda \in \mathbb{C}$. Moreover, it holds that $\mathrm{Pf}(C)^2 = \det(C)$ (note that this is consistent with the fact that the Pfaffian of an odd anti-symmetric matrix is defined to be zero, since the determinant of an odd anti-symmetric matrix is zero). Another useful identity is

$$\mathrm{Pf}\left(\bigoplus_{j=1}^{n} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} \right) = \prod_{j=1}^{n} \lambda_j. \tag{S30}$$

Now we recall the well-known Wick's theorem, which states that the any Majorana product expectation value over a free-fermionic state can be computed efficiently given access to its correlation matrix.

Lemma 7 (Wick's Theorem [3, 36]). *Let ρ be a free-fermionic state with the associated correlation matrix $\Gamma(\rho)$. Then, we have*

$$\mathrm{Tr}(\gamma_S \rho) = i^{|S|/2}\,\mathrm{Pf}(\Gamma(\rho)|_S), \tag{S31}$$

where $\gamma_S = \gamma_{\mu_1} \cdots \gamma_{\mu_{|S|}}$, and $S = \{\mu_1, \ldots, \mu_{|S|}\} \subseteq [2n]$ with $1 \le \mu_1 < \cdots < \mu_{|S|} \le 2n$, while $\Gamma(\rho)|_S$ is the restriction of the matrix $\Gamma(\rho)$ to the rows and columns corresponding to elements in S.

Note that, since, for any $S \subseteq [2n]$ the restriction of the correlation matrix $\Gamma|_S$ is still anti-symmetric, its Pfaffian is well-defined. The Pfaffian of $\Gamma|_S$ can be computed efficiently in time $\Theta(|S|^3)$.

Definition 7 (Parity). *The parity operator is defined as the operator:*

$$Z^{\otimes n} = (-1)^n \gamma_1 \gamma_2 \cdots \gamma_{2n-1}\gamma_{2n}. \tag{S32}$$

The parity of a quantum state ρ is defined as the expectation values of the parity operator, i.e.,

$$\mathrm{Parity}(\rho) := \mathrm{Tr}\big(Z^{\otimes n}\rho\big).$$

Lemma 8 (Gaussian states are eigenstates of the parity operator). *Any Gaussian pure state $|\psi_Q\rangle := U_Q|0^n\rangle$ associated with the orthogonal matrix $Q \in \mathrm{O}(2n)$ satisfies:*

$$Z^{\otimes n}|\psi_Q\rangle = \det(Q)\,|\psi_Q\rangle\,. \tag{S33}$$

Thus, we also have $\mathrm{Parity}(\psi_Q) = \det(Q)$.

Proof. We have

$$Z^{\otimes n}|\psi_Q\rangle = (-i)^n\gamma_{[2n]}|\psi_Q\rangle = (-i)^n U_Q U_Q^\dagger \gamma_{[2n]} U_Q|0^n\rangle = (-i)^n \det(Q) U_Q \gamma_{[2n]}|0^n\rangle \tag{S34}$$

$$= \det(Q) U_Q Z^{\otimes n}|0^n\rangle = \det(Q)\,|\psi_Q\rangle\,, \tag{S35}$$

where the first step follows from Jordan-Wigner, and we defined $\gamma_{[2n]} := \prod_{j=1}^{n}\gamma_j$. The third step follows from Eq. S20. □

From this lemma, it follows that if two pure fermionic Gaussian states have different parity, then they have also zero overlap (however, the viceversa is not true: two pure Gaussian states with the same parity can have zero overlap, e.g., $|00\rangle$ and $|11\rangle$). This result can also be derived using Wick's Theorem (Lemma 7). In fact, for a possibly mixed free-fermionic state ρ, we have

$$\mathrm{Parity}(\rho) = \mathrm{Tr}\big(Z^{\otimes n}\rho\big) = \mathrm{Pf}(\Gamma(\rho)). \tag{S36}$$

Furthermore, according to the properties of the Pfaffian, we obtain:

$$\mathrm{Pf}(\Gamma(\rho)) = \Big(\prod_{j=1}^{n}\lambda_j\Big)\det(Q), \tag{S37}$$

where $Q \in \mathrm{O}(2n)$ and $\{\lambda_j\}_{j=1}^{n}$ are respectively the orthogonal matrix and the normal eigenvalues associated with the normal form of $\Gamma(\rho)$. If the Gaussian state ρ is pure, then all the normal eigenvalues are equal to one, hence the parity is equal to $\det(Q)$.

We now mention an important formula that relates the overlap of two pure fermionic Gaussian states to their correlation matrices [36].

Lemma 9 (Overlap between two pure Gaussian states [36]). *The overlap between two pure Gaussian states $|\psi_1\rangle, |\psi_2\rangle$ is:*

$$|\langle\psi_1|\psi_2\rangle|^2 = \left|\mathrm{Pf}\left(\frac{1}{2}(\Gamma(\psi_1)+\Gamma(\psi_2))\right)\right|. \tag{S38}$$

It can be shown that the preceding formula is consistent with the fact that two Gaussian states with opposite parity have zero overlap: in fact, the Pfaffian of the sum of the correlation matrices associated to the two pure Gaussian states with opposite parity must be zero, as follows from Corollary 2.4.(b) of Ref. [37].

In our discussion, we leverage the following lemma, which is available in the literature in various forms (for instance, see Ref. [38]).

Lemma 10 (Purification of a mixed free-fermionic state.). *Any n-qubits mixed free-fermionic state ρ can be purified into a pure free-fermionic state $|\psi_\rho\rangle$ of $2n$-qubits. Specifically, the purified state vector $|\psi_\rho\rangle$ corresponds to the free-fermionic state associated with the correlation matrix*

$$\Gamma(\psi_\rho) = \begin{pmatrix} \Gamma(\rho) & \sqrt{I_{2n}+\Gamma^2(\rho)} \\ -\sqrt{I_{2n}+\Gamma^2(\rho)} & -\Gamma(\rho) \end{pmatrix}. \tag{S39}$$

Proof. Since any free-fermionic state is fully specified by its correlation matrix, we only need to demonstrate that $\Gamma(|\psi\rangle\langle\psi|)$ is a valid correlation matrix corresponding to a pure state, and that the partial trace of this pure state corresponds to ρ. This latter assertion is trivial, as taking the partial trace with respect to qubits indexed by $E := \{n+1,\dots,2n\}$ of $|\psi\rangle\langle\psi|$ involves considering only the restriction of $\Gamma(|\psi\rangle\langle\psi|)$ to the first diagonal block, corresponding to $\Gamma(\rho)$, and thus yielding the state ρ [3]. Therefore, we are left to demonstrate that $\Gamma(|\psi\rangle\langle\psi|)$ is a valid correlation matrix corresponding to a pure state. In particular, we need to show that it is real-anti-symmetric with eigenvalues $\{\pm i\}_{j=1}^{2n}$. The fact that it is anti-symmetric follows from the fact that $\sqrt{I_{2n}+\Gamma^2(\rho)}$ is Hermitian. Since it is anti-symmetric and real, its eigenvalues are purely imaginary. We are left to show that the eigenvalues are all one in absolute value. This follows from the fact that $\Gamma(|\psi\rangle\langle\psi|)$ is unitary, as can be verified by inspection. □

Particle-number preserving fermionic states

In this section, we introduce standard notions related to particle-number preserving fermionic states, which form a common subset of fermionic states often considered in condensed matter physics. This concept will be useful for deriving a particle-number preserving version of the inequality we establish for general free-fermionic states in the subsequent section.

Definition 8 (Creation and annihilation operators)**.** *The annihilation operators* $\{a_j\}_{j=1}^n$ *and creation operators* $\{a_j^\dagger\}_{j=1}^n$ *are defined as:*

$$a_j := \frac{\gamma_{2j-1} + i\gamma_{2j}}{2}, \quad a_j^\dagger := \frac{\gamma_{2j-1} - i\gamma_{2j}}{2}. \tag{S40}$$

for all $j \in [n]$.

They satisfy the commutation relations $\{a_k, a_l\} = 0$, $\{a_k, a_l^\dagger\} = \delta_{k,l}$ for each $k, l \in [n]$. Moreover, they satisfy $a_k^\dagger a_k = \frac{1}{2}(I - Z_j) = |1\rangle\!\langle 1|_k$ for each $k \in [n]$. Majorana operators can be then written as $\gamma_{2k-1} = a_j + a_j^\dagger$ and $\gamma_{2j} = -i(a_j - a_j^\dagger)$ for each $k \in [n]$.

Definition 9 (Particle number operator)**.** *The operator* $\hat{N} := \sum_{i=1}^n a_i^\dagger a_i$ *is denoted as the particle number operator.*

The computational basis forms a set of eigenstates for the particle number operator:

$$\hat{N} |x_1, \dots, x_n\rangle = (x_1 + \cdots + x_n) |x_1, \dots, x_n\rangle , \tag{S41}$$

where $x_1, \dots, x_n \in \{0, 1\}$. The eigenvalue $|x| := x_1 + \cdots + x_n$ of the particle-number operator is the Hamming weight of the bitstring $x := (x_1, \dots, x_n)$.

Definition 10 (Particle number preserving states)**.** *A state* ρ *is is said to be particle number preserving if and only if it commutes with the particle number operator, i.e.,* $[\hat{N}, \rho] = 0$.

From this definition, it follows that any particle-number preserving pure state is an eigenstate of the particle-number operator $\hat{N}$, and, more generally, any particle-number preserving mixed state can be written as a convex combination of eigenstates of the particle-number operator.
We now define the particle-number preserving correlation matrix of a quantum state ρ.

Definition 11 (Particle-number preserving correlation matrix)**.** *Given a state* ρ*, we define its particle number-preserving correlation matrix* $C(\rho)$ *as the* $n \times n$ *matrix such that, for each* $j, k \in [n]$*, we have:*

$$[C(\rho)]_{j,k} := \mathrm{Tr}\left(a_j^\dagger a_k \rho\right), \tag{S42}$$

It is easy to see that the particle-number preserving correlation matrix is an Hermitian matrix. In fact, for each $j, k \in [n]$, we have

$$[C(\rho)]_{j,k}^* = \mathrm{Tr}\left((a_j^\dagger a_k \rho)^*\right) = \mathrm{Tr}\left((a_j^\dagger a_k \rho)^\dagger\right) = \mathrm{Tr}\left(\rho a_k^\dagger a_j\right) = [C(\rho)]_{k,j}, \tag{S43}$$

Thus, it can be unitarily diagonalized.

Lemma 11 (Relation between the correlation matrix and the particle-number preserving one of a particle-number preserving state)**.** *Let* ρ *be a particle-number preserving quantum state. The correlation matrix* $\Gamma(\rho)$ *can be written in terms of the particle-number preserving correlation matrix* $C(\rho)$ *as follows:*

$$\Gamma(\rho) = (I - 2\,\mathrm{Re}(C(\rho)) \otimes iY + (2\,\mathrm{Im}(C(\rho))) \otimes I, \tag{S44}$$

where $\mathrm{Re}(\cdot)$ *and* $\mathrm{Im}(\cdot)$ *are the entry-wise real and immaginary part.*

Proof. Since ρ is a particle-number preserving quantum state, then it commutes with the particle-number operator $[\hat{N}, \rho] = 0$, which implies that ρ can be diagonalized as $\rho = \sum_{j=1}^{2^n} p_j |\psi_j\rangle\!\langle\psi_j|$, where $\{p_j\}_{j=1}^{2^n}$ are non-negative numbers which add up to one and $\{|\psi_j\rangle\}_{j=1}^{2^n}$ are eigenstates of the particle number operators. Hence, for all $j, k \in [n]$, we have that:

$$\mathrm{Tr}\left(\rho a_i^\dagger a_j^\dagger\right) = \sum_{m=1}^{2^n} p_m \langle\psi_m| a_i^\dagger a_j^\dagger |\psi_m\rangle = 0, \tag{S45}$$

where the last equality follows from the fact that $|\psi_m\rangle$ and $a_i^\dagger a_j^\dagger|\psi_m\rangle$ are two vectors which are in the span of two different orthogonal eigenspaces of the particle number operator (i.e., associated with two different Hamming weight). Similarly, we have $\mathrm{Tr}\Big(\rho a_i^\dagger a_j^\dagger\Big) = 0$.

For all $j, k \in [n]$, we have:

$$\begin{aligned}
[\Gamma(\rho)]_{2j-1,2k} &= -i\,\mathrm{Tr}(\gamma_{2j-1}\gamma_{2k}\rho) = \mathrm{Tr}\Big((a_j + a_j^\dagger)(a_k^\dagger - a_k)\rho\Big) = \mathrm{Tr}\Big(a_j a_k^\dagger \rho\Big) - \mathrm{Tr}\Big(a_j^\dagger a_k \rho\Big) && \text{(S46)}\\
&= \delta_{j,k} - \mathrm{Tr}\Big(a_k^\dagger a_j \rho\Big) - \mathrm{Tr}\Big(a_j^\dagger a_k \rho\Big) = \delta_{j,k} - [C(\rho)]^*_{j,k} - [C(\rho)]_{j,k} && \text{(S47)}\\
&= [I - 2\,\mathrm{Re}(C(\rho)]_{j,k}, && \text{(S48)}
\end{aligned}$$

where in the third step we have used Eq. (S45), in the fourth step we have used the commutation relation of annihilation and creation operators, in the fifth step we have used the definition of $C(\rho)$ and the fact that it is Hermitian. For all $j, k \in [n]$, we also have:

$$[\Gamma(\rho)]_{2j,2k-1} = -[\Gamma(\rho)]_{2k-1,2j} = -[I - 2\,\mathrm{Re}(C(\rho)]_{k,j} = -[I - 2\,\mathrm{Re}(C(\rho)]_{j,k}, \tag{S49}$$

where in the first step we use the fact that $\Gamma(\rho)$ is anti-symmetric, in the second step we used Eq.(S48), and in the last step the fact that $I - 2\,\mathrm{Re}(C(\rho)$ is a symmetric matrix. Moreover, for all $j \neq k \in [n]$, it follows that:

$$\begin{aligned}
[\Gamma(\rho)]_{2j-1,2k-1} &= -i\,\mathrm{Tr}(\gamma_{2j-1}\gamma_{2k-1}\rho) = -i\,\mathrm{Tr}\Big((a_j + a_j^\dagger)(a_k + a_k^\dagger)\rho\Big) = -i\,\mathrm{Tr}\Big(a_j a_k^\dagger \rho\Big) - i\,\mathrm{Tr}\Big(a_j^\dagger a_k \rho\Big) && \text{(S50)}\\
&= i[C(\rho)]^*_{j,k} - i[C(\rho)]_{j,k} = [2\,\mathrm{Im}(C(\rho)]_{j,k}, && \text{(S51)}
\end{aligned}$$

Similarly, we also have, for all $j \neq k \in [n]$:

$$[\Gamma(\rho)]_{2j,2k} = -i\,\mathrm{Tr}(\gamma_{2j}\gamma_{2k}\rho) = i\,\mathrm{Tr}\Big((a_j - a_j^\dagger)(a_k - a_k^\dagger)\rho\Big) = -i\,\mathrm{Tr}\Big(a_j a_k^\dagger \rho\Big) - i\,\mathrm{Tr}\Big(a_j^\dagger a_k \rho\Big) = [2\,\mathrm{Im}(C(\rho)]_{j,k}, \tag{S52}$$

Thus, Eq.(S44) follows.

□

From the previous Lemma, it follows that for two particle-number preserving state ρ and σ and any p-norms with $p \in [1, \infty]$, we have:

$$\begin{aligned}
\|\Gamma(\rho) - \Gamma(\sigma)\|_p &= 2\|\mathrm{Re}(C(\rho) - C(\sigma)) \otimes iY + \mathrm{Im}(C(\rho) - C(\sigma)) \otimes I\|_p && \text{(S53)}\\
&\leq 2\,2^{1/p}\|\mathrm{Re}(C(\rho) - C(\sigma))\|_p + 2\,2^{1/p}\|\mathrm{Im}(C(\rho) - C(\sigma))\|_p, && \text{(S54)}\\
&\leq 4\,2^{1/p}\|C(\rho) - C(\sigma)\|_p, && \text{(S55)}
\end{aligned}$$

where in the second step we have used the triangle inequality and the fact that $\|A \otimes B\|_p = \|A\|_p\|A\|_p$, and in the last step the fact that $\mathrm{Re}(A) = (A + A^*)/2$ and $\mathrm{Im}(A) = -i(A - A^*)/2$.

Lemma 12 (Relation between eigenvalues of the correlation matrices)**.** *Let ρ be a particle-number preserving quantum state. Let $\{D_j\}_{j=1}^n$ be the eigenvalues of the particle-number preserving correlation matrix $C(\rho)$. There exists an orthogonal matrix which puts the correlation matrix $\Gamma(\rho)$ in the normal form (as in Lemma 5) with normal eigenvalues*

$$\lambda_j = 1 - 2D_j,$$

for each $j \in [n]$.

Proof. Since $C(\rho)$ is Hermitian, for the spectral theorem, there exists $u \in \mathrm{U}(n)$, such that $C(\rho) = uDu^\dagger$, where D is a diagonal (real) matrix. We now define the matrix O

$$O = \mathrm{Re}(u) \otimes I + \mathrm{Im}(u) \otimes iY. \tag{S56}$$

This matrix O is orthogonal (and symplectic), as it can be verified by using that

$$\mathrm{Re}(u)\,\mathrm{Re}(u)^t + \mathrm{Im}(u)\,\mathrm{Im}(u)^t = I, \qquad \mathrm{Re}(u)\,\mathrm{Im}(u)^t - \mathrm{Im}(u)\,\mathrm{Re}(u)^t = 0, \tag{S57}$$

which follow from the unitarity of u. Now, using Eq.(S56), Eq.(S57) and the fact that for particle-preserving states, $\Gamma(\rho)$ can be written in terms of $C(\rho)$ as in Eq.(S44), it can be verified by inspection that

$$O^T\Gamma(\rho)O = \mathrm{diag}(1 - 2D_1, \dots, 1 - 2D_n) \otimes iY. \tag{S58}$$

Thus, the normal eigenvalues of $\Gamma(\rho)$ are $\{1 - 2D_j\}_{j=1}^n$, where D_j are the eigenvalues of $C(\rho)$. □

Using the upper bound in Eq.(S55) and the eigenvalues relation in Lemma 12, we can directly transfer many of the inequalities that we show in the following section to the particle-preserving case.

III. Norm inequalities for free and non-free fermionic states

In this section, we derive key relations concerning free-fermionic states, laying the groundwork for our subsequent analysis of property testing and tomography. We start by introducing a key lemma which will be pivotal in our proofs.

Lemma 13 (Gentle measurement lemma (or quantum union bound) [39]). *Let $\varepsilon_1, \dots, \varepsilon_M > 0$, where $M \in \mathbb{N}$. Consider the projectors $\{P_i\}_{i=1}^M$. Let ρ be a quantum state. If $\operatorname{Tr}(P_i\rho) \geq 1 - \varepsilon_i$ holds for all $i \in [n]$, then*

$$\left\| \rho - \frac{P_n \dots P_1 \rho P_1 \dots P_M}{\operatorname{Tr}(P_n \dots P_1 \rho P_1 \dots P_M)} \right\|_1 \leq 2\sqrt{\sum_{i\in[M]} \varepsilon_i}\,. \tag{S59}$$

We leverage the *gentle measurement lemma* to establish the following result.

Lemma 14 (Trace distance between a pure free-fermionic state and an arbitrary state). *For a pure free-fermionic state $|\psi\rangle$ and an arbitrary (possibly non-free-fermionic) state ρ, it holds that*

$$\| \rho - |\psi\rangle\!\langle\psi| \,\|_1 \leq \sqrt{\|\Gamma(\rho) - \Gamma(|\psi\rangle\!\langle\psi|)\|_1}\,. \tag{S60}$$

Proof. Since $|\psi\rangle$ is a free-fermionic state, it can be expressed as $|\psi\rangle = U_Q |0^n\rangle$ for a free-fermionic unitary associated with $Q \in \mathrm{O}(2n)$. Define $\rho' := U_Q^\dagger \rho U_Q$. For any $j \in [n]$, we have

$$\operatorname{Tr}\Big(|0\rangle\!\langle 0|_j\, \rho'\Big) = \frac{1}{2} + \frac{1}{2}\left[\Gamma(\rho')\right]_{2j-1,2j} =: 1 - \varepsilon_j, \tag{S61}$$

where we have used $|0\rangle\!\langle 0|_j = (I + Z_j)/2 = (I - i\gamma_{2j-1}\gamma_{2j})/2$ and $\varepsilon_j := (1 - [\Gamma(\rho')]_{2j-1,2j})/2$. Now, we have

$$\| \rho - |\psi\rangle\!\langle\psi| \,\|_1 = \| \rho' - |0^n\rangle\!\langle 0^n| \,\|_1 \leq 2\sqrt{\sum_{j=1}^n \varepsilon_j} = 2\sqrt{\sum_{j=1}^n \frac{1 - [\Gamma(\rho')]_{2j-1,2j}}{2}}, \tag{S62}$$

where we used the unitary invariance of the one-norm and the gentle measurement Lemma 13. Let Λ be the matrix $\Lambda := \bigoplus_{j=1}^n \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = \Gamma(|0^n\rangle\!\langle 0^n|)$. Observe that $\sum_{j=1}^n [\Gamma(\rho')]_{2j-1,2j} = \frac{1}{2}\operatorname{Tr}\big(\Lambda^\dagger \Gamma(\rho')\big)$. Using this and Eq.(S62), we have

$$\begin{aligned}
\| \rho - |\psi\rangle\!\langle\psi| \,\|_1 &\leq \sqrt{\operatorname{Tr}\left(I_{2n} - \Lambda^\dagger \Gamma(\rho')\right)} \\
&\leq \sqrt{\|I_{2n} - \Lambda^\dagger \Gamma(\rho')\|_1} \\
&= \sqrt{\|\Lambda - \Gamma(U_Q^\dagger \rho U_Q)\|_1} \\
&= \sqrt{\|\Lambda - Q^T \Gamma(\rho) Q\|_1} \\
&= \sqrt{\|\Gamma(|\psi\rangle\!\langle\psi|) - \Gamma(\rho)\|_1},
\end{aligned} \tag{S63}$$

where in the second step we used Hölder inequality, in the third step the definition of one-norm, in the third step the unitary invariance of the one-norm and the definition of ρ', in the fourth step the fact that $\Gamma(U_Q^\dagger \rho U_Q) = Q^T \Gamma(\rho) Q$, and in the last step the unitary invariance of the one-norm and the fact that $\Gamma(|\psi\rangle\!\langle\psi|) = Q\Gamma(|0^n\rangle\!\langle 0^n|)Q^T$. □

Lemma 15 (Trace distance between a free-fermionic state and the maximally mixed state). *Let σ be an n-qubits free-fermionic state, and $d := 2^n$. Then we have*

$$\left\| \sigma - \frac{I_d}{d} \right\|_1 \leq \frac{1}{2}\|\Gamma(\sigma)\|_1\,. \tag{S64}$$

Proof. Since σ is a free-fermionic state, it can be expressed as $\sigma = U_Q \bigotimes_{j=1}^n \left(\frac{I + \lambda_j Z_j}{2}\right) U_Q^\dagger$, where U_Q is a free-fermionic unitary with $Q \in O(2n)$, and $\{\lambda_j\}_{j=1}^n \in [-1,1]$. Therefore, we have

$$\begin{aligned} \left\| \sigma - \frac{I_d}{d} \right\|_1 &= \left\| \bigotimes_{j=1}^n \left(\frac{I + \lambda_j Z_j}{2} \right) - \frac{I_d}{d} \right\|_1 \\ &= \left\| \bigotimes_{j=1}^n \left(\frac{I + \lambda_j Z_j}{2} \right) - \bigotimes_{j=1}^n \frac{I}{2} \right\|_1 \\ &\le \sum_{j=1}^n \left\| \frac{I + \lambda_j Z_j}{2} - \frac{I}{2} \right\|_1 \\ &= \sum_{j=1}^n |\lambda_j| \,, \end{aligned} \tag{S65}$$

where the first step utilizes the unitary invariance of the one-norm, and the second step applies the triangle inequality. We conclude by observing that

$$\|\Gamma(\sigma)\|_1 = \left\| \bigoplus_{j=1}^n \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} \right\|_1 = 2 \sum_{j=1}^n |\lambda_j| \,. \tag{S66}$$

□

Lemma 16 (Lower bound on trace distance in terms of correlation matrices). *Given two quantum states ρ and σ, their trace distance is lower bounded by the operator norm difference*

$$\|\rho - \sigma\|_1 \ge \|\Gamma(\rho) - \Gamma(\sigma)\|_\infty \tag{S67}$$

of their correlation matrices $\Gamma(\rho)$ and $\Gamma(\sigma)$.

Proof. Due to Hölder's inequality, we have

$$\|\rho - \sigma\|_1 \ge \sup_{\|W\|_\infty = 1} |\operatorname{Tr}(W(\rho - \sigma))|. \tag{S68}$$

Now, let us restrict the operators W to the form $W = U_Q^\dagger i\gamma_j\gamma_k U_Q$, where $j,k \in [2n]$ and U_Q is a free-fermionic unitary associated with an orthogonal matrix $Q \in \mathrm{O}(2n)$. Indeed, note that $\|U_Q^\dagger i\gamma_j\gamma_k U_Q\|_\infty = \|i\gamma_j\gamma_k\|_\infty = 1$. It holds that

$$\|\rho - \sigma\|_1 \ge \sup_{\|W\|_\infty = 1} |\operatorname{Tr}(W(\rho - \sigma))| = \sup_{\substack{j,k \in [2n] \\ Q \in \mathrm{O}(2n)}} \left|\operatorname{Tr}\left(U_Q^\dagger i\gamma_j\gamma_k U_Q(\rho - \sigma)\right)\right|. \tag{S69}$$

We then have

$$\begin{aligned} \sup_{\substack{j,k \in [2n] \\ Q \in \mathrm{O}(2n)}} \left|\operatorname{Tr}\left(U_Q^\dagger i\gamma_j\gamma_k U_Q(\rho - \sigma)\right)\right| &= \sup_{\substack{j,k \in [2n] \\ Q \in \mathrm{O}(2n)}} \left|\operatorname{Tr}\left(i\gamma_j\gamma_k U_Q(\rho - \sigma)U_Q^\dagger\right)\right| \\ &= \sup_{\substack{j,k \in [2n] \\ Q \in \mathrm{O}(2n)}} |(Q(\Gamma(\rho) - \Gamma(\sigma))Q^T)_{j,k}|, \end{aligned} \tag{S70}$$

where in the last step we used that $\Gamma(U_Q\rho U_Q^\dagger) = Q\Gamma(\rho)Q^T$. Since $\Gamma(\rho) - \Gamma(\sigma)$ is real and anti-symmetric, it can be brought into a normal form $\Gamma(\rho) - \Gamma(\sigma) = O'\Lambda' O'^T$, where $\Lambda' = \bigoplus_{i=1}^n \begin{pmatrix} 0 & \lambda_i' \\ -\lambda_i' & 0 \end{pmatrix}$ and $\{\pm i\lambda_i'\}_{i=1}^n$ are the purely imaginary eigenvalues of $\Gamma(\rho) - \Gamma(\sigma)$. By choosing $Q = O'^T$, we have

$$\sup_{\substack{j,k \in [2n] \\ Q \in \mathrm{O}(2n)}} |(Q'(\Gamma(\rho) - \Gamma(\sigma))Q'^T)_{j,k}| \ge \sup_{j,k \in [2n]} |\Lambda'_{j,k}| = \sup_{i \in [n]} |\lambda_i'| = \|\Gamma(\rho) - \Gamma(\sigma)\|_\infty \tag{S71}$$

that concludes the proof. □

Lemma 17. *Let A and B be two $2n \times 2n$ anti-symmetric real matrices with eigenvalues $\{\pm i\lambda_k(A)\}_{k=1}^n$ and $\{\pm i\lambda_k(B)\}_{k=1}^n$ respectively, where $\lambda(A)_1 \leq \cdots \leq \lambda_n(A)$ and $\lambda(B)_1 \leq \cdots \leq \lambda_n(B)$. We then have*

$$\|A - B\|_\infty \geq |\lambda_k(A) - \lambda_k(B)|, \tag{S72}$$

for any $k \in [n]$.

Proof. This follows from the fact that $C := iA$ and $D := iB$ are Hermitian matrices. Applying *Weyl's perturbation theorem* (see Ref. [40], section VI), which states that given two $2n \times 2n$ Hermitian matrices C and D with eigenvalues $c_1 \leq \cdots \leq c_{2n}$ and $d_1 \leq \cdots \leq d_{2n}$, we have

$$\|C - D\|_\infty \geq |c_j - d_j|, \tag{S73}$$

for any $j \in [2n]$. This implies that

$$\|A - B\|_\infty = \|C - D\|_\infty \geq \max_{j \in [2n]} |c_j - d_j| = \max_{k \in [n]} |\lambda_k(A) - \lambda_k(B)|. \tag{S74}$$

□

Theorem 5 (Trace distance upper bound between two pure free-fermionic states)**.** *Let ψ_1, ψ_2 be two pure free-fermionic states with correlation matrices $\Gamma(\psi_1), \Gamma(\psi_2)$. Assuming that $\|\Gamma(\psi_1) - \Gamma(\psi_2)\|_\infty < 2$, it holds that*

$$\|\psi_1 - \psi_2\|_1 \leq \frac{1}{2}\|\Gamma(\psi_1) - \Gamma(\psi_2)\|_2. \tag{S75}$$

Otherwise, if the quantity $\|\Gamma(\psi_1) - \Gamma(\psi_2)\|_\infty$ (which is always ≤ 2) is equal to 2, then we simply have $\|\psi_1 - \psi_2\|_1 = 2$.

Proof. First of all, we have

$$\|\psi_1 - \psi_2\|_1 = 2\sqrt{1 - |\langle\psi_1|\psi_2\rangle|^2}. \tag{S76}$$

This can be seen by considering $Q := \psi_1 - \psi_2$. The Hermitian matrix Q has a rank of at most 2, which means it can have at most two non-zero eigenvalues denoted as λ_1 and λ_2. Since the trace of Q is zero, we have $\lambda_2 = -\lambda_1$. Additionally, we know that $\mathrm{Tr}(Q^2) = \lambda_1^2 + \lambda_2^2 = 2\lambda_1^2$, and $\mathrm{Tr}(Q^2) = 2(1 - |\langle u|v\rangle|^2)$. Therefore, we can conclude that $\lambda_1 = \sqrt{1 - |\langle\psi_1|\psi_2\rangle|^2}$. The 1-norm of Q is given by $\|Q\|_1 = |\lambda_1| + |\lambda_2|$, which simplifies to $\|Q\|_1 = 2\sqrt{1 - |\langle\psi_1|\psi_2\rangle|^2}$. From Lemma 9, it follows that:

$$|\langle\psi_1|\psi_2\rangle|^2 = \sqrt{\det\left(\frac{\Gamma(\psi_1) + \Gamma(\psi_2)}{2}\right)}, \tag{S77}$$

where we used that $(\mathrm{Pf}(A))^2 = \det(A)$ (note that the determinant of an antisymmetric matrix is positive). Thus, we have

$$|\langle\psi_1|\psi_2\rangle|^2 = \sqrt{\det(\Gamma(\psi_1)^T)\det\left(\frac{\Gamma(\psi_1) + \Gamma(\psi_2)}{2}\right)} = \sqrt{\det\left(\frac{\mathbb{1} + \Gamma(\psi_1)^T\Gamma(\psi_2)}{2}\right)} = \sqrt{\det\left(\frac{\mathbb{1} + X}{2}\right)} \tag{S78}$$

where the first step follows because $\det(\Gamma(\psi_1)^T) = \det(\Gamma(\psi_1)) = 1$ (see Remark 1), the second step follows from $\det(A)\det(B) = \det(AB)$ and the fact that $\Gamma(\psi_1)$ is an orthogonal matrix (see Remark 1). In the last step, we defined $X := \Gamma(\psi_1)^T\Gamma(\psi_2)$, which is also an orthogonal matrix (being product of two orthogonal matrices). Since X is an normal matrix, also $2^{-1}(\mathbb{1} + X)$ is normal, thus its determinant is equal to the product of its eigenvalues. Thus:

$$|\langle\psi_1|\psi_2\rangle|^2 = \sqrt{\det\left(\frac{\mathbb{1} + X}{2}\right)} = \sqrt{\prod_{j=1}^{2n}\left(\frac{\mathbb{1} + \lambda_j(X)}{2}\right)}, \tag{S79}$$

where we denoted as $\{\lambda_j(X)\}_{j=1}^{2n}$ the eigenvalues of X. Since X is orthogonal, we also have that for each $j \in [2n]$, there exists $\phi_j \in \mathbb{R}$ such that $\lambda_j(X) = e^{i\phi_j}$.

We are now going to show that all eigenvalues of X have multiplicity two. Let $|v\rangle$ be an eigenstate of X corresponding to the eigeinvalue λ:

$$X|v\rangle = \lambda|v\rangle. \tag{S80}$$

We also have that:

$$X(\Gamma(\psi_2)\,|v\rangle^*) = \Gamma(\psi_1)^T\Gamma(\psi_2)^2\,|v\rangle^* = -\Gamma(\psi_1)^T\,|v\rangle^* = -\Gamma(\psi_1)^T\frac{1}{\lambda^*}(X\,|v\rangle)^* = \lambda(\Gamma(\psi_2)\,|v\rangle^*), \tag{S81}$$

where the third step follows from the fact that $\Gamma(\psi_2)$ is anti-symmetric and orthogonal and the fifth step from the fact that $\lambda^{-1} = \lambda^*$. Thus, $\Gamma(\psi_2)\,|v\rangle^*$ and $|v\rangle$ are both eigenstates of X with eigenvalue λ. Note that they must be different vectors. In fact, if it holds that $\Gamma(\psi_2)\,|v\rangle^* = e^{i\theta}\,|v\rangle$ for $\theta \in [0, 2\pi]$, then multiplying by $\Gamma(\psi_2)$ we also have

$$-\,|v\rangle^* = e^{i\theta}\Gamma(\psi_2)\,|v\rangle = e^{i\theta}(\Gamma(\psi_2)\,|v\rangle^*)^* = e^{i\theta}(e^{i\theta}\,|v\rangle)^* = |v\rangle^*\,, \tag{S82}$$

Thus, we have $|v\rangle^* = -\,|v\rangle^*$, which is an absurd. Thus we have shown that all eigenvalues of X have multiplicity two. Thus, without loss of generality, we can assume that $\lambda_{n+k}(X) = \lambda_k(X)$ for $k \in [n]$. Hence, from Eq. S79, we have

$$|\langle\psi_1|\psi_2\rangle|^2 = \prod_{j=1}^{n}\left(\frac{\mathbb{1} + \lambda_j(X)}{2}\right), \tag{S83}$$

If an eigenvalue $\lambda_j(X) = e^{i\phi_j}$ is not real (which implies that its associated eigenstate is not a real vector), then also $\lambda_j^*(X) = e^{-i\phi_j}$ will be a distinct eigenvalue of X (as follows by simply taking the complex conjugate of Eq. (S80)). The remaining eigenvalues will be $+1$ or -1. Let us denote with $2n_c$ the number of not-real eigenvalues (they are even, as they come in pairs), with n_+ the number of $+1$ eigenvalues, and with n_- the number of -1 eigenvalues. So that we have

$$n_+ + n_- + 2n_c = n. \tag{S84}$$

Thus, the X's eigenvalues will be

$$\{\lambda_1(X), \dots, \lambda_n(X)\} = \{\underbrace{e^{i\phi_1}, e^{-i\phi_1}, \dots, e^{i\phi_{n_c}}, e^{-i\phi_{n_c}}}_{2n_c}, \underbrace{+1, \dots, +1}_{n_+}, \underbrace{-1, \dots, -1}_{n_-}\}, \tag{S85}$$

where $\{e^{i\phi_j}\}_{j=1}^{n_c}$ are not real (without loss of generality). Hence, we find

$$\begin{aligned}|\langle\psi_1|\psi_2\rangle|^2 &= \delta_{n_-,0}\prod_{j=1}^{n_c}\frac{1}{4}\left(1 + e^{i\phi_j}\right)\left(1 + e^{-i\phi_j}\right)\\ &= \delta_{n_-,0}\prod_{j=1}^{n_c}\frac{1}{2}\left(1 + \cos(\phi_j)\right)\\ &= \delta_{n_-,0}\prod_{j=1}^{n_c}\left(1 - \sin^2(\phi_j)\right)\\ &\geq \delta_{n_-,0}\left(1 - \sum_{j=1}^{n_c}\sin^2(\phi_j)\right),\end{aligned} \tag{S86}$$

where in the last step we used Weierstrass product inequality. Next, we can rewrite

$$\begin{aligned}\|\Gamma(\psi_1) - \Gamma(\psi_2)\|_2^2 &= \|1 - \Gamma(\psi_1)^T\Gamma(\psi_2)\|_2^2\\ &= \|1 - X\|_2^2\\ &= \sum_{j=1}^{2n}|1 - \lambda_j(X)|^2\\ &= 2\sum_{j=1}^{n}|1 - \lambda_j(X)|^2\\ &= 2\left(\sum_{j=1}^{n_c}\left(|1 - e^{i\phi_j}|^2 + |1 - e^{-i\phi_j}|^2\right) + \sum_{j=1}^{n_+}0 + \sum_{j=1}^{n_-}2\right)\\ &= 16\sum_{j=1}^{n_c}\sin^2(\phi_j/2) + 4n_-,\end{aligned} \tag{S87}$$

where in the last step we used that $|1-e^{i\phi_j}|=2|\sin(\phi_j/2)|$. If $n_->0$, Eq.(S86) implies that $|\langle\psi_1|\psi_2\rangle|^2=0$. Thus, using Eq.(S76), we have

$$\|\psi_1-\psi_2\|_1=2,\quad \text{if } n_->0. \tag{S88}$$

If $n_-=0$, Eqs. (S86),(S87) imply that:

$$|\langle\psi_1|\psi_2\rangle|^2\geq 1-\frac{1}{16}\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_2^2, \tag{S89}$$

Thus, by Eq.(S76), we arrive at

$$\|\psi_1-\psi_2\|_1\leq\frac{1}{2}\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_2,\quad \text{if } n_-=0. \tag{S90}$$

We are now only left to show that the condition $n_-=0$ is satisfied if and only if it holds that $\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_\infty<2$. This is indeed the case, since the quantity (which is always ≤ 2)

$$\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_\infty=\|1-X\|_\infty \tag{S91}$$

can be equal to 2 if and only if X has at least a -1 eigenvalues if and only if $n_->0$. □

Remark 3 (Saturation of the inequality). *We note that the above upper bound is saturated for all pure free-fermionic state ψ_1,ψ_2 with number of modes/qubits $n\leq 3$. Thus, we get*

$$\|\psi_1-\psi_2\|_1=\begin{cases}\frac{1}{2}\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_2, & \textit{if } \|\Gamma(\psi_1)-\Gamma(\psi_2)\|_\infty<2,\\ 2, & \textit{if } \|\Gamma(\psi_1)-\Gamma(\psi_2)\|_\infty=2.\end{cases} \tag{S92}$$

Proof. The case $\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_\infty=2$ is analogous to the previous proof, so let us focus on $\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_\infty<2$. Using the same notation of the previous proof, we have that $n_-=0$, i.e., the number of -1 eigenvalues of $X:=\Gamma(\psi_1)^T\Gamma(\psi_2)$ is zero. Hence, because of Eq. (S86), we have

$$|\langle\psi_1|\psi_2\rangle|^2=\prod_{j=1}^{n_c}\left(1-\sin^2(\phi_j)\right). \tag{S93}$$

From Eq.(S84) and using that $n\leq 3$, we get

$$2n_c+n_+\leq 3, \tag{S94}$$

which implies that $n_c=0$ or $n_c=1$.
If $n_c=0$, we have $|\langle\psi_1|\psi_2\rangle|^2=1$, which implies $\|\psi_1-\psi_2\|_1=0$. Furthermore, because of Eq. (S87), we also have $\frac{1}{2}\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_2=0$.
If $n_c=1$, we then have

$$|\langle\psi_1|\psi_2\rangle|^2=1-\sin^2(\phi_1)=1-\frac{1}{16}\|\Gamma(\psi_1)-\Gamma(\psi_2)\|_2^2, \tag{S95}$$

where in the first step we have used Eq. (S93), and in the second step we have used Eq. (S87). Thus, we reach the conclusion by using that $\|\psi_1-\psi_2\|_1=2\sqrt{1-|\langle\psi_1|\psi_2\rangle|^2}$. □

Next, we present an upper bound on the trace distance between two (possibly mixed) Gaussian states in terms of the norm difference of their respective correlation matrices.

Theorem 6 (Trace distance upper bound between two mixed free-fermionic states). *Let ρ,σ be two (possibly mixed) free-fermionic states. Then it holds*

$$\|\rho-\sigma\|_1\leq\sqrt{\|\Gamma(\rho)-\Gamma(\sigma)\|_1+\frac{1}{2}\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2}. \tag{S96}$$

Moreover, we also have

$$\mathcal{F}(\sigma,\rho)\geq 1-\frac{1}{8}\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2-\frac{1}{4}\|\Gamma(\rho)-\Gamma(\sigma)\|_1, \tag{S97}$$

where $\mathcal{F}(\rho,\sigma):=\mathrm{Tr}\left(\sqrt{\sqrt{\sigma}\rho\sqrt{\sigma}}\right)^2$ is the fidelity between ρ and σ.

Proof. By using Lemma 10, we can purify ρ and σ to two pure free-fermionic states ψ_ρ and ψ_σ with correlation matrix

$$\Gamma(\psi_\rho) = \begin{pmatrix} \Gamma(\rho) & \sqrt{I+\Gamma(\rho)^2} \\ -\sqrt{I+\Gamma(\rho)^2} & -\Gamma(\rho) \end{pmatrix}. \tag{S98}$$

This means

$$\begin{aligned} \|\Gamma(\psi_\rho)-\Gamma(\psi_\sigma)\|_2^2 &= 2\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2 + 2\|\sqrt{I+\Gamma(\rho)^2}-\sqrt{I+\Gamma(\sigma)^2}\|_2^2 \\ &\leq 2\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2 + 2\|\Gamma(\rho)^2-\Gamma(\sigma)^2\|_1 \\ &\leq 2\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2 + 2\|\Gamma(\rho)(\Gamma(\rho)-\Gamma(\sigma))\|_1 + 2\|(\Gamma(\rho)-\Gamma(\sigma))\Gamma(\sigma)\|_1 \\ &\leq 2\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2 + 4\|\Gamma(\rho)-\Gamma(\sigma)\|_1, \end{aligned} \tag{S99}$$

where in the first step we have used that the square of the 2-norm of the entire matrix is given by the sum of the square of the 2-norm of each sub-block (as follows by the fact that, if A_1 and A_2 are orthogonal with respect the Hilbert-Schmidt scalar product, then $\|A_1\otimes B_1 + A_2\otimes B_2\|_2^2 = \|A_1\otimes B_1\|_2^2 + \|A_2\otimes B_2\|_2^2$). In the second step we have used the inequality (Ref. [40], Eq. X.23)

$$\|A^{1/t}-B^{1/t}\|_p \leq \|A-B\|_{p/t}^{1/t}, \tag{S100}$$

which is valid for each $t\in[1,\infty), p\in[1,\infty]$ and positive matrix A and B. In particular, for our case we use $p=t=2$. In the third step we have used triangle inequality, and in the fourth step the Holder inequality for the one-norm

$$\|AB\|_1 \leq \min(\|A\|_\infty\|B\|_1, \|B\|_\infty\|A\|_1), \tag{S101}$$

and the fact that the infinity norm of any correlation matrix is upper bounded by 1. From the fact that the fidelity of two mixed state is the maximum over all the possible purifications, we conclude that

$$\mathcal{F}(\sigma,\rho) \geq |\langle\psi_\rho|\psi_\sigma\rangle|^2 = 1-\frac{1}{4}\|\psi_\rho-\psi_\sigma\|_1^2, \tag{S102}$$

where we used Eq.(S76). By using Theorem 5, we have that, if $\|\Gamma(\psi_\rho)-\Gamma(\psi_\sigma)\|_\infty < 1$, then

$$\|\psi_\rho-\psi_\sigma\|_1 \leq \frac{1}{2}\|\Gamma(\psi_\rho)-\Gamma(\psi_\sigma)\|_2. \tag{S103}$$

The condition $\|\Gamma(\psi_\rho)-\Gamma(\psi_\sigma)\|_\infty < 1$ is satisfied if and only if the number of -1 eigenvalues of $X := \Gamma(\psi_\rho)^\dagger\Gamma(\psi_\sigma)$ is zero (as discussed also in the proof of Theorem 5). However, in this case, we can assume that X has always zero -1 eigenvalues Thus, by Eq.(S102) and Eq.(S103), we have:

$$\mathcal{F}(\sigma,\rho) \geq 1-\frac{1}{16}\|\Gamma(\psi_\rho)-\Gamma(\psi_\sigma)\|_2^2 \tag{S104}$$

$$\geq 1-\frac{1}{8}\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2 - \frac{1}{4}\|\Gamma(\rho)-\Gamma(\sigma)\|_1, \tag{S105}$$

where in the last step we used Eq.(S99). Thus, by using Fuchs van de Graaf inequality (Eq.(8)), we have

$$\|\rho-\sigma\|_1 \leq \sqrt{\|\Gamma(\rho)-\Gamma(\sigma)\|_1 + \frac{1}{2}\|\Gamma(\rho)-\Gamma(\sigma)\|_2^2} \leq \sqrt{\frac{3}{2}\|\Gamma(\rho)-\Gamma(\sigma)\|_1}, \tag{S106}$$

□

If in the previous Theorem we have the additional assumption that $\|\Gamma(\rho)-\Gamma(\sigma)\|_1 < 1$, then it follows that

$$\|\rho-\sigma\|_1 \leq \sqrt{\frac{3}{2}}\|\Gamma(\rho)-\Gamma(\sigma)\|_1. \tag{S107}$$

A. Quantifying non-Gaussianity: Distance from the set of free-fermionic states

In this section, our objective is to establish lower bounds on the minimum trace distance between a state ρ and the set of free-fermionic states. This distance serves as a metric for the inherent "magic" in a given state, providing a precise quantification of its "non-free-fermionic" or "non-Gaussianity" degree. The presented lower bounds on the proposed measure of non-free-fermionic degree are carefully designed to enable time and sample-efficient estimation up to a constant precision in an experimental setting. This capability is crucial for quantifying the extent to which a state exhibits non-free-fermionic behavior in experimental scenarios.

We will derive bounds in different scenarios: one without prior assumptions on the state ρ and another assuming that ρ is pure or, more generally, has a rank at most R. Moreover, we consider two distinct sets of free-fermionic states: $\mathcal{G}_{\text{mixed}}$ and $\mathcal{G}_R$. Here, $\mathcal{G}_{\text{mixed}}$ represents the set of all free-fermionic states, while $\mathcal{G}_R$ represents the set of free-fermionic states constrained to those with a rank at most R. We begin with a simple result, addressing the case where ρ is an arbitrary state and we consider its distance from the set $\mathcal{G}_R$.

Theorem 7 (Lower bound on the distance of an arbitrary state from the set of free-fermionic states with rank at most R)**.** *Let ρ be an arbitrary quantum state. Denote with $\mathcal{G}_R$ the set of free-fermionic states restricted to those states with rank at most R. Let $\lambda_\kappa(\Gamma(\rho))$ with $\kappa := \lceil \log_2(R) \rceil + 1$ denote the (possibly negative) κ-th smallest normal eigenvalue of the correlation matrix of ρ. We then have*

$$\min_{\sigma \in \mathcal{G}_R} \|\rho - \sigma\|_1 \geq 1 - \lambda_\kappa(\Gamma(\rho)). \tag{S108}$$

Proof. By virtue of Lemma 16, we further establish

$$\|\rho - \sigma\|_1 \geq \|\Gamma(\rho) - \Gamma(\sigma)\|_\infty. \tag{S109}$$

Furthermore, according to Lemma 17, the infinity norm difference serves as a lower bound for the difference in eigenvalues

$$\|\Gamma(\rho) - \Gamma(\sigma)\|_\infty \geq |\lambda_j(\Gamma(\rho)) - \lambda_j(\Gamma(\sigma))|, \tag{S110}$$

where $\{\lambda_j(\Gamma(\rho))\}_{j=1}^n$ and $\{\lambda_j(\Gamma(\sigma))\}_{j=1}^n$ are the normal eigenvalues of the two correlation matrices ordered in increasing order. We then have

$$\|\Gamma(\rho) - \Gamma(\sigma)\|_\infty \geq |\lambda_\kappa(\Gamma(\rho)) - 1| = 1 - \lambda_\kappa(\Gamma(\rho)), \tag{S111}$$

where we used that because of Lemma 2 $\lambda_j(\Gamma(\sigma)) = 1$ for all $j \in \{\kappa, \dots, n\}$ and for all $\sigma \in \mathcal{G}_R$. The result thus follows. □

From this, it follows the results when restricting to the set of pure free-fermionic states $\mathcal{G}_{\text{pure}} \equiv \mathcal{G}_{R=1}$.

Corollary 1 (Lower bound on the distance of an arbitrary state from the set of pure free-fermionic states)**.** *Let ρ be a quantum state. Let $\lambda_{\min}$ denote the smallest normal eigenvalue of the correlation matrix of ρ. We then have*

$$\min_{\sigma \in \mathcal{G}_{\text{pure}}} \|\rho - \sigma\|_1 \geq 1 - \lambda_{\min}. \tag{S112}$$

Next, we establish a lower bound on the distance between a quantum state ρ and the set of all free-fermionic states $\mathcal{G}_{\text{mixed}}$. It is crucial to mention that in our previous discussion, we focused on the set of free-fermionic states with a rank no greater than R. For pedagogical reasons, we begin by assuming that ρ is pure. Later, we will extend our analysis to ρ having a rank at most R.

Theorem 8 (Lower bound on the distance of a pure state from the set of all free-fermionic states)**.** *Let ρ be a pure state. Let $\lambda_{\min}$ denote the (possibly negative) smallest normal eigenvalue of the correlation matrix of ρ. Then, we have*

$$\min_{\sigma \in \mathcal{G}_{\text{mixed}}} \|\rho - \sigma\|_1 \geq \frac{1}{2}\left(1 - \lambda_{\min}\right). \tag{S113}$$

Here, $\mathcal{G}_{\text{mixed}}$ is the set of all free-fermionic states.

Proof. Because of Lemma 16, we can write for any $\sigma \in \mathcal{G}_{\text{mixed}}$ the lower bound

$$\|\rho - \sigma\|_1 \geq \|\Gamma(\rho) - \Gamma(\sigma)\|_\infty \tag{S114}$$

to the 1-norm. Let us denote as $\{\lambda_i^\rho\}_{i=1}^n$ the eigenvalues of $\Gamma(\rho)$ and $\{\lambda_i^\sigma\}_{i=1}^n$ the eigenvalues of $\Gamma(\sigma)$ for an arbitrary free-fermionic state σ. The bound in Eq. (S114) translates to $\|\rho-\sigma\|_1 \geq \max_i |\lambda_i^\rho - \lambda_i^\sigma|$ using the fact that the infinity norm difference serves as a lower bound for the difference in eigenvalues [41]. Contrasting this, we also have that [41]

$$\|\rho-\sigma\|_1 \geq \|\mathrm{diag}(1,0,\ldots,0)-\mathrm{diag}(z_{\max},\ldots,z_d)\|_1 = |1-z_{\max}| + \sum_{i=2}^{d} z_i = 2(1-z_{\max}), \tag{S115}$$

where $\{z_i\}_{i=1}^n$ are the ordered eigenvalues of the (in general) mixed free-fermionic state σ. We know that the eigenvalues z_i of σ are related to the (positive) normal eigenvalues $\{\lambda_i^\sigma\}_{i=1}^n$ of the correlation matrix $\Gamma(\sigma)$ because the diagonal form of σ reads $\bigotimes_{i=1}^n \frac{I+\lambda_i^\sigma Z_i}{2}$. Therefore,

$$z_{\max} = \prod_{i=1}^{n} \frac{1}{2}(1+\lambda_i^\sigma) \leq \frac{1+\min_{i\in[n]}\lambda_i^\sigma}{2}. \tag{S116}$$

Plugging this upper bound on $z_{\max}$ into Eq. (S115), we get, for any $\sigma \in \mathcal{G}_{\mathrm{mixed}}$, the lower bound

$$\|\rho-\sigma\|_1 \geq (1-\min_{i\in[n]}\lambda_i^\sigma) \tag{S117}$$

to the 1-norm distance. Therefore, we have two lower bounds to the 1-norm distance $\|\rho-\sigma\|_1$, and we can consider the extremum over σ and lower bound it with the maximum between these two universal lower bounds (valid for any σ). We thus write

$$\begin{aligned}\min_{\sigma\in\mathcal{G}_{\mathrm{mixed}}} \|\rho-\sigma\|_1 &\geq \min_{\sigma\in\mathcal{G}_{\mathrm{mixed}}} \max\{\max_{i\in[n]}|\lambda_i^\rho-\lambda_i^\sigma|, \max_{i\in[n]}(1-\lambda_i^\sigma)\} \\ &= \min_{\vec{\lambda}^\sigma\in[-1,1]^n} \max_{i\in[n]} \max\{|\lambda_i^\rho-\lambda_i^\sigma|,(1-\lambda_i^\sigma)\} \\ &= \max_{i\in[n]} \min_{\lambda^\sigma\in[-1,1]} \max\{|\lambda_i^\rho-\lambda^\sigma|,(1-\lambda^\sigma)\} \\ &= \max_{i\in[n]} \frac{1-\lambda_i^\rho}{2}.\end{aligned} \tag{S118}$$

We can exchange the minimum and maximum because they act independently, and the last step follows because the function is maximized for $\lambda^\sigma = \frac{1+\lambda_i^\rho}{2}$. Therefore, we obtain the lower bound

$$\min_{\sigma\in\mathcal{G}_{\mathrm{mixed}}} \|\rho-\sigma\|_1 \geq \frac{1-\min_i\lambda_i^\rho}{2} \equiv \frac{1}{2}(1-\lambda_{\min}) \tag{S119}$$

on the minimal trace norm. This proves our claim. □

Theorem 9 (Lower bound on the distance of a bounded rank state from the set of all free-fermionic states)**.** *Let ρ be a quantum state with rank $\mathrm{rank}(\rho) \leq R$. Let $\sigma \in \mathcal{G}_{\mathrm{mixed}}$. Let $\Gamma(\rho)$ be the correlation matrix associated to ρ and let $\lambda_1^\rho, \lambda_2^\rho, \ldots, \lambda_n^\rho$ be its normal eigenvalues in decreasing order. Assume that $R \leq 2^r$ for some $r \in [0,n]$ and denote $\bar{\lambda} = \lambda_{r+1}^\rho$. Then the trace distance is lower bounded by*

$$\min_{\sigma\in\mathcal{G}_{\mathrm{mixed}}} \|\rho-\sigma\|_1 \geq \frac{(1-\bar{\lambda})^{r+1}}{1+(r+1)(1-\bar{\lambda})^r}. \tag{S120}$$

In particular, this implies for $\bar{\lambda} \geq \frac{1}{2}$,

$$\min_{\sigma\in\mathcal{G}_{\mathrm{mixed}}} \|\rho-\sigma\|_1 \geq \frac{(1-\bar{\lambda})^{r+1}}{2}. \tag{S121}$$

For $R = 1$ it reduces to the bound in Theorem 8 valid for pure states ρ.

Proof. First of all, let us make use of Lemma 16 to bound $\|\rho-\sigma\|_1 \geq \|\Gamma(\rho)-\Gamma(\sigma)\|_\infty \geq |\bar{\lambda} - \lambda_{\log_2 R+1}^\sigma|$ for a arbitrary free-fermionic state $\sigma \in \mathcal{G}_{\mathrm{mixed}}$. Then, similar to Eq. (S115), we can lower bound [41]

$$\begin{aligned}\|\rho-\sigma\|_1 &\geq \left\|\mathrm{diag}(z_1^\rho,\ldots,z_R^\rho,0,\ldots,0)-\mathrm{diag}(z_1^\sigma,\ldots,z_R^\sigma,z_{R+1}^\sigma,\ldots,z_d^\sigma)\right\|_1 \\ &= \sum_{i=1}^{R}|z_i^\rho - z_i^\sigma| + \sum_{i=R+1}^{d} z_i^\sigma \geq 1 - \sum_{i=1}^{R} z_i^\sigma + \sum_{i=R+1}^{d} z_i^\sigma = 2 - 2\sum_{i=1}^{R} z_i^\sigma\,,\end{aligned} \tag{S122}$$

where z_i^σ are the non-increasingly ordered eigenvalues of σ. We also have that

$$\sum_{i=1}^{R} z_i =: \|\sigma\|_{\mathrm{KF},R} \tag{S123}$$

is a Ky Fan norm of σ. In the eigenbasis of σ, we can define

$$\sigma = \bigotimes_{i=1}^{r+1} \frac{1-\lambda_i Z_i}{2} \otimes \bigotimes_{i=r+2}^{n} \frac{1-\lambda_i Z_i}{2} =: \sigma_1 \otimes \sigma_2. \tag{S124}$$

It follows that

$$\begin{aligned}\|\sigma\|_{\mathrm{KF},R} = \|\sigma_1 \otimes \sigma_2\|_{\mathrm{KF},R} = \left\|\sigma_1 \otimes \sum_{k=1}^{2^{n-r-1}} \alpha_k \left|\Psi_k\right\rangle \left\langle\Psi_k\right|\right\|_{\mathrm{KF},R} &\leq \sum_{k=1}^{2^{n-r-1}} \alpha_k \left\|\sigma_1 \otimes \left|\Psi_k\right\rangle \left\langle\Psi_k\right|\right\|_{\mathrm{KF},R} \\ \leq \sum_{k=1}^{2^{n-r-1}} \alpha_k \|\sigma_1\|_{\mathrm{KF},R} \leq \|\sigma_1\|_{\mathrm{KF},R}\end{aligned} \tag{S125}$$

where $\sigma_2 = \sum_{k=1}^{2^{n-r-1}} \alpha_k \left|\Psi_k\right\rangle \left\langle\Psi_k\right|$ is the spectral decomposition of σ_2 and we have used that $\|\rho \otimes |\Psi\rangle\langle\Psi|\|_{\mathrm{KF},R} = \|\rho\|_{\mathrm{KF},R}$ as well as the norm inequality. As such, $\|\sigma\|_{\mathrm{KF},R}$ is maximal, if σ_2 is pure, i.e., $\lambda_k = 1$ for $k > r+1$. In general, we have for any state σ'

$$\begin{aligned}\left\|\sigma' \otimes \left(\alpha \frac{\mathbb{1}+\bar{\lambda}Z}{2} + (1-\alpha)\frac{\mathbb{1}}{2}\right)\right\|_{\mathrm{KF},R} &\leq \alpha \left\|\sigma' \otimes \frac{\mathbb{1}+\bar{\lambda}Z}{2}\right\|_{\mathrm{KF},R} + (1-\alpha) \left\|\sigma' \otimes \frac{\mathbb{1}}{2}\right\|_{\mathrm{KF},R} \\ &= \alpha \left\|\sigma' \otimes \frac{\mathbb{1}+\bar{\lambda}Z}{2}\right\|_{\mathrm{KF},R} + (1-\alpha) \|\sigma'\|_{\mathrm{KF},R/2} \\ &\leq \left\|\sigma' \otimes \frac{\mathbb{1}+\bar{\lambda}Z}{2}\right\|_{\mathrm{KF},R}\end{aligned} \tag{S126}$$

where we have used that $\|\sigma' \otimes \mathbb{1}/2\|_{\mathrm{KF},R} = \|\sigma'\|_{\mathrm{KF},R/2}$ since appending the maximally mixed state doubles multiplicity of the singular values, while halving their respective value. In the last line we used that for any 2 level state ρ_2, $\|\rho_1 \otimes \rho_2\|_{\mathrm{KF},R} \geq \|\rho\|_{\mathrm{KF},R/2}$. Since $\lambda_i \leq \lambda$, we can use this procedure to upper-bound the norm of σ_1 by $\tilde{\sigma} = \bigotimes_{i=1}^{r+1} \frac{1+\bar{\lambda}Z}{2}$.

$$\begin{aligned}\|\sigma_1\|_{\mathrm{KF},R} \leq \|\tilde{\sigma}\|_{\mathrm{KF},R} &= \max_{\bar{S}\subset\{0,1\}^{r+1}, |S|=R} \sum_{s\in\bar{S}} \prod_{i=1}^{r+1} \left(\frac{1+(-1)^{s_i}\bar{\lambda}}{2}\right) \\ &= 1 - \min_{\bar{S}_c\subset\{0,1\}^{r+1}, |S_c|=2^{r+1}-R} \sum_{s\in\bar{S}} \prod_{i=1}^{r+1} \left(\frac{1+(-1)^{s_i}\bar{\lambda}}{2}\right) \\ &\leq 1 - (2^{r+1}-R) \left(\frac{1-\bar{\lambda}}{2}\right)^{r+1} \\ &\leq 1 - \frac{\left(1-\bar{\lambda}\right)^{r+1}}{2}\end{aligned} \tag{S127}$$

where we have bounded the sum by its smallest term. Therefore, we can write the following two bounds we need to optimize over for $\|\rho - \sigma\|_1$ and $\sigma \in \mathcal{G}_{\mathrm{mixed}}$

$$\begin{aligned}\|\rho - \sigma\|_1 &\geq \max_{\lambda\in[0,1]} \min\left((1-\lambda)^{r+1}, |\lambda - \bar{\lambda}|\right) \\ &= \min_{\lambda\in[0,1]} \max\left((1-\lambda)^{r+1}, |\lambda - \bar{\lambda}|\right).\end{aligned} \tag{S128}$$

We can find a lower bound for this expression by inserting a particular λ. For this we use the difference function of the two expressions $f(\lambda) = (1-\lambda)^{r+1} - (x+\bar{\lambda})$ which holds for $\lambda \in [\bar{\lambda}, 1]$ which is the area of interest. By applying Newtons method once starting with $\lambda_0 = \bar{\lambda}$, we obtain

$$\lambda_1 = \bar{\lambda} + \frac{(1-\bar{\lambda})^{r+1}}{1+(r+1)(1-\bar{\lambda})^{r}}. \tag{S129}$$

Since $f(\lambda)$ monotonously decreases and is convex on the interval, we can be sure that $\lambda_1 \leq \lambda^*$, the root of f. This means that $(1-\lambda_1)^{r+1} \geq |\lambda_1 - \bar{\lambda}|$, which allows us to conclude that

$$\|\rho - \sigma\|_1 \geq \frac{(1-\bar{\lambda})^{r+1}}{1+(r+1)(1-\bar{\lambda})^r}\,. \tag{S130}$$

In particular, we have for $\bar{\lambda} \geq 1/2$

$$1+(r+1)(1-\bar{\lambda})^r \leq 1 + \frac{r+1}{2^r} \leq 2 \tag{S131}$$

which concludes the proof. □

IV. Property testing of free-fermionic states

In this section, we address the problem of property testing free-fermionic states. Our goal is to determine whether a given quantum state ρ is close to or far from the set of all free-fermionic states $\mathcal{G}_{\text{mixed}}$. To enable an efficient testing algorithm, we must make certain assumptions about the rank of the state ρ, as we show. Assuming that ρ is pure (i.e., rank one), we present an efficient learning algorithm that relies solely on single-qubit measurements (as detailed in Subsection IV A). However, when no assumptions are made about the rank of the state ρ, we establish the general hardness of the problem. Information-theoretically, it requires $\Omega(\text{rank}(\rho))$ copies to be solved (as discussed in Subsection IV B). Moreover, we provide a matching upper bound by introducing a single-copy algorithm. This algorithm utilizes only single-copy or free-fermionic measurements and is efficient as long as $\text{rank}(\rho) = O(\text{poly}(n))$ (explored in Subsection IV C).
Similarly, we show that there is an efficient property-testing algorithm in the case when ρ is an arbitrary quantum state and the goal is to determine whether a given quantum state ρ is close to or far from the set of pure free-fermionic states $\mathcal{G}_{\text{pure}}$. We also show an information theoretic lower bound to solve the property testing problem when ρ is arbitrary and consider $\mathcal{G}_R$, that is, the set of all free-fermionic states with rank at most R. This section concludes by providing a matching upper bound for the above scenario. We formalize the property testing problem as follows

Problem 2 (Property testing of free-fermionic states)**.** *Given N copies of an unknown quantum state ρ, with the promise that it falls into one of two distinct scenarios $\varepsilon_B > \varepsilon_A \geq 0$.*

- ***Case A:*** *There exists a free-fermionic state $\sigma \in \mathcal{G}$ such that $\|\rho - \sigma\|_1 \leq \varepsilon_A$.*
- ***Case B:*** *The state ρ is ε_B-far from all free-fermionic states σ, i.e., $\min_{\sigma \in \mathcal{G}} \|\rho - \sigma\|_1 > \varepsilon_B$.*

Determine whether we are in Case A or Case B by performing arbitrary measurements on the queried copies of the state ρ.

Further restrictions on the state ρ and precise specifications regarding the set of free-fermionic states $\mathcal{G}$ considered (e.g., $\mathcal{G} = \mathcal{G}_{\text{pure}}$, $\mathcal{G} = \mathcal{G}_{\text{mixed}}$, $\mathcal{G} = \mathcal{G}_R$) must be provided as input to the problem. Before delving into more details, we establish a preliminary lemma that will be instrumental later.

Lemma 18 (Sample complexity for infinity norm approximation of the correlation matrix via Pauli measurements)**.** *Let $N \geq 16(n^4/\varepsilon_{\text{stat}}^2)\log(n^2/\delta)$ be the number of copies of an n-qubit state ρ. Through single-qubit Pauli-basis measurements, we can find a real and anti-symmetric matrix $\hat{\Gamma}$ such that, with probability at least $1-\delta$, it holds that*

$$\left\|\hat{\Gamma} - \Gamma(\rho)\right\|_\infty < \varepsilon_{\text{stat}}. \tag{S132}$$

Proof. For $j < k \in [2n]$, we estimate $[\Gamma(\rho)]_{j,k} = -\text{Tr}(i\gamma_j\gamma_k\rho)$. For each $i\gamma_j\gamma_k$, which are $M := n(2n-1)$ in total, we measure

$$N' \geq \frac{2}{\varepsilon^2}\log\left(\frac{2M}{\delta}\right) \tag{S133}$$

many copies of ρ in the Pauli basis, obtaining outcomes $\{\hat{X}_m\}_{m=1}^{N'}$, where $\hat{X}_m \in \{-1,+1\}$. Define $\hat{\Gamma}_{j,k} := \frac{1}{N'}\sum_{m=1}^{N'}\hat{X}_m$. By Hoeffding's inequality, we have

$$\Pr\left(|\hat{\Gamma}_{j,k} - [\Gamma(\rho)]_{j,k}| \geq \varepsilon\right) \leq 2\exp\left(-\frac{2N'\varepsilon^2}{(b-a)^2}\right) \tag{S134}$$

where $a := -1$ and $b := 1$. By the union bound, we have

$$\Pr\left(\forall j < k : |\hat{\Gamma}_{j,k} - [\Gamma(\rho)]_{j,k}| < \varepsilon\right) = 1 - \sum_{i<j} \Pr\left(|\hat{\Gamma}_{j,k} - [\Gamma(\rho)]_{j,k}| \geq \varepsilon\right) \geq 1 - 2M \exp\left(-\frac{N'\varepsilon^2}{2}\right). \tag{S135}$$

By using that $N' \geq \frac{2}{\varepsilon^2}\log\left(\frac{2M}{\delta}\right)$, we have that this probability is greater than $1-\delta$. The total number of measurements is $N = N'M$. Finally, employing the Gershgorin circle theorem, we have

$$\left\|\hat{\Gamma} - \Gamma(\rho)\right\|_\infty \leq 2n\varepsilon. \tag{S136}$$

By choosing $\varepsilon = \varepsilon_{\mathrm{stat}}/2n$, we can draw our conclusions. Moreover, note that by construction $\hat{\Gamma}$ is real and anti-symmetric. □

While sequentially estimating correlation matrix entries in the Pauli basis may not be the most sample-efficient, it proves convenient for experiments due to its easy implementation. Alternatively, measuring commuting observables simultaneously [42] reduces sample complexity by n but requires a slightly more intricate setup. For completeness, we present a Lemma establishing a sample complexity upper bound for estimating the correlation matrix using this refined measurement scheme. The idea is to partition observables $O^{(j,k)} := -i\gamma_j\gamma_k$ into $2n-1$ sets of commuting observables. Commuting Pauli observables can be measured simultaneously via a Clifford Gaussian measurements [42]. Notably, different Pauli observables $-i\gamma_j\gamma_k$ commute only if associated with different Majorana operators. This allows us to partition $M = (2n-1)n$ observables into $2n-1$ sets, each containing n commuting Pauli observables. We refer to Ref. [42], Appendix C, for partition details, omitted here for brevity.

Lemma 19 (Sample complexity for infinity norm approximation of the correlation matrix via commuting observables)**.** *Let $\varepsilon_{\mathrm{stat}}, \delta > 0$. Assume access to $N \geq \lceil (8n^3/\varepsilon^2_{\mathrm{stat}})\log(4n^2/\delta) \rceil$ copies of an n-qubit state ρ. Using N single-copy measurements, with probability $\geq 1-\delta$, we can construct an anti-symmetric real matrix $\hat{\Gamma}$ such that*

$$\left\|\hat{\Gamma} - \Gamma(\rho)\right\|_\infty \leq \varepsilon_{\mathrm{stat}}. \tag{S137}$$

Proof. For each of the $2n-1$ sets of commuting Pauli, find the Clifford C allowing simultaneous measurement of such observables, and measure N' copies of $C\rho C^\dagger$ in the computational basis. Note that we can choose such Clifford to be also Gaussian. This because such Clifford diagonalizes the free fermionic Hamiltonian given by the sum of the commuting Pauli, hence it can be chosen to be Gaussian. For each $A^{(j,k)}$, obtain outcomes $\{A^{(j,k)}_m\}^{N'}_{m=1}$, where $A^{(j,k)}_m \in \{-1,+1\}$. The unbiased estimators are

$$\hat{\Gamma}_{j,k} := \frac{1}{N'}\sum_{m=1}^{N'} A^{(j,k)}_m. \tag{S138}$$

Hoeffding's inequality and union bound imply

$$N' \geq \frac{2}{\varepsilon^2_{\mathrm{stat}}}\log\left(\frac{4n}{\delta}\right) \tag{S139}$$

suffices to ensure $|\hat{\Gamma}_{j,k} - \mathrm{Tr}(A^{(j,k)}\rho)| < \varepsilon_{\mathrm{stat}}$ for each $j < k \in [2n]$ with probability at least $1-\delta$. The total number of measurements needed is $N = N'(2n-1)$, concluding as in the previous lemma. □

Analogously, we get also the following by just using that $\|B\|_2 \leq 2n\max_{i,j\in[2n]}|B_{i,j}|$ for any matrix $B \in \mathbb{C}^{2n\times 2n}$.

Lemma 20 (Sample complexity for 2-norm approximation of the correlation matrix via commuting observables)**.** *Let $\varepsilon_{\mathrm{stat}}, \delta > 0$. Assume access to $N \geq \lceil (8n^3/\varepsilon^2_{\mathrm{stat}})\log(4n^2/\delta) \rceil$ copies of an n-qubit state ρ. Using N single-copy measurements, with probability $\geq 1-\delta$, we can construct an anti-symmetric real matrix $\hat{\Gamma}$ such that*

$$\left\|\hat{\Gamma} - \Gamma(\rho)\right\|_2 \leq \varepsilon_{\mathrm{stat}}. \tag{S140}$$

Algorithm 1: Property testing algorithm for pure free-fermionic states

```
Input: Error thresholds $\varepsilon_A, \varepsilon_B$, failure probability $\delta$. $N := \lceil 8(n^3/\varepsilon_{\text{stat}}^2)\log\big(4n^2/\delta\big)\rceil$ copies of the pure state $\rho$, where
    $\varepsilon_{\text{stat}} < \frac{1}{2}(\frac{\varepsilon_B^2}{2n} - 2\varepsilon_A)$. Let $\varepsilon_{\text{T}} := \frac{1}{2}\left(\frac{\varepsilon_B^2}{2n} + 2\varepsilon_A\right)$.
Output: Output either Case A or Case B.
Step 1: Estimate the entries of the correlation matrix using $N$ single-copy measurements, resulting in the estimated $2n \times 2n$ matrix $\hat{\Gamma}$;
Step 2: Find $\hat{\lambda}_{\text{min}}$, which corresponds to the smallest singular value of $\hat{\Gamma}$;
Step 3: if $\hat{\lambda}_{\text{min}} \geq 1 - \varepsilon_{\text{T}}$ then
    Output: Case A
else
    Output: Case B
```

A. Efficient testing of pure free-fermionic states
