We will now show an efficient quantum learning algorithm to solve Problem 2 when ρ is a assumed to be pure, having as assumption that $\varepsilon_B, \varepsilon_A \in (0,1)$ are such that $\varepsilon_B > 2\sqrt{n\varepsilon_A}$. The proposed algorithm uses only single copies of the state ρ. The set of free-fermionic state $\mathcal{G}$ that will be considered can be either the set of all free-fermionic states $\mathcal{G}_{\text{mixed}}$ or the set of free-fermionic states restricted to the pure ones $\mathcal{G}_{\text{pure}}$. The high-level idea of the algorithm is to output A (the state is close to the free-fermionic set) if the eigenvalues of the estimated correlation matrix are all close to 1, while outputting B otherwise. We present now the following Theorem which show the correctness of the algorithm presented in Table 1.

Theorem 10 (Efficient pure free-fermionic testing)**.** *Let ρ be an n-qubit pure state. Assume $\varepsilon_B, \varepsilon_A \in (0,1)$ such that $\varepsilon_B > 2\sqrt{n\varepsilon_A}$, $\delta \in (0,1]$, and $\varepsilon_{\text{stat}} < \frac{1}{2}(\frac{\varepsilon_B^2}{2n} - 2\varepsilon_A)$. Assume that ρ is one of the two cases detailed in Problem 2, i.e., there exists a free-fermionic state $\sigma \in \mathcal{G}$ such that $\|\rho - \sigma\|_1 \leq \varepsilon_A$ or $\min_{\sigma\in\mathcal{G}} \|\rho - \sigma\|_1 > \varepsilon_B$. The set $\mathcal{G}$ considered here can be either the set of all free-fermionic states $\mathcal{G}_{\text{mixed}}$ or the set of pure free-fermionic states $\mathcal{G}_{\text{pure}}$. Then there exists a quantum learning algorithm (1) which can solve Problem 2 using $N = 8(n^3/\varepsilon_{\text{stat}}^2)\log\big(4n^2/\delta\big)$ single-copies measurements of the state ρ with a probability of success at least $1-\delta$.*

Proof. Let $\varepsilon_{\text{stat}} > 0$ be an accuracy parameter to be fixed later. By Lemma 18, with $N \geq 8(n^3/\varepsilon_{\text{stat}}^2)\log\big(4n^2/\delta\big)$, single-qubit Pauli-basis measurements we can find a matrix $\hat{\Gamma}$ such that, with probability at least $1-\delta$, it holds that $\left\|\hat{\Gamma} - \Gamma(\rho)\right\|_\infty < \varepsilon_{\text{stat}}$. This implies that for all $k \in [n]$ [41]

$$|\hat{\lambda}_k - \lambda_k| < \varepsilon_{\text{stat}}, \tag{S141}$$

where $\{\hat{\lambda}_k\}_{k=1}^n, \{\lambda_k\}_{k=1}^n$ are the normal eigenvalues of $\hat{\Gamma}$ and $\Gamma(\rho)$, respectively. We can put $\hat{\Gamma}$ in its normal form

$$\hat{\Gamma} = \hat{O}\hat{\Lambda}\hat{O}^T, \tag{S142}$$

where

$$\hat{\Lambda} = \bigoplus_{i=1}^{n} \begin{pmatrix} 0 & \hat{\lambda}_i \\ -\hat{\lambda}_i & 0 \end{pmatrix} \tag{S143}$$

and find its eigenvalues. Our algorithm now works as follows. Let ε_{T} be a parameter to fix later. If for all $k \in [n]$, we have $\hat{\lambda}_k \geq 1 - \varepsilon_{\text{T}}$, then we output A, otherwise B. In case we output A, we need to proof that there exists a free-fermionic state σ such that $\|\rho - \sigma\|_1 \leq \varepsilon_B$. From Eq.(S141), we have that for all $k \in [2n]$

$$\lambda_k \geq \hat{\lambda}_k - \varepsilon_{\text{stat}} \geq 1 - \varepsilon_{\text{T}} - \varepsilon_{\text{stat}}. \tag{S144}$$

The anti-symmetry of the correlation matrix $\Gamma(\rho)$ implies the existence of an orthogonal matrix O such that $\Gamma(\rho) = O\Lambda O^T$, where $\Lambda = \bigoplus_{i=1}^n \begin{pmatrix} 0 & \lambda_i \\ -\lambda_i & 0 \end{pmatrix}$. Moreover, we have $\Gamma(U_O^\dagger \rho U_O) = \Lambda$, where U_O is the free-fermionic unitary associated with O. This leads to

$$\mathrm{Tr}\Big(Z_k U_O^\dagger \rho U_O\Big) = \Gamma(U_O^\dagger \rho U_O)_{2k-1,2k} = \Lambda_{2k-1,2k} = \lambda_k. \tag{S145}$$

Consequently, we obtain

$$\mathrm{Tr}\Big(|0\rangle\!\langle 0|_k\, U_O^\dagger \rho U_O\Big) \geq \frac{1+\lambda_k}{2} \geq 1 - \frac{\varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}}}{2}, \tag{S146}$$

where we used that $|0\rangle\!\langle 0|_k = (I + Z_k)/2$. Applying the quantum union bound (Lemma 13), we deduce

$$\Big\| U_O^\dagger \rho U_O - |0^n\rangle\!\langle 0^n| \Big\|_1 \leq 2\sqrt{n\left(\frac{\varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}}}{2}\right)}. \tag{S147}$$

Taking $\sigma := U_O\, |0^n\rangle\!\langle 0^n|\, U_O^\dagger$, we have successfully demonstrated the existence of a free-fermionic state σ that closely approximates ρ in terms of the one-norm distance, i.e., $\|\rho - \sigma\|_1 \leq \sqrt{2n\,(\varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}})}$. To ensure the validity of this approximation, we must impose the condition

$$\sqrt{2n(\varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}})} \leq \varepsilon_B, \tag{S148}$$

which constitutes the initial requirement for determining the values of ε_{T} and $\varepsilon_{\mathrm{stat}}$, which we will fix at a later stage. Let us analyze the case in which we output case B, i.e., we observe there exists $k \in [2n]$ such that $\hat{\lambda}_k < 1 - \varepsilon_{\mathrm{T}}$. In this case, from Eq. (S141), we have

$$\lambda_k \leq \hat{\lambda}_k + \varepsilon_{\mathrm{stat}} < 1 - \varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}}. \tag{S149}$$

Using Theorem 7 and Theorem 8, we establish the following inequality

$$\min_{\sigma \in \mathcal{G}} \|\rho - \sigma\|_1 \geq \frac{1 - \min\limits_{k \in [n]}(\lambda_k)}{2}, \tag{S150}$$

where $\mathcal{G}$ can represent either the set of all free-fermionic states, denoted as $\mathcal{G}_{\mathrm{mixed}}$, or the set of all pure free-fermionic states, denoted as $\mathcal{G}_{\mathrm{pure}}$. If we had considered only the set of pure free-fermionic states, the lower bound would be $1 - \min\limits_{k\in[n]} \lambda_k$, without the factor of one-half, as indicated by Lemma 7. However, Eq. (S150) holds true for both $\mathcal{G}_{\mathrm{mixed}}$ and $\mathcal{G}_{\mathrm{pure}}$. From this and Eq. (S149) we have that

$$\min_{\sigma \in \mathcal{G}} \|\rho - \sigma\|_1 \geq \frac{1 - (1 - \varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}})}{2} = \frac{\varepsilon_{\mathrm{T}} - \varepsilon_{\mathrm{stat}}}{2}. \tag{S151}$$

Therefore we impose that

$$\frac{\varepsilon_{\mathrm{T}} - \varepsilon_{\mathrm{stat}}}{2} > \varepsilon_A. \tag{S152}$$

Putting together the two inequalities in Eq. (S148) and Eq.(S152), we have

$$2\varepsilon_A + \varepsilon_{\mathrm{stat}} < \varepsilon_{\mathrm{T}} \leq \frac{\varepsilon_B^2}{2n} - \varepsilon_{\mathrm{stat}}. \tag{S153}$$

Therefore, assuming $\varepsilon_B > \sqrt{4n\varepsilon_A}$, we can choose

$$\varepsilon_{\mathrm{T}} = \frac{1}{2}(\frac{\varepsilon_B^2}{2n} + 2\varepsilon_A) \tag{S154}$$

and

$$\varepsilon_{\mathrm{stat}} < \frac{1}{2}(\frac{\varepsilon_B^2}{2n} - 2\varepsilon_A). \tag{S155}$$

□

The preceding theorem was presented under the assumption that ρ is pure, and the set of free-fermionic states considered can either be the set of all (possibly mixed) free-fermionic states $\mathcal{G}_{\mathrm{mixed}}$ or the more restricted set of all pure free-fermionic states $\mathcal{G}_{\mathrm{pure}}$. However, if we focus solely on the set of all pure free-fermionic states $\mathcal{G}_{\mathrm{pure}}$, we can establish an analogous result without assuming that ρ is pure; i.e., it can be an arbitrary quantum state. The theorem is detailed as follows, and the algorithm is the same as Algorithm 1 with slightly different accuracy parameters, as detailed below.

Theorem 11 (Efficient Pure free-fermionic testing with arbitrary input states). *Let ρ be an arbitrary n-qubit state. Assume $\varepsilon_B, \varepsilon_A \in (0,1)$ such that $\varepsilon_B > \sqrt{2n\varepsilon_A}$, $\delta \in (0,1]$, and $\varepsilon_{\text{stat}} := \frac{1}{4}(\frac{\varepsilon_B^2}{2n} - \varepsilon_A)$. Assume that ρ satisfies one of the two cases detailed in Problem 2, i.e., there exists a free-fermionic state $\sigma \in \mathcal{G}_{\text{pure}}$ such that $\|\rho - \sigma\|_1 \leq \varepsilon_A$ or $\min_{\sigma \in \mathcal{G}_{\text{pure}}} \|\rho - \sigma\|_1 > \varepsilon_B$. Then, there exists a quantum learning algorithm which, utilizing only single-copies measurements, can solve Problem 2 using $N = 8(n^3/\varepsilon_{\text{stat}}^2)\log\left(4n^2/\delta\right)$ copies of the state ρ with a probability of success at least $1 - \delta$.*

Proof. The proof is analogous to the one of the previous theorem, but instead of Eq. (S150), it utilizes Lemma 8, which has no assumptions on the state ρ and provides the inequality

$$\min_{\sigma \in \mathcal{G}_{\text{pure}}} \|\rho - \sigma\|_1 \geq 1 - \min_{k \in [n]} (\lambda_k). \tag{S156}$$

Following the same steps as before, we conclude that, assuming $\varepsilon_B > \sqrt{2n\varepsilon_A}$, we can choose $\varepsilon_{\text{T}} = \frac{1}{2}(\frac{\varepsilon_B^2}{2n} + \varepsilon_A)$ and $\varepsilon_{\text{stat}} = \frac{1}{4}(\frac{\varepsilon_B^2}{2n} - \varepsilon_A)$. Note that, throughout the proof of Theorem 10, there was no need to assume that ρ is a pure state. □

B. Hardness of testing general mixed free-fermionic states

In this section, we establish the general hardness of the free-fermionic property testing problem 2, demonstrating the necessity for $\Omega(2^n)$ copies of the state when no prior assumptions on the state and no restrictions on the set of all free-fermionic states are provided. This is a constraint in sample complexity. The core of this complexity arises from recognizing that the maximally mixed state is free-fermionic. This insight allows us to leverage the hardness of identity testing, that is, to reduce the free-fermionic testing problem to distinguishing whether the underlying state is the maximally mixed state or far from it in trace distance, which is a notoriously hard problem. The following theorem is essential in our reduction:

Theorem 12 (Hardness of identity testing ([15])). *Let $\rho \in \mathcal{S}\left(\mathbb{C}^d\right)$ be a d-dimensional quantum state. Then $0.15\frac{d}{\varepsilon^2}$ copies are necessary to test whether it is the maximally mixed state $\frac{I_d}{d}$ or $\left\|\rho - \frac{I_d}{d}\right\|_1 > \varepsilon$, with at least a $2/3$ probability of success.*

The subsequent theorem delineates the hardness of testing free-fermionic states, providing a reduction to identity testing as outlined in Algorithm 2.

Algorithm 2: Reduction of testing free-fermionic states to identity testing

```
Input: Error threshold $\varepsilon > 0$. $N := \lceil(8(36n^3/\varepsilon^2)\log\left(400n^2\right) + N_{\text{free testing}})\rceil$ copies of $\rho$, where $N_{\text{free testing}}$ is the number of
       copies sufficient to solve property testing of free-fermionic state (problem 2).
Output: Output either $\frac{I_d}{d}$ or $\left\|\rho - \frac{I_d}{d}\right\|_1 > \varepsilon$.
Step 1: Estimate the entries of the correlation matrix of $\rho$ using $8(n^3/\varepsilon_{\text{stat}}^2)\log\left(400n^2\right)$ single-copy measurements, resulting in the
    estimated $2n \times 2n$ matrix $\hat{\Gamma}$;
Step 2: if $\left\|\hat{\Gamma}\right\|_\infty > \varepsilon/2$ then
    Output: $\left\|\rho - \frac{I_d}{d}\right\|_1 > \varepsilon$.
else
    Step 3: Run the free-fermionic property testing algorithm using $N_{\text{free testing}}$ copies of $\rho$, which returns that $\rho$ is "Free-fermions" or
      "Far from free-fermions";
    if "Free-fermions" then
        Output: $\rho = \frac{I_d}{d}$.
    else
        Output: $\left\|\rho - \frac{I_d}{d}\right\|_1 > \varepsilon$.
```

Theorem 13 (Hardness of testing free-fermionic states (Problem 2)). *At least $N = \Omega(\frac{2^n}{\varepsilon_B^2})$ copies of the state ρ are necessary to solve the free-fermionic property testing problem (Problem 2) with a probability of success at least $\frac{2}{3}$. This holds when no prior assumptions about ρ are provided, and the set $\mathcal{G}$ considered is that of all free-fermionic states.*

Proof. In the following, we establish that the existence of an efficient solver for the free-fermionic testing Problem 2 (requiring $O(\text{poly}(n))$ copies of the state for resolution) implies the existence of an efficient solver for the Identity testing problem, a known hard problem (Theorem 12). Let $\varepsilon > 0$. Let ρ be an n-qubit quantum state with the promise that ρ is either the maximally mixed state $\frac{I_d}{d}$ or $\left\|\rho - \frac{I_d}{d}\right\|_1 > \varepsilon$. The reduction outlined in Table 2 commences by estimating the correlation matrix $\Gamma(\rho)$ using $8(n^3/\varepsilon_{\text{stat}}^2)\log(400n^2)$ copies of ρ, yielding a real anti-symmetric matrix $\hat{\Gamma}$ guaranteed to satisfy (due to Lemma 18) $\|\hat{\Gamma} - \Gamma(\rho)\|_\infty \leq \varepsilon_{\text{stat}}$ with at least 0.99 probability of success, where $\varepsilon_{\text{stat}}$ is a parameter to be fixed later. Our primary criterion involves assessing $\|\hat{\Gamma}\|_\infty$. If $\|\hat{\Gamma}\|_\infty > \varepsilon_{\text{T}}$ (where ε_{T} is a fixed threshold to be determined later), we output that ρ is far from the maximally mixed state, i.e., $\left\|\rho - \frac{I_d}{d}\right\|_1 > \varepsilon$; otherwise, we proceed. We aim to prove that if $\|\hat{\Gamma}\|_\infty > \varepsilon_{\text{T}}$, then ρ cannot be the maximally mixed state. This is substantiated by the inequality

$$\|\rho - \frac{I_d}{d}\|_1 \geq \|\Gamma(\rho) - \Gamma(I_d/d)\|_\infty = \|\Gamma(\rho)\|_\infty \geq \|\hat{\Gamma}\|_\infty - \varepsilon_{\text{stat}} > \varepsilon_{\text{T}} - \varepsilon_{\text{stat}}, \tag{S157}$$

where the first step utilizes the inequality in Lemma 16 and the second step the fact that $\Gamma(\frac{I_d}{d}) = 0$. By choosing $\varepsilon_{\text{T}} > \varepsilon_{\text{stat}}$, we can ensure that $\|\rho - \frac{I_d}{d}\|_1 > 0$, implying that we are not in the case where ρ corresponds to the maximally mixed state but in the other case. Subsequently, if $\|\hat{\Gamma}\|_\infty \leq \varepsilon_{\text{T}}$, we proceed to employ a free-fermionic testing solver for Problem 2 with an accuracy parameter $\varepsilon_B = \varepsilon$ and $\varepsilon_A = 0$, consuming $N_{\text{free testing}}$ copies of the state ρ. If the output indicates that the underlying state is a free-fermionic state, we output that ρ is the maximally mixed state; otherwise, if the solver outputs that the state is far from the free-fermionic set, we output that ρ is far from the maximally mixed state. To validate that we cannot be in the case that ρ is the maximally mixed state when outputting that the state is far from free-fermionic, we note that the maximally mixed state is free-fermionic, and therefore it holds that

$$\varepsilon < \min_{\sigma \in \mathcal{G}} \|\rho - \sigma\|_1 \leq \left\|\rho - \frac{I_d}{d}\right\|_1. \tag{S158}$$

Conversely, if the output of the free-fermionic testing solver indicates that the state is free-fermionic, we need to demonstrate that we cannot be in the case that $\left\|\rho - \frac{I_d}{d}\right\|_1 > \varepsilon$. This follows from the inequality

$$\|\rho - \frac{I_d}{d}\|_1 \leq \frac{1}{2}\|\Gamma(\rho)\|_1 \leq n\|\Gamma(\rho)\|_\infty \leq n\left(\left\|\hat{\Gamma} - \Gamma(\rho)\right\|_\infty + \left\|\hat{\Gamma}\right\|_\infty\right) \leq n(\varepsilon_{\text{stat}} + \varepsilon_{\text{T}}), \tag{S159}$$

where the first step uses Lemma 15, and the second step utilizes the fact that $\|\Gamma(\rho)\|_1 \leq 2n\|\Gamma(\rho)\|_\infty$. To satisfy the condition $n(\varepsilon_{\text{T}} + \varepsilon_{\text{stat}}) \leq \varepsilon$, we set $\varepsilon_{\text{stat}} = \varepsilon_{\text{T}}/2$, which implies $\varepsilon_{\text{T}} \leq 2\varepsilon/(3n)$. Consequently, choosing $\varepsilon_{\text{T}} = \varepsilon/(3n)$ is adequate to conclude the reduction. Hence, in accordance with Theorem 12, we infer that $N_{\text{free testing}}$ must satisfy $N_{\text{free testing}} = \Omega(\frac{2^n}{\varepsilon^2})$ for solving the free-fermionic testing problem with at least a $2/3$ probability of success. □

As the reader can appreciate from the proof of the hardness of Problem 2, the difficulty arises from the unknown quantum state being arbitrarily close to the maximally mixed state, which is known to be challenging to test. Therefore, a natural assumption to facilitate Problem 2 is to assume the state ρ to have at most a fixed rank. In this context, we establish a fundamental lower bound on the number of copies required to solve the free-fermionic testing problem, which depends on the rank of the quantum state.

Theorem 14 (Lower bound for free-fermionic testing of states with bounded rank). *Let $\varepsilon_B > 0$. Let ρ be a quantum state such that $\operatorname{rank}(\rho) \leq 2^r$ with $r \in [n]$. To solve the free-fermionic testing property testing (Problem 2) with at least a $2/3$ probability of success, $N = \Omega(2^r/\varepsilon_B^2)$ copies are necessary. This holds when considering the set $\mathcal{G}$ in Problem 2 corresponding to the set of all free-fermionic states $\mathcal{G}_{\text{mixed}}$.*

Proof. Choose ρ of the form $\rho = \rho_r \otimes |\chi\rangle\langle\chi|$, where $|\chi\rangle$ is a pure free-fermionic state on $(n-r)$-qubits. Moreover, impose the promise that ρ_r is either the maximally mixed state on the first r-qubits, i.e., $\rho_r = 2^{-r}I_{2^r}$, or ρ_r satisfies $\|\rho_r - 2^{-r}I_{2^r}\|_1 > \varepsilon_B$. In both cases, it is clear that ρ has at most rank 2^r. By Theorem 12, to solve this problem with at least a $2/3$ probability of success, $N = \Omega(2^r/\varepsilon_B^2)$ copies of the state ρ_r are necessary. The proof now follows the same lines as the proof of Theorem 13, but on an effective space of r qubits. □

The same lower bound applies when considering the state ρ to be an arbitrary state, while restricting the set $\mathcal{G}$ in Problem 2 to be the set of all free-fermionic states with rank at most R, denoted by $\mathcal{G}_R$.

Theorem 15 (Lower bound for free-fermionic testing with respect to the set of bounded rank free-fermionic states $\mathcal{G}_R$). *Let $\varepsilon_B > 0$. For an arbitrary quantum state ρ, if we consider $\mathcal{G}$ in Problem 2 to correspond to the set $\mathcal{G}_R$ of all free-fermionic states with rank at most $R := 2^r$, where $r \in [n]$, then to solve the free-fermionic testing property testing (Problem 2) with at least a $2/3$ probability of success, $N = \Omega(2^r/\varepsilon_B^2)$ copies are necessary.*

Proof. The proof follows the same lines as the previous theorem, and everything holds analogously, even with the assumption that the set to be considered is $\mathcal{G}_R$ instead of $\mathcal{G}_{\text{mixed}}$. □

C. Efficient testing of low-rank free-fermionic states

In the preceding subsection, we established information-theoretic lower bounds for solving the free-fermionic property testing problem. Specifically, we demonstrated that when the input n-qubit state ρ has a rank less than or equal to 2^r, where $r \in [n]$, a minimum of $\Omega(2^r)$ copies is required. Similarly, when no assumptions are made about ρ, but $\mathcal{G}$ in Problem 2 corresponds to the set $\mathcal{G}_R$ of all free-fermionic states with rank at most $R := 2^r$, then $N = \Omega(2^r)$ copies are necessary.
Now, we address the question of whether an algorithm can match these information-theoretic lower bounds. We notice that if $r = O(\log(n))$, i.e., $R = O(\mathrm{poly}(n))$, then such an algorithm would be efficient. The following theorem provides an affirmative answer to this question.

Theorem 16 (Upper bound for free-fermionic testing with respect to the set of bounded rank free-fermionic states $\mathcal{G}_R$). *Let ρ be any n-qubit state. Assume error thresholds $\varepsilon_B, \varepsilon_A \in (0,1)$ such that*

$$\varepsilon_B > \sqrt{2^5(n-r)\varepsilon_A}, \tag{S160}$$

and consider a failure probability $\delta \in (0,1]$. Suppose ρ falls into one of two cases in Problem 2: either there exists a free-fermionic state $\sigma \in \mathcal{G}_R$ with $\|\rho - \sigma\|_1 \le \varepsilon_A$ (Case A), or $\min_{\sigma\in\mathcal{G}_R} \|\rho-\sigma\|_1 > \varepsilon_B$ (Case B), where $R := 2^r$ with $r \in [n]$.
Then, a quantum learning algorithm (Algorithm 3) can solve Problem 2 using

$$N := \lceil 8(n^3/\varepsilon_{\mathrm{stat}}^2)\log\left(8n^2/\delta\right) + N_{\mathrm{tom}}(\varepsilon_{\mathrm{tom}}, \delta/2, r)\rceil \tag{S161}$$

copies of the state ρ with a success probability at least $1-\delta$. Here, $N_{\mathrm{tom}}(\varepsilon_{\mathrm{tom}}, \delta/2, r)$ is the number of copies sufficient for a full state tomography algorithm (e.g., [43]) of an r-qubit state with accuracy $\varepsilon_{\mathrm{tom}}$ and failure probability at most $\delta/2$. Here, $\varepsilon_{\mathrm{stat}} < \frac{1}{2}\left(\frac{\varepsilon_B^2}{2^5(n-r)} - \varepsilon_A\right)$ and $\varepsilon_{\mathrm{tom}} := \frac{1}{2}(\frac{\varepsilon_B}{2} - \varepsilon_A)$.

Algorithm 3: Property testing algorithm for bounded rank free-fermionic states

```
Input: Let $R = 2^r$, with $r \in [n]$. Error thresholds $\varepsilon_A, \varepsilon_B$ such that $\varepsilon_B > \sqrt{2^5(n-r)\varepsilon_A}$, failure probability $\delta$.
    $N := \lceil 8(n^3/\varepsilon_{\mathrm{stat}}^2)\log(8n^2/\delta) + N_{\mathrm{tom}}(\varepsilon_{\mathrm{tom}}, \delta/2, r)\rceil$ copies of $\rho$. Here, $N_{\mathrm{tom}}(\varepsilon_{\mathrm{tom}}, \delta/2, r)$ is the number of copies sufficient
    for full state tomography of an $r$-qubit state with accuracy $\varepsilon_{\mathrm{tom}}$ and failure probability at most $\delta/2$. Let
    $\varepsilon_{\mathrm{stat}} < \frac{1}{2}\left(\frac{\varepsilon_B^2}{2^5(n-r)} - \varepsilon_A\right)$, $\varepsilon_{\mathrm{T}} > (\varepsilon_{\mathrm{stat}} + \varepsilon_A)$, $\varepsilon_{\mathrm{tom}} := \frac{1}{2}(\frac{\varepsilon_B}{2} - \varepsilon_A)$ and $\varepsilon_{\mathrm{T},2} \le \frac{1}{2}(\frac{\varepsilon_B}{2} + \varepsilon_A)$.
Output: Output either Case A or Case B.
Step 1: Estimate the entries of the correlation matrix of $\rho$ using $\lceil 8(n^3/\varepsilon_{\mathrm{stat}}^2)\log(8n^2/\delta)\rceil$ single-qubit measurements, resulting in the
  matrix $\hat{\Gamma}$ ;
Step 2: Find $\hat{\lambda}_{r+1}$, the $(r+1)$-th smallest singular value of $\hat{\Gamma}$ ;
Step 3: if $\hat{\lambda}_{r+1} \le 1 - \varepsilon_{\mathrm{T}}$ then
    Output: Case B
else
    Step 4: Evolve $\rho$ with the free-fermionic unitary $U_{\hat{O}}$, where $\hat{O}$ is the orthogonal matrix that puts $\hat{\Gamma}$ in its normal form. ;
    Step 5: Full state tomography on the first $r$ qubits of $U_{\hat{O}}\rho U_{\hat{O}}^{\dagger}$, which returns the state $\hat{\rho}_r'$ with correlation matrix $\Gamma_r$;
    Output: Case B if $\|\hat{\rho}_r' - \sigma(\hat{\Gamma}_r)\| > \varepsilon_{\mathrm{T},2}$, else Case A. Here, $\sigma(\hat{\Gamma}_r)$ is the free-fermionic state associated with the correlation
      matrix $\hat{\Gamma}_r$ of $\hat{\rho}_r'$.
```

Proof. Let $\varepsilon_{\mathrm{stat}}$ be an accuracy parameter, yet to be determined. According to Lemma 18, with $N \ge 8(n^3\varepsilon_{\mathrm{stat}}^2)\log\left(8n^2/\delta\right)$ single-qubit measurements, we can construct a matrix $\hat{\Gamma}$ such that, with a probability of at least $1-\delta/2$, it satisfies $\|\hat{\Gamma} - \Gamma(\rho)\|_\infty < \varepsilon_{\mathrm{stat}}$. Consequently, for each sorted (normal) eigenvalue λ_k of the correlation matrix, it holds that $|\hat{\lambda}_k - \lambda_k| < \varepsilon_{\mathrm{stat}}$, where $\hat{\lambda}_k$ is the k-th eigenvalue of $\hat{\Gamma}$. Now, consider that if ρ were a free-fermionic state with rank bounded by R, the first r eigenvalues could potentially be less than one, while the remaining $n-r$ should be one (as per Lemma 2). We proceed to perform our first check. If $\hat{\lambda}_{r+1} \ge 1 - \varepsilon_{\mathrm{T}}$, we continue; otherwise, we output B, where $\varepsilon_{\mathrm{T}} > 0$ is an error threshold to be fixed later. In case we output B, let us demonstrate that we cannot be in case A. We need to show that $\min_{\sigma\in\mathcal{G}_R}\|\rho-\sigma\|_1 > \varepsilon_A$. We have

$$\min_{\sigma\in\mathcal{G}_R}\|\rho-\sigma\|_1 \ge 1 - \lambda_{r+1} \ge 1 - \hat{\lambda}_{r+1} - \varepsilon_{\mathrm{stat}} > \varepsilon_{\mathrm{T}} - \varepsilon_{\mathrm{stat}}, \tag{S162}$$

where the first inequality follows from Theorem 7. Therefore, by choosing

$$\varepsilon_{\mathrm{T}} - \varepsilon_{\mathrm{stat}} > \varepsilon_A, \tag{S163}$$

we successfully ensure that ρ cannot be in case A. This condition forms the first criterion for determining the accuracy parameter $\varepsilon_{\mathrm{stat}}$ and the threshold ε_{T}. To proceed, we define $\hat{O}$ as the orthogonal matrix such that $\hat{O}\hat{\Gamma}\hat{O}^T = \hat{\Lambda}$, where

$$\hat{\Lambda} := \bigoplus_{k=1}^{n} \begin{pmatrix} 0 & \hat{\lambda}_k \\ -\hat{\lambda}_k & 0 \end{pmatrix} \tag{S164}$$

and define $U_{\hat{O}}$ as the associated free-fermionic unitary. Consider the state $\rho' := U_{\hat{O}}\rho U_{\hat{O}}^{\dagger}$. We observe that

$$|\Gamma(\rho')_{j,k} - (\hat{\Lambda})_{j,k}| \leq \|\Gamma(\rho') - \hat{\Lambda}\|_\infty \leq \|\Gamma(\rho) - \hat{\Gamma}\|_\infty \leq \varepsilon_{\mathrm{stat}}, \tag{S165}$$

leveraging the relationships $\Gamma(\rho') = \hat{O}\Gamma(\rho)\hat{O}^T$ and $\hat{\Lambda} = \hat{O}\hat{\Gamma}\hat{O}^T$, Cauchy-Schwartz, and the definition of the infinity norm. Consequently, we establish $\Gamma(\rho')_{j,k} \geq (\hat{\Lambda})_{j,k} - \varepsilon_{\mathrm{stat}}$. Specifically, for $k \geq r+1$, we find:

$$\mathrm{Tr}(Z_k\rho') = \Gamma(\rho')_{2k-1,k} \geq (\hat{\Lambda})_{2k-1,2k} - \varepsilon_{\mathrm{stat}} = \hat{\lambda}_k - \varepsilon_{\mathrm{stat}} \geq 1 - \varepsilon_{\mathrm{T}} - \varepsilon_{\mathrm{stat}}, \tag{S166}$$

where $Z_k = -i\gamma_{2k-1}\gamma_{2k}$ represents the Z-Pauli operator acting on the k-th qubit. Consequently, we also find $\mathrm{Tr}(|0\rangle\langle 0|_k\, \rho') \geq 1 - (\varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}})/2$. Employing Lemma 13, we derive:

$$\left\|\rho' - \phi \otimes |0^{n-r}\rangle\langle 0^{n-r}|\right\|_1 \leq 2\sqrt{(n-r)(\varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}})/2}, \tag{S167}$$

where $\phi\otimes|0^{n-r}\rangle\langle 0^{n-r}|$ represents the post-measurement state obtained after measuring the outcomes corresponding to $|0^{n-r}\rangle$ in the last $n-r$ qubits. Define the subsystem E with sites $E = [r+1, \ldots, n]$ and define

$$\rho'_r := \mathrm{tr}_E[\rho'] = \mathrm{tr}_E[U_{\hat{O}}\rho U_{\hat{O}}^{\dagger}]. \tag{S168}$$

We also have

$$\begin{aligned} \left\|\rho' - \rho'_r \otimes |0^{n-r}\rangle\langle 0^{n-r}|\right\|_1 &\leq \left\|\rho' - \phi \otimes |0^{n-r}\rangle\langle 0^{n-r}|\right\|_1 + \|\phi - \rho'_r\|_1 \\ &\leq \left\|\rho' - \phi \otimes |0^{n-r}\rangle\langle 0^{n-r}|\right\|_1 + \left\|\phi \otimes |0^{n-r}\rangle\langle 0^{n-r}| - \rho'\right\|_1 \\ &\leq 4\sqrt{(n-r)(\varepsilon_{\mathrm{T}} + \varepsilon_{\mathrm{stat}})/2}, \end{aligned} \tag{S169}$$

where in the first step, we used the triangle inequality, in the second step, the data-processing inequality ($\|\,\mathrm{tr}_E(\rho - \sigma)\|_1 \leq \|\rho - \sigma\|_1$ for any quantum states ρ, σ), and in the last step, we used Eq.(S167). We now perform full-state tomography on the first r qubits of ρ'. More precisely, using copies of ρ'_r, we can output a state $\hat{\rho}'_r$ such that, with a probability of at least $1 - \delta/2$, we find that

$$\|\hat{\rho}'_r - \rho'_r\|_1 \leq \varepsilon_{\mathrm{tom}}. \tag{S170}$$

There are various algorithms for full-state tomography that utilize single-copy measurements (see, e.g., Ref. [43]), all having sample complexity that scales exponentially with the number of qubits constituting the quantum state, in our case, r. Furthermore, through the computation of the correlation matrix of $\hat{\rho}'_r$, we can compute its correlation matrix $\hat{\Gamma}_r$, which satisfies

$$\left\|\hat{\Gamma}_r - \Gamma(\rho'_r)\right\|_\infty \leq \|\hat{\rho}'_r - \rho'_r\|_1 \leq \varepsilon_{\mathrm{tom}}, \tag{S171}$$

where we have invoked Lemma 16. Now, let us consider the free-fermionic state $\sigma(\hat{\Gamma}_r)$ associated with the correlation matrix $\hat{\Gamma}_r$. Our second discrimination test hinges on the quantity $\left\|\hat{\rho}'_r - \sigma(\hat{\Gamma}_r)\right\|_1$, which can be computed with a time complexity scaling as $O(\exp(r))$, which is efficient as long as the rank of ρ is $O(\mathrm{poly}(n))$. If $\left\|\hat{\rho}'_r - \sigma(\hat{\Gamma}_r)\right\|_1 \leq \varepsilon_{\mathrm{T},2}$, we output A; otherwise, we output B. In the case of outputting A, our goal is to demonstrate that we cannot be in case B. Specifically, we show that there exist a free-fermionic state closer, in trace distance, than ε_B to ρ. Consider the free-fermionic state

$U_{\hat{O}}^{\dagger}\left(\sigma(\hat{\Gamma}_r)\otimes|0^{n-r}\rangle\langle 0^{n-r}|\right)U_{\hat{O}}$, which is readily free-fermionic. We have

$$\begin{aligned}&\left\|\rho-U_{\hat{O}}^{\dagger}\left(\sigma(\hat{\Gamma}_r)\otimes|0^{n-r}\rangle\langle 0^{n-r}|\right)U_{\hat{O}}\right\|_1\\&=\left\|\rho'-\sigma(\hat{\Gamma}_r)\otimes|0^{n-r}\rangle\langle 0^{n-r}|\right\|_1\\&\le\|\rho'-\rho'_r\otimes|0^{n-r}\rangle\langle 0^{n-r}|\|_1+\left\|\rho'_r-\sigma(\hat{\Gamma}_r)\right\|_1\\&\le\|\rho'-\rho'_r\otimes|0^{n-r}\rangle\langle 0^{n-r}|\|_1+\|\rho'_r-\hat{\rho}'_r\|_1+\left\|\hat{\rho}'_r-\sigma(\hat{\Gamma}_r)\right\|_1\\&\le 4\sqrt{(n-r)(\epsilon_{\mathrm{T}}+\epsilon_{\mathrm{stat}})/2}+\epsilon_{\mathrm{tom}}+\varepsilon_{\mathrm{T},2},\end{aligned}\tag{S172}$$

where in the first inequality, we used the unitary invariance of the trace norm; in the second and third steps, we applied the triangle inequality; and in the last step, we used the previously derived bound. Now, we must ensure

$$4\sqrt{(n-r)(\epsilon_{\mathrm{T}}+\epsilon_{\mathrm{stat}})/2}+\epsilon_{\mathrm{tom}}+\varepsilon_{\mathrm{T},2}\le\varepsilon_B.\tag{S173}$$

Now, let us explore the scenario where we output case B. Considering that the application of a free-fermionic unitary $U_{\hat{O}}$ and the partial trace map a free-fermionic state into another free-fermionic state [3], we employ the data processing inequality, leading to the inequality

$$\min_{\sigma\in\mathcal{G}_R}\|\rho-\sigma\|_1=\min_{\sigma\in\mathcal{G}_R}\|\rho'-\sigma\|\ge\min_{\sigma_R\in\mathcal{G}_R}\|\rho_R-\sigma_R\|.\tag{S174}$$

Now, let us demonstrate that if $\|\hat{\rho}'_R-\sigma(\hat{\Gamma}_R)\|>\varepsilon_{\mathrm{T},2}$, we cannot be in case A. To establish this, let us first express the lower bounds

$$\|\rho'_R-\sigma_R\|_1\ge\begin{cases}\left\|\hat{\Gamma}_R-\Gamma(\sigma_R)\right\|_\infty-\varepsilon_{\mathrm{tom}}\\\left\|\hat{\rho}'_R-\sigma(\hat{\Gamma}_R)\right\|_1-\varepsilon_{\mathrm{tom}}-\alpha\left\|\hat{\Gamma}_R-\Gamma(\sigma_R)\right\|_\infty^{1/2}\end{cases},\tag{S175}$$

where, for the first bound, we utilize Lemma 16 and the triangle inequality, namely

$$\|\rho'_R-\sigma_R\|_1\ge\|\Gamma(\rho'_R)-\Gamma(\sigma_R)\|_\infty\ge\left\|\hat{\Gamma}_R-\Gamma(\sigma_R)\right\|_\infty-\varepsilon_{\mathrm{tom}},\tag{S176}$$

and for the second bound, by utilizing Theorem 6 and triangle inequality, we have

$$\begin{aligned}\|\rho'_R-\sigma_R\|_1&\ge\|\rho'_r-\sigma(\hat{\Gamma}_R)\|_1-\|\sigma(\hat{\Gamma}_R)-\sigma_R\|_1\\&\ge\|\rho'_R-\sigma(\hat{\Gamma}_R)\|_1-\alpha\|\hat{\Gamma}_R-\Gamma(\sigma_R)\|_\infty^{1/2},\end{aligned}\tag{S177}$$

with $\alpha:=2\sqrt{n}$. Our objective is to optimize and find the threshold corresponding to a universal lower bound. To achieve this, we solve the equation

$$\left\|\hat{\rho}'_R-\sigma(\hat{\Gamma}_R)\right\|_1-\varepsilon_{\mathrm{tom}}-\alpha\left\|\hat{\Gamma}_R-\Gamma(\sigma_R)\right\|_\infty^{1/2}=\left\|\hat{\Gamma}_R-\Gamma(\sigma_R)\right\|_\infty-\varepsilon_{\mathrm{tom}},\tag{S178}$$

for $\|\hat{\Gamma}_R-\Gamma(\sigma_R)\|_\infty$. Let $y:=\|\hat{\Gamma}_R-\Gamma(\sigma_R)\|_\infty^{1/2}$ and $b:=\|\hat{\rho}'_R-\sigma(\hat{\Gamma}_R)\|_1$. Solving such equation reduces to solving $y^2+\alpha y-b=0$. Substituting the solution in the previous inequality, we obtain

$$\begin{aligned}\min_{\sigma_R\in\mathcal{G}_R}\|\rho'_R-\sigma_R\|_1&\ge\|\rho'_R-\sigma(\hat{\Gamma}_R)\|_1-2\sqrt{n}(\sqrt{n+\|\rho'_R-\sigma(\hat{\Gamma}_R)\|_1}-\sqrt{n})-\varepsilon_{\mathrm{tom}}\\&\ge\|\rho'_R-\sigma(\hat{\Gamma}_R)\|_1-\frac{1}{6n}\|\rho'_R-\sigma(\hat{\Gamma}_R)\|_1^2-\varepsilon_{\mathrm{tom}}\end{aligned}\tag{S179}$$

where we have used the inequality $\sqrt{1+x}\le 1+\frac{x}{2}-\frac{x^2}{32}$ valid for $x\in[0,8]$. Now, we only need to impose that, given $\left\|\hat{\rho}'_R-\sigma(\hat{\Gamma}_R)\right\|_1>\varepsilon_{\mathrm{T},2}$, we cannot be in case A and, therefore, impose

$$\varepsilon_{T,2}-\frac{\varepsilon_{T,2}^2}{6n}-\varepsilon_{\mathrm{tom}}>\varepsilon_A.\tag{S180}$$

To satisfy the constraints in Eq. (S163), (S173), and (S180), we need to choose the constants $\varepsilon_{\mathrm{stat}}$, ε_{T}, $\varepsilon_{\mathrm{tom}}$, and $\varepsilon_{\mathrm{T},2}$. We start by imposing the two inequalities (which implies Eq. (S173))

$$4\sqrt{(n-r)(\epsilon_{\mathrm{T}}+\epsilon_{\mathrm{stat}})/2} \leq \frac{\varepsilon_B}{2}, \tag{S181}$$

$$\epsilon_{\mathrm{tom}}+\varepsilon_{\mathrm{T},2} \leq \frac{\varepsilon_B}{2}. \tag{S182}$$

Therefore, we have "disentangled" the three inequalities in Eq. (S163), (S173), and (S180) into two systems of two inequalities, the first containing stat and ϵ_{T} involving Eq. (S163) and (S181), and the other one containing ϵ_{tom} and $\varepsilon_{\mathrm{T},2}$ involving Eq. (S180) and (S182). By solving the one involving Eq. (S163) and (S181), we get

$$\varepsilon_{\mathrm{T}} > (\varepsilon_{\mathrm{stat}}+\varepsilon_A), \tag{S183}$$

$$\varepsilon_{\mathrm{stat}} < \frac{1}{2}\left(\frac{\varepsilon_B^2}{2^5(n-r)}-\varepsilon_A\right). \tag{S184}$$

Moreover, by solving the one involving Eq. (S180) and (S182), we get

$$\epsilon_{\mathrm{tom}} \leq \frac{\varepsilon_B}{2}-\varepsilon_{\mathrm{T},2}, \tag{S185}$$

$$\varepsilon_{\mathrm{T},2} \leq 6n\left(1-\sqrt{1-\frac{\frac{\varepsilon_B}{2}+\varepsilon_A}{6n}}\right). \tag{S186}$$

The latter inequality is satisfied by choosing $\varepsilon_{\mathrm{T},2} \leq \frac{1}{2}(\frac{\varepsilon_B}{2}+\varepsilon_A)$, which implies

$$\epsilon_{\mathrm{tom}} \leq \frac{1}{2}\left(\frac{\varepsilon_B}{2}-\varepsilon_A\right). \tag{S187}$$

By union bound, the total failure probability of the protocol is at most $1-\delta$. □

The previous theorem was presented under the assumption that ρ is an arbitrary n-qubit state, and the set of free-fermionic states considered is $\mathcal{G}_R$, i.e., the set of free-fermionic states with rank at most $R=2^r$, where $r\in[n]$. However, if we assume that ρ has at most rank R, then we can consider the largest set $\mathcal{G}_{\mathrm{mixed}}$, and we can establish an analogous result. The theorem is detailed as follows, and the algorithm is the same as Algorithm 3 with slightly different accuracy parameters, as detailed below.

Theorem 17 (Upper bound for free-fermionic testing for a bounded rank quantum state). *Let ρ be any n-qubit state with rank at most 2^r, where $r\in[n]$. Assume error thresholds $\varepsilon_B,\varepsilon_A\in(0,1)$ such that $\varepsilon_B>\sqrt{2^5(n-r)(2\varepsilon_A)^{1/(r+1)}}$, and consider a failure probability $\delta\in(0,1]$. Suppose ρ falls into one of two cases in Problem 2: either there exists a free-fermionic state $\sigma\in\mathcal{G}_{\mathrm{mixed}}$ with $\|\rho-\sigma\|_1\leq\varepsilon_A$ (Case A), or $\min_{\sigma\in\mathcal{G}_{\mathrm{mixed}}}\|\rho-\sigma\|_1>\varepsilon_B$ (Case B). Then, a quantum learning algorithm (Algorithm 3) can solve Problem 2 using*

$$N := \lceil 8(n^3/\varepsilon_{\mathrm{stat}}^2)\log(8n^2/\delta)+N_{\mathrm{tom}}(\varepsilon_{\mathrm{tom}},\delta/2,r)\rceil$$

copies of the state ρ with a success probability at least $1-\delta$. Here, $N_{\mathrm{tom}}(\varepsilon_{\mathrm{tom}},\delta/2,r)$ is the number of copies sufficient for a full state tomography algorithm (see, e.g., Ref. [43]) of an r-qubit state with accuracy $\varepsilon_{\mathrm{tom}}$ and failure probability at most $\delta/2$. Here, we impose

$$\varepsilon_{\mathrm{T}} > (\varepsilon_{\mathrm{stat}}+(2\varepsilon_A)^{\frac{1}{r+1}}), \tag{S188}$$

$$\varepsilon_{\mathrm{stat}} < \frac{1}{2}\left(\frac{\varepsilon_B^2}{2^5(n-r)}-(2\varepsilon_A)^{\frac{1}{r+1}}\right), \tag{S189}$$

$$\varepsilon_{\mathrm{T},2} \leq \frac{1}{2}(\frac{\varepsilon_B}{2}+\varepsilon_A), \tag{S190}$$

$$\epsilon_{\mathrm{tom}} \leq \frac{1}{2}\left(\frac{\varepsilon_B}{2}-\varepsilon_A\right) \tag{S191}$$

Proof. The proof is the same as the one of the previous theorem, but this time we have utilized instead of Eq.(S162) the expression

$$\min_{\sigma\in\mathcal{G}_{\mathrm{mixed}}}\|\rho-\sigma\|_1 \geq \frac{1}{2}(1-\lambda_{r+1})^{r+1}, \tag{S192}$$

which follows from Lemma 9. From this, it follows that (using the same notation as in the previous proof)

$$\min_{\sigma\in\mathcal{G}_{\text{mixed}}} \|\rho-\sigma\|_1 > \frac{1}{2}(\varepsilon_{\text{stat}}-\varepsilon_{\text{T}})^{r+1}. \tag{S193}$$

Hence, we have the condition

$$(\varepsilon_{\text{T}}-\varepsilon_{\text{stat}})^{r+1} > 2\varepsilon_A. \tag{S194}$$

This is the only condition that is different from the ones in the previous Theorem. We impose

$$\begin{aligned}
\varepsilon_{\text{T}} &> (\varepsilon_{\text{stat}} + (2\varepsilon_A)^{\frac{1}{r+1}}), && \text{(S195)}\\
\varepsilon_{\text{stat}} &< \frac{1}{2}\left(\frac{\varepsilon_B^2}{2^5(n-r)} - (2\varepsilon_A)^{\frac{1}{r+1}}\right), && \text{(S196)}\\
\varepsilon_{\text{T},2} &\le \frac{1}{2}(\frac{\varepsilon_B}{2} + \varepsilon_A), && \text{(S197)}\\
\epsilon_{\text{tom}} &\le \frac{1}{2}\left(\frac{\varepsilon_B}{2} - \varepsilon_A\right) && \text{(S198)}
\end{aligned}$$

and this suffices to satisfy all the constraints. □

V. Efficient tomography of mixed free-fermionic states and improved pure states tomography

In this section, we present an algorithm for learning n-qubit mixed free-fermionic states in trace distance. The algorithm is efficient in terms of samples, time, and memory, and is a straightforward consequence of Lemma 6, which establishes a relationship between the trace distance of mixed free-fermionic states and the one-norm difference of their correlation matrices. It is worth noting that previous works have provided sample complexity bounds to learn free-fermionic states [11, 16, 17] (in parts by the same authors), but they are limited to the pure case scenario. Moreover, we improve over their sample complexity for the pure case scenario as well.

Algorithm 4: Learning mixed free-fermionic states

```
Input: Error threshold $\varepsilon > 0$, failure probability $\delta > 0$. $N = \lceil 128(n^5/\varepsilon^4)\log(4n^2/\delta)\rceil$ copies of the mixed free-fermionic state $\rho$.
Output: A classical description of a state $\hat{\rho}$, such that $\|\hat{\rho}-\rho\|_1 \le \varepsilon$ with at least $1-\delta$ success probability.
Step 1: Estimate the entries of the correlation matrix of $\rho$ using $N$ single-copy measurements, resulting in the estimated $2n \times 2n$ matrix $\hat{\Gamma}$;
Step 2: Put $\hat{\Gamma}$ in its normal form $\hat{\Gamma} = \hat{O}\hat{\Lambda}\hat{O}^T$, where $\hat{O} \in \mathrm{O}(2n)$, and $\hat{\Lambda}$ is the matrix determined by the normal eigenvalues $\{\hat{\lambda}_j\}_{j=1}^n$. ;
return $\hat{O}$ and $\{\hat{\lambda}_i\}_{i=1}^n$, so that $\hat{\rho} := G_{\hat{O}}\left(\bigotimes_{j=1}^n \frac{I+\hat{\lambda}_j Z_j}{2}\right)G_{\hat{O}}^\dagger$, where $G_{\hat{O}}$ is the free-fermionic unitary associated with $\hat{O}$.
```

Theorem 18 (Tomography of free-fermionic mixed states). *Let ρ be a free-fermionic state. For $\varepsilon \in (0,1)$ and $\delta \in (0,1]$, there exists a quantum learning algorithm (outlined in table 4) that, utilizing $N = \lceil 128(n^5/\varepsilon^4)\log(4n^2/\delta)\rceil$ single-copies of the state ρ learns an efficient representation of a state $\hat{\rho}$ such that:*

$$\|\hat{\rho}-\rho\|_1 \le \varepsilon, \tag{S199}$$

with a probability of success at least $1-\delta$.

Proof. Let $\varepsilon_{\text{stat}} > 0$ be an accuracy parameter to be fixed later. By Lemma 19, with $N \ge 8(n^3/\varepsilon_{\text{stat}}^2)\log(4n^2/\delta)$ copies of the state, we can find a matrix $\hat{\Gamma}$ such that, with probability at least $1-\delta$, it holds that $\left\|\hat{\Gamma}-\Gamma(\rho)\right\|_\infty < \varepsilon_{\text{stat}}$. Since $\hat{\Gamma}$ is a valid correlation matrix, i.e., it is real-anti-symmetric and has normal eigenvalues in absolute value less than or equal to one, it corresponds to a free-fermionic state $\hat{\rho}$ (due to Lemma 6). Therefore, the matrix $\Gamma(\hat{\rho}) := \hat{\Gamma}$ fully identifies the free-fermionic state $\hat{\rho}$. In particular, $\hat{\Gamma}$ can be expressed in its normal form $\hat{\Gamma} = \hat{O}\hat{\Lambda}\hat{O}^T$, where $\hat{O} \in \mathrm{O}(2n)$, and $\hat{\Lambda} = \bigoplus_{k=1}^n \begin{pmatrix} 0 & \hat{\lambda}_k \\ -\hat{\lambda}_k & 0 \end{pmatrix}$, and $\hat{\rho}$ assumes the form

$$\hat{\rho} := G_{\hat{O}}\left(\bigotimes_{j=1}^n \frac{I+\hat{\lambda}_j Z_j}{2}\right)G_{\hat{O}}^\dagger, \tag{S200}$$

where $G_{\hat{O}}$ is the free-fermionic unitary associated with $\hat{O}$. By Theorem 6, we have

$$\|\hat{\rho}-\rho\|_1 \leq 2\sqrt{n\|\Gamma(\hat{\rho})-\Gamma(\rho)\|_\infty}. \tag{S201}$$

By choosing $\varepsilon_{\text{stat}} = \varepsilon^2/(4n)$, we can conclude. □

Corollary 2 (Tomography of free-fermionic states via single Pauli measurements). *Let ρ be a free-fermionic quantum state. For $\varepsilon \in (0,1)$ and $\delta \in (0,1]$ there exist a learning algorithm that utilize $N = 256(n^6/\varepsilon^4)\log\left(4n^2/\delta\right)$ copies of the state and only single-qubit Pauli measurements to learn an efficient classical representation $\hat{\rho}$ of the state ρ obeying $\|\rho-\hat{\rho}\|_1 \leq \varepsilon$.*

Proof. The proof follows identically to that of Theorem 18. The only difference lies in the estimation of the correlation matrix $\hat{\Gamma}$, which, if estimated through single-qubit Pauli measurements, requires $N = 16(n^4/\varepsilon^2_{\text{stat}})\log\left(4n^2/\delta\right)$ copies of the state ρ, as detailed in Lemma 18. □

We now show also the following improved learning algorithm for pure free-fermionic states, which is a direct implication of Lemma 20 and our novel inequality valid for pure Gaussian states (Theorem 5):

Proposition 2 (Tomography of pure free-fermionic states). *Let ψ be a free-fermionic quantum state. For $\varepsilon \in (0,1)$ and $\delta \in (0,1]$ there exist a learning algorithm that utilize $N = 32(n^3/\varepsilon^2)\log\left(4n^2/\delta\right)$ copies of the state and only single-copies measurements to learn an efficient classical representation of the state $\hat{\psi}$ obeying $\|\psi-\hat{\psi}\|_1 \leq \varepsilon$.*

Efficient learning of quantum states prepared with few fermionic non-Gaussian gates

(Dated: March 1, 2024)

The experimental realization of increasingly complex quantum states underscores the pressing need for new methods of state learning and verification. In one such framework, quantum state tomography, the aim is to learn the full quantum state from data obtained by measurements. Without prior assumptions on the state, this task is prohibitively hard. Here, we present an efficient algorithm for learning states on n fermion modes prepared by any number of Gaussian and at most t non-Gaussian gates. By Jordan-Wigner mapping, this also includes n-qubit states prepared by nearest-neighbour matchgate circuits with at most t SWAP-gates. Our algorithm is based exclusively on single-copy measurements and produces a classical representation of a state, guaranteed to be close in trace distance to the target state. The sample and time complexity of our algorithm is $\mathrm{poly}(n, 2^t)$; thus if $t = \mathcal{O}(\log(n))$, it is efficient. We also show that, if t scales *slightly* more than logarithmically, any learning algorithm to solve the same task must be inefficient, under common cryptographic assumptions. We also provide an efficient property testing algorithm that, given access to copies of a state, determines whether such state is far or close to the set of states for which our learning algorithm works. Beyond tomography, our work sheds light on the structure of states prepared with few non-Gaussian gates and offers an improved upper bound on their circuit complexity.

Introduction

Quantum state tomography is the task of reconstructing a classical description of a quantum state from experimental data [1, 2]. Beyond its foundational significance in quantum information theory, it stands as the gold standard for verification and benchmarking of quantum devices [2]. However, in the absence of any prior assumptions on the state to be learned, one encounters necessarily the *curse of dimensionality* of the Hilbert space: learning the classical description of a generic quantum state demands resources that grow exponentially with the number of qubits [1, 3]. Simply storing and outputting the density matrix of a state already results in an exponential cost in time. This raises the crucial question of identifying classes of quantum states that can be efficiently learned using a number of state copies and time scaling at most *polynomially* with the system size. Only a few classes of states are currently known to be efficiently learnable — in particular, matrix product states [2, 4], finitely-correlated states [5], high-temperature Gibbs states [6], states prepared by shallow quantum circuits [7], stabilizer states [8], quantum phase states [9], and fermionic Gaussian states [10, 11]. The latter class of states comprises those prepared by fermionic Gaussian circuits [12], also referred to as free fermionic evolutions or fermionic linear-optics circuits [13, 14]. Via Jordan-Wigner mapping, such states on n fermionic modes can also be viewed as n-qubit states, prepared by generalized matchgate circuits [14–16]. Fermionic Gaussian states states play a key role in condensed matter physics and quantum chemistry, via the Hartree-Fock method and in the context of Fermi Liquid and Bardeen-Cooper-Schrieffer theories [17–20]. These states are also essential in understanding many exactly solvable spin models [21–23]. In quantum computing, fermionic Gaussian states are primarily recognized for their efficient classical simulability [13, 15, 16]. As in the case of Clifford circuits, for which the introduction of magic gates, such as T-gates, allows to reach universal quantum computation [24], also for the case of Gaussian circuits the inclusion of certain magic gates [25–27], for example SWAP gates [26], allows to reach universality. If the number t of T-gates in a Clifford circuit is low, the resulting states can still be efficiently simulated classically [28–30]; it has also been recently demonstrated that such states, termed as t-doped stabilizer states [31, 32], are still efficiently learnable [33–35]. Similarly, in the past year, it has been shown that Gaussian circuits with a few magic gates are also classically simulable [36–38]. However, the learnability of such "t-doped fermionic Gaussian states" remains unknown and this motivates the core-question of our work:

Can we efficiently learn states prepared by Gaussian operations (e.g. matchgates) and a few magic gates?

We answer it by proposing a quantum algorithm of polynomial time and sample complexity that uses only single-copy measurements and learns a classical description of a t-doped fermionic Gaussian state; the learned state is guaranteed to be close to the true state in trace distance. Our presentation is framed in the language of qubits, but the results seamlessly translate into the fermionic formalism. Our learning algorithm may also be feasible to implement in near-term fermionic analog quantum simulators [39, 40], like cold atoms in optical lattices [41], since we only utilize time evolutions of simple few-body fermionic Hamiltonians [42]. The core of our algorithm relies on a result of independent interest, elucidating the structure of states in question. In particular, for any t-doped fermionic Gaussian state $|\psi\rangle$ we show that there exists a Gaussian operation G such that

$G^\dagger |\psi\rangle = |\phi\rangle \otimes |0^{n-\kappa t}\rangle$, where $|\phi\rangle$ is supported on κt qubits and κ is a small constant. Informally, this says that all the magic of such states can be *compressed* to a few qubits via a Gaussian operation. The proof of our compression theorem is constructive, which has implications for the circuit complexity of $|\psi\rangle$ and for improved preparation of doped fermionic Gaussian states.

The high level idea of the learning algorithm is to first learn a Gaussian unitary G which *compresses* the magic, apply it to the state, and then perform full state state tomography on the first few qubits alone. Our learning algorithm has a time complexity $\mathcal{O}(\mathrm{poly}(n, 2^t))$, i.e. it scales polynomially in the system size n and exponentially in the number of non-Gaussian gates t. Thus it is efficient as long as the number of non-Gaussian gates is $t = \mathcal{O}(\log(n))$. Furthermore, we establish that the task of learning such states is computationally intractable when the number of non-Gaussian gates scales *slightly* more than logarithmically, under a common cryptography assumption [43–46]. We show the latter result using the theory of pseudorandom quantum states [47, 48] and qubit-to-fermion mappings [23]. In doing that, we bring pseudorandom quantum states, so far explored only for qubit-based systems, to the fermionic realm. Our learning algorithm generalizes the one presented by Aaronson et al. [33], which is tailored to learn only those states prepared by *particle-number conserving* Gaussian gates and $t = 0$ (in our work we relax both of these assumptions). Furthermore, our algorithm extends to all compressible states, i.e., those which can be written as $|\psi\rangle = G\,|\phi\rangle \otimes |0^{n-\kappa t}\rangle$. We also propose an efficient method to *test* if a given state is close or far from the set of compressible states, by showing an efficiently estimatable quantity that lower bounds the distance to this set.

It should be noted that the concept of magic compression was first introduced in the context of Clifford+T circuits by Leone, Oliviero et al. [49, 50] and later exploited for learning t-doped stabilizer states [33, 34]. Our strategy of proving non-Gaussianity compression and applying it to quantum state tomography was inspired by these earlier works. It is an intriguing fact that a similar compression theorem holds in our context, even though the mathematical structures of stabilizer states and fermionic Gaussian states appear quite different.

In the next sections we summarize our findings, stating more precisely our results and the essential ideas that underlie them. In the Supplementary Material, we provide the technical details.

Preliminaries

Our work can be applied to two distinct and naively separate settings: a system of n qubits with 1D matchgates circuits and their magic gates (e.g., SWAP gates), or a native fermionic system of n modes with states prepared by fermionic Gaussian evolutions and local non-Gaussian evolutions. These two perspectives are mathematically related through the Jordan-Wigner mapping. We will use it now as a *definition* of Majorana operators, thus directly aligning our discussion with the qubit language. Majorana operators, denoted as γ_{2k-1} and γ_{2k} for $k \in [n] := \{1, \dots, n\}$, are defined in terms of standard Pauli operators as $\gamma_{2k-1} := (\prod_{j=1}^{k-1} Z_j)X_k$ and $\gamma_{2k} := (\prod_{j=1}^{k-1} Z_j)Y_k$. Alternatively, they can be defined in the fermionic language through their anticommutation relations [13, 51]. A fermionic Gaussian unitary G is a unitary that satisfies $G^\dagger \gamma_\mu G = \sum_{\nu=1}^{2n} O_{\mu,\nu}\gamma_\nu$ for any $\mu \in [2n]$, where $O \in \mathrm{O}(2n)$ is an orthogonal matrix. The product of two Gaussian unitaries is Gaussian. Notably, a one-to-one correspondence exists between Gaussian unitaries up to a global phase and $\mathrm{O}(2n)$ orthogonal matrices. Given an orthogonal matrix, it is known how to exactly implement the associated Gaussian unitary using $\mathcal{O}(n^2)$ 2-local qubits or 2-local fermionic Gaussian operations [36, 52]. A pure fermionic Gaussian state can be defined as $|\psi\rangle = G\,|0^n\rangle$, where G is a Gaussian unitary and $|0^n\rangle$ denotes the zero computational basis state. Given a quantum state ρ, its correlation matrix $C(\rho)$ is defined as the real anti-symmetric $2n \times 2n$ matrix with elements $[C(\rho)]_{j,k} := -\frac{i}{2}\,\mathrm{Tr}\,(\gamma_j\gamma_k\rho)$, for any $j < k \in [2n]$. We have that $C(G\rho G^\dagger) = OC(\rho)O^T$, for any Gaussian unitary G associated with $O \in \mathrm{O}(2n)$. A well-known result in linear algebra [53] asserts that any real anti-symmetric matrix C can be decomposed in the so-called 'normal form':

$$C = O \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} O^T, \tag{1}$$

where O is an orthogonal matrix in $\mathrm{O}(2n)$ and $\lambda_j \geq 0$, for any $j \in [n]$, are dubbed as 'normal' eigenvalues, ordered in increasing order. We denote the trace distance between two quantum states $|\psi\rangle$ and $|\phi\rangle$ as $d_{\mathrm{tr}}(|\psi\rangle, |\phi\rangle) := \frac{1}{2}\| |\psi\rangle\langle\psi| - |\phi\rangle\langle\phi| \|_1$. Given a matrix A, its operator norm $\|A\|_\infty$ is defined as its largest singular value. We refer to the Supplementary Material (SM) for more preliminaries.

Structure of t-doped Gaussian states

States prepared by Gaussian circuits applied to a computational basis state are efficiently simulable classically. However, by incorporating 'non-Gaussian', or 'magic' operations, such as SWAP-gates [15, 26], one can render Gaussian circuits universal for quantum computation. The term 'magic gate' comes from a loose parallel to Clifford circuits, which are efficiently simulable per se but become universal upon introduction of 'magic' non-Clifford T-gates.

Here we consider non-Gaussian operations generated by κ Majorana operators $\{\gamma_{\mu(r)}\}_{r=1}^{\kappa}$, where $\mu(1),\ldots,\mu(\kappa) \in [2n]$. Examples of such non-Gaussian operations for $\kappa = 4$ are the SWAP-gate or a unitary $\exp(i\theta\gamma_1\gamma_5\gamma_6\gamma_8)$ for $\theta \in \mathbb{R}$; for $\kappa = 3$, an example is $\exp(\theta\gamma_2\gamma_6\gamma_7)$. We refer to κ as the maximum Majorana locality of the employed non-Gaussian gates.

Definition 1 (t-doped fermionic Gaussian state)**.** *A state $|\psi\rangle$ is a (t,κ)-doped Gaussian state if it can be prepared by Gaussian unitaries $\{G_i\}_{i=0}^{t}$ and t non-Gaussian κ-local gates $\{W_i\}_{i=1}^{t}$, specifically*

$$|\psi\rangle = G_t W_t \cdots G_1 W_1 G_0 |0^n\rangle \,, \tag{2}$$

where κ-local means that each non-Gaussian gate involves at most κ Majorana operators. Informally, a state is t-doped Gaussian if it is (t,κ)-doped Gaussian for some fixed constant κ.

Similarly, we denote the unitary $U_t := G_t W_t \cdots G_1 W_1 G_0$ as a t-doped Gaussian unitary. We now present our main result concerning the structure of t-doped Gaussian states: it is possible to compress all the 'non-Gaussianity' of the state into a localized region of the system via a Gaussian operation. This motivates the following definition.

Definition 2 (t-compressible Gaussian state)**.** *Let $t \in [n]$. A state $|\psi\rangle$ is (Gaussian) t-compressible if and only if*

$$|\psi\rangle = G(|\phi\rangle \otimes |0^{n-t}\rangle), \tag{3}$$

where G is a Gaussian operation, and $|\phi\rangle$ is a state supported solely on the first t qubits.

In the following, we assume $\kappa t \leq n$.

Theorem 3 (Magic compression in t-doped Gaussian states)**.** *Any (t,κ)-doped Gaussian state is κt-compressible.*

Proof sketch. Let $U_t |0^n\rangle$ be the t-doped state, where $U_t = (\prod_{t'=1}^{t} G_{t'} W_{t'}) G_0$ is the t-doped unitary. We rearrange U_t as $U_t = \tilde{G}_t G_{\text{aux}} \prod_{t'=1}^{t} (G_{\text{aux}}^{\dagger} \tilde{W}_{t'} G_{\text{aux}}) G_{\text{aux}}^{\dagger}$, introducing a Gaussian operation G_{aux} to be fixed and defining $\tilde{W}_{t'} := \tilde{G}_{t'-1}^{\dagger} W_{t'} \tilde{G}_{t'-1}$ and $\tilde{G}_{t'} := G_{t'}..G_0$. We require that G_{aux} satisfies $G_{\text{aux}}^{\dagger} |0^n\rangle = |0^n\rangle$, and that each $G_{\text{aux}}^{\dagger} \tilde{W}_{t'} G_{\text{aux}}$ is supported non-trivially only on the first κt qubits. The latter is enforced by demanding that the Heisenberg evolution, via $\tilde{G}_{t'-1} G_{\text{aux}}$, of each Majorana operator involved in the Hamiltonian generating $W_{t'}$, has non-trivial support exclusively on the first κt qubits. The existence of G_{aux} is shown by demonstrating the existence of its associated orthogonal matrix O_{aux}. The requirements on G_{aux} translate into the demand that O_{aux} must be symplectic and such that it sends κt fixed vectors to the span of the first $2\kappa t$ canonical basis vectors. The existence of such O_{aux} can be proven via the isomorphism between real $2n \times 2n$ symplectic orthogonal matrices and $n \times n$ unitaries [54]. Additional details are provided in the Supplementary Material (see Theorem 27). □

Note that while a (t,κ)-doped Gaussian state is a κt-compressible Gaussian state, the reverse implication does not hold due to circuit complexity arguments. Similarly to Theorem 3, we show that any t-doped Gaussian unitary can be represented as:

$$U_t = G_A(u_t \otimes I) G_B, \tag{4}$$

where G_A and G_B denote Gaussian operations, and u_t is a unitary operator supported on $\lceil \kappa t/2 \rceil$ qubits (with $\lceil \cdot \rceil$ denoting rounding to the next integer), as elaborated in the Supplementary Material (Theorem 26). Notably, if U_t is a particle number conserving unitary [13], then G_A, u_t and G_B can also be chosen as such.

Our proof of Theorem 3 is constructive, i.e., given a classical description of the circuit that prepares $|\psi\rangle$, it provides an efficient procedure for finding the compressing Gaussian circuit G and the state $|\phi\rangle$. The decomposition of t-doped Gaussian states (unitaries) reveals also that they have a circuit complexity, i.e., number of local gates needed for implementing the state (unitary), upper bounded by $\mathcal{O}(n^2 + t^3)$ (Proposition 30 in SM). This provides a better circuit complexity upper bound compared to the naive $\mathcal{O}(n^2 t)$ implied by definition 1 for $\kappa = \mathcal{O}(1)$. Hence, our construction reveals also a method to compress the circuit depth (and not only the magic). Remarkably, analogous results hold for the Clifford+T gates circuits [50].

In the Clifford case [33], the notion of *stabilizer dimension* was introduced for quantifying the degree of "stabilizerness". Here, in analogy to this, we define the *Gaussian dimension* of a state as the number of normal eigenvalues of its correlation matrix that are equal to one. By using Eq.(1), it can be shown that a state has a Gaussian dimension of $n - t$ if and only if it is t-compressible. Therefore, (t,κ)-doped Gaussian states have a Gaussian dimension of $n - \kappa t$.

Learning Algorithm

We present an algorithm for learning t-compressible Gaussian states, or, equivalently, quantum states with $n-t$ Gaussian dimension. Note that this is a broader class than t-doped Gaussian states; as an example unrelated to t-doped states, ground states of quantum impurity models are approximately of this form (as shown in [55]). By definition, any t-compressible Gaussian state $|\psi\rangle$ can be factorized as $G^\dagger|\psi\rangle = |\phi\rangle \otimes |0^{n-t}\rangle$, where $G^\dagger$ is Gaussian and $|\phi\rangle$ is a state on t qubits. At a high level, our strategy is to learn the Gaussian unitary $G^\dagger$, apply it to $|\psi\rangle$, and then perform full state tomography solely on the first t qubits to learn $|\phi\rangle$. Since full state tomography algorithms scale exponentially with the number of qubits [56], for $t = \mathcal{O}(\log(n))$ our algorithm will be efficient.

Algorithm 1: Learning Algorithm

```
Input: $\mathcal{O}(\mathrm{poly}(2^t, n))$ copies of $|\psi\rangle$, accuracy $\varepsilon$, failure probability $\delta$.
Output: A classical description of $|\hat{\psi}\rangle$, such that $d_{\mathrm{tr}}(|\hat{\psi}\rangle, |\psi\rangle) \leq \varepsilon$ with probability at least $1-\delta$.
Estimate the correlation matrix of $|\psi\rangle$ using $\lceil 256\frac{n^5}{\varepsilon^4}\log\left(12\frac{n^2}{\delta}\right)\rceil$ copies, yielding $\hat{C}$;
Expressing $\hat{C}$ in its normal form (Eq.(1)), find the Gaussian unitary $\hat{G}$ associated with $\hat{O} \in \mathrm{O}(2n)$;
Set $N_t := \lceil 2N_{\mathrm{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3}) + 24\log\left(\frac{3}{\delta}\right)\rceil$ (where $N_{\mathrm{tom}}$ is the number of copies for $t$-qubit state tomography);
for $i \leftarrow 1$ to $N_t$ do
    Apply $\hat{G}^\dagger$ to $|\psi\rangle$;
    Measure the last $n-t$ qubits in the computational basis;
    If the outcome is $|0^{n-t}\rangle$, proceed; otherwise, discard and move to the next iteration;
    Perform a step of state tomography [56, 57] on the remaining $t$ qubits;
Consider the $t$-qubit state $|\hat{\phi}\rangle$ obtained from tomography;
return $\hat{G}$ and $|\hat{\phi}\rangle$, which identify $|\hat{\psi}\rangle := \hat{G}(|\hat{\phi}\rangle \otimes |0^{n-t}\rangle)$;
```

To delve deeper, the initial phase of our learning algorithm entails estimating the correlation matrix entries through single-copy measurements. This can be achieved using different methods outlined in the Supplementary Material, such as measurements in the Pauli basis, global Clifford Gaussian measurements [58], or fermionic classical shadows [52, 59, 60]. The estimated correlation matrix $\hat{C}$ is subsequently transformed into its normal form in Eq.(1) to yield the corresponding orthogonal matrix $\hat{O}$ associated with the Gaussian operation $\hat{G}$. (We use the hat symbol to denote the objects estimated from the measurements.) Applying the inverse operation $\hat{G}^\dagger$ to $|\psi\rangle$ results in a state that exhibits high fidelity with a state, which is tensor product of an arbitrary state on the first t qubits and the zero computational basis state on the remaining $n-t$ qubits. Consequently, the learning algorithm queries multiple copies of $|\psi\rangle$ (one at a time), applies $\hat{G}^\dagger$ to them and measures the last $n-t$ qubits. If the outcome of such measurements correspond to $|0^{n-t}\rangle$, then the algorithm proceeds with a step of pure state tomography [56, 57] on the t-qubits state. The state tomography routine performed in the compressed space yields the state $|\hat{\phi}\rangle$. The final output of the learning algorithm is $|\hat{\psi}\rangle := \hat{G}(|\hat{\phi}\rangle \otimes |0^{n-t}\rangle)$, and an efficient classical representation can be provided if $t = \mathcal{O}(\log(n))$. Namely, to specify $|\hat{\psi}\rangle$, it is sufficient to provide the complete description of the t-qubit state $|\hat{\phi}\rangle$ and the orthogonal matrix $\hat{O} \in \mathrm{O}(2n)$ associated with $\hat{G}$.

We now present a theorem which formalizes and proves the efficiency of the discussed procedure, outlined in Algorithm 1, to learn doped Gaussian states or, more generally, t-compressible Gaussian states.

Theorem 4 (Learning algorithm guarantees)**.** *Let $|\psi\rangle$ be a t-compressible Gaussian state, and $\varepsilon, \delta \in (0,1]$. Utilizing $\mathcal{O}(\mathrm{poly}(n, 2^t))$ single-copy measurements and computational time, Algorithm 1 outputs a classical representation of a state $|\hat{\psi}\rangle$, such that $d_{\mathrm{tr}}(|\hat{\psi}\rangle, |\psi\rangle) \leq \varepsilon$ with probability $\geq 1-\delta$.*

Proof sketch. Using $\mathcal{O}(\mathrm{poly}(n))$ copies of $|\psi\rangle$, we estimate its correlation matrix C, yielding $\hat{C}$ such that $\|\hat{C} - C\|_\infty \leq \varepsilon_c$ with a failure probability $\leq \frac{\delta}{3}$, where $\varepsilon_c := \varepsilon^2/(4(n-t))$. Expressing $\hat{C}$ in its normal form (Eq.(1)), we find the Gaussian unitary $\hat{G}$ associated to $\hat{O} \in \mathrm{O}(2n)$. Let $|\psi'\rangle := \hat{G}^\dagger|\psi\rangle$. As detailed in the Supplementary Material, we derive $\langle\psi'| Z_k |\psi'\rangle \geq 1 - 2\varepsilon_c$ for each $k \in \{t+1, \dots, n\}$ and, by Quantum Union Bound [61] we get $d_{\mathrm{tr}}(|\phi\rangle \otimes |0^{n-t}\rangle, |\psi'\rangle) \leq \frac{\varepsilon}{2}$, where $|\phi\rangle \otimes |0^{n-t}\rangle$ corresponds to the state obtained by measuring the last $n-t$ qubits of $\hat{G}^\dagger|\psi\rangle$ in the computational basis and obtaining the outcome corresponding to $|0^{n-t}\rangle$, an event which occurs with probability $\geq 1 - \varepsilon^2/4$. By querying $\lceil 2N_{\mathrm{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3}) + 24\log\left(\frac{3}{\delta}\right)\rceil$ copies of $|\psi\rangle$, and, for each copy, applying $\hat{G}^\dagger$ and measuring the last $n-t$ qubits, we get the outcome $|0^{n-t}\rangle$ at least $N_{\mathrm{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3})$ times, with failure probability $\leq \frac{\delta}{3}$ due to Chernoff bound. Here, $N_{\mathrm{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3})$ is the number of copies sufficient for full state tomography [56] of a t-qubit state with an $\frac{\varepsilon}{2}$ accuracy and a failure probability $\leq \frac{\delta}{3}$. Performing the t-qubit tomography on all the copies where the outcome $|0^{n-t}\rangle$ occurred yields $|\hat{\phi}\rangle$ such that $d_{\mathrm{tr}}(|\hat{\phi}\rangle, |\phi\rangle) \leq \frac{\varepsilon}{2}$, with a failure probability $\leq \frac{\delta}{3}$. Defining $|\hat{\psi}\rangle := \hat{G}(|\hat{\phi}\rangle \otimes |0^{n-t}\rangle)$, we have $d_{\mathrm{tr}}(|\hat{\psi}\rangle, |\psi\rangle) \leq d_{\mathrm{tr}}(|\hat{\phi}\rangle, |\phi\rangle) + d_{\mathrm{tr}}(|\phi\rangle \otimes |0^{n-t}\rangle, \hat{G}^{\dagger}|\psi\rangle)$. This is $\leq \varepsilon$ if the algorithm does not fail, an event occurring with probability $\geq 1-\delta$ due to the union bound. □

Theorem 4 is re-stated and rigorously proven in the Supplemental Material as Theorem 44. The sample, time and memory complexity of our algorithm for learning t-compressible states exhibits a polynomial dependence on n and an exponential dependence on t: specifically, the $\mathrm{poly}(n)$ contribution (specifically an $\mathcal{O}(n^5)$ scaling) arises solely from estimating and post-processing the correlation matrix, while the $\exp(t)$ contribution arises from full state tomography on t-qubits. It is easy to see that the dependence on t is optimal, because learning t-compressible states is at least as hard as learning an arbitrary pure state on t qubits and thus requires at least $\Omega(\exp(t))$ copies of the state [3].

However, if we focus on the subclass of t-doped Gaussian states, a classical shadow tomography based algorithm presented in [62, 63] achieves $\mathcal{O}(\mathrm{poly}(n,t))$ sample complexity. Specifically, this algorithm requires a number of copies that scales polynomially with the circuit complexity of the state, and t-doped states have a circuit complexity $\mathcal{O}(\mathrm{poly}(n,t))$. However, the time complexity of the algorithm in [62, 63] scales exponentially with the number of qubits n, while our algorithm's time complexity scales only polynomially (although always exponentially in t). This observation also applies to t-doped stabilizer states learning analyzed in recent works [33, 34].

Time complexity lower bound

It is natural to wonder whether there exist algorithms for learning t-doped Gaussian states with time complexity scaling in t as $\mathcal{O}(\mathrm{poly}(t))$. We establish that the answer is no (see Proposition 50 in SM), relying on a widely-believed cryptography assumption. Specifically, we show that certain families of pseudorandom quantum states [47, 48] can be generated using a polynomial number of local non-Gaussian gates. This implies that if there were an algorithm with polynomial time complexity in t for learning t-doped Gaussian states, quantum computers could solve RingLWE [64] in polynomial time, which is considered unlikely [43–45, 64–66]. While this rules out the existence of efficient algorithms if t scales polynomially with the number of qubits n, it does not yet preclude the existence of efficient algorithms if t grows *slightly* more than logarithmically, for example $t = \mathcal{O}((\log n)^2)$. However, we can rule out this possibility by making the stronger assumption that quantum computers cannot solve RingLWE in sub-exponential time [43–46]. This implies that the time complexity of any algorithm to learn $\tilde{\mathcal{O}}(t)$-doped Gaussian states (where $\tilde{\mathcal{O}}(\cdot)$ hides polylogarithmic factors) would necessarily be $\exp(\Omega(t))$. In other words, the following holds.

Theorem 5 (Time-complexity lower bound, informal)**.** *Assuming that quantum computers cannot solve* RingLWE *in sub-exponential time, then there is no time efficient algorithm to learn $\tilde{\omega}(\log(n))$-doped Gaussian state which outputs a description of an efficiently preparable quantum state. Here, $\tilde{\omega}(\log(n)) := \omega(\log(n)\mathrm{polyloglog}(n))$.*

This would prove that the time complexity in t of our algorithm is essentially optimal, because our algorithm is efficient as long as $t = \mathcal{O}(\log(n))$. We show Theorem 5 by efficiently encoding the pseudorandom quantum states constructions [63] via a specific qubits-to-fermions mapping [23] into other states produced by the same number of gates, all of which are now local non-Gaussian. Crucially for our construction, this mapping sends local qubit operations to local fermionic operations with only a constant overhead in the number of qubits. Please refer to the Supplementary Material (Proposition 52) for more details.

Testing Gaussian dimension

We have introduced an algorithm for efficiently learning states with a high Gaussian dimension, specifically those promised to be t-compressible with a small t. A natural question arises: How can we test the Gaussian dimension of a state? In other words, how can we determine if the underlying state is close or far from the set of t-compressible states? In our Supplementary Material, using ideas developed in [67] for the case of Gaussian states ($t=0$), we establish that the minimum trace distance between a state $|\psi\rangle$ and the set of t-compressible Gaussian states, denoted by $\mathcal{G}_t$, satisfies:

$$\frac{1-\lambda_{t+1}}{2} \leq \min_{|\phi_t\rangle \in \mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) \leq \sqrt{\sum_{k=t+1}^{n} \frac{1-\lambda_k}{2}}, \tag{5}$$

where $\{\lambda_k\}_{k=1}^n$ represents the normal eigenvalues of the correlation matrix of $|\psi\rangle$ ordered in increasing order. These inequalities imply that $|\psi\rangle$ is close in trace distance to the set $\mathcal{G}_t$ if and only if λ_{t+1} is close to one. In particular, assuming that $|\psi\rangle$ is either a state in $\mathcal{G}_t$ or $\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) \geq \varepsilon$, we can determine with at least $1-\delta$ probability which of the two cases is true by accurately estimating λ_{t+1}. Specifically, $\mathcal{O}((n^5/\varepsilon^4)\log(n^2/\delta))$ copies of the state suffice for this purpose. Notably, this complexity scaling for testing is independent from t, in contrast to learning.

Conclusions

In this work, we have presented an algorithm for efficiently learning t-doped fermionic Gaussian states, with sample and time complexity scaling as $\mathcal{O}(\mathrm{poly}(n, 2^t))$. Additionally, we have established, under standard cryptography assumptions, that there is no learning algorithm for such class of states with a polynomial dependence on t in the time complexity. Crucially, our algorithm utilizes solely experimentally feasible single-copy measurements. Its working idea is based on a theorem that we prove, which says that all the non-Gaussianity in a t-doped fermionic Gaussian state can be efficiently compressed onto $\mathcal{O}(t)$ qubits through a Gaussian operation. This observation carries potential significance beyond the scope of learning, particularly within the context of quantum many-body theory or within circuit compilation. Thus, the results presented in this work, besides being directly relevant to device verification and benchmarking, among other tasks, hold fundamental significance for quantum information theory, as they reveal more about the structure of Gaussian states with fermionic magic gates. Additionally, we introduce a variety of useful analytical techniques, such as new ways to leverage the Quantum Union Bound [61] in the context of fermionic states, which are likely to find applications in future research.

Our work offers new directions for further research. For instance, an open question arising from this work is to study the noise-robustness of our protocol, and whether t-doped Gaussian unitaries can be efficiently learned in the scenario where the input states to the unitary and measurements at the end can be chosen: the particular case of $t = 0$ has already been solved in Ref. [68] and it would be interesting to generalize it. Additionally, a promising future direction is the one of extending the results presented in this work to the domain of continuous variable systems and bosonic Gaussian states. Finally, an intriguing question to explore is whether the classical simulability of a class of states, under precise notions of classical simulability, generally implies learnability in trace distance.

Supplementary Material

In this supplementary material, we provide a more comprehensive level of detail and explanation for certain aspects covered in the main text.

Contents

Supplementary Material I: Preliminaries

A. Notation and basics

In this work, we employ the following notation. $\mathcal{L}(\mathbb{C}^d)$ denotes the set of linear operators acting on the d-dimensional complex vector space $\mathbb{C}^d$. Additionally, we use $[d]$ to represent the set of integers from 1 to d, i.e., $[d] := \{1, \dots, d\}$. We denote with $\mathrm{Mat}(d, \mathbb{F})$ the set of $d \times d$ matrices over the field $\mathbb{F}$. Let $v \in \mathbb{C}^d$ be a vector, and let $p \in [1, \infty]$. The p-norm of v is denoted by $\|v\|_p$, defined as $\|v\|_p := (\sum_{i=1}^d |v_i|^p)^{1/p}$. The Schatten p-norm of a matrix $A \in \mathbb{C}^d$, with $p \in [1, \infty]$, is given by $\|A\|_p := \mathrm{Tr}\Big((\sqrt{A^\dagger A})^p\Big)^{1/p}$, corresponding to the p-norm of the vector of singular values of A. The trace norm and the Hilbert-Schmidt norm are important instances of Schatten p-norms, denoted as $\|\cdot\|_1$ and $\|\cdot\|_2$ respectively. The Hilbert-Schmidt norm is induced by the Hilbert-Schmidt scalar product $\langle A,B\rangle_{HS} := \mathrm{Tr}\big(A^\dagger B\big)$ for $A,B\in\mathcal{L}(\mathbb{C}^d)$. The infinity norm, $\|\cdot\|_\infty$, of a matrix is defined as its largest singular value. This norm can be interpreted as the limit of the Schatten p-norm of the matrix as p approaches infinity. For any unitaries U and V, and a matrix A, we have the unitary invariance property $\|UAV\|_p = \|A\|_p$. Also, $\|A\otimes B\|_p = \|A\|_p\|B\|_p$ for $A,B\in\mathcal{L}(\mathbb{C}^d)$. We denote with $\mathrm{U}(n)$ the group of $n\times n$ unitary matrices. We denote $\mathrm{O}(2n)$ as the group of real orthogonal $2n\times 2n$ matrices. $\mathrm{Sp}(2n,\mathbb{R})$ denotes the group of symplectic matrices over the real field, defined as

$$\mathrm{Sp}(2n,\mathbb{R}) := \{S\in\mathrm{Mat}(2n,\mathbb{R})\,:\, S\Omega S^T = \Omega\}, \tag{S1}$$

where $\Omega := \bigoplus_{i=1}^n \begin{pmatrix} 0 & 1\\ -1 & 0\end{pmatrix}$. The n-qubits Pauli operators are represented as elements of the set $\{I,X,Y,Z\}^{\otimes n}$, where I,X,Y,Z represent the standard single qubit Pauli. Pauli operators are traceless, Hermitian, they square to the identity, and form an orthogonal basis with respect to the Hilbert-Schmidt scalar product for the space of linear operators. We define the set of quantum states as $\mathcal{S}(\mathbb{C}^d) := \{\rho\in\mathcal{L}(\mathbb{C}^d)\,:\,\rho\geq 0,\ \mathrm{Tr}(\rho)=1\}$. The trace distance between two pure quantum states $|\psi\rangle, |\phi\rangle\in\mathbb{C}^d$ is defined as $d_{\mathrm{tr}}(|\psi\rangle, |\phi\rangle) := \frac{1}{2}\||\psi\rangle\!\langle\psi| - |\phi\rangle\!\langle\phi|\|_1$.

For a function $f(n)$, if there exists a constant c and a specific input size n_0 such that $f(n)\leq c\cdot g(n)$ for all $n\geq n_0$, where $g(n)$ is a well-defined function, then we express it as $f(n) = \mathcal{O}(g(n))$. This notation signifies the upper limit of how fast a function grows in relation to $g(n)$.

For a function $f(n)$, if there exists a constant c and a specific input size n_0 such that $f(n)\geq c\cdot g(n)$ for all $n\geq n_0$, where $g(n)$ is a well-defined function, then we express it as $f(n) = \Omega(g(n))$. This notation signifies the lower limit of how fast a function grows in relation to $g(n)$.

For a function $f(n)$, if for any constant c, there exists an input size n_0 such that $f(n) > c\cdot g(n)$ for all $n\geq n_0$, where $g(n)$ is a well-defined function, then then we express it as $f(n) = \omega(g(n))$. This notation implies that the function grows strictly faster than the provided lower bound.

B. Basics of probability theory

In this section, we present fundamental results from probability theory useful in our work.

Lemma 6 (Union Bound)**.** *Let $A_1, A_2,\dots, A_M$ be events in a probability space. The probability of the union of these events is bounded by the sum of their individual probabilities:*

$$\Pr\left(\bigcup_{i=1}^M A_i\right) \leq \sum_{i=1}^M \Pr(A_i).$$

Lemma 7 (Chernoff Bound)**.** *Consider a set of independent and identically distributed random variables $\{X_i\}_{i=1}^N$ with binary outcomes, taking values in $\{0,1\}$. Define $X := \sum_{i=1}^N X_i$ and $\mu := \mathbb{E}[X]$. For any $\alpha\in(0,1)$, the probability of X being less than $(1-\alpha)$ times its expected value is exponentially bounded as follows:*

$$\Pr\left[X\leq (1-\alpha)\mu\right] \leq \exp\left(-\frac{\alpha^2\mu}{2}\right).$$

Lemma 8 (Hoeffding's Inequality)**.** *Let $\{X_i\}_{i=1}^N$ be independent and identically distributed (i.i.d) random variables with values in $[a,b]\subseteq\mathbb{R}$. For any $\varepsilon > 0$, the probability of the deviation of $\hat{X} := (\sum_{i=1}^N X_i)/N$ from its expected value is exponentially bounded as follows:*

$$\Pr\left(\left|\frac{1}{N}\sum_{i=1}^N X_i - \mathbb{E}[\hat{X}]\right| \geq \varepsilon\right) \leq 2\exp\left(-\frac{2N\varepsilon^2}{(b-a)^2}\right).$$

Corollary 9. *For any $\varepsilon > 0$ and $\delta > 0$, let $\{X_i\}_{i=1}^N$ be i.i.d. random variables with values in $[a,b]\subseteq\mathbb{R}$ and $\hat{X} := (\sum_{i=1}^N X_i)/N$. According to Hoeffding's inequality, a sample size N satisfying*

$$N \geq \frac{(b-a)^2}{2\varepsilon^2}\log\left(\frac{2}{\delta}\right)$$

suffices to guarantee that $|\frac{1}{N}\sum_{i=1}^N X_i - \mathbb{E}[\hat{X}]| < \varepsilon$ with a probability of at least $1-\delta$.

C. Fermionic Gaussian states

In this section, we explore the definitions and essential properties of fermionic Gaussian states. We focus on a system consisting of n qubits or n fermionic modes, resulting in a Hilbert space dimension of 2^n. More precisely, our work is approached from two perspectives: examining a system of n qubits with 1D matchgates circuits and their magic gates (e.g., SWAP gates), or an equivalent native fermionic system of n modes with states prepared by fermionic Gaussian evolutions and local non-Gaussian evolutions. These perspectives are mathematically connected through the Jordan-Wigner mapping, which we use now for defining Majorana operators in terms of Pauli operators.

Definition 10 (Majorana Operators)**.** *For each $k \in [n]$, Majorana operators are defined as:*

$$\gamma_{2k-1} := \left(\prod_{j=1}^{k-1} Z_j\right) X_k, \quad \gamma_{2k} := \left(\prod_{j=1}^{k-1} Z_j\right) Y_k. \tag{S2}$$

Majorana operators can also be defined directly in the fermionic language through their anticommutation relations [13, 51]. Majorana operators are Hermitian, traceless, and their squares yield the identity, as deducible from their definitions. Moreover, distinct Majorana operators exhibit anticommutativity and orthogonality with respect to the Hilbert-Schmidt inner product.

Definition 11 (Majorana Ordered Products)**.** *Given a set $S := \{\mu_1, \ldots, \mu_{|S|}\} \subseteq [2n]$ with $1 \leq \mu_1 < \cdots < \mu_{|S|} \leq 2n$, we define the Majorana product operator as $\gamma_S = \gamma_{\mu_1} \cdots \gamma_{\mu_{|S|}}$ if $S \neq \emptyset$, and $\gamma_\emptyset = I$ otherwise.*

The 4^n distinct ordered Majorana products are orthogonal to each other with respect the Hilbert-Schmidt inner product, therefore they form a basis for the linear operators $\mathcal{L}\big(\mathbb{C}^{2^n}\big)$.

Definition 12 (Fermionic Gaussian Unitary (FGU))**.** *A fermionic Gaussian unitary G_O is a unitary operator satisfying:*

$$G_O^\dagger \gamma_\mu G_O = \sum_{\nu=1}^{2n} O_{\mu,\nu} \gamma_\nu \tag{S3}$$

for any $\mu \in [2n]$, where $O \in \mathrm{O}(2n)$ is an orthogonal matrix.

Since the ordered products of Majorana operators γ_μ with $\mu \in [2n]$ form a basis for the linear operators, it is sufficient to specify how a unitary acts under conjugation on the $2n$ Majorana operators γ_μ, where $\mu \in [2n]$, to uniquely determine the unitary up to a phase. Thus, there is a one-to-one mapping between n-qubit fermionic Gaussian unitaries (up to a global phase) and orthogonal matrices $\mathrm{O}(2n)$. In particular, given $O \in \mathrm{O}(2n)$, it is possible to build the associated unitary using at most $\mathcal{O}(n(n-1)/2)$ 2-qubit FGU operations. For a more detailed explanation on how to map an $\mathrm{O}(2n)$ matrix to a fermionic Gaussian unitary, refer to [36, 52, 69]. From the previous definition, it readily follows that $G_O^\dagger = G_{O^T}$. Moreover we have that the product of two Gaussian unitaries is Gaussian, namely $(G_{O_1}G_{O_2})^\dagger \gamma_\mu G_{O_1}G_{O_2} = \sum_{\nu=1}^{2n}(O_1O_2)_{\mu,\nu}\gamma_\nu$. To streamline notation, we will frequently refer to fermionic Gaussian unitaries G_O simply as G when there is no need to specify the associated orthogonal matrix. Now, we define a fermionic Gaussian state.

Definition 13 (Fermionic Gaussian State)**.** *An n-qubit state $|\psi\rangle$ is a (pure) fermionic Gaussian state if it can be expressed as $|\psi\rangle = G\,|0^n\rangle$, where G is a fermionic Gaussian unitary.*

It is noteworthy that any computational basis state $|x\rangle$ is a Gaussian state. This stems from the observation that each Pauli X_i gate acting on the i-th qubit, where $i \in [n]$, is a fermionic Gaussian unitary. An additional useful identity is $Z_j = -i\gamma_{2j-1}\gamma_{2j}$. Thus, the density matrix of a pure fermionic Gaussian state associated to an orthogonal matrix $O \in \mathrm{O}(2n)$ can be written as:

$$G_O\,|0^n\rangle\!\langle 0^n|\,G_O^\dagger = G_O\left(\prod_{j=1}^{n}\frac{I - i\gamma_{2j-1}\gamma_{2j}}{2}\right)G_O^\dagger = \prod_{j=1}^{n}\left(\frac{I - i\tilde{\gamma}_{2j-1}\tilde{\gamma}_{2j}}{2}\right), \tag{S4}$$

where $\tilde{\gamma}_\mu := G_O\gamma_\mu G_O^\dagger = \sum_{\nu=1}^{2n} O^T_{\mu,\nu}\gamma_\nu$ for each $\mu \in [2n]$.

We now proceed to define the correlation matrix for any (possibly non-Gaussian) state.

Definition 14 (Correlation Matrix)**.** *For any n-qubit quantum state ρ, its correlation matrix $C(\rho)$ is defined as:*

$$[C(\rho)]_{j,k} := -\frac{i}{2}\operatorname{Tr}\left([\gamma_j, \gamma_k]\,\rho\right), \tag{S5}$$

where $j, k \in [2n]$.

The correlation matrix of any state is real and anti-symmetric, possessing eigenvalues in pairs $\pm i\lambda_j$ for $j \in [2n]$, where λ_j are real numbers such that $|\lambda_j| \leq 1$. The correlation matrix of a quantum state, when evolved using fermionic Gaussian unitaries, undergoes a transformation through conjugation with the corresponding orthogonal matrix, as articulated in the following lemma.

Lemma 15 (Transformation of the Correlation Matrix under FGU)**.** *For a given n-qubit state ρ, we have:*

$$C(G_O \rho G_O^\dagger) = OC(\rho)O^T, \tag{S6}$$

for any orthogonal matrix $O \in \mathrm{O}(2n)$ and associated fermionic Gaussian unitary G_O.

This result is readily verified through the definitions of the correlation matrix and fermionic Gaussian unitary. The state $|x\rangle$ is characterized by a correlation matrix of the form:

$$C(|x\rangle\langle x|) = \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & (-1)^{x_i} \\ -(-1)^{x_i} & 0 \end{pmatrix}. \tag{S7}$$

Hence, for a fermionic Gaussian state $|\psi\rangle := G_O |0^n\rangle$, the correlation matrix takes the form:

$$C(|\psi\rangle\langle\psi|) = O \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} O^T. \tag{S8}$$

In the subsequent discussion, we will use $C(|\psi\rangle)$ to denote the correlation matrix of a pure state $|\psi\rangle$. If the state $|\psi\rangle$ is a pure Gaussian state, then each of the eigenvalues of $C(|\psi\rangle)$ is one in absolute value. Moreover, it is worth noting that every real anti-symmetric matrix can be decomposed in the following form:

Lemma 16 (Normal form of Real Anti-Symmetric Matrices [53])**.** *Any real anti-symmetric matrix C can be decomposed in the so-called 'normal-form':*

$$C = O \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} O^T, \tag{S9}$$

where O is an orthogonal matrix in $\mathrm{O}(2n)$ and $\lambda_j \geq 0 \in \mathbb{R}$, for any $j \in [n]$, are ordered in increasing order. The eigenvalues of C are $\pm i\lambda_j$ where $\lambda_j \in \mathbb{R}$ for any $j \in [n]$.

Definition 17 (Normal eigenvalues)**.** *Given a real-antisymmetric matrix decomposed as in the previous Lemma 16, $\{\lambda_j\}_{j=1}^n$ are dubbed as the 'normal eigenvalues' of the matrix.*

D. Particle-number preserving unitaries

In this section, we introduce the concept of particle-number preserving fermionic unitaries and establish definitions and facts useful for subsequent discussions. We begin by defining creation and annihilation operators.

Definition 18 (Creation and Annihilation Operators)**.** *The annihilation operators are defined as:*

$$a_j := \frac{\gamma_{2j-1} + i\gamma_{2j}}{2}, \tag{S10}$$

for any $j \in [n]$. The creation operators $\{a_j^\dagger\}_{j=1}^n$ are defined as the adjoints of the annihilation operators.

Definition 19 (Particle Number Operator)**.** *The operator $\hat{N} := \sum_{i=1}^n a_i^\dagger a_i$ is denoted as the particle number operator.*

The computational basis forms a set of eigenstates for the particle number operator:

$$\hat{N} |x_1, \dots, x_n\rangle = (x_1 + \dots + x_n) |x_1, \dots, x_n\rangle, \tag{S11}$$

where $x_1, \dots, x_n \in \{0, 1\}$.

Definition 20 (Particle Number Preserving Unitaries)**.** *A unitary U is said to be particle number preserving if and only if*

$$U^\dagger \hat{N} U = \hat{N}, \tag{S12}$$

where $\hat{N} := \sum_{i=1}^n a_i^\dagger a_i$ is the particle number operator.

Definition 21 (Symplectic Group)**.** *The group of real symplectic matrices, denoted as* $\mathrm{Sp}(2n,\mathbb{R})$*, is defined as*

$$\mathrm{Sp}(2n,\mathbb{R}) := \{S \in \mathrm{Mat}(2n,\mathbb{R}) \,:\, S\Omega S^T = \Omega\}, \tag{S13}$$

where $\Omega := \bigoplus_{i=1}^{n} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} = \bigoplus_{i=1}^{n} iY$*.*

It is often convenient to express Ω as $\Omega = I_n \otimes iY$, where I_n denotes the $n \times n$ identity matrix. Note that Ω in the literature is sometimes defined (see, e.g., [54]) as $iY \otimes I_n = \begin{pmatrix} 0_n & I_n \\ -I_n & 0_n \end{pmatrix}$, but the two definitions are equivalent up to orthogonal transformation.

Now, we state an important proposition that will be useful in the subsequent section.

Proposition 22 ($\mathrm{U}(n)$ is Isomorphic to $\mathrm{O}(2n)\cap\mathrm{Sp}(2n,\mathbb{R})$)**.** *The set of unitaries* $\mathrm{U}(n)$ *is isomorphic to the set of real symplectic orthogonal matrices* $\mathrm{O}(2n) \cap \mathrm{Sp}(2n,\mathbb{R})$*.*

In particular, any orthogonal symplectic matrix $O \in \mathrm{O}(2n) \cap \mathrm{Sp}(2n,\mathbb{R})$ *can be written as follows:*

$$O = \mathrm{Re}(u) \otimes I + \mathrm{Im}(u) \otimes iY, \tag{S14}$$

where $u \in \mathrm{U}(n)$ *is an* $n \times n$ *unitary.*

Proof. We refer the reader to Appendix B.1. of the book [54]. □

We now present a Lemma, which shows (some) equivalent definitions of a particle-number preserving fermionic Gaussian unitary.

Lemma 23 (Particle Number Preserving Gaussian Unitary)**.** *Let* G *be a fermionic Gaussian unitary associated with the orthogonal matrix* $O \in \mathrm{O}(2n)$*. The following points are equivalents:*

1. *G is particle number-preserving,*
2. $G\,|0^n\rangle\!\langle 0^n|\,G^\dagger = |0^n\rangle\!\langle 0^n|$*,*
3. *O is symplectic orthogonal, i.e.,* $O \in \mathrm{O}(2n) \cap \mathrm{Sp}(2n,\mathbb{R})$*.*

Proof. If G is particle number-preserving, then

$$G^\dagger \hat{N} G\,|0^n\rangle = \hat{N}\,|0^n\rangle = 0, \tag{S15}$$

where the first equality uses Definition 20. This implies $\hat{N}G\,|0^n\rangle = 0$. Since the ground space corresponding to the zero eigenvalue of the particle number operator $\hat{N}$ is one-dimensional and spanned by $|0^n\rangle$, it follows that $G\,|0^n\rangle$ is equal to $|0^n\rangle$, up to a phase. Thus, 1. implies 2.

Noting that $|0^n\rangle\!\langle 0^n|$ is a Gaussian state with a correlation matrix $\Omega = \bigoplus_{j=1}^{n} iY$, we deduce that the correlation matrix of $G\,|0^n\rangle\!\langle 0^n|\,G^\dagger$ is $O\Omega O^T$. Therefore the condition $G\,|0^n\rangle\!\langle 0^n|\,G^\dagger = |0^n\rangle\!\langle 0^n|$ is equivalent to $O\Omega O^T = \Omega$, i.e., O is a real symplectic orthogonal matrix. This proves that 2. is equivalent to 3.

Now, let us assume that $O \in \mathrm{O}(2n) \cap \mathrm{Sp}(2n,\mathbb{R})$. Then, we have for $l \in [n]$:

$$G^\dagger a_l G = G^\dagger \left(\frac{\gamma_{2l-1} + i\gamma_{2l}}{2}\right) G = \sum_{j=1}^{2n} (O_{2l-1,j} + iO_{2l,j})\,\frac{\gamma_j}{2} \tag{S16}$$

$$= \sum_{j=1}^{n} (O_{2l-1,2j-1} + iO_{2l,2j-1})\,\frac{\gamma_{2j-1}}{2} + \sum_{j=1}^{n} (O_{2l-1,2j} + iO_{2l,2j})\,\frac{\gamma_{2j}}{2}, \tag{S17}$$

$$= \sum_{j=1}^{n} (\mathrm{Re}(u)_{l,j} + i\,\mathrm{Im}(u)_{l,j})\,\frac{\gamma_{2j-1}}{2} + \sum_{j=1}^{n} (-\,\mathrm{Im}(u)_{l,j} + i\,\mathrm{Re}(u)_{l,j})\,\frac{\gamma_{2j}}{2}, \tag{S18}$$

$$= \sum_{j=1}^{n} u_{l,j}\,\frac{(\gamma_{2j-1} + i\gamma_{2j})}{2} = \sum_{j=1}^{n} u_{l,j} a_j. \tag{S19}$$

where in the fourth equality we used that $O \in \mathrm{O}(2n) \cap \mathrm{Sp}(2n,\mathbb{R})$, and so, because of Proposition 22, it can be written as $O = \mathrm{Re}(u) \otimes I + \mathrm{Im}(u) \otimes iY$ where $u \in \mathrm{U}(n)$ is a $n \times n$ unitary. Similarly, we have $G^\dagger a_l G = \sum_{j=1}^{n} u^*_{l,j} a^\dagger_j$. This implies

$$G^\dagger \hat{N} G = \sum_{l=1}^{n} G^\dagger a_l^\dagger a_l G = \sum_{l,j,k=1}^{n} u^*_{l,j} u_{l,k} a_j^\dagger a_k = \sum_{j=1}^{n} a_j^\dagger a_j = \hat{N}, \tag{S20}$$

where we used the unitarity of u in the last step. This proves that 3. implies 1. □

Supplementary Material II: Structure of t-doped Gaussian unitaries and states

In this section, we analyze the concept of t-doped fermionic Gaussian unitaries and states.

Definition 24 (t-Doped Fermionic Gaussian Unitary)**.** *A unitary U_t is a (t,κ)-doped fermionic Gaussian unitary if it can be decomposed in terms of Gaussian unitaries $\{G_i\}_{i=0}^t$ and at most t non-Gaussian κ-local gates $\{W_i\}_{i=1}^t$, specifically*

$$U_t = G_t W_t \cdots G_1 W_1 G_0. \tag{S21}$$

Here κ-local refers to the number of distinct Majorana operators that generate each non-Gaussian gate. Informally, a unitary is t-doped Gaussian if it is (t,κ)-doped Gaussian for some fixed constant κ.

In our work, we consider non-Gaussian gates $W_{t'}$ for $t' \in [t]$, each generated by $\kappa \leq 2n$ in κ fixed Majorana operators $\{\gamma_{\mu(t',j)}\}_{j=1}^{\kappa}$, where $\mu(t',1),\dots,\mu(t',\kappa) \in [2n]$. For $\kappa = 3$, an example of a non-Gaussian gate is $\exp(\theta\gamma_1\gamma_2\gamma_3) = \exp(-iY_1\theta)$, where $\theta \in \mathbb{R}$, and for $\kappa = 4$, an example is the SWAP-gate.

Definition 25 (t-Doped Fermionic Gaussian State)**.** *An n-qubit state $|\psi\rangle$ is a (t,κ)-doped (informally, t-doped) fermionic Gaussian state if it can be expressed as $|\psi\rangle = U_t |0^n\rangle$, where U_t is a (t,κ)-doped (t-doped) fermionic Gaussian unitary.*

A. Compression of t-doped Gaussian unitaries and states

We start by presenting a Theorem which shows how all non-Gaussianity in a t-doped unitary can be 'compressed' or 'moved' to the first few qubits.

Theorem 26 (Compression of Non-Gaussianity in t-Doped Unitaries)**.** *Any (t,κ)-doped fermionic Gaussian unitary U_t can be expressed as:*

$$U_t = G_A(u_t \otimes I)G_B, \tag{S22}$$

where G_A, G_B are Gaussian unitaries, and u_t is a unitary supported exclusively on $\lceil \frac{\kappa t}{2} \rceil$ qubits.

Proof. Let us denote $M := \kappa t$. We express the t-doped unitary as $U_t = (\prod_{t'=1}^t G_{t'}W_{t'})G_0$. Rearranging it, we have

$$U_t = \tilde{G}_t \prod_{t'=1}^{t} \tilde{W}_{t'}, \tag{S23}$$

where $\tilde{W}_{t'} := \tilde{G}_{t'-1}^\dagger W_{t'} \tilde{G}_{t'-1}$ and $\tilde{G}_{t'} := G_{t'}..G_0$. Informally, the idea behind this rewriting is that Gaussian operations act nicely under conjugation. Next, we rewrite

$$U_t = \tilde{G}_t G_{\text{aux}} \prod_{t'=1}^{t} (G_{\text{aux}}^\dagger \tilde{W}_{t'} G_{\text{aux}}) G_{\text{aux}}^\dagger, \tag{S24}$$

by introducing a Gaussian operation G_{aux} that we fix later and that will be responsible for moving all the non-Gaussian gates to the first qubits. Now, we set:

$$G_A := \tilde{G}_t G_{\text{aux}} \tag{S25}$$

$$u_t := \prod_{t'=1}^{t} (G_{\text{aux}}^\dagger \tilde{W}_{t'} G_{\text{aux}}) \tag{S26}$$

$$G_B := G_{\text{aux}}^\dagger. \tag{S27}$$

Note that G_A so-defined is Gaussian because the product of Gaussian unitaries is Gaussian, and G_B is clearly Gaussian because the adjoint of a Gaussian unitary is Gaussian. We need to show that it is possible to choose G_{aux} such that u_t is supported only on the first $\lceil M/2 \rceil$ qubits.

More precisely, we will require that G_{aux} ensures that each $G_{\text{aux}}^\dagger \tilde{W}_{t'} G_{\text{aux}}$ is generated by the first M Majorana operators alone. We will achieve it by ensuring that the Heisenberg evolution under $\tilde{G}_{t'-1}G_{\text{aux}}$, of each Majorana that generates $W_{t'}$, has non-trivial support exclusively on the first M Majorana operators. To find G_{aux} with the desired property, we will find the associated orthogonal matrix O_{aux}. Let $\{\mu(t',r)\}_{t'\in[t],r\in[\kappa]}$, with $\mu(t',r)\in[2n]$, be the set of indices of Majorana operators generating the t'-th non-Gaussian gate (listed in increasing order). For example, consider $\kappa=4$ and the t'-th non-Gaussian gate $W_{t'}:=\exp(i\gamma_2\gamma_4\gamma_6\gamma_9+i\gamma_4)$. In this case, $\mu(t',3)=6$. For each such Majorana operator $\gamma_{\mu(t',r)}$, where $r\in[2n]$, its Heisenberg evolution yields

$$G_{\text{aux}}^{\dagger}\tilde{G}_{t'-1}^{\dagger}\gamma_{\mu(t',r)}\tilde{G}_{t'-1}G_{\text{aux}}=\sum_{m=1}^{2n}(O_{t'-1}O_{\text{aux}})_{\mu(t',r),m}\gamma_m, \tag{S28}$$

where $O_{t'-1}$ is the orthogonal matrix associated with $\tilde{G}_{t'-1}$. Our demand on the support of Heisenberg-evolved $\gamma_{\mu(t',r)}$ implies

$$(O_{t'-1}O_{\text{aux}})_{\mu(t',r),m}=(O_{\text{aux}}^TO_{t'-1}^T)_{m,\mu(t',r)}=0 \tag{S29}$$

for any $m\in\{M+1,\dots,2n\}$.

Let us denote as $\{\mathbf{e}_i\}_{i=1}^{2n}$ the canonical basis vectors of $\mathbb{R}^{2n}$. For easy notation, we now denote the unit norm vectors $\{O_{t'-1}^T\mathbf{e}_{\mu(t',r)}\}_{t'\in[t],r\in[\kappa]}$ with the set of vectors $\{\mathbf{v}_j\}_{j=1}^{M}$ (remember that $M=\kappa t$). We can prove the existence of such O_{aux} by proving the existence of its transpose $O:=O_{\text{aux}}^T$. In such notation, the condition in Eq.(S29) reads as:

$$\mathbf{e}_m^TO\mathbf{v}_j=0, \tag{S30}$$

for any $j\in[M]$ and $m\in\{M+1,\dots,2n\}$. In other words, we need to prove the existence of an orthogonal matrix O that maps any given real vectors $\mathbf{v}_1,\dots,\mathbf{v}_M\in\mathbb{R}^{2n}$, where $M\le 2n$, to the span of the first M canonical basis vectors of $\mathbb{R}^{2n}$. The existence of such a matrix is readily established by selecting an orthonormal basis for $W:=\text{Span}(\mathbf{v}_1,\dots,\mathbf{v}_M)$ and defining the orthogonal matrix that maps this orthonormal basis to the first $\dim(W)\le M$ canonical basis vectors. This concludes the proof. □

The subsequent Theorem 27 demonstrates the compression of t-doped Gaussian states.

Theorem 27 (Compression of Non-Gaussianity in t-doped Gaussian states). *Any (t,κ)-doped fermionic Gaussian state $|\psi\rangle$ can be represented as:*

$$|\psi\rangle=G(|\phi\rangle\otimes|0^{n-\kappa t}\rangle), \tag{S31}$$

where G is a Gaussian unitary, and $|\phi\rangle$ is a state supported exclusively on κt qubits.

Proof. Let $|\psi\rangle:=U_t|0^n\rangle$, where $U_t=(\prod_{t'=1}^{t}G_{t'}W_{t'})G_0$ is a t-doped fermionic Gaussian unitary. The proof begins analogously to the one of the previous Theorem 26 and it uses the same notation. In particular, we have:

$$U_t=\tilde{G}_tG_{\text{aux}}\prod_{t'=1}^{t}(G_{\text{aux}}^{\dagger}\tilde{W}_{t'}G_{\text{aux}})G_{\text{aux}}^{\dagger}, \tag{S32}$$

where $\tilde{W}_{t'}:=\tilde{G}_{t'-1}^{\dagger}W_{t'}\tilde{G}_{t'-1}$ and $\tilde{G}_{t'}:=G_{t'}..G_0$. We set, as before

$$G_A:=\tilde{G}_tG_{\text{aux}} \tag{S33}$$

$$u_t:=\prod_{t'=1}^{t}(G_{\text{aux}}^{\dagger}\tilde{W}_{t'}G_{\text{aux}}) \tag{S34}$$

$$G_B:=G_{\text{aux}}^{\dagger}. \tag{S35}$$

However, now, we require that u_t has support on the first M qubits, where $M:=\kappa t$ (while in the previous proof of Theorem 26 we requested $\lceil M/2\rceil$), or, equivalently, we request that the generators of $G_{\text{aux}}^{\dagger}\tilde{W}_{t'}G_{\text{aux}}$ for any $t'\in[t]$ involve only the first $2M$ Majorana operators.

This time we also impose that $G_{\text{aux}}^{\dagger}|0^n\rangle=|0^n\rangle$. This implies that $O_{\text{aux}}^T\in\text{Sp}(2n,\mathbb{R})$ (where O_{aux} is the orthogonal matrix associated to G_{aux}), i.e. O_{aux}^T must be a symplectic orthogonal matrix, because of Lemma 23. We now define $O:=O_{\text{aux}}^T$.

Similarly to the previous theorem and using the same notation, we can ensure that u_t is supported only on the first M qubits by demonstrating the existence of an orthogonal, but this time also symplectic, matrix O that satisfies:

$$\mathbf{e}_m^TO\mathbf{v}_j=0, \tag{S36}$$

for any $j\in[M]$ with arbitrary $\mathbf{v}_1,\dots,\mathbf{v}_M$ real vectors, and $m\in\{2M+1,\dots,2n\}$. The existence of such O follows from the subsequent Lemma 28, which crucially uses the isomorphism between $2n\times 2n$ symplectic orthogonal real matrices and $n\times n$ unitaries [54]. □

Lemma 28 (Compression via Symplectic Orthogonal Transformations)**.** *Let $\{\mathbf{e}_i\}_{i=1}^{2n}$ be the canonical basis of $\mathbb{R}^{2n}$. Let $\mathbf{v}_1, \dots, \mathbf{v}_M \in \mathbb{R}^{2n}$ be a set of unit-norm real vectors, where $M \leq n$. There exists an orthogonal symplectic matrix $O \in \mathrm{O}(2n) \cap \mathrm{Sp}(2n, \mathbb{R})$ such that*

$$\mathbf{e}_i^T O \mathbf{v}_j = 0, \tag{S37}$$

for all $i \in \{2M+1, \dots, 2n\}$ and $j \in [M]$, meaning that all $\{O\mathbf{v}_j\}_{j=1}^{M}$ are exclusively supported on the span of the first $2M$ canonical basis vectors.

Proof. Orthogonal symplectic matrices $O \in \mathrm{O}(2n) \cap \mathrm{Sp}(2n, \mathbb{R})$ have a bijective correspondence with unitary matrices $U \in \mathrm{U}(n)$ through a well-defined vector space mapping [54] (see Proposition 22). Specifically, for a $2n$-dimensional real vector $\mathbf{w} := (w_1, \dots, w_{2n})$, there exists a bijective mapping to an n-dimensional complex vector $\mathbf{f}(\mathbf{w}) := (w_1 - iw_2, \dots, w_{2n-1} - iw_{2n})$. A unitary transformation U in this n-dimensional complex space corresponds to an orthogonal symplectic transformation O in the corresponding $2n$-dimensional real space, and vice versa. Thus, finding a unitary U that maps the span of $\mathbf{f}(\mathbf{v}_1), \dots, \mathbf{f}(\mathbf{v}_M)$ to the span of the first M canonical basis vectors of this n-dimensional complex space implies the existence of a symplectic orthogonal matrix O that maps $\mathbf{v}_1, \dots, \mathbf{v}_M$ to the span of the first $2M$ canonical basis vectors of the $2n$-dimensional real space. To establish the existence of such a unitary, consider the complex vector subspace $W := \mathrm{Span}(\mathbf{f}(\mathbf{v}_1), \dots, \mathbf{f}(\mathbf{v}_M))$ of dimension at most M. By selecting an orthonormal basis for this subspace, we can construct a unitary matrix U that maps this basis to the first $\dim(W) \leq M$ canonical basis vectors. Hence, the existence of the required unitary matrix is confirmed, implying the existence of a symplectic orthogonal matrix O that maps $\mathbf{v}_1, \dots, \mathbf{v}_M$ to the span of the first $2M$ canonical basis vectors. This concludes our proof. □

It is noteworthy that the 'compressed size' obtained for t-doped unitaries, which is $\lceil \kappa t/2 \rceil$, is less than κt which we proved for t-doped Gaussian states.

B. Compression of t-doped Gaussian particle-number preserving unitaries

The subsequent Proposition 29 demonstrates that the compression of t-doped Gaussian unitaries can also be achieved in the particle-number preserving case.

Proposition 29 (Particle number preserving t-doped unitaries)**.** *Let U_t be a t-doped fermionic Gaussian unitary, as per Definition 24, where all the unitaries that compose U_t are particle-number preserving. Then U_t can be decomposed as:*

$$U_t := G_A (u_t \otimes I) G_B, \tag{S38}$$

where G_A and G_B are Gaussian unitaries which preserve the number of particles (see Definition 20) and u_t is a particle-number preserving possibly non-Gaussian unitary supported on κt qubits.

Proof. The proof of such proposition follows the same lines as the one of Theorem 27. In fact, by inspecting the proof, it readily follows that the so-defined G_A is particle-number preserving. The fact that G_B and u_t are particle-number preserving follows from the condition $G_{\mathrm{aux}}^{\dagger} |0^n\rangle = |0^n\rangle$, where $G_B := G_{\mathrm{aux}}^{\dagger}$ and by Lemma 23. □

C. Circuit complexity of t-doped Gaussian unitaries and states

The circuit complexity of a unitary (state) is defined as the minimum number of $\mathcal{O}(1)$-local gates needed for implementing the unitary (state). We will consider locality both in the qubit and in the fermionic sense; in the latter case it refers to the number of distinct Majorana operators that generate each non-Gaussian gate. Our subject of interest is the scaling of the complexity of a t-doped unitary. Throughout this section, we assume $\kappa = \mathcal{O}(1)$ and let $t = t(n)$ change in some way with n. By Definition 24, a t-doped Gaussian unitary U_t can be written as $U_t = G_t W_t \cdots G_1 W_1 G_0$, where $\{G_i\}_{i=0}^{t}$ are Gaussian unitaries and $\{W_i\}_{i=1}^{t}$ are, possibly non-Gaussian, κ-local fermionic gates. From this definition and using the fact that any Gaussian unitary can be decomposed as the product of $\leq 2n(2n-1)/2$ (fermionic) 2-local gates [36, 52], the fermionic circuit complexity of t-doped Gaussian unitaries is upper-bounded by $\mathcal{O}(n^2 t)$. The same can be shown for qubit circuit complexity (see below). But more importantly, we have proven earlier that a t-doped Gaussian unitary can be decomposed as $U_t = G_A(u_t \otimes I) G_B$, where G_A, G_B are Gaussians and u_t is a unitary on $\lceil \frac{\kappa t}{2} \rceil$ qubits. In the following, we show that such decomposition reveals an improved upper bound on the circuit complexity of t-doped Gaussian unitaries.

Proposition 30 (Circuit complexity of t-doped Gaussian unitaries)**.** *The circuit complexity $\mathcal{C}(U_t)$ of a t-doped Gaussian unitary U_t is (both in the qubit and fermionic sense):*

$$\mathcal{C}(U_t) = \begin{cases} \mathcal{O}(n^2 + t^3), & \text{if } \kappa t \leq n \\ \mathcal{O}(n^2 t), & \text{otherwise.} \end{cases} \tag{S39}$$

Proof. Let us assume that $\kappa t \leq n$. Then, U_t can be written as $U_t = G_A(u_t \otimes I)G_B$, where G_A, G_B are Gaussians and u_t is a unitary on $\lceil \frac{\kappa t}{2} \rceil$ qubits. In fact, u_t is itself a (t, κ)-doped Gaussian unitary on $\lceil \frac{\kappa t}{2} \rceil$ qubits. It is not directly obvious, but will be shown momentarily; this will imply the desired circuit complexity $\mathcal{O}(t^3)$. We recall our definitions used in the proof of Theorem 26. We have $\tilde{G}_{t'} := G_{t'}..G_0$ for $t' \in [t]$ and a Gaussian unitary G_{aux}, and set

$$u_t := \prod_{t'=1}^{t} (G_{\text{aux}}^\dagger \tilde{G}_{t'-1}^\dagger W_{t'} \tilde{G}_{t'-1} G_{\text{aux}}) = \prod_{t'=1}^{t} w_{t'}, \tag{S40}$$

where we defined the unitaries $w_{t'} := G_{\text{aux}}^\dagger \tilde{G}_{t'-1}^\dagger W_{t'} \tilde{G}_{t'-1} G_{\text{aux}}$ which act only on the first $\lceil \frac{\kappa t}{2} \rceil$ qubits (equivalently, fermionic modes). We note that $w_{t'}$ is generated by κ Majorana operator superpositions of form $\sum_{i=1}^{\kappa t} [\tilde{\mathbf{v}}_j]_i \gamma_i$, $j \in [\kappa(t'-1)+1, \kappa t']$; here $\tilde{\mathbf{v}}_j := O\mathbf{v}_j$ (cf. notation O and $\mathbf{v}_j$ from the proof of Theorem 26). Hence, for each of these (non-local) non-Gaussian unitaries $w_{t'}$, we can find a Gaussian operation $g_{t'}$ on the first $\lceil \frac{\kappa t}{2} \rceil$ qubits whose associated orthogonal matrix rotates vectors $\tilde{\mathbf{v}}_j$ into the span of the first κ basis vectors. As a result, we have $w_{t'} = g_{t'}^\dagger \tilde{w}_{t'} g_{t'}$, where $\tilde{w}_{t'}$ is now a κ-local non-Gaussian unitary generated by the first κ Majorana operators. By implication, it is also a local qubit gate acting on the first $\lceil \frac{\kappa}{2} \rceil$ qubits. From this it follows that the circuit complexity of each $w_{t'}$ scales as that of a Gaussian $g_{t'}$. As $g_{t'}$ acts on the first $O(t)$ qubits/fermionic modes, its circuit complexity is $O(t^2)$ both in the qubit and the fermionic sense. Therefore, the circuit complexity of u_t is $t\mathcal{O}(t^2) = \mathcal{O}(t^3)$. Moreover, the circuit complexity (both qubit and fermionic) to implement G_A and G_B is $\mathcal{O}(n^2)$. Putting the above observations together, it follows that the circuit complexity of U_t is $\mathcal{O}(n^2 + t^3)$. As long as $\kappa t \leq n$, this upper bound is tighter than the one which proof follows from the t-doped definition, namely $\mathcal{O}(n^2 t)$.

The qubit (and not only fermionic) circuit complexity of $\mathcal{O}(n^2 t)$ for $\kappa t > n$ can be found in a similar way as the complexity of $\mathcal{O}(t^3)$ we showed for u_t above. In particular, consider any κ-local non-Gaussian fermionic unitary $W_{t'}$ which participates in U_t. Using auxilliary Gaussian rotations, its generating Majorana operators can be mapped to $\{\gamma_1, .., \gamma_\kappa\}$, resulting in a unitary supported by the first $\lceil \frac{\kappa}{2} \rceil$ qubits alone. The asymptotic qubit complexity of U_t is thus determined by that of remaining t Gaussian layers, yielding $\mathcal{O}(n^2 t)$ as promised. □

This Proposition reveals that t-doped fermion Gaussian unitaries allow not only a 'spatial compression for the magic', but also a compression of the circuit depth.

D. t-compressible Gaussian states

We now introduce the notion of t-compressible fermionic Gaussian state, a class of states that includes the one of t-doped Gaussian states. We now reiterate Definition 2 for convenience. Throughout this section, we assume that $t \in [n]$.

Definition 31 (t-compressible Gaussian state)**.** *A state $|\psi\rangle$ is a t-compressible (Gaussian) state if and only if it can be represented as $|\psi\rangle = G(|\phi\rangle \otimes |0^{n-t}\rangle)$, where G is a Gaussian operation, and $|\phi\rangle$ is a pure state supported solely on the first t qubits.*

A t-doped Gaussian state is also a κt-compressible Gaussian state because of Theorem 27. However, the reverse is not true because of circuit complexity arguments: t-doped Gaussian states exhibit a circuit complexity of at most $\mathcal{O}(n^2 t)$. In contrast, a t-compressible state features a circuit complexity of $\mathcal{O}(n^2 + \exp(t))$, representing the complexity needed for implementing a single Gaussian operation and preparing a generic state supported on t qubits.

In the subsequent Proposition, we elucidate the structure of the correlation matrix of any t-compressible state, such as t-doped states.

Proposition 32 (Correlation Matrix of a t-compressible Gaussian State)**.** *The correlation matrix $C(|\psi\rangle)$ of a t-compressible Gaussian state $|\psi\rangle$ can be expressed as:*

$$C(|\psi\rangle) = O \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} O^T, \tag{S41}$$

where $\lambda_j \leq 1$ for $j \in [t]$ and $\lambda_j = 1$ for $j \in \{t+1, \ldots, n\}$, and $O \in \mathrm{O}(2n)$ is an orthogonal matrix.

Proof. As per Definition 31, we represent $|\psi\rangle$ as $|\psi\rangle = G(|\phi\rangle \otimes |0^{n-t}\rangle)$, where G is a Gaussian operation and $|\phi\rangle$ is a pure state supported solely on the first t qubits. Utilizing Lemma 16, we can express the correlation matrix $C(|\psi\rangle)$ as follows:

$$C(|\psi\rangle) = QC(|\phi\rangle \otimes \left|0^{n-t}\right\rangle)Q^T \tag{S42}$$

$$= Q\left(C(|\phi\rangle) \oplus C(\left|0^{n-t}\right\rangle)\right)Q^T, \tag{S43}$$

where $Q \in \mathrm{O}(2n)$ is the orthogonal matrix associated to the Gaussian unitary G. By Eq.(S7), we have:

$$C(\left|0^{n-t}\right\rangle) = \bigoplus_{j=1}^{n-t} \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}. \tag{S44}$$

Since $C(|\phi\rangle)$ is an antisymmetric real matrix, we can decompose it into its normal form (Lemma 16):

$$C(|\phi\rangle) = O_t \bigoplus_{j=1}^{t} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix} O_t^T \tag{S45}$$

The proof concludes by definining $O := Q(O_t \oplus I_{2n-2t})$. □

The previous proposition reveals that t-compressible states exhibit at least $n-t$ normal eigenvalues which are exactly one. This motivates the following definition, in analogy to the stabilizer dimension defined in the stabilizer case [33].

Definition 33 (Gaussian dimension of a state)**.** *The Gaussian dimension of a state is defined as the number of the normal eigenvalues of its correlation matrix which are equal to one.*

In the following, we show that this is also a sufficient condition for a state to be Gaussian t-compressible.

Lemma 34 (Sufficient Condition for t-Compressibility)**.** *Let $|\psi\rangle$ be an n-qubit quantum state. If $|\psi\rangle$ has Gaussian dimension of $n-t$, then $|\psi\rangle$ is a t-compressible Gaussian state.*

Proof. The correlation matrix of $|\psi\rangle$ can be written in its normal form as $C(|\psi\rangle) = O\Lambda O^T$, where $\Lambda := \bigoplus_{j=1}^{n} \begin{pmatrix} 0 & \lambda_j \\ -\lambda_j & 0 \end{pmatrix}$, and $O \in \mathrm{O}(2n)$. The $\{\lambda_j\}_{i=1}^{n}$ are the normal eigenvalues such that the last $n-t$ are equal to one. Consider the state $|\psi'\rangle := G_O^\dagger |\psi\rangle$ where G_O is the Gaussian unitary associated with O. Then, $C(\psi') = O^T C(|\psi\rangle)O = \Lambda$. In particular,

$$\mathrm{Tr}(|\psi'\rangle\!\langle\psi'|\, Z_k) = C(\psi')_{2k-1,2k} = \Lambda_{2k-1,2k} = 1, \tag{S46}$$

for each $k \in \{t+1, \dots, n\}$. Therefore, $|\psi'\rangle$ must be of the form $|\psi'\rangle = |\phi\rangle \otimes |0^{n-t}\rangle$, where $|\phi\rangle$ is an arbitrary state on the first t qubits. Therefore, we have $|\psi\rangle = G_O(|\phi\rangle \otimes |0^{n-t}\rangle)$, which is a t-compressible state. □

Hence, Proposition 32 and Lemma 34 prove the following.

Proposition 35 (Equivalence between t-compressibily and $n-t$ Gaussian dimension)**.** *A n-qubit state is t-compressible if and only if its Gaussian dimension is $n-t$.*

Note that Proposition 35 also proves that a quantum state is a pure Gaussian state if and only if its Gaussian dimension is n. Furthermore, as a direct consequence of the proof of Lemma 34, we establish that the Gaussian unitary associated with a t-compressible Gaussian state can be selected as the Gaussian unitary corresponding to any orthogonal matrix placing its correlation matrix in the normal form (Lemma 16). This is summarized as follows:

Lemma 36. *Every t-compressible Gaussian state $|\psi\rangle$ can be written as $|\psi\rangle := G_O(|\phi\rangle \otimes |0^{n-t}\rangle)$, where G_O is chosen as the Gaussian unitary associated with an orthogonal matrix $O \in \mathrm{O}(2n)$ that arranges its correlation matrix in the normal form described in Lemma 16, and $|\phi\rangle$ is a state supported on t qubits.*

Supplementary Material III: Tomography algorithm

In this section, we present a detailed and rigorous analysis of the tomography algorithm for t-compressible states outlined in the main text (Algorithm 1) and reiterated in Algorithm 2 for ease of reference and to include extra details. Throughout this section, we assume that $t \in [n]$.

Algorithm 2: Learning Algorithm for t-compressible fermionic Gaussian states

```
Input: Accuracy $\varepsilon$, failure probability $\delta$, $N := \lceil \frac{256n^5}{\varepsilon^4}\log\left(\frac{12n^2}{\delta}\right) + 2N_{\mathrm{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3}) + 24\log\left(\frac{3}{\delta}\right)\rceil$ copies of the $t$-compressible state
    $|\psi\rangle$, where $N_{\mathrm{tom}}$ is the number of copies needed for $t$-qubit pure state tomography with accuracy $\frac{\varepsilon}{2}$ and failure probability $\frac{\delta}{3}$.
Output: A classical description of $|\hat{\psi}\rangle$, ensuring $d_{\mathrm{tr}}(|\hat{\psi}\rangle, |\psi\rangle) \leq \varepsilon$ with probability at least $1-\delta$.
Estimate the correlation matrix of $|\psi\rangle$ using $\lceil \frac{256n^5}{\varepsilon^4}\log\left(\frac{12n^2}{\delta}\right)\rceil$ single-copy measurements (see Lemma 38), obtaining $\hat{C}$;
Express $\hat{C}$ in its normal form $\hat{C} = \hat{O}\hat{\Lambda}\hat{O}^T$ (Eq.(1)) and find the Gaussian unitary $G_{\hat{O}}$ associated with $\hat{O} \in \mathrm{O}(2n)$;
for $i \leftarrow 1$ to $\lceil 2N_{\mathrm{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3}) + 24\log\left(\frac{3}{\delta}\right)\rceil$ do
    Apply $G_{\hat{O}}^{\dagger}$ to $|\psi\rangle$;
    Measure the last $n-t$ qubits in the computational basis;
    if the outcome corresponds to $|0^{n-t}\rangle$ then
        Proceed;
    else
        Discard and move to the next iteration;
    Perform a step of pure state tomography [56] on the remaining $t$ qubits;
Obtain the $t$-qubit state $|\hat{\phi}\rangle$ from tomography;
return $\hat{O}$ and $|\hat{\phi}\rangle$, which identify $|\hat{\psi}\rangle := G_{\hat{O}}^{\dagger}(|\hat{\phi}\rangle \otimes |0^{n-t}\rangle)$;
```

A. Useful lemmas and subroutines

Let us start with a Lemma, which gives a sample complexity upper bound to estimate the correlation matrix of a state using single-qubit Pauli-basis measurements. We recall that the correlation matrix of a state ρ is a real antisymmetric matrix, defined as:

$$[C(\rho)]_{j,k} = \mathrm{Tr}(O^{(j,k)}\rho), \tag{S47}$$

where $O^{(j,k)} := -i\gamma_j\gamma_k$, for $j < k \in [2n]$ (and the other elements are given by the antisymmetricity of the matrix). Note that $O^{(j,k)}$ are Pauli observables. Thus, we have a total of $M := n(2n-1)$ Pauli expectation values to estimate.

Lemma 37 (Sample Complexity for Estimating the Correlation Matrix by Pauli measurements)**.** *Let $\varepsilon_c, \delta > 0$. Assume to have access to $N \geq N_c(n, \varepsilon_c, \delta)$, with*

$$N_c(n, \varepsilon_c, \delta) := \left\lceil \frac{8n^3(2n-1)}{\varepsilon_c^2}\log\left(\frac{2n(2n-1)}{\delta}\right)\right\rceil, \tag{S48}$$

copies of an n-qubit state ρ. Utilizing only N single-copies measurements in the Pauli basis, with probability $\geq 1-\delta$, we can construct an anti-symmetric real matrix $\hat{C}$ such that it satisfies:

$$\left\|\hat{C} - C(\rho)\right\|_{\infty} \leq \varepsilon_c. \tag{S49}$$

Proof. Let $\varepsilon > 0$ an accuracy parameter to be fixed. For each $j < k \in [2n]$, we measure N' copies of ρ in the Pauli basis corresponding to $O^{(j,k)}$, obtaining outcomes $\{X_m^{(j,k)}\}_{m=1}^{N'}$, where $X_m^{(j,k)} \in \{-1,+1\}$. Let $\hat{C}_{j,k} := \frac{1}{N'}\sum_{m=1}^{N'} X_m^{(j,k)}$. Hoeffding's inequality (specifically Corollary 9) implies that $N' \geq (4/(2\varepsilon^2))\log(2M/\delta)$ suffices to guarantee that, with probability at least $1-\delta/M$, we have $|\hat{C}_{j,k} - \mathrm{Tr}(O^{(j,k)}\rho)| < \varepsilon$. By using the union bound, we conclude that the probability that this holds for any $j < k \in [2n]$ is at least $1-\delta$. More specifically:

$$\Pr\Big(\forall j < k \in [2n] : |\hat{C}_{j,k} - \mathrm{Tr}(O^{(j,k)}\rho)| < \varepsilon\Big) = 1 - \Pr\Big(\exists j < k \in [2n] : |\hat{C}_{j,k} - \mathrm{Tr}(O^{(j,k)}\rho)| \geq \varepsilon\Big) \tag{S50}$$

$$\geq 1 - \sum_{j<k\in[2n]} \Pr\Big(|\hat{C}_{j,k} - \mathrm{Tr}(O^{(j,k)}\rho)| \geq \varepsilon\Big) \tag{S51}$$

$$\geq 1 - \delta. \tag{S52}$$

Therefore, the total number of measurements needed is $N = N'M$. Now, we can conclude by transferring the error to the operator norm. Let $A := \hat{C} - C(\rho)$. For the definition of the operator norm, we have $\|A\|_{\infty} := \sup_{|\psi\rangle}\sqrt{|\langle\psi|\, A^{\dagger}A\, |\psi\rangle|}$. Thus, we have:

$$\left|\langle\psi| A^\dagger A |\psi\rangle\right| \leq \sum_{i,j,k=1}^{2n} \left|\langle\psi| |i\rangle\langle i| A^\dagger |j\rangle\langle j| A |k\rangle\langle k| |\psi\rangle\right| = 2n\varepsilon^2 \sum_{i,k=1}^{2n} |\langle\psi|i\rangle| \, |\langle k|\psi\rangle| \leq 4n^2\varepsilon^2 \tag{S53}$$

where, in the first step, we inserted the resolution of the identity and applied the triangle inequality, in the second step, we applied the upper bound on each matrix element, and, in the last step, we used the Cauchy-Schwartz inequality. Hence, we have $\left\|\hat{C} - C(\rho)\right\|_\infty \leq 2n\varepsilon$. We conclude by choosing $\varepsilon_c := \varepsilon/2n$. □

While the sequential estimation of individual correlation matrix entries by measurements in the Pauli basis, as described above, may not be the most sample-efficient approach, it might be convenient to adopt in an experiment because of its easy implementation scheme. However, instead of independently estimating each correlation matrix entry, one could choose to simultaneously measure mutually commuting observables [58] or utilize the fermionic classical shadow protocol introduced in [52, 59, 60]. This refinement would lead to a reduction in sample complexity by a factor of n, at the cost of implementing a slightly more complicated measurement scheme.

For completeness, we present now a Lemma which gives a sample complexity upper bound for estimating the correlation matrix using a commuting observables measurement scheme. The idea is to partition the observables $O^{(j,k)} := -i\gamma_j\gamma_k$, for $j < k \in [2n]$ into disjoint sets of commuting observables. Subsequently, one employs the fact that commuting Pauli observables can be measured simultaneously via a Clifford measurement [58, 70]. A crucial observation is that two different Pauli observables of the form $-i\gamma_j\gamma_k$ commute if and only if they are associated with different Majorana operators. Using this observation, we can partition these $M = (2n-1)n$ observables into $2n-1$ disjoint sets, each containing n commuting Pauli observables. We refer to [58] Appendix C for details of such a partition, and we omit repeating the construction here. However, we point out that the required Clifford transformations can be chosen to be Gaussian as well.

Lemma 38 (Sample Complexity for Estimating the Correlation Matrix by Grouping Commuting Observables)**.** *Let $\varepsilon_c, \delta > 0$. Assume to have access to $N \geq N_c(n, \varepsilon_c, \delta)$, with*

$$N_c(n, \varepsilon_c, \delta) := \left\lceil \frac{8n^2(2n-1)}{\varepsilon_c^2} \log\left(\frac{2n(2n-1)}{\delta}\right) \right\rceil, \tag{S54}$$

copies of an n-qubit state ρ. Utilizing N single-copy (Gaussian) measurements, with probability $\geq 1-\delta$, we can construct an anti-symmetric real matrix $\hat{C}$ such that it satisfies:

$$\left\|\hat{C} - C(\rho)\right\|_\infty \leq \varepsilon_c. \tag{S55}$$

Proof. For each of the $2n-1$ sets of commuting Pauli, we find the Clifford U that allows us to simultaneously measure such commuting Pauli in the given set, i.e. we map each of the n Pauli to $\{Z_k\}_{k=1}^n$. Now this Clifford can also be chosen to be Gaussian. Indeed, the key constraint on U is that each of the different Paulis of the form $-i\gamma_j\gamma_k$ with $j < k \in [2n]$ (where pairs (j,k) are non-overlapping since these Paulis commute) is mapped to $\{Z_k\}_{k=1}^n$ with $Z_k := -i\gamma_{2k-1}\gamma_{2k}$. This constraint can be satisfied by using a Gaussian operation associated to the orthogonal matrix which is a permutation of the Majorana indices from the commuting Paulis into the Majorana indices from the Z-Paulis. Consequently, we measure N' copies of $U\rho U^\dagger$ in the computational basis. Thus, for each $O^{(j,k)}$, we obtain outcomes $\{X_m^{(j,k)}\}_{m=1}^{N'}$, where $X_m^{(j,k)} \in \{-1,+1\}$. The unbiased estimators are $\hat{C}_{j,k} := \frac{1}{N'}\sum_{m=1}^{N'} X_m^{(j,k)}$. As before, Hoeffding's inequality and union bound imply that $N' \geq (2/\varepsilon^2)\log(2M/\delta)$ suffices to guarantee that the probability of $|\hat{C}_{j,k} - \mathrm{Tr}(O^{(j,k)}\rho)| < \varepsilon$ holding for each $j < k \in [2n]$ is at least $1-\delta$. Therefore, the total number of measurements needed is $N = N'(2n-1)$. We can conclude as in the previous Lemma. □

Lemma 39 (Perturbation bounds on the normal eigenvalues of correlation matrices)**.** *Let A and B be two $2n \times 2n$ anti-symmetric real matrices with normal eigenvalues $\{\lambda_k(A)\}_{k=1}^n$ and $\{\lambda_k(B)\}_{k=1}^n$ respectively ordered in increasing order. Then, we have:*

$$|\lambda_k(A) - \lambda_k(B)| \leq \|A - B\|_\infty, \tag{S56}$$

for any $k \in [n]$.

Proof. This follows from the fact that $C := iA$ and $D := iB$ are Hermitian matrices. Applying Weyl's Perturbation Theorem (see Ref. [71], section VI), which states that two $2n \times 2n$ Hermitian matrices C and D, with eigenvalues $c_1 \leq \cdots \leq c_{2n}$ and $d_1 \leq \cdots \leq d_{2n}$, satisfy:

$$\|C - D\|_\infty \geq \max_{j\in[n]} |c_j - d_j|. \tag{S57}$$

Since A and B are antisymmetric, their eigenvalues are $\{\pm i\lambda_k(A)\}_{k=1}^n$ and $\{\pm i\lambda_k(B)\}_{k=1}^n$ respectively. Hence, the eigenvalues of C and D are $\{\pm\lambda_k(A)\}_{k=1}^n$ and $\{\pm\lambda_k(B)\}_{k=1}^n$ respectively. This implies that:

$$\|A-B\|_\infty = \|C-D\|_\infty \geq \max_{j\in[2n]} |c_j - d_j| = \max_{k\in[n]} |\lambda_k(A)-\lambda_k(B)|. \tag{S58}$$

□

To formalize our learning algorithm, it is useful to invoke the following well-known lemma.

Lemma 40 (Quantum Union Bound (Adapted) [61, 72, 73])**.** *Let $\rho := |\psi\rangle\!\langle\psi|$ be a pure state, and let $\{\varepsilon_i\}_{i=1}^n \in [0,1]$. Consider a subset of qubit indices $\mathcal{Q} \subseteq [n]$. If $\operatorname{tr}\Big(|0\rangle\!\langle 0|_q\,\rho\Big) \geq 1-\varepsilon_i$ for each $q\in\mathcal{Q}$, then, when the qubits in $\mathcal{Q}$ are sequentially measured in the computational basis, all outcomes correspond to $|0\rangle$ with a probability of at least $1-\sum_{i=1}^n \varepsilon_i$. If all measurements correspond to $|0\rangle$, the trace distance between the post-measurement state $|\psi_{\mathrm{post}}\rangle$ and the initial state $|\psi\rangle$ is given by:*

$$d_{\mathrm{tr}}(|\psi\rangle, |\psi_{\mathrm{post}}\rangle) \leq \sqrt{\sum_{i=1}^n \varepsilon_i}, \tag{S59}$$

where $P = \bigotimes_{q\in\mathcal{Q}} |0\rangle\!\langle 0|_q$, and $|\psi_{\mathrm{post}}\rangle := P|\psi\rangle / \|P|\psi\rangle\|_2$.

We now leverage this known lemma to prove the following.

Lemma 41. *Let $|\psi\rangle$ be a t-compressible Gaussian state. Given an estimate $\hat{C}$ for the correlation matrix $C(|\psi\rangle)$, there exists a Gaussian operation $\hat{G}$ such that:*

$$d_{\mathrm{tr}}(|\phi\rangle\otimes|0^{n-t}\rangle, \hat{G}^\dagger|\psi\rangle) \leq \sqrt{(n-t)\left\|\hat{C}-C(|\psi\rangle)\right\|_\infty}, \tag{S60}$$

where $|\phi\rangle\otimes|0^{n-t}\rangle$ corresponds to the post-measurement state obtained by measuring the last $n-t$ qubits of the state $\hat{G}^\dagger|\psi\rangle$ in the computational basis and obtaining the outcome corresponding to $|0^{n-t}\rangle$. This event occurs with a probability of at least $1-(n-t)\left\|\hat{C}-C\right\|_\infty$.

Proof. According to Proposition 32, the correlation matrix $C := C(|\psi\rangle)$ can be put in the form $C = O\Lambda O^{\mathrm{T}}$, where $O\in \mathrm{O}(2n)$ and $\Lambda = i\bigoplus_{j=1}^n \lambda_j(C)Y$. Here, $\lambda_j \leq 1$ for $j\in[t]$ and $\lambda_j = 1$ for $j\in\{t+1,\dots n\}$, and Y represents the Y-Pauli matrix. Let $\varepsilon_c := \left\|\hat{C}-C\right\|_\infty$, then we have (because of Lemma 39) that $|\lambda_j(\hat{C})-\lambda_j(C)| \leq \varepsilon_c$, where $\{\pm\lambda_j(\hat{C})\}_{j=1}^n$ and $\{\pm\lambda_j(C)\}_{j=1}^n$ are the normal eigenvalues of the matrices $\hat{C}$ and C respectively. Thus, we have:

$$\lambda_m(\hat{C}) \geq 1-\varepsilon_c, \tag{S61}$$

for $m\in\{t+1,\dots n\}$. We can now express the real anti-symmetric matrix $\hat{C}$ in its normal form $\hat{C} = \hat{O}\hat{\Lambda}\hat{O}^T$, where $\hat{O}\in\mathrm{O}(2n)$ is an orthogonal matrix and $\hat{\Lambda}$ is a matrix of the form $\hat{\Lambda} = i\bigoplus_{j=1}^n \lambda_j(\hat{C})Y$, with $\lambda_j(\hat{C})\in\mathbb{R}$ for any $j\in[n]$. Next, consider the state $|\psi'\rangle := \hat{G}^\dagger|\psi\rangle$, where $\hat{G}$ is the Gaussian unitary associated to $\hat{O}^T$. It holds that $|C(\psi')_{j,k} - (\hat{\Lambda})_{j,k}| \leq \varepsilon_c$, where we used that $C(\psi') = \hat{O}^T C(|\psi\rangle)\hat{O}$, $\hat{\Lambda} = \hat{O}^T\hat{C}\hat{O}$, Cauchy-Schwarz and the definition of infinity norm. Therefore, we have $C(\psi')_{j,k} \geq (\hat{\Lambda})_{j,k} - \varepsilon_c$. In particular, for $m\in\{t+1,\dots,n\}$, we get:

$$\begin{aligned}
\operatorname{Tr}(Z_m\psi') &= C(\psi')_{2m-1,2m} &\text{(S62)}\\
&\geq (\hat{\Lambda})_{2m-1,2m} - \varepsilon_c &\text{(S63)}\\
&= \lambda_m(\hat{C}) - \varepsilon_c &\text{(S64)}\\
&\geq 1-2\varepsilon_c, &\text{(S65)}
\end{aligned}$$

where $Z_m = -i\gamma_{2m-1}\gamma_{2m}$ is the Z-Pauli operator acting on the m-th qubit and in the last step we used Eq.(S61). Therefore, we also have $\operatorname{Tr}(|0\rangle\!\langle 0|_m\,\psi') \geq 1-\varepsilon_c$. By using the Quantum Union Bound (Lemma 40), we have:

$$d_{\mathrm{tr}}(|\psi'\rangle, |\phi\rangle\otimes|0^{n-t}\rangle) \leq \sqrt{(n-t)\varepsilon_c}, \tag{S66}$$

where $|\phi\rangle\otimes|0^{n-t}\rangle$ is the post-measurement state after having measured the outcomes corresponding to $|0^{n-t}\rangle$ in the last $n-t$ qubits. By Lemma 40, this scenario occurs with probability at least $1-(n-t)\varepsilon_c$. □

In the following, we mention the guarantees of a full pure state tomography algorithm, which demonstrates optimal dependence on the number of qubits and uses only single-copies measurements, albeit with a trade-off in accuracy compared to other algorithms [3, 74]. This is an example of a procedure that we can utilize in our t-qubits full state tomography step of our learning algorithm.

Lemma 42 (Fast State Tomography [56]). *For any unknown n-qubit pure state $|\psi\rangle$, there exists a quantum algorithm that, utilizing $N_{\text{tom}}(n,\varepsilon,\delta) := \mathcal{O}\big(2^n n\log(1/\delta)\varepsilon^{-4}\big)$ copies of $|\psi\rangle$ and $T_{\text{tom}}(n,\varepsilon,\delta) := \mathcal{O}\big(4^n n^3\log(1/\delta)\varepsilon^{-5}\big)$ time, generates a classical representation of a state $|\tilde{\psi}\rangle$ that is ε-close to $|\psi\rangle$ in trace distance with probability at least $1-\delta$. Furthermore, the algorithm requires only single-copy Clifford measurements and classical post-processing.*

Next, we provide a lemma that is useful in the proof of the subsequent Theorem 44.

Lemma 43 (Boosting the probability of success). *Let $\delta > 0$ and $N' \in \mathbb{N}$. Consider an algorithm $\mathcal{A}$ that succeeds with a probability of $p_{\text{succ}} \geq \frac{3}{4}$. If we execute $\mathcal{A}$ a total of $m \geq \lceil 2N' + 24\log(\frac{1}{\delta})\rceil$ times, then $\mathcal{A}$ will succeed at least N' times with a probability of at least $1-\delta$.*

Proof. We will employ a Chernoff bound 7 to establish this result. Define binary random variables $\{X_i\}_{i=1}^m$ as follows:

$$X_i = \begin{cases} 1 & \text{if } \mathcal{A} \text{ succeeds,} \\ 0 & \text{if } \mathcal{A} \text{ fails.} \end{cases} \tag{S67}$$

Define $\hat{X} := \sum_{i=1}^m X_i$. We have $\mathbb{E}[\hat{X}] = mp_{\text{succ}}$. Moreover, we aim to upper bound by δ the probability that $\mathcal{A}$ succeeds fewer than N' times, which is $\Pr\big(\hat{X} \leq N'\big)$. We first write it as $\Pr\big(\hat{X} \leq N'\big) = \Pr\big(\hat{X} \leq (1-\alpha)\,\mathbb{E}[\hat{X}]\big)$, where we defined $\alpha := 1 - \frac{N'}{mp_{\text{succ}}}$. Note that α satisfies $\alpha \geq \frac{1}{3}$, if

$$m \geq 2N', \tag{S68}$$

exploiting the fact that $p_{\text{succ}} \geq \frac{3}{4}$. Applying the Chernoff bound, we obtain:

$$\Pr\Big(\hat{X} \leq (1-\alpha)\mathbb{E}[\hat{X}]\Big) \leq \exp\left(-\frac{\alpha^2\mathbb{E}[\hat{X}]}{2}\right) = \exp\left(-\frac{\alpha^2}{2}p_{\text{succ}}m\right). \tag{S69}$$

This is upper bounded by δ if

$$m \geq \frac{2}{p_{\text{succ}}\alpha^2}\log\left(\frac{1}{\delta}\right). \tag{S70}$$

Therefore, choosing m as follows satisfies Eq. (S68) and Eq. (S70):

$$m \geq 2N' + \frac{2}{\left(\frac{3}{4}\right)\left(\frac{1}{3}\right)^2}\log\left(\frac{1}{\delta}\right) = 2N' + 24\log\left(\frac{1}{\delta}\right), \tag{S71}$$

where we used the fact that $p_{\text{succ}} \geq \frac{3}{4}$ and $\alpha \geq \frac{1}{3}$. □

B. Joining the pieces: proof of correctness

We now present the main theorem which puts together the lemmas we have discussed. It demonstrates that to learn t-doped fermionic Gaussian states, or more generally t-compressible Gaussian states, with $t = \mathcal{O}(\log(n))$, only resources scaling polynomially in the number of qubits are required.

Theorem 44 (Efficient Learning of t-Compressible Gaussian States). *Let $|\psi\rangle$ be a t-compressible Gaussian state, and consider $\varepsilon, \delta \in (0,1]$. By utilizing*

$$N \geq \frac{256n^5}{\varepsilon^4}\log\left(\frac{12n^2}{\delta}\right) + 2N_{\text{tom}}\left(t, \frac{\varepsilon}{2}, \frac{\delta}{3}\right) + 24\log\left(\frac{3}{\delta}\right) \tag{S72}$$

single-copy measurements and

$$T \geq \mathcal{O}(n^3) + T_{\text{tom}}\left(t, \frac{\varepsilon}{2}, \frac{\delta}{3}\right) \tag{S73}$$

computational time, Algorithm 2 yields a classical representation of a state $|\hat{\psi}\rangle$, satisfying $d_{\text{tr}}(|\hat{\psi}\rangle, |\psi\rangle) \leq \varepsilon$ with probability $\geq 1-\delta$.

Here, $N_{\text{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3})$ and $T_{\text{tom}}(t, \frac{\varepsilon}{2}, \frac{\delta}{3})$ respectively denote the number of copies and computational time sufficient for full state tomography of a t-qubit state with an $\varepsilon/2$ accuracy and a failure probability of at most $\delta/3$ (using the notation of Lemma 42).

Proof. The learning procedure is outlined in Algorithm 2 (or Algorithm 1 in the main text). We now establish its efficiency and correctness. According to Lemma 38, $N_c(n, \varepsilon_c, \delta/3)$ single copies of $|\psi\rangle$ are sufficient to construct an anti-symmetric real matrix $\hat{C}$ such that $\left\|\hat{C} - C\right\|_\infty \leq \varepsilon_c$ with a probability of at least $1 - \delta/3$. Here, we set $\varepsilon_c := \varepsilon^2/(4(n-t))$. Then, we can find the orthogonal matrix $\hat{O} \in \mathrm{O}(2n)$ such that it puts $\hat{C}$ in its normal form Eq.(1), which can be performed in $\mathcal{O}(n^3)$ time. Employing this, we construct the associated Gaussian unitary $\hat{G}$ (a task achievable in time $\mathcal{O}(n^3)$, see [36, 52]). Subsequently, we consider the state $\hat{G}^\dagger |\psi\rangle$. As per Lemma 41, we have

$$d_{\text{tr}}(|\phi\rangle \otimes \left|0^{n-t}\right\rangle, \hat{G}^\dagger |\psi\rangle) \leq \frac{\varepsilon}{2}, \tag{S74}$$

where $|\phi\rangle \otimes |0^{n-t}\rangle$ corresponds to the post-measurement state obtained by measuring the last $n-t$ qubits of the state $\hat{G}^\dagger |\psi\rangle$ in the computational basis and obtaining the outcome corresponding to $|0^{n-t}\rangle$. The probability of such an occurrence, as per Lemma 41, is at least $1 - \varepsilon^2/4 \geq 3/4$. Thus, the algorithm proceeds iteratively by querying a total of m copies of $|\psi\rangle$. In each iteration, it applies the unitary $\hat{G}^\dagger$ to $|\psi\rangle$ and computational basis measurements on the last $n-t$ qubits. By choosing $m := \lceil 2N_{\text{tom}}(t, \varepsilon/2, \delta/3) + 24\log(3/\delta)\rceil$, it is guaranteed that the measurements outcome corresponding to $|0^{n-t}\rangle$ occurred at least $N_{\text{tom}}(t, \varepsilon/2, \delta/3)$ with probability at least $1 - \delta/3$ (this follows by Lemma 43). Applying the tomography algorithm of Lemma 42 to the first t qubits of all the copies where we obtained the outcome corresponding to $|0^{n-t}\rangle$, we obtain an output state $|\hat{\phi}\rangle$ such that it is guaranteed that:

$$d_{\text{tr}}(|\hat{\phi}\rangle, |\phi\rangle) \leq \frac{\varepsilon}{2}, \tag{S75}$$

with a probability of at least $1 - \delta/3$. Our output state is $|\hat{\psi}\rangle := \hat{G}(|\hat{\phi}\rangle \otimes |0^{n-t}\rangle)$, and the information about such a state is provided in the output by providing the orthogonal matrix $\hat{O} \in \mathrm{O}(2n)$, which identifies $\hat{G}$, and the t-qubit state $|\hat{\phi}\rangle$.

Considering the trace distance between $|\hat{\psi}\rangle$ and $|\psi\rangle$ and applying the triangle inequality with $\hat{G}(|\phi\rangle \otimes |0^{n-t}\rangle)$ as the reference state, we have:

$$d_{\text{tr}}(|\hat{\psi}\rangle, |\psi\rangle) \leq d_{\text{tr}}(|\hat{\phi}\rangle, |\phi\rangle) + d_{\text{tr}}(|\phi\rangle \otimes \left|0^{n-t}\right\rangle, \hat{G}^\dagger |\psi\rangle), \tag{S76}$$

where in the last step we use the unitary-invariance of the trace distance and $d_{\text{tr}}(|\hat{\phi}\rangle \otimes |0^{n-t}\rangle, |\phi\rangle \otimes |0^{n-t}\rangle) = d_{\text{tr}}(|\hat{\phi}\rangle, |\phi\rangle)$. The algorithm's overall failure probability is contingent on the potential failure of any of the three subroutines—specifically, correlation matrix estimation, measurement of the last $n-t$ qubits, and the tomography protocol. Each subroutine is associated with a failure probability of at most $\delta/3$. Consequently, by the union bound, the algorithm's total failure probability is at most δ. Utilizing Eqs.(S74),(S75),(S76) and assuming the case in which the algorithm does not fail, we deduce $d_{\text{tr}}(|\hat{\psi}\rangle, |\psi\rangle) \leq \varepsilon$. The overall sample complexity is determined by the number of copies needed to estimate the correlation matrix $N_c(n, \varepsilon_c, \delta/3)$ plus the copies m for tomography, i.e., a total number of copies

$$N = \left\lceil \frac{256n^5}{\varepsilon^4} \log\left(\frac{12n^2}{\delta}\right) + 2N_{\text{tom}}\left(t, \frac{\varepsilon}{2}, \frac{\delta}{3}\right) + 24\log\left(\frac{3}{\delta}\right) \right\rceil, \tag{S77}$$

suffices, which is $\mathcal{O}(\mathrm{poly}(n) + \exp(t))$. On the other hand, the time complexity involves post-processing of the estimated correlation matrix, requiring $\mathcal{O}(n^3)$ time, and the time-complexity for full-state tomography which is $\mathcal{O}(\exp(t))$. □

Remark 45. *The output state of Algorithm 1 is $|\hat{\psi}\rangle := \hat{G}(|\hat{\phi}\rangle \otimes |0^{n-t}\rangle)$. Specifically, to provide a classical representation of $|\hat{\psi}\rangle$ in the output, it suffices to give the orthogonal matrix $\hat{O} \in \mathrm{O}(2n)$ associated with $\hat{G}$ and the classical description of the t-qubit state $|\hat{\phi}\rangle$. Therefore, the memory necessary to store the classical description of the state outputted by Algorithm 1 is $\mathcal{O}(\mathrm{poly}(n, 2^t))$, similarly to its time and sample complexity.*

Supplementary Material IV: Testing t-compressible states

In this section, we address property testing problem, i.e. the problem of determining whether a state is close or far from the set of states t-compressible states (or equivalently we test the Gaussian dimension of a state). We begin by establishing an upper bound on the trace distance between a state and the set of t-compressible Gaussian states. Subsequently, we present a lower bound on the same quantity. Finally, we leverage these two bounds to develop a testing algorithm for t-compressible Gaussian states.

We note that the testing problem in the context of fermionic Gaussian states ($t = 0$) was also unsolved. However, a forthcoming paper [67] addresses the testing problem for general, possibly mixed, fermionic Gaussian states. Here, we generalize the results presented in [67] regarding pure Gaussian testing to the scenario of t-compressible Gaussian states, using ideas developed in [67].

A. Approximate t-compressible state

We observed in Lemma 34 that when $n - t$ normal eigenvalues of a state's correlation matrix are precisely one, the state is a t-compressible state. However, when these eigenvalues are close to one, we may inquire about the existence of a t-compressible state in close proximity. This inquiry is formalized in the subsequent Proposition 46.

Proposition 46 (Check the closeness to a t-compressible Gaussian state)**.** *Let $|\psi\rangle$ be a quantum state. Let $\{\lambda_i\}_{i=1}^n$ be the normal eigenvalues of its correlation matrix ordered in increasing order. Then, there exists a t-compressible Gaussian state $|\psi_t\rangle$ such that:*

$$d_{\mathrm{tr}}(|\psi_t\rangle , |\psi\rangle) \leq \sqrt{\sum_{k=t+1}^{n} \frac{1}{2}(1-\lambda_k)}. \tag{S78}$$

In particular, $|\psi_t\rangle$ can be chosen as $|\psi_t\rangle := G_O(|\phi\rangle \otimes |0^{n-t}\rangle)$, where G_O is the Gaussian unitary associated with the orthogonal matrix $O \in \mathrm{O}(2n)$ that puts the correlation matrix of $|\psi\rangle$ in its normal form (Lemma 16), and $|\phi\rangle \otimes |0^{n-t}\rangle$ is the state obtained by projecting the state $G_O^\dagger |\psi\rangle$ onto the zero state on the last $n - t$ qubits.

Proof. We can define the state $|\psi'\rangle := G_O^\dagger |\psi\rangle$. We have:

$$\mathrm{Tr}(|\psi'\rangle\!\langle\psi'| \, Z_k) = C(\psi')_{2k-1,2k} = \Lambda_{2k-1,2k} = \lambda_k = 1 - (1 - \lambda_k), \tag{S79}$$

for each $k \in \{t + 1, \dots , n\}$. By using that $Z_k = 2 \, |0\rangle\!\langle 0|_k - I$, we have:

$$\mathrm{Tr}(|\psi'\rangle\!\langle\psi'| \, |0\rangle\!\langle 0|_k) = 1 - \frac{(1-\lambda_k)}{2} \tag{S80}$$

By Quantum Union Bound (Lemma 40), we have:

$$d_{\mathrm{tr}}(|\psi'\rangle , |\phi\rangle \otimes |0^{n-t}\rangle) \leq \sqrt{\sum_{k=t+1}^{n} \frac{(1-\lambda_k)}{2}}. \tag{S81}$$

Therefore, by using the unitarity invariance of the trace-norm, we can conclude. □

From this, it readily follows that trace distance between the state and the set of t-compressible pure Gaussian states $\mathcal{G}_t$ is upper bounded by:

$$\min_{|\phi_t\rangle \in \mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle , |\phi_t\rangle) \leq \sqrt{(n-t)\frac{(1-\lambda_{t+1})}{2}}. \tag{S82}$$

B. Lower bound on the trace distance from the set of t-compressible states

In this section, we establish a lower bound on the trace distance of a state from the set of t-compressible Gaussian states. We denote the set of pure t-compressible Gaussian states as $\mathcal{G}_t$. In the following proof, we follow the derivation presented in Ref. [67] for the case of pure Gaussian states ($t = 0$), extending it to t-compressible states.

Proposition 47. *Let $|\psi\rangle$ be a quantum state, and let $\{\lambda_i\}_{i=1}^n$ be the normal eigenvalues of its correlation matrix, ordered in increasing order. The lower bound on the trace distance between the state and the set of t-compressible pure Gaussian states $\mathcal{G}_t$ is given by:*

$$\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) \geq \frac{1}{2}(1-\lambda_{t+1}) \tag{S83}$$

Proof. Consider an arbitrary operator O with $\|O\|_\infty \leq 1$, to be fixed later. Then, we have:

$$\begin{aligned}\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) &= \min_{|\phi_t\rangle\in\mathcal{G}_t} \frac{1}{2}\| \, |\psi\rangle\!\langle\psi| - |\phi_t\rangle\!\langle\phi_t| \, \|_1 &\text{(S84)}\\ &\geq \min_{|\phi_t\rangle\in\mathcal{G}_t} \frac{1}{2}|\operatorname{Tr}(O(|\psi\rangle\!\langle\psi| - |\phi_t\rangle\!\langle\phi_t|))|, &\text{(S85)}\end{aligned}$$

where in the last step, we used Holder's inequality.

Let $C(|\psi\rangle)$ and $C(|\phi_t\rangle)$ be the correlation matrices of $|\psi\rangle$ and $|\phi_t\rangle$, respectively. Since $C(|\psi\rangle) - C(|\phi_t\rangle)$ is real and anti-symmetric, it can be brought into its normal form $C(|\psi\rangle) - C(|\phi_t\rangle) = Q^T\Lambda' Q$, where $\Lambda' = \bigoplus_{j=1}^n i\sigma'_j Y$ and $\{\sigma'_j\}_{j=1}^n$ are the normal eigenvalues of $C(|\psi\rangle) - C(|\phi_t\rangle)$ and $Q \in \mathrm{O}(2n)$ is an orthogonal matrix (Lemma 16).

Now, choose the operator O in the form $O = U_Q^\dagger i\gamma_{2k-1}\gamma_{2k}U_Q$, where $k \in [n]$ and U_Q is a Gaussian unitary associated with the orthogonal matrix $Q \in \mathrm{O}(2n)$. Note that $\|O\|_\infty = 1$. Fix k as a value of j that maximizes $|\sigma'_j|$. Thus, we have:

$$\begin{aligned}|\operatorname{Tr}(O(|\psi\rangle\!\langle\psi| - |\phi_t\rangle\!\langle\phi_t|))| &= |[C(U_Q|\psi\rangle) - C(U_Q|\phi_t\rangle)]_{2k-1,2k}| &\text{(S86)}\\ &= |[Q(C(|\psi\rangle) - C(|\phi_t\rangle))Q^T]_{2k-1,2k}| &\text{(S87)}\\ &= |\sigma'_k| &\text{(S88)}\\ &= \max_{j\in[n]} |\sigma'_j| &\text{(S89)}\\ &= \|C(|\psi\rangle) - C(|\phi_t\rangle)\|_\infty, &\text{(S90)}\end{aligned}$$

where in the first step we used the definition of correlation matrix, in the second step we used Lemma 15 and in the last step we used the fact that the largest normal eigenvalues of an anti-symmetric matrix corresponds to the infinity norm of the matrix. Therefore, combining with (S85), we have:

$$\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) \geq \frac{1}{2}\min_{|\phi_t\rangle\in\mathcal{G}_t} \|C(|\psi\rangle) - C(|\phi_t\rangle)\|_\infty. \tag{S91}$$

Now, by applying Lemma 39, we have:

$$\|C(|\psi\rangle) - C(|\phi_t\rangle)\|_\infty \geq |\lambda(C(|\psi\rangle)_{t+1} - \lambda(C(|\phi_t\rangle)_{t+1}|, \tag{S92}$$

where $\lambda(C)_{t+1}$ denotes the $t+1$-th smallest normal eigenvalue of a correlation matrix C. Since $|\phi_t\rangle$ is a t-compressible Gaussian state, its Gaussian dimension is $n-t$ (because of Proposition 35), hence its $t+1$-th smallest normal eigenvalue must be one. Therefore, the desired lower bound is obtained. □

C. Testing the Gaussian dimension of a state

We present an efficient algorithm (Algorithm 3) for property testing of t-compressible states, where $\mathcal{G}_t$ represents the set of n-qubits t-compressible Gaussian states, or equivalently the set of states with $n-t$ Gaussian dimension. The algorithm takes copies of a state $|\psi\rangle$ as input and determines whether $\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) \leq \varepsilon_A$ or $\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) \geq \varepsilon_B$, with the promise that one of these cases is true, where $\varepsilon_B > \varepsilon_A \geq 0$.

We provide the details of the testing algorithm in Algorithm 3. The correctness of this algorithm is established by the following theorem, the proof of which follows the same steps as proofs presented in [67].

Theorem 48 (Efficient t-Compressible Gaussian Testing). *Let $|\psi\rangle$ be an n-qubit pure state. Assume $\varepsilon_B, \varepsilon_A \in [0,1]$ such that $\varepsilon_B > \sqrt{(n-t)\varepsilon_A}$, $\delta \in (0,1]$, and $\varepsilon_{\mathrm{corr}} = (\frac{\varepsilon_B^2}{n-t} - \varepsilon_A)$. Assume that $|\psi\rangle$ is such that $\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) \leq \varepsilon_A$ or $\min_{|\phi_t\rangle\in\mathcal{G}_t} d_{\mathrm{tr}}(|\psi\rangle, |\phi_t\rangle) > \varepsilon_B$. Then, Algorithm 3 can discriminate between these two scenarios using $N = \lceil 16(n^3/\varepsilon_{\mathrm{corr}}^2)\log\big(4n^2/\delta\big)\rceil$ single-copy measurements of the state $|\psi\rangle$ with a probability of success at least $1-\delta$.*

```
Algorithm 3: Property Testing Algorithm for $t$-Compressible Gaussian States
Input: Error thresholds $\varepsilon_A, \varepsilon_B$, failure probability $\delta$. $N := \lceil 16(n^3/\varepsilon_{\text{corr}}^2)\log\big(4n^2/\delta\big)\rceil$ copies of the pure state $|\psi\rangle$, where
    $\varepsilon_{\text{corr}} = (\frac{\varepsilon_B^2}{n-t} - \varepsilon_A)$. Let $\varepsilon_{\text{test}} := \Big(\frac{\varepsilon_B^2}{n-t} + \varepsilon_A\Big)$.
Output: Output either "$\varepsilon_A$-close to the set of $t$-compressible states" or "$\varepsilon_B$-far from $t$-compressible states set".
Step 1: Estimate the entries of the correlation matrix using $N$ single-copy measurements, resulting in the estimated $2n \times 2n$ matrix $\hat{\Gamma}$;
Step 2: Find $\{\hat{\lambda}_k\}_{k=1}^n$, which corresponds to the ordered normal eigenvalues of $\hat{\Gamma}$;
Step 3: if $\hat{\lambda}_{t+1} \geq 1 - \varepsilon_{\text{test}}$ then
    Output: "$\varepsilon_A$-close to the set of $t$-compressible states".
else
    Output: "$\varepsilon_B$-far from $t$-compressible states set."
```

Proof. Let $\varepsilon_{\text{corr}} > 0$ be an accuracy parameter to be fixed later. By Lemma 38, with $N \geq 8(n^3/\varepsilon_{\text{corr}}^2)\log\big(4n^2/\delta\big)$ single-copy measurements, we can find a matrix $\hat{\Gamma}$ such that, with probability at least $1-\delta$, it holds that $\left\|\hat{\Gamma} - \Gamma(|\psi\rangle)\right\|_\infty \leq \varepsilon_{\text{corr}}$. This implies that for all $k \in [n]$, we have $|\hat{\lambda}_k - \lambda_k| \leq \varepsilon_{\text{corr}}$, where $\{\hat{\lambda}_k\}_{k=1}^n, \{\lambda_k\}_{k=1}^n$ are the normal eigenvalues of $\hat{\Gamma}$ and $\Gamma(|\psi\rangle)$ respectively. Let $\varepsilon_{\text{test}}$ be a parameter to fix later. If $\hat{\lambda}_{t+1} \geq 1 - \varepsilon_{\text{test}}$, we aim to show that $\min_{|\phi_t\rangle \in \mathcal{G}_t} d_{\text{tr}}(|\psi\rangle, |\phi_t\rangle) \leq \varepsilon_B$, otherwise, we aim to show that $\min_{|\phi_t\rangle \in \mathcal{G}_t} d_{\text{tr}}(|\psi\rangle, |\phi_t\rangle) > \varepsilon_A$. Thus, we first assume that $\hat{\lambda}_{t+1} \geq 1 - \varepsilon_{\text{test}}$. From Lemma 46, we have that:

$$\min_{|\phi_t\rangle \in \mathcal{G}_t} d_{\text{tr}}(|\psi\rangle, |\phi_t\rangle) \leq \sqrt{\frac{(n-t)}{2}(1-\lambda_{t+1})} \leq \sqrt{\frac{(n-t)}{2}(1-\hat{\lambda}_{t+1}+\varepsilon_{\text{corr}})} \leq \sqrt{\frac{(n-t)}{2}(\varepsilon_{\text{test}}+\varepsilon_{\text{corr}})}. \tag{S93}$$

Therefore we need to ensure that $\sqrt{\frac{(n-t)}{2}(\varepsilon_{\text{test}}+\varepsilon_{\text{corr}})} \leq \varepsilon_B$. Let us analyze now the case in which $\hat{\lambda}_{t+1} < 1 - \varepsilon_{\text{test}}$. From Lemma 47, we have:

$$\min_{|\phi_t\rangle \in \mathcal{G}_t} d_{\text{tr}}(|\psi\rangle, |\phi_t\rangle) \geq \frac{1}{2}(1-\lambda_{t+1}) \geq \frac{1}{2}(1-\hat{\lambda}_{t+1}-\varepsilon_{\text{corr}}) > \frac{1}{2}(\varepsilon_{\text{test}}-\varepsilon_{\text{corr}}) \tag{S94}$$

Therefore, we impose that $\frac{\varepsilon_{\text{test}}-\varepsilon_{\text{corr}}}{2} \geq \varepsilon_A$. The two mentioned inequalities are satisfied by choosing $\varepsilon_{\text{test}} = (\frac{\varepsilon_B^2}{n-t} + \varepsilon_A)$ and $\varepsilon_{\text{corr}} = (\frac{\varepsilon_B^2}{n-t} - \varepsilon_A)$, by assuming that $\varepsilon_B > \sqrt{(n-t)\varepsilon_A}$. □

Supplementary Material V: Pseudorandomness from t-doped Gaussian states and time complexity lower bound

We have presented an algorithm for learning t-doped fermionic Gaussian states with a time complexity scaling as $\mathcal{O}(\text{poly}(n, 2^t))$ (assuming that the Majorana locality κ of each non-Gaussian gate is constant in the number of qubits). Thus, as long as $t = \mathcal{O}(\log(n))$, the algorithm is efficient, i.e., the total run-time is polynomial in the number of qubits. In this section, we delve into establishing lower bounds on the time complexity for learning t-doped fermionic Gaussian states. We begin by demonstrating that, under a well-believed cryptography assumption [43–45, 64–66], no algorithm can learn t-doped fermionic Gaussian states with time complexity scaling in t as $\mathcal{O}(\text{poly}(t))$. This rules out efficient algorithms if t scales polynomially with the number of qubits n. However, under a stronger cryptography assumption [43–46], we can establish that when t scales *slightly* faster than logarithmically in the number of qubits n, i.e., $t = \tilde{\omega}(\log(n))$, there exists no efficient algorithm to learn t-doped fermionic Gaussian states, where we defined $\tilde{\omega}(\log(n)) := \omega(\log(n)\text{polyloglog}(n))$.

A. t-doped Gaussian states cannot be learned in polynomial time in t

Our cryptography assumption relies on the conjecture that a specific problem, namely "Learning With Errors over Rings" RingLWE [64], is hard to solve by quantum computers [43–45, 64–66]. Detailed definitions and discussions about RingLWE can be found in [64]. Informally, RingLWE is a variant of the more general "Learning With Errors" (LWE) problem specialized to polynomial rings over finite fields, where the LWE problem is to distinguish random linear equations, perturbed by a small amount of noise, from truly uniform ones.

Crucial to our proof is a lemma, adapted from [63] (which strongly relies on previous work [43, 47, 48]), presented below:

Lemma 49 (Adapted from Theorem 14 in [63])**.** *Assume that* RingLWE *cannot be solved by quantum computers in polynomial time. Then, there exists a set $\mathcal{S}_{\mathrm{PRS}}$ of k-qubits pure quantum states, known as pseudorandom quantum states, with the following properties:*

1. *Any state in $\mathcal{S}_{\mathrm{PRS}}$ can be prepared using $\tilde{\mathcal{O}}(k)$ Toffoli and Hadamard gates (here, $\tilde{\mathcal{O}}(\cdot)$ hides* $\mathrm{polylog}(\cdot)$ *factors).*

2. *States in the set $\mathcal{S}_{\mathrm{PRS}}$ cannot be learned in time complexity $\mathcal{O}(\mathrm{poly}(t))$ by quantum computers. More specifically, let $\rho \in \mathcal{S}_{\mathrm{PRS}}$ be an unknown quantum state. Then there is no quantum algorithm that, using $\mathcal{O}(\mathrm{poly}(k))$ copies of ρ and computational time, with probability at least $2/3$ outputs a classical description of a state $\hat{\rho}$ which can be prepared in polynomial time on a quantum computer such that $\mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \leq 1/8$.*

Now we use this Lemma to show that there is no algorithm for learning t-doped states with a $\mathcal{O}(\mathrm{poly}(t))$ computational time scaling in t.

Proposition 50 (No $\mathrm{poly}(t)$ algorithm to learn t-doped states)**.** *Assume that* RingLWE *cannot be solved by quantum computers in polynomial time. Then there is no quantum algorithm that, given access to copies of a t-doped fermionic Gaussian n-qubits state ρ and with a time complexity scaling in t as $\mathcal{O}(\mathrm{poly}(t))$, outputs a classical description of a quantum state $\hat{\rho}$ such that it can be prepared in polynomial time on a quantum computer and, with probability at least $2/3$, it holds that $\mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \leq 1/8$.*

Proof. Consider an n-qubit state of the form $|\phi\rangle \otimes |0^{n-k}\rangle$, where $|\phi\rangle$ is a k-qubit state in the set $\mathcal{S}_{\mathrm{PRS}}$ defined in Lemma 49. Let $|\phi\rangle = U_{\mathrm{PRS}}\,|0^k\rangle$, prepared by a unitary U_{PRS} that can be implemented using $\tilde{\mathcal{O}}(k)$ Hadamard and Toffoli gates, as per Lemma 49. The Toffoli gates can be implemented in turn using Hadamard, CNOT, T-gates, and T-gates inverse. For each gate in the system, utilizing a standard SWAP-exchange trick, we can make any gate acting on some qubits of the system to act only on the first two qubits through a cascade of SWAP gates. This incurs a total overhead factor of $\mathcal{O}(k)$ in the total number of gates. The SWAP gates between nearest-neighbor qubits are local non-Gaussian gates, since they can be expressed as $\mathrm{SWAP}_{i,i+1} = e^{-i\frac{\pi}{4}} \exp\big(i\frac{\pi}{4}(X_iX_{i+1} + Y_iY_{i+1} + Z_iZ_{i+1})\big)$, which have Majorana locality equal to 4 (due to the Jordan-Wigner mapping). Also the other gates, now acting on the first two qubits, are (possibly) non-Gaussian gates with Majorana locality at most 4. This is because the Pauli operators in the generator of each gate can be expressed in terms of Majorana operators via the Jordan-Wigner transformation. This results in a total of $t = \tilde{\mathcal{O}}(k^2)$ local non-Gaussian gates required to prepare the state. Thus, the $|\phi\rangle$ is a t-doped Gaussian state with $\kappa = 4$ Majorana local non-Gaussian gates. Now, due to Lemma 49, there exists no learning algorithm to learn such a state in time $\mathcal{O}(\mathrm{poly}(k)) = \mathcal{O}(\mathrm{poly}(t))$, with error less than $1/8$ and probability of success at least $2/3$. □

B. Learning $\tilde{\omega}(\log(n))$-doped Gaussian states is hard

The previous Proposition rules out efficient algorithms when $t = \Omega(\mathrm{poly}(n))$. However, our proposed algorithm is not anymore efficient when $t = \tilde{\omega}(\log(n))$, while it is efficient for $t = \mathcal{O}(\log(n))$. If we were to make the stronger assumption, namely that RingLWE cannot be solved by quantum computers in sub-exponential time [43–46], then we can rule out that efficient algorithm for $t = \tilde{\omega}(\log(n))$ exists (which means faster than $\omega(\log(n))$ but hiding polyloglog factors). For showing this, we need first the following Lemma adapted by [63].

Lemma 51 (Adapted from Theorem 14 and 15 in [63])**.** *Assume that* RingLWE *cannot be solved by quantum computers in sub-exponential time. Then, there exists a set $\mathcal{S}_{\mathrm{PRS}}$ of k-qubit pure quantum states, known as pseudorandom quantum states, with the following properties:*

1. *Any state in $\mathcal{S}_{\mathrm{PRS}}$ can be prepared using $\tilde{\mathcal{O}}(k)$ Toffoli and Hadamard gates (here, $\tilde{\mathcal{O}}(\cdot)$ hides* $\mathrm{polylog}(\cdot)$ *factors).*

2. *Any algorithm to learn states from the set $\mathcal{S}_{\mathrm{PRS}}$ must have $\exp(\Omega(k))$ time complexity. More specifically, let $\rho \in \mathcal{S}_{\mathrm{PRS}}$ be an unknown quantum state. Then any quantum algorithm that, by querying copies of ρ, with probability at least $2/3$ outputs a classical description of a state $\hat{\rho}$ which can be prepared in sub-exponential time on a quantum computer such that $\mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \leq 1/8$, must have $\exp(\Omega(k))$ time-complexity.*

Now we use this to prove the following Proposition, also stated informally in the main text as Theorem 5. It reaches stronger conclusion than Proposition 50, but at the cost of stronger cryptography assumption. The idea of the following proof is to use a more compact qubits-to-fermion mapping than Jordan-Wigner, namely a modification of the one introduced by Kitaev [23], which would allow to create pseudorandom quantum states with no overhead in the number of non-Gaussian gates compared to the number of Toffoli and Hadamard gates. In the following, we recall that $\tilde{\omega}(\log(n))$ is defined as $\tilde{\omega}(\log(n)) := \omega(\log(n)\mathrm{polyloglog}(n)))$.

Proposition 52 (Learning $\tilde{\omega}(\log(n))$-doped Gaussian states is hard)**.** *Assume that* RingLWE *cannot be solved by quantum computers in sub-exponential time. Then, there is no efficient (i.e.,* $\mathcal{O}(\mathrm{poly}(n))$ *time) quantum algorithm that, by querying copies of a* $\tilde{\omega}(\log(n))$*-doped Gaussian state* ρ*, with probability at least* $2/3$ *outputs a description of a state* $\hat{\rho}$ *which can be prepared in polynomial time on a quantum computer such that* $\mathrm{d}_{\mathrm{tr}}(\rho,\hat{\rho}) \leq 1/8$*.*

Proof. Following a similar approach as in the proof of Proposition 50, we begin by defining a state $|\phi\rangle \otimes |0^{n-k}\rangle$, where $|\phi\rangle = U_{\mathrm{PRS}}\,|0^k\rangle$ represents a k-qubit state in the set $\mathcal{S}_{\mathrm{PRS}}$ as defined in Lemma 51. This state can be efficiently prepared using a unitary U_{PRS} with $\tilde{\mathcal{O}}(k)$ Hadamard and Toffoli gates, which, in turn, can be implemented using Hadamard gates, CNOTs, T-gates, and their inverses. In contrast to the previous proof in Proposition 50, an application of the same argument would not yield the desired conclusion due to the unfavorable quadratic overhead introduced by the SWAP-exchange trick in the number of non-Gaussian gates. That trick was necessary due to the use of Jordan-Wigner transformation. However, we can employ a more efficient qubits-to-fermions mapping, specifically a modified version of the one introduced by Kitaev [23]. Hereafter, we will refer to it as the "Kitaev encoding." Our objective is to construct a fermionic state encoding $|\phi\rangle$ using a circuit of size $\tilde{\mathcal{O}}(k)$ composed of Gaussian and $\kappa = 4$ local non-Gaussian gates. We employ a mapping of k qubits into $2k$ fermionic modes using Majorana operators $\{\gamma_{\alpha,j} \,|\, j \in [k],\, \alpha \in \{0,\,x,\,y,\,z\}\}$. These $4k$ Majorana operators are defined in terms of $4k$ Pauli strings via Jordan-Wigner, with an arbitrarily fixed operator ordering. We are now going to leverage the formalism and basics of stabilizer codes, for more in-depth information, refer to [75]. The Kitaev encoding involves defining a stabilizer code of $2k$ physical qubits encoded in k logical qubits, characterized by the following k stabilizer generators $\{s_j\}_{j=1}^{k}$ and logical Pauli operators $\{X_j^{\mathrm{KE}}, Z_j^{\mathrm{KE}}\}_{j=1}^{k}$:

$$s_j := \gamma_{0,j}\gamma_{x,j}\gamma_{y,j}\gamma_{z,j}, \tag{S95}$$

$$X_j^{\mathrm{KE}} := i\gamma_{y,j}\gamma_{z,j}, \tag{S96}$$

$$Z_j^{\mathrm{KE}} := i\gamma_{x,j}\gamma_{y,j}. \tag{S97}$$

for each $j \in [k]$. Note that these operators explicitly satisfy the algebraic conditions on stabilizer generators and logical Pauli operators. The Kitaev encoding is associated to a Clifford transformation V_{KE} such that:

$$V_{\mathrm{KE}} X_j V_{\mathrm{KE}}^{\dagger} = X_j^{\mathrm{KE}}, \tag{S98}$$

$$V_{\mathrm{KE}} Z_j V_{\mathrm{KE}}^{\dagger} = Z_j^{\mathrm{KE}}, \tag{S99}$$

for each $j \in [k]$, and:

$$V_{\mathrm{KE}} Z_j V_{\mathrm{KE}}^{\dagger} = s_j, \tag{S100}$$

for each $j \in \{k+1,\dots,2k\}$. The last equation ensures that $V_{\mathrm{KE}}\,|0^{2k}\rangle$ is an eigenstate with $+1$ eigenvalue for each of the stabilizer generators $\{s_j\}_{j=1}^{k}$, while Eq.(S99) implies that $V_{\mathrm{KE}}\,|0^{2k}\rangle$ is an eigenstate with $+1$ eigenvalue for each $\{Z_j^{\mathrm{KE}}\}_{j=1}^{k}$. Thus, $V_{\mathrm{KE}}\,|0^{2k}\rangle$ is a valid "logical zero" stabilizer state. Exploiting the fact that $V_{\mathrm{KE}}\,|0^{2k}\rangle$ is an eigenstate with $+1$ eigenvalues of $\{Z_j^{\mathrm{KE}}\}_{j=1}^{k}$ and $\{s_j Z_j^{\mathrm{KE}}\}_{j=1}^{k}$, its density matrix can be written as:

$$V_{\mathrm{KE}}\,|0^{2k}\rangle\!\langle 0^{2k}|\,V_{\mathrm{KE}}^{\dagger} = \prod_{j=1}^{k}\left(\frac{I + s_j Z_j^{\mathrm{KE}}}{2}\right)\prod_{j=k}^{2k}\left(\frac{I + Z_j^{\mathrm{KE}}}{2}\right) = \prod_{j=1}^{k}\left(\frac{I - i\gamma_{0,j}\gamma_{z,j}}{2}\right)\prod_{j=k}^{2k}\left(\frac{I + i\gamma_{x,j}\gamma_{y,j}}{2}\right). \tag{S101}$$

From this, we observe that $V_{\mathrm{KE}}\,|0^{2k}\rangle$ is a fermionic Gaussian state because it can be written in the form of Eq.(S4), noting that signed permutation matrices are orthogonal matrices. Moreover, we denote $Y_j^{\mathrm{KE}} := -iZ_j^{\mathrm{KE}}X_j^{\mathrm{KE}} = i\gamma_{x,j}\gamma_{z,j}$. The Kitaev encoding, as defined, ensures that the local qubit gates are mapped onto local fermionic ones. In particular, the gates of the circuit U_{PRS} that prepares the pseudorandom state $|\phi\rangle = U_{\mathrm{PRS}}\,|0^k\rangle$— the Hadamard H, CNOT, and T-gate — are, up to an overall phase, mapped onto

$$\mathrm{H}_j^{\mathrm{KE}} := V_{\mathrm{KE}}\mathrm{H}_j V_{\mathrm{KE}}^{\dagger} = V_{\mathrm{KE}}\left(Z_j\frac{I + iY_j}{\sqrt{2}}\right)V_{\mathrm{KE}}^{\dagger} = Z_j^{\mathrm{KE}}\frac{I + iY_j^{\mathrm{KE}}}{\sqrt{2}} = e^{-\frac{\pi}{2}\gamma_{x,j}\gamma_{y,j}}e^{-\frac{\pi}{4}\gamma_{z,j}\gamma_{x,j}}, \tag{S102}$$

$$\mathrm{CNOT}_{j,l}^{\mathrm{KE}} := V_{\mathrm{KE}}\mathrm{CNOT}_{j,l}V_{\mathrm{KE}}^{\dagger} = e^{i\frac{\pi}{4}(1 - Z_j^{\mathrm{KE}})(I - X_l^{\mathrm{KE}})} = e^{i\frac{\pi}{4}(I - i\gamma_{x,j}\gamma_{y,j})(I - i\gamma_{y,l}\gamma_{z,l})}, \tag{S103}$$

$$\mathrm{T}_j^{\mathrm{KE}} := V_{\mathrm{KE}}\mathrm{T}_j V_{\mathrm{KE}}^{\dagger} = e^{i\frac{\pi}{8}Z_j^{\mathrm{KE}}} = e^{-\frac{\pi}{8}\gamma_{x,j}\gamma_{y,j}}, \tag{S104}$$

for each $j \neq l \in [k]$. The only non-Gaussian among these is the encoding of the CNOT gate, which has Majorana locality $\kappa = 4$. This implies that the encoding of the circuit U_{PRS}, i.e. $U_{\mathrm{PRS}}^{\mathrm{KE}} := V_{\mathrm{KE}}U_{\mathrm{PRS}}V_{\mathrm{KE}}^{\dagger}$, is a t-doped fermionic Gaussian unitary with local non-Gaussian gates and $t = \tilde{\mathcal{O}}(k)$. Thus, we have that the Kitaev encoding of the pseudorandom state $|\phi\rangle = U_{\mathrm{PRS}} \left|0^k\right\rangle$ is:

$$|\phi\rangle_{\mathrm{KE}} := V_{\mathrm{KE}} |\phi\rangle \otimes \left|0^k\right\rangle = V_{\mathrm{KE}} U_{\mathrm{PRS}} \left|0^{2k}\right\rangle = U_{\mathrm{PRS}}^{\mathrm{KE}} V_{\mathrm{KE}} \left|0^{2k}\right\rangle . \tag{S105}$$

Since $V_{\mathrm{KE}} \left|0^{2k}\right\rangle$ is a Gaussian state and $U_{\mathrm{PRS}}^{\mathrm{KE}}$ is a t-doped Gaussian unitary with $t = \tilde{\mathcal{O}}(k)$, then $V_{\mathrm{KE}} |\phi\rangle \otimes \left|0^k\right\rangle$ is a t-doped Gaussian state with $t = \tilde{\mathcal{O}}(k)$. The Majorana locality of each non-Gaussian gate is at most 4.

Using an arbitrary algorithm $\mathcal{A}$ for learning a t-doped fermionic Gaussian state, we will now define a protocol for learning the pseudorandom state $|\phi\rangle$. Given a copy of a state $|\phi\rangle$ on k qubits, we use k auxiliary qubits in state $|0\rangle$ and apply the Clifford transformation V_{KE}. This means it can be produced by a circuit with $O(k^2)$ 2-qubit gates [76]. The resulting $|\phi\rangle_{\mathrm{KE}}$ can be input to $\mathcal{A}$ as a copy of a t-doped fermionic Gaussian state for $t = \tilde{\mathcal{O}}(k)$. Using the number of copies of $|\phi\rangle$ given by sample complexity of $\mathcal{A}$, we learn a description of a state $\hat{\rho}_{\mathrm{KE}}$ which, with probability at least $2/3$, satisfies:

$$d_{\mathrm{tr}}(\hat{\rho}_{\mathrm{KE}}, \rho_{\mathrm{KE}}) \leq \frac{1}{8}, \tag{S106}$$

where we defined ρ_{KE} to be the density matrix associated with $|\phi\rangle_{\mathrm{KE}}$. By defining $\hat{\rho} := \mathrm{Tr}_{\{k+1,\dots,2k\}} \left(V_{\mathrm{KE}}^{\dagger} \hat{\rho}_{\mathrm{KE}} V_{\mathrm{KE}} \right)$, where $\mathrm{Tr}_{\{k+1,\dots,2k\}}(\cdot)$ indicates the partial trace with respect to the qubits $\{k+1, \dots, 2k\}$, we also have:

$$d_{\mathrm{tr}}(\hat{\rho}, |\phi\rangle\!\langle\phi|) \leq d_{\mathrm{tr}}(V_{\mathrm{KE}}^{\dagger} \hat{\rho}_{\mathrm{KE}} V_{\mathrm{KE}}, |\phi\rangle\!\langle\phi| \otimes \left|0^k\right\rangle\!\left\langle 0^k\right|) = d_{\mathrm{tr}}(V_{\mathrm{KE}}^{\dagger} \hat{\rho}_{\mathrm{KE}} V_{\mathrm{KE}}, V_{\mathrm{KE}}^{\dagger} \rho_{\mathrm{KE}} V_{\mathrm{KE}}) = d_{\mathrm{tr}}(\hat{\rho}_{\mathrm{KE}}, \rho_{\mathrm{KE}}) \leq \frac{1}{8}, \tag{S107}$$

where in the first step we used that the partial trace does not increase the trace distance between two states [77]. Hence, we found a state $\hat{\rho}$ which is in trace distance close to the target state $|\phi\rangle\!\langle\phi|$. To recap, we produced the learning algorithm for a pseudorandom state $|\phi\rangle$ from a learning algorithm for t-doped fermionic Gaussian states. The pseudorandom state learning algorithm has the same sample complexity as the fermionic one, and the time complexity $T_{\mathrm{PRS}} = S_{\mathrm{f}} \cdot O(k^2) + T_{\mathrm{f}}$ where T_{f} and S_{f} are time and sample complexity of the fermionic learner. If there is a fermionic learner whose time and sample complexity scale subexponentially in k, the same property carries over to the pseudorandom states learner. By Lemma 51, this would contradict the cryptographic assumption that RingLWE cannot be solved by quantum computers in sub-exponential time. Hence, the time complexity of the fermionic learner needs to be $\exp(\Omega(k))$. If $k = \omega(\log(n))$, then this implies that any algorithm to learn t-doped fermionic Gaussian states with $t = \tilde{\mathcal{O}}(k) = \omega(\log(n)\mathrm{polyloglog}(n))$ must be inefficient, i.e., its time complexity must be $\omega(\mathrm{poly}(n))$. □

Concept learning of parameterized quantum models from limited measurements

(Dated: July 26, 2024)

Classical learning of the expectation values of observables for quantum states is a natural variant of learning quantum states or channels. While the current learning-theoretic framework establishes the sample complexity and the number of measurement shots per sample required for learning such statistical quantities, the interplay between these two variables has not been adequately quantified before. In this work, we quantify and demonstrate the asymmetrical effects of the two variables on the performance of concept learning. Specifically, increasing the sample size enhances the learning performance of classical machines, even with single-shot estimates, while the improvements from increasing measurements become asymptotically trivial beyond a constant factor. When the total queries to quantum systems is fixed, such asymmetrical effects imply an asymmetrical trade-off between them. Through bias-variance-noise decomposition, we further show the practical impact of finite measurement noise on the training of classical machines. Finally, we apply the framework to study the impact of measurement noise on the classical surrogation of parameterized quantum circuit models. Our work provides new tools to analyse the operational influence of finite measurement noise in classical learning of quantum systems.

I. INTRODUCTION

The potential computational capabilities of quantum computers have garnered much interest in recent years from both academia and industry. In particular, it has been suggested that quantum computers have the potential to simulate quantum systems with an exponential speedup compared to classical computers [1, 2]. However, these hard-to-simulate computational tasks could potentially be efficiently learned by classical machines given access to data extracted from the associated quantum processes [3–11]. Such a learning task relies on quantum and classical computers alike to extract relevant information from quantum states via quantum measurements [12, 13] and subsequently to conduct learning of the desired properties of quantum states. Some of these quantum properties can be formulated and represented by mathematical models, which we can learn using classical learning algorithms. Examples of such *quantum models* include expectation values of quantum observables given a variational quantum circuit [14] or ground state properties of quantum systems [9–11]. Understanding how classical machines can learn quantum models is therefore essential, as it sheds light on the potential and limitations of quantum information processing.

Quantum systems exhibit inherent probabilistic behaviour, and measurements on such systems are typically subjected to statistical fluctuations. When only a limited number of measurements are made on a quantum model, the observed outcomes may deviate from the true underlying quantum models due to the measurement/shot noise. Hence, apart from the number of training data inputs N_1, the number of measurement shots (per data input) N_s is also a key quantity in determining the learning performance of classical learners. Current works often consider shot noise as an error term that needs to be mitigated and rely on its minimization to ensure learnability [8, 9, 11]. In these scenarios, the effects of altering N_1 and N_s are typically discussed separately, with N_s assumed to be sufficient enough as to not affect the analysis regarding N_1 and the learning performance.

In this work, we discuss asymmetrical effects that these two quantities have on the performance of classical machines in learning quantum models. That is, increasing N_1 enhances the learning performance of classical models, even when observed outcomes are estimated with limited measurement shots, e.g., in the single-shot limit [15] when $N_s = 1$. On the other hand, for a fixed training data size N_1, we find that improvements in learning performances from increasing the number of measurement shots N_s become asymptotically trivial beyond a constant factor.

In practice, extrinsic factors such as monetary budgets force one to fix the total number of queries to quantum models, thereby coupling N_1 and N_s since increasing N_1 will reduce N_s and vice versa[1]. This poses an interesting learning-theoretic question: *given a fixed number of queries to quantum models, will classical machines learn better with training datasets consisting of more inputs with noisier labels (larger N_1 but smaller N_s) or fewer in-*

† patrick@comp.nus.edu.sg

[1] The simplest method of defining the total cost of querying the quantum model we wish to learn is $N = N_1 N_s$.

puts with cleaner labels (smaller N_1 but larger N_s)? Our analytical results show that, asymptotically, it is always better to sample from different inputs when sampling a data point incurs the same cost as conducting a duplicate measurement. The optimal performance is achieved when labels are estimated with only one measurement shot. As shown in Figure 1, our classical machines learn better with training datasets consisting of more inputs with the noisiest labels. Yet, realistically, it is cheaper to produce more samples for a fixed parameter setting in quantum models than to change the parameter settings each time. In this scenario, we analytically show that there exists an optimal pair of N_1 and N_s that will maximize the performance of the classical models.

Our analysis is based on the learning-theoretic framework of *probabilistic concepts* (p-concept) [16]. Stemming from the probabilistic nature of quantum measurements, there is no deterministic mapping of the input data to the observed outcomes (known in statistical learning theory as a *concept* [17]) that can capture the behaviour of the quantum model. Nonetheless, there is some structure to this uncertainty. That is, quantum models represent the conditional expectation of their unbiased estimators. As this is precisely how p-concepts are defined, one could formulate quantum models as p-concepts.

The p-concept setting was first introduced in a quantum setup in Scott Aaronson's seminal paper [18] and subsequently in Refs. [19–22]. While these works, along with our own, identify shot noise as structural randomness that allows us to cast quantum models as p-concepts, they primarily focus on the usage of the fat-shattering dimension, a complexity measure that shows the expressiveness of the set of p-concepts we are interested in learning. In these prior work, the fat-shattering dimension is used to quantify the difficulty of learning quantum states [18–20], measurements [21], and quantum circuits [22]. In contrast, our work utilizes kernel theory and the respective learnability results to investigate the impact of shot noise in learning quantum models using classical machine learning models. Furthermore, our framework disentangles the contributions of the classical representation of quantum models, the size of the training dataset, and the number of measurement shots, providing a new perspective to investigate their individual roles in learning quantum models.

We further assess the impacts of shot noise on the actual training of classical machines. Following the bias-variance-noise decomposition, we show the implicit impacts of shot noise on the bias and variance of classical models. Specifically, high shot noise will lead to high variance in classical models, which is consistent with observations in the literature [23, 24]. Finally, we apply our framework to numerically study the impact of shot noise on the classical surrogation of parameterized quantum circuit models. The numerical results are consistent with our theoretical predictions.

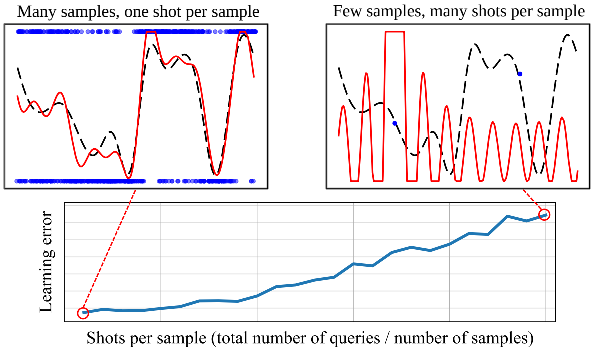

FIG. 1. Fixing the total number of queries to quantum models imposes constraints on the number of inputs and the number of shots per input: noisier (more accurate) estimates [BLUE DOTS] of the target function [BLACK-DASHED LINE] are acquired if more (fewer) inputs are considered. Classical machines trained with these inputs and associated function estimates will output the prediction [RED SOLID LINE].

II. PRELIMINARIES

In this section, we will first introduce two frameworks in statistical learning theory that we use to provide learning guarantees, the deterministic concept learning framework and the probabilistic concept learning framework. Then, we will provide a brief introduction to the types of quantum models considered in this work.

A. Probabilistic concept learning

Let $\mathcal{X} = \mathbb{R}^m$ and $\mathcal{Y} \subset \mathbb{R}$ be the data and label spaces, respectively. Further, we assume that data points $\boldsymbol{x}$ are independently and identically distributed (i.i.d.) according to some unknown but fixed distribution $p(\boldsymbol{x})$ and the label space $\mathcal{Y}$ is a compact and convex subspace of $\mathbb{R}$.

In the learning-theoretic setting, there are two types of functions of interest: *concept* and *hypothesis*. A concept c is a function that maps the data space to the label space, i.e., $c : \mathcal{X} \to \mathcal{Y}$. A particular set of these functions with specific properties forms a *concept class* $\mathcal{C} \subseteq \mathcal{Y}^{\mathcal{X}}$. In the deterministic learning setting, a concept maps data points $\boldsymbol{x} \in \mathcal{X}$ to associated labels $y \in \mathcal{Y}$, i.e., a data sample is given by $(\boldsymbol{x}, y)$ where $\boldsymbol{x}$ is sampled from $p(\boldsymbol{x})$ and $y = c(\boldsymbol{x})$. Similarly, a hypothesis is defined as $h : \mathcal{X} \to \mathcal{Y}$, and a subset of these functions forms a *hypothesis class* $\mathcal{H} \subseteq \mathcal{Y}^{\mathcal{X}}$. Then, given a collection of samples $\mathcal{S} = (\boldsymbol{x}_i, c(\boldsymbol{x}_i))_{i=1}^{N_1}$where $\boldsymbol{x}_i \sim p(\boldsymbol{x})$, a learning algorithm selects a hypothesis $h \in \mathcal{H}$ such that the difference between $h(\boldsymbol{x})$ and the corresponding label $y = c(\boldsymbol{x})$ is low under some performance measure.

The *probabilistic concept* (p-concept) and the p-concept class are defined in a similar fashion.

Definition 1 (p-concept)**.** *Let $P_{\boldsymbol{x}}(\mathcal{Y})$ be a conditional probability distribution over the label space $\mathcal{Y}$, with probability density specified as $p(y|\boldsymbol{x})$ for each input $\boldsymbol{x} \in \mathcal{X}$.*

We call p-concept *a function* $c : \mathcal{X} \to \mathcal{Y}$ *defined as the conditional expectation value of* y *given* $\boldsymbol{x}$ *arising from* p*:*

$$c : \mathcal{X} \to \mathcal{Y} \tag{1}$$

$$\boldsymbol{x} \mapsto c(\boldsymbol{x}) = \mathbb{E}_{y\sim p(y|\boldsymbol{x})}[y]. \tag{2}$$

Definition 2 (p-concept class)**.** *Let* $\mathcal{P} \subseteq \{P_{\boldsymbol{x}}(\mathcal{Y})\}$ *be a subset of all conditional probability distributions over the label space. For each distribution* $P_{\boldsymbol{x}}(\mathcal{Y}) \in \mathcal{P}$*, which specifies the conditional distribution* $p(y|\boldsymbol{x})$ *of* y *given* $\boldsymbol{x}$*, the corresponding* p*-concept is defined as per Definition 1. Then, a* p-concept class *is the class of functions* $\mathcal{C}$ *that corresponds to all functions arising from the set* $\mathcal{P}$ *of probability distributions:*

$$\mathcal{C} := \{c : \boldsymbol{x} \mapsto \mathbb{E}_{y\sim p(y|\boldsymbol{x})}[y] \,|\, P_{\boldsymbol{x}}(\mathcal{Y}) \in \mathcal{P}\}. \tag{3}$$

Noteworthy is that defining this concept class explicitly from a set of conditional distributions does not impose any limitations on what these functions can be. For any function $f \in \mathcal{Y}^{\mathcal{X}}$, one can always interpret it as a p-concept in an infinite number of ways. For instance, one could consider simply the probability distribution that always returns the value of the function $p(y|\boldsymbol{x}) = \delta(y - f(\boldsymbol{x}))$[2]. Alternatively, one could consider any random function $\xi(\boldsymbol{x})$ with zero mean $\mathbb{E}[\xi(\boldsymbol{x})] = 0$, and then one obtains a p-concept as the expectation value of the random function $f(\boldsymbol{x})+\xi(\boldsymbol{x})$. Indeed, there are infinitely many different probability distributions that give rise to the same p-concept class[3]. Nonetheless, some of these distributions can be generated via physically realizable processes, which are the focus of this work.

Contrasting with the deterministic learning setting, in the p-concept learning setting, the samples $(\boldsymbol{x}, y)$ are obtained by sampling the joint distribution $\mathcal{D} = p(\boldsymbol{x})p(y|\boldsymbol{x})$ with $c(\boldsymbol{x}) = \mathbb{E}_{y\sim p(y|\boldsymbol{x})}[y]$. In this work, we further consider a flexible setting that allows for access to $p(y|\boldsymbol{x})$. That is, given a data point $\boldsymbol{x}$, we can obtain multiple i.i.d. random labels from $p(y|\boldsymbol{x})$, e.g., $y_1, \dots, y_{N_s} \sim p(y|\boldsymbol{x})$, and use these labels to estimate the empirical mean of the random labels $\bar{y}_{N_s} = \frac{1}{N_s}\sum_{i=1}^{N_s} y_i$. Such sampling then averaging procedure can be directly modelled as the sampling process $(\boldsymbol{x}, \bar{y}_{N_s}) \sim \bar{\mathcal{D}}_{N_s} = p(\boldsymbol{x})p(\bar{y}_{N_s}|\boldsymbol{x})$ where $\bar{y}_{N_s}$ is distributed with variance $\sigma^2_{\bar{y}_{N_s}|\boldsymbol{x}} = \sigma^2_{y|\boldsymbol{x}}/N_s$ and $\sigma^2_{y|\boldsymbol{x}} = \mathrm{Var}_{y\sim p(y|\boldsymbol{x}_i)}[y]$. By construction, for all $N_s \in \mathbb{N}$, $p(\bar{y}_{N_s}|\boldsymbol{x})$ gives the same p-concept as $p(y|\boldsymbol{x})$, i.e.,

$$c(\boldsymbol{x}) = \mathbb{E}_{y\sim p(y|\boldsymbol{x})}[y] = \mathbb{E}_{\bar{y}_{N_s}\sim p(\bar{y}_{N_s}|\boldsymbol{x})}[\bar{y}_{N_s}]. \tag{4}$$

For ease of notation, we let $c(\boldsymbol{x}) := \mathbb{E}_{\bar{y}_{N_s}}[\bar{y}_{N_s}|\boldsymbol{x}]$ and implicitly assume the dependence of $\bar{y}_{N_s}$ and $\bar{\mathcal{D}}_{N_s}$ on N_s, and denote them as $\bar{y}$ and $\bar{\mathcal{D}}$, respectively.

In the p-concept learning setting, a learning algorithm similarly select a hypothesis h from a hypothesis class $\mathcal{H}$ such that the difference between $h(\boldsymbol{x})$ and the corresponding p-concept $c(\boldsymbol{x})$ is low under some performance measure. Here, we define two different performance measures: explicit and implicit loss. In particular, the explicit loss of h is defined as

$$\ell_{\mathrm{expl}}(h) = (h(\boldsymbol{x}) - c(\boldsymbol{x}))^2 \tag{5}$$

while the implicit loss of h is defined as

$$\ell_{\mathrm{impl}}(h) = (h(\boldsymbol{x}) - \bar{y})^2. \tag{6}$$

That is, the explicit loss directly measures the performance of h concerning the target p-concept $c(\boldsymbol{x})$, while the implicit loss indirectly quantifies the differences between $h(\boldsymbol{x})$ and $c(\boldsymbol{x})$ through the noisy labels $\bar{y}$ as $c(\boldsymbol{x}) = \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]$. Averaging both losses over all data points yields their respective risks: explicit risk

$$R_{\mathrm{expl}}(h) := \mathop{\mathbb{E}}_{(\boldsymbol{x},\bar{y})\sim\bar{\mathcal{D}}}[(h(\boldsymbol{x}) - c(\boldsymbol{x}))^2] \tag{7}$$

and implicit risk

$$R_{\mathrm{impl}}(h) := \mathop{\mathbb{E}}_{(\boldsymbol{x},\bar{y})\sim\bar{\mathcal{D}}}[(h(\boldsymbol{x}) - \bar{y})^2]. \tag{8}$$

The decomposition of $R_{\mathrm{impl}}(h)$, i.e.,

$$R_{\mathrm{impl}}(h) = R_{\mathrm{expl}}(h) + \mathop{\mathbb{E}}_{(\boldsymbol{x},\bar{y})\sim\bar{\mathcal{D}}}[(\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}] - \bar{y})^2] \tag{9}$$

$$= R_{\mathrm{expl}}(h) + R_{\mathrm{impl}}(\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]), \tag{10}$$

shows that the implicit and explicit risks are related by a constant shift. Hence, a small $R_{\mathrm{impl}}(h)$ implies a small $R_{\mathrm{expl}}(h)$ and vice versa.

In practice, the distribution $\bar{\mathcal{D}}$ and the exact p-concept $c(\boldsymbol{x})$ are inaccessible as we only have access to finite samples drawn from the distribution $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$ with $(\boldsymbol{x}_i, \bar{y}_i) \sim \bar{\mathcal{D}}$ and $c(\boldsymbol{x}) = \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]$. Therefore, instead of minimizing the implicit or explicit risks, we will minimize the empirical (implicit) risk

$$\widehat{R}(h) := \frac{1}{N_1}\sum_{i=1}^{N_1}(h(\boldsymbol{x}_i) - \bar{y}_i)^2. \tag{11}$$

using samples $\mathcal{S}$ to obtain the optimal hypothesis that well approximates the underlying p-concept rather than the noisy label. That is, we aim to achieve low R_{expl} by minimizing $\widehat{R}$. Note that we have provide a glossary of error definitions in Table I for ease of reference.

There is nothing that formally distinguishes a p-concept from a "regular" concept in the probably approximately correct (PAC) framework [16, 17]. Instead, the role of the probability distribution only comes forward when we talk about the learnability of such concepts.

[2] In this case, the p-concepts reduce to the "regular" concepts defined in Ref. [17].

[3] The original definition of p-concepts given by Kearns and Schapire [16] is simply a generalization of *concepts* in PAC learning [17] in terms of the function range, while the actual probabilistic component is defined with the learnability of p-concept classes. Here we take a slightly different approach and define p-concepts such that the element of probability is captured within the definition of p-concepts itself.

Name	Notation	Definition
Explicit loss	$\ell_{\text{expl}}(h)$	$(h(\boldsymbol{x}) - c(\boldsymbol{x}))^2$
Implicit loss	$\ell_{\text{impl}}(h)$	$(h(\boldsymbol{x}) - \bar{y})^2$
Explicit risk	$R_{\text{expl}}(h)$	$\mathbb{E}_{(\boldsymbol{x},\bar{y})\sim\bar{\mathcal{D}}}[(h(\boldsymbol{x})-c(\boldsymbol{x}))^2]$
Implicit risk	$R_{\text{impl}}(h)$	$\mathbb{E}_{(\boldsymbol{x},\bar{y})\sim\bar{\mathcal{D}}}[(h(\boldsymbol{x}) - \bar{y})^2]$
Empirical risk	$\widehat{R}(h)$	$\frac{1}{N_1}\sum_{i=1}^{N_1}(h(\boldsymbol{x}_i) - \bar{y}_i)^2$

TABLE I. Glossary of error terms used in our paper. Explicit (implicit) loss and risk are associated with the p-concept $c(\boldsymbol{x})$ (noisy labels $\bar{y}$), while the empirical risk is the empirical version of the *implicit* risk. We have subsumed the subscript in the empirical risk for ease of notation.

Definition 3 (p-concept learning)**.** *Let $N_s \in \mathbb{N}$ be the number of random labels (per data input) and $\mathcal{P} = \{p(\bar{y}|\boldsymbol{x})\}$ be a set of conditional probability distributions over $\mathcal{Y}$ associated with a p-concept class*

$$\mathcal{C} := \{c : \boldsymbol{x} \mapsto \mathbb{E}_{\bar{y}\sim p(\bar{y}|\boldsymbol{x})}[\bar{y}] \,|\, p(\bar{y}|\boldsymbol{x}) \in \mathcal{P}\}. \tag{12}$$

We say $\mathcal{C}$ is p-concept learnable *if there exists an algorithm $\mathcal{A}$ such that:*

1. *for any error tolerance ε and success probability δ,*
2. *for any conditional distribution $p(\bar{y}|\boldsymbol{x}) \in \mathcal{P}$ and corresponding p-concept $c \in \mathcal{C}$ in the class, and*
3. *for any probability distribution $p(\boldsymbol{x})$,*

the learning algorithm $\mathcal{A}$, when given as input a training set $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$, where $(\boldsymbol{x}_i)_{i=1}^{N_1} \sim D^{N_1}$, and each $\bar{y}_i \sim p(\bar{y}|\boldsymbol{x})$, produces a hypothesis h fulfilling

$$\mathbb{P}\left(R_{\text{expl}}(h) \leq \varepsilon\right) \geq 1 - \delta, \tag{13}$$

where $R_{\text{expl}}(h)$ is the risk functional defined in Equation (7) and the probability is over both: the sampling of training sets $(\boldsymbol{x}_i)_{i=1}^{N_1}$ of size N_1 and the sampling of random labels $\bar{y}$ conditional on each $\boldsymbol{x}_i$.

Further, $\mathcal{C}$ is efficiently p-concept learnable *if $\mathcal{A}$ has runtime polynomial in $1/\varepsilon$, $1/\delta$, and $\sigma^2_{\bar{y}|\boldsymbol{x}}$, the conditional variance of $\bar{y}$ given $\boldsymbol{x}_i$ for each $i \in \{1, \dots, N_1\}$. (Runtime efficiency implies sample efficiency, runtime of $\mathcal{A}$ upperbounds N_1).*

When there is no uncertainty in the given label, the p-concept learning model will reduce to the PAC learning model [17]. This is captured in Definition 3 by letting $N_s \to \infty$, and in this regime, we have $R_{\text{impl}}(\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]) = 0$ hence $R_{\text{expl}}(h) = R_{\text{impl}}(h)$.

1. Hypothesis class for modelling probabilistic concepts

To model the p-concepts, we consider the following hypothesis class

$$\mathcal{H} = \left\{h(\boldsymbol{x}) = u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle)\,;\, \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x}) \in \mathbb{R}^p\right\}, \tag{14}$$

where $u : \mathbb{R} \to \mathcal{Y}$ is an L-Lipschitz function that matches the label space $\mathcal{Y}$, $\boldsymbol{w}$ are weight vectors with bounded 2-norm $\|\boldsymbol{w}\|_2 \leq B$ and $\boldsymbol{\phi} : \mathbb{R}^m \to \mathbb{R}^p$ is the feature map that maps $\boldsymbol{x}$ to a higher dimensional feature space with $p > m$ and $\|\phi(\boldsymbol{x})\|_2 \leq 1$, and $\langle\cdot\,,\cdot\rangle$ is the usual inner product. This hypothesis class consists of two components (i) the feature map $\boldsymbol{\phi}(\boldsymbol{x})$ and (ii) the link function u, each serving different roles.

The feature map dictates the class of realizable functions and given two feature vectors $\boldsymbol{\phi}(\boldsymbol{x}), \boldsymbol{\phi}(\boldsymbol{x}')$, their inner product is equal to the kernel function

$$k(\boldsymbol{x}, \boldsymbol{x}') = \langle \boldsymbol{\phi}(\boldsymbol{x}), \boldsymbol{\phi}(\boldsymbol{x}')\rangle. \tag{15}$$

Interestingly, one could express the same class of functions in terms of the kernel. Computing the kernel function $k(\boldsymbol{x}, \boldsymbol{x}')$ directly without explicitly evaluating the feature vectors and their inner products is known as the kernel trick. Note that $\mathcal{H}$ reduces to the typical kernel machines when u is set to be the identity function.

The function u, on the other hand, provides us extra flexibility to incorporate the information about the p-concepts. As discussed, one does not necessarily have access to the exact p-concept $c(\boldsymbol{x})$ but rather to the samples $(\boldsymbol{x}, \bar{y}) \sim \bar{\mathcal{D}} = p(\boldsymbol{x})p(\bar{y}|\boldsymbol{x})$. Direct optimizing kernel machines with the empirical risk $\widehat{R}(\cdot)$ using the training samples $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$ yields

$$g(\boldsymbol{x}) = \sum_{i=1}^{N_1} a_i k(\boldsymbol{x}, \boldsymbol{x}_i). \tag{16}$$

However, this kernel-based model might be too expressive for p-concept modelling as it tends to overfit the noisy labels. Crucially, the link function u can be used to restrict the size of the model class, allowing us to suppress their tendency to overfit. For the sake of clarity, we will postpone the illustrations of the above-mentioned role of u to the latter sections as the examples could be more appropriately understood in the quantum context.

Now, we are ready to express the p-concepts in terms of the hypothesis class. That is,

$$\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}] = c(\boldsymbol{x}) = u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle + \xi(\boldsymbol{x})), \tag{17}$$

where $\xi(\boldsymbol{x}) \in [-M, M]$ is some noise function with $\mathbb{E}_{\boldsymbol{x}}[\xi(\boldsymbol{x})^2] \leq \epsilon_1$ that captures how well one can approximate p-concepts using hypotheses from $\mathcal{H}$. By the L-lipschitz property of u and $\mathbb{E}_{\boldsymbol{x}}[\xi(\boldsymbol{x})^2] \leq \epsilon_1$, we have

$$R_{\text{expl}}(h) = \mathbb{E}_{\bar{\mathcal{D}}}[(h(\boldsymbol{x}) - c(\boldsymbol{x}))^2] \leq L^2\epsilon_1. \tag{18}$$

That is, low ϵ_1 implies low approximation error of $c(\boldsymbol{x})$ using $h \in \mathcal{H}$. This approximation enables us to systematically reduce the learning task to the search of appropriate feature map $\boldsymbol{\phi}(\boldsymbol{x})$, the link function u and the design of efficient algorithms to learn the weight vector $\boldsymbol{w}$.

B. The family of parameterized quantum models

In this work, we are interested in learning a family of parameterized quantum models $f_{\boldsymbol{\theta}}(\boldsymbol{x})$

$$\mathcal{F} = \{f_{\boldsymbol{\theta}}(\boldsymbol{x}) = \mathrm{tr}(\rho_{\boldsymbol{\theta}}(\boldsymbol{x})O) \,|\, \boldsymbol{\theta} \in \Theta\}\,. \tag{19}$$

where $\rho_{\boldsymbol{\theta}}(\boldsymbol{x})$ are parameterized quantum states with parameters $\boldsymbol{\theta} \in \Theta = \mathbb{R}^r$ and input data $\boldsymbol{x} \in \mathcal{X} = \mathbb{R}^m$ while O is an arbitrary Hermitian observable. The quantum states $\rho_{\boldsymbol{\theta}}(\boldsymbol{x}) = \mathcal{M}_{\boldsymbol{\theta},\boldsymbol{x}}(\rho_0)$ could be prepared by applying parameterized quantum channels $\mathcal{M}_{\boldsymbol{\theta},\boldsymbol{x}}(\cdot)$ on some initial state ρ_0. In particular, we will focus on specific quantum channels that are generated by parameterized quantum circuits (PQCs). We remark that our analysis can be directly extended to other quantum channels including ground state preparation channels [9–11].

1. PQCs and their classical Fourier representations

Let $\boldsymbol{x} = (x_1, \ldots, x_m) \in \mathcal{X} = [0, 2\pi)^m$ be a vector of data points, $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_m) \in \Theta = [0, 2\pi)^r$ be a vector of parameters, $U(\boldsymbol{x}, \boldsymbol{\theta})$ be the unitary that represents the PQCs, $|\mathbf{0}\rangle = |0\rangle^{\otimes n}$ and O be an arbitrary Hermitian observable. We define the PQC model as

$$f_{\boldsymbol{\theta}}(\boldsymbol{x}) = \langle \mathbf{0}| \, U^\dagger(\boldsymbol{x}, \boldsymbol{\theta}) O U(\boldsymbol{x}, \boldsymbol{\theta}) \, |\mathbf{0}\rangle\,. \tag{20}$$

For a given $U(\cdot, \boldsymbol{\theta})$ and O, we define the PQC model class $\mathcal{F}_{U,O}$ as

$$\mathcal{F}_{U,O} = \left\{ f_{\boldsymbol{\theta}}(\cdot) = \langle \mathbf{0}| \, U^\dagger(\cdot, \boldsymbol{\theta}) O U(\cdot, \boldsymbol{\theta}) \, |\mathbf{0}\rangle \ \middle|\ \boldsymbol{\theta} \in \Theta \right\} \tag{21}$$

for all $\boldsymbol{x} \in \mathcal{X}$.

The parameterized unitary $U(\boldsymbol{x}, \boldsymbol{\theta})$ consists of a sequence of two different types of parameterized quantum gates. The first type of parameterized quantum gates is controlled by parameters $\boldsymbol{\theta}$, while the second type embeds data points x_i into the PQCs via unitary evolution

$$V_{(j,k)}(x_j) = e^{-iH_k^{(j)} x_j}, \tag{22}$$

generated by some Hamiltonian $H_k^{(j)}$. Given this parameterization strategy, it is well-known that PQC models could be written as a Fourier series[4] [29, 30]

$$f_{\boldsymbol{\theta}}(\boldsymbol{x}) = \sum_{\boldsymbol{\omega} \in \tilde{\Omega}} c_{\boldsymbol{\omega}}(\boldsymbol{\theta}) e^{i\langle \boldsymbol{\omega}, \boldsymbol{x}\rangle}, \tag{23}$$

where the frequency spectrum $\tilde{\Omega}$ is determined by the ensemble of eigenvalues of embedding Hamiltonian $\{H_k^{(j)}\}_{j,k}$ and the coefficients $c_{\boldsymbol{\omega}}(\boldsymbol{\theta})$ depend on the quantum gates parameterized by $\boldsymbol{\theta}$.

Equation (23) can be further simplified by noting that the non-zero frequencies in $\tilde{\Omega}$ come in pairs, i.e., $\boldsymbol{\omega}, -\boldsymbol{\omega} \in \tilde{\Omega}$, allowing us to split $\tilde{\Omega}$ into two components. That is, $\tilde{\Omega} := \Omega \cup (-\Omega)$ with $\Omega \cap (-\Omega) = \{\boldsymbol{\omega}_0\}$, where $\boldsymbol{\omega}_0 = (0, \ldots, 0) \in \tilde{\Omega}$ is the vector of zero frequencies. Let $\Omega = \{\boldsymbol{\omega}_0, \boldsymbol{\omega}_1, \ldots, \boldsymbol{\omega}_{|\Omega|}\}$ and for all $\boldsymbol{\omega} \in \Omega \backslash \{\boldsymbol{\omega}_0\}$, we have

$$a_{\boldsymbol{\omega}}(\boldsymbol{\theta}) := c_{\boldsymbol{\omega}}(\boldsymbol{\theta}) + c_{-\boldsymbol{\omega}}(\boldsymbol{\theta}) \tag{24}$$

$$b_{\boldsymbol{\omega}}(\boldsymbol{\theta}) := i(c_{\boldsymbol{\omega}}(\boldsymbol{\theta}) - c_{-\boldsymbol{\omega}}(\boldsymbol{\theta})). \tag{25}$$

Given this definition, Equation (23) can be equivalently written as

$$f_{\boldsymbol{\theta}}(\boldsymbol{x}) = c_{\boldsymbol{\omega}_0}(\boldsymbol{\theta}) + \sum_{i=1}^{|\Omega|-1} (a_{\boldsymbol{\omega}_i}(\boldsymbol{\theta}) \cos(\langle \boldsymbol{\omega}_i, \boldsymbol{x}\rangle) + b_{\boldsymbol{\omega}_i}(\boldsymbol{\theta}) \sin(\langle \boldsymbol{\omega}_i, \boldsymbol{x}\rangle)) \tag{26}$$

Identifying the corresponding weight vectors $\boldsymbol{w}$

$$\boldsymbol{w}_F(\boldsymbol{\theta}) = \sqrt{|\Omega|} \begin{pmatrix} c_{\boldsymbol{\omega}_0}(\boldsymbol{\theta}) \\ a_{\boldsymbol{\omega}_1}(\boldsymbol{\theta}) \\ b_{\boldsymbol{\omega}_1}(\boldsymbol{\theta}) \\ \vdots \\ a_{\boldsymbol{\omega}_{|\Omega|-1}}(\boldsymbol{\theta}) \\ b_{\boldsymbol{\omega}_{|\Omega|-1}}(\boldsymbol{\theta}) \end{pmatrix}^{\mathsf{T}} \tag{27}$$

and the trigonometric polynomial feature map

$$\boldsymbol{\phi}_F(\boldsymbol{x}) = \frac{1}{\sqrt{|\Omega|}} \begin{pmatrix} 1 \\ \cos(\langle \boldsymbol{\omega}_1, \boldsymbol{x}\rangle) \\ \sin(\langle \boldsymbol{\omega}_1, \boldsymbol{x}\rangle) \\ \vdots \\ \cos\left(\langle \boldsymbol{\omega}_{|\Omega|-1}, \boldsymbol{x}\rangle\right) \\ \sin\left(\langle \boldsymbol{\omega}_{|\Omega|-1}, \boldsymbol{x}\rangle\right) \end{pmatrix} \tag{28}$$

enables us to express the PQC model as a linear model with respect to the feature map $\boldsymbol{\phi}_F$, i.e.,

$$f_{\boldsymbol{\theta}}(\boldsymbol{x}) = \langle \boldsymbol{w}_F(\boldsymbol{\theta}), \boldsymbol{\phi}_F(\boldsymbol{x})\rangle, \tag{29}$$

and the associated kernel function is given by $k_F(\boldsymbol{x}, \boldsymbol{x}') = \langle \boldsymbol{\phi}_F(\boldsymbol{x}), \boldsymbol{\phi}_F(\boldsymbol{x}')\rangle$.

2. Data extraction from parameterized quantum models

In general, one does not have direct access to $f_{\boldsymbol{\theta}}(\boldsymbol{x})$. Instead, they are estimated using finite samples from measurement procedures such as direct measurement or classical shadow methods, as described in Appendix A. We denote outputs of such estimation procedures as $\bar{y}$ and their dependency on the data point $\boldsymbol{x}$, parameter $\boldsymbol{\theta}$, and the number of measurement shots N_s are implicitly assumed. In addition, they are unbiased estimators of $f_{\boldsymbol{\theta}}(\boldsymbol{x})$, i.e.,

$$f_{\boldsymbol{\theta}}(\boldsymbol{x}) = \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}, \boldsymbol{\theta}]. \tag{30}$$

[4] The Fourier expansion in this work mainly follows the treatment in Ref. [25, 26] but equivalent Fourier representation of PQC models can be obtained by other Fourier expansion methods [27, 28]

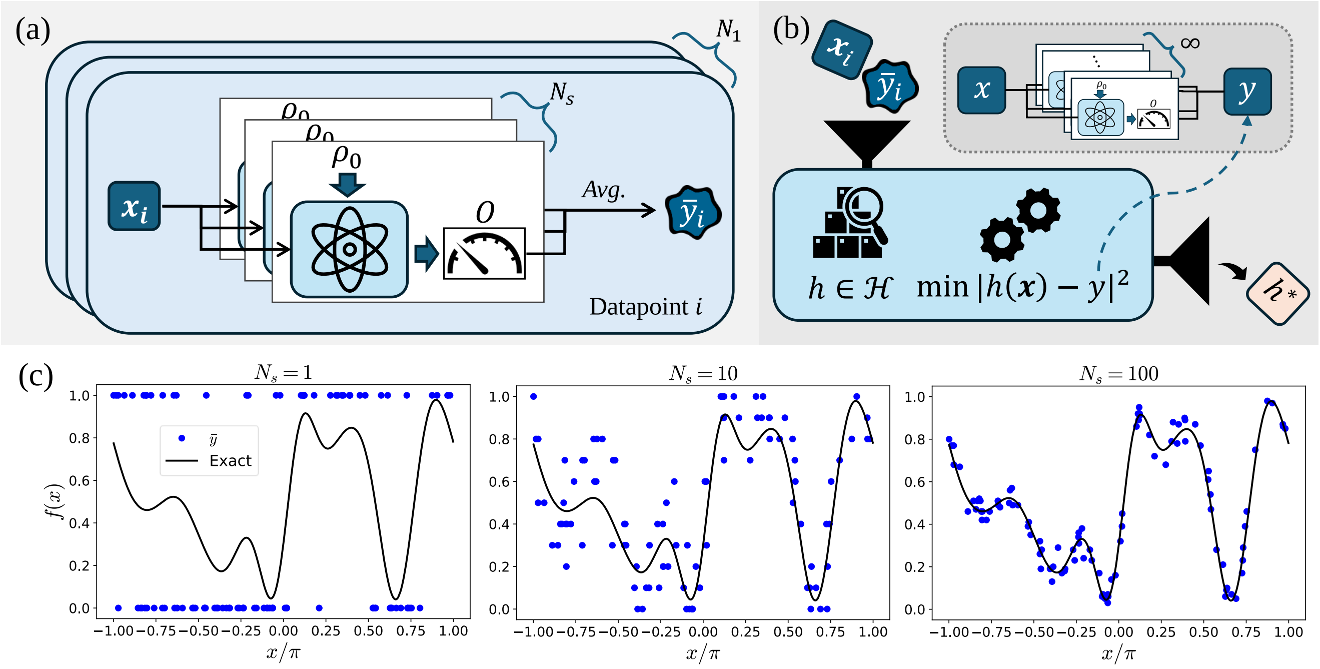

FIG. 2. Concept learning of parameterized quantum models. (a) To learn quantum models, one needs to probe the quantum model with N different input data points $\boldsymbol{x}$, and construct an estimator of the quantum model $y = f(\boldsymbol{x})$ conditioned on the input. Such estimators $\bar{y}$ can be constructed by taking the average over N_s duplicate quantum measurements. (b) Using data pairs $(\boldsymbol{x}_i, \bar{y}_i)$ collected from the quantum model, the task is to classically learn a representation h^* of the quantum model such that the output of classical representation $h(\boldsymbol{x})$ is close to the underlying expected output $y = f(\boldsymbol{x})$ of the quantum model for any arbitrary $\boldsymbol{x}$. As illustrated in (c), the number of measurement shots N_S will determine the closeness between the estimator $\bar{y}$ (blue dots) and the underlying expected value $f(x)$ (black solid line).

For ease of notation, we will drop the conditional dependency of the expectation on $\boldsymbol{\theta}$ from now on.

Now, we describe the procedures for obtaining labelled data points from a given $f_{\boldsymbol{\theta}}$. Without loss of generality, we let $p(\boldsymbol{x})$ be a uniform distribution of input $\boldsymbol{x}$. As depicted in Figure 2 (a), a set of N i.i.d. samples of $\boldsymbol{x}$ is first drawn from $p(\boldsymbol{x})$ and subsequently input to the quantum model to collect their associated labels $\bar{y}$ via the procedures described in Appendix A using N_s measurement repetitions. This gives the set of data $\mathcal{S} = \{\boldsymbol{x}_i, \bar{y}_i\}_{i=1}^{N}$. Shown in Figure 2 (c) are the labels $\bar{y}$ estimated with $N_s = 1, 10, 100$.

III. PARAMETERIZED QUANTUM MODELS AS PROBABILISTIC CONCEPTS

One can immediately deduce from Equation (30) that parameterized quantum models (PQMs) are p-concepts. Now, we will show that the hypothesis class defined in Section II A 1 is an appropriate model class for the learning of PQMs. Modelling PQMs using the hypothesis from $\mathcal{H}$, as defined in Equation (14), assumes the following: there exist a feature map $\boldsymbol{\phi}(\boldsymbol{x})$, a function u, a weight vector $\boldsymbol{w}$, and a noise function $\xi(\boldsymbol{x})$ such that the PQMs

Algorithm 1: The learning algorithm

```
Input: Labelled training data $\{(\boldsymbol{x}_i, \bar{y}_i)\}_{i=1}^{N_1} \in \mathcal{X} \times \mathcal{Y}$,
       non-decreasing $L$-Lipschitz function
       $u : \mathbb{R} \to \mathcal{Y}$, kernel function $k$ corresponding to
       feature map $\boldsymbol{\phi}$, learning rate $\lambda > 0$, number of
       iterations $T$, labelled held-out data of size $N_2$
       $\{(\boldsymbol{p}_j, \bar{q}_j)\}_{j=1}^{N_2} \in \mathcal{X} \times \mathcal{Y}$
$\alpha^i := 0 \in \mathbb{R}^{N_1}$
for $t = 1, \ldots, T$ do
    $h^t(\boldsymbol{x}) := u\left(\sum_{i=1}^{N_1} \alpha_i^t k(\boldsymbol{x}, \boldsymbol{x}_i)\right)$
    for $i = 1, 2, \ldots, N_1$ do
        $\alpha_i^{t+1} := \alpha_i^t + \frac{\lambda}{N_1}(\bar{y}_i - h^t(\boldsymbol{x}_i))$
Output: $h^r$ where
        $r = \arg\min_{t \in \{1,\ldots,T\}} \frac{1}{N_2} \sum_{j=1}^{N_2} (\bar{q}_j - h^t(\boldsymbol{p}_j))^2$
```

can be expressed as

$$\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}] = \mathrm{tr}(\rho_{\boldsymbol{\theta}}(\boldsymbol{x})O) = u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle + \xi(\boldsymbol{x})), \qquad (31)$$

with $||\boldsymbol{w}||_2 \le B$, $\xi(\boldsymbol{x}) \in [-M, M]$, and $\mathbb{E}_{\boldsymbol{x}}[\xi(\boldsymbol{x})^2] \le \epsilon_1$. Hence, the aim here is to find an appropriate function u that contains information on the PQM as well as construct the feature map $\boldsymbol{\phi}(\boldsymbol{x})$ that efficiently approximates a PQM.

A. Algorithm for concept learning of parameterized quantum models

By expressing the PQMs in terms of the hypothesis in $\mathcal{H}$, we systematically reduce the modelling problem to the search of the appropriate feature map $\boldsymbol{\phi}(\boldsymbol{x})$, link function u, and optimal weight $\boldsymbol{w}^*$. As the first two attributes are highly dependent on the problem at hand, we will defer their discussion to Section IV. In this section, we will assume $\boldsymbol{\phi}(\boldsymbol{x})$ and u are known and focus on the algorithm part of the problem.

Consider a PQM $\mathrm{tr}(\rho(\boldsymbol{x})O)$ that can be approximated by a feature map $\boldsymbol{\phi}(\boldsymbol{x})$ and a known L-Lipschitz non-decreasing function $u : \mathbb{R} \to \mathcal{Y}$, as per Equation (31). The task of learning PQMs could be formulated as the search of the optimal weight vector $\boldsymbol{w}^*$ such that the output hypothesis $h^*(\boldsymbol{x}) = u(\langle \boldsymbol{w}^*, \boldsymbol{\phi}(\boldsymbol{x})\rangle)$ minimizes the explicit risk

$$R_{\mathrm{expl}}(h^*) = \mathbb{E}_{\bar{\mathcal{D}}}[(u(\langle \boldsymbol{w}^*, \boldsymbol{\phi}(\boldsymbol{x})\rangle) - \mathrm{tr}(\rho(\boldsymbol{x})O))^2]. \quad (32)$$

As discussed in Section II A, we will only have access to finite samples drawn from the distribution $\bar{\mathcal{D}}$. Hence, we will be minimizing the empirical risk $\widehat{R}(h)$ in Equation (11) using some training samples $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$ with $(\boldsymbol{x}_i, \bar{y}_i) \sim \bar{\mathcal{D}}$ instead of $R_{\mathrm{expl}}(h)$. Note that the extra u in the empirical risk makes the optimization non-convex. As detailed in Figure 2 (b), while the classical machine learns from a noisy dataset consisting of shot noise from quantum measurements, our objective is to enable the classical machine to approximate the underlying p-concept of the PQM, i.e., the expected value of the measured outcomes of PQMs.

Shown in Algorithm 1 is an iterative-based method that learns PQMs under some mild assumptions. While our algorithm is derived from the iterative method in Ref. [31], we extended the provable guarantee of the original algorithm to include the number of measurement shots N_s used to estimate $\bar{y}$ and show its operational role in the algorithm. The analytical guarantee enables us to understand the contributions of errors and the intuitive explanation of the working principle of Algorithm 1 is provided in Appendix B 1.

Theorem 1 (p-concept learnability of PQMs). *We are given a quantum observable O such that $\|O\|_\infty = \Delta$. With this observable, we have quantum model whose expected output can be expressed as a classical representation as follows: $\mathrm{tr}(\rho(\boldsymbol{x})O) = u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle + \xi(\boldsymbol{x}))$, where $u : \mathbb{R} \to [-\Delta, \Delta]$ is a known L-Lipschitz non-decreasing function, $\xi : \mathbb{R}^m \to [-M, M]$ such that $\mathbb{E}_{\boldsymbol{x}}[\xi(\boldsymbol{x})^2] \leq \epsilon_1$, $\|\boldsymbol{w}\|_2 \leq B$, and $\|\phi(\boldsymbol{x})\|_2 \leq 1$. Considering a training dataset of N_1 i.i.d. samples of $\boldsymbol{x}$ as input to the quantum model, and whose label is the sample mean of the output of the quantum model sampled over N_s measurements. Let the conditional variance of an individual measurement averaged over all $\boldsymbol{x}$ be $\bar{\sigma}$. For $\delta \in (0, 1)$, with probability $1-\delta$, setting the learning rate $\lambda = \frac{1}{L}$ and given a validation dataset size of $N_2 = \mathcal{O}(N_1 \Delta^2 \log(\frac{T}{\delta}))$, after $T = \mathcal{O}(\frac{BL}{\epsilon_4})$ iterations, Algorithm 1 outputs a hypothesis $h \in \mathcal{H}$ such that*

$$R_{\mathrm{expl}}(h) \leq \mathcal{O}(L\Delta\sqrt{\epsilon_1} + L\Delta M \epsilon_2 + LB\Delta\epsilon_3 + LB\epsilon_4 + \Delta^2\epsilon_5), \quad (33)$$

where $\epsilon_2 = \sqrt[4]{\frac{\log(\frac{1}{\delta})}{N_1}}$, $\epsilon_3 = \sqrt{\frac{1}{N_1}}$, $\epsilon_4 = \sqrt{\frac{\bar{\sigma}\log(\frac{1}{\delta})}{N_1 N_s}}$, $\epsilon_5 = \sqrt{\frac{\log(\frac{1}{\delta})}{N_1}}$, and $\bar{\sigma} = \mathbb{E}_{\boldsymbol{x}}[\sigma^2_{y|\boldsymbol{x}}]$.

The proof of this theorem can be found in Appendix B 2. As shown in Equation (33), four different error sources will affect the performance of the models: (i) the approximation error ϵ_1, (ii) the data sampling errors ϵ_2 and ϵ_5, (iii) the learnability error ϵ_3, and (iv) the label sampling error ϵ_4. Firstly, the approximation error ϵ_1 captures the intrinsic error that can be achieved by our hypothesis class as it tells us how far away our hypothesis $h(\boldsymbol{x})$ is from the true function $\mathrm{tr}(\rho(\boldsymbol{x})O)$ we wish to learn, i.e., $\mathbb{E}_{\boldsymbol{x}}[\xi(\boldsymbol{x})^2] \leq \epsilon_1$. It is therefore impossible to obtain a small risk if the approximation error is high to begin with. On the other hand, the data sampling errors ϵ_2 and ϵ_5 capture the statistical noise arising from the finite data samples provided to the learning algorithm while the learnability error ϵ_3 stems from Rademacher complexity and quantifies the hardness of learning with the given hypothesis class. Both of these errors can be minimized by providing more data samples. Lastly, the label sampling error ϵ_4 is influenced by three attributes, the averaged variance $\mathbb{E}_{\boldsymbol{x}}[\sigma^2_{y|\boldsymbol{x}}]$, the number of training data points N_1, and the number of measurement shots N_s. Increasing either N_1 or N_s could reduce the label sampling error. Additionally, a measurement scheme that results in smaller variance will require fewer training data points and measurement shots to achieve a smaller ϵ_4 error.

B. Asymmetrical effects of N_1 and N_s

While the individual implications of all four types of errors are straightforward to deduce, jointly analysing the last three sources of error leads to an interesting observation regarding the asymmetrical effects of N_1 and N_s on classical learning of quantum models. On the one hand, increasing N_s can only decrease the label sampling error ϵ_4 but not the data sampling errors ϵ_2 and ϵ_5 and the learnability error ϵ_3. On the other hand, increasing N_1 will simultaneously decrease all three errors, and ϵ_4 approaches 0 regardless of the value of N_s. Consequently, one could set $N_s = 1$ when N_1 is sufficiently large. This observation aligns with intuition, as the labels are dependent on the parameters. By sampling across the training points, one effectively samples across various labels, thereby providing a reasonable estimation of quantum models. In contrast, increasing the resolution of the labels does not provide extra information on other data points. This observation is summarised in Corollary 1 and numerically illustrated in Figure 3 (a). For simplicity, we assume $\delta = 0.01$, and $\bar{\sigma} = L = B = \Delta = 1$.

Corollary 1 (Asymmetrical effects of N_1 and N_s)**.** *Let all variables defined as per Theorem 1. For the hypothesis class $\mathcal{H}$ with link function u, feature map $\boldsymbol{\phi}(\boldsymbol{x})$ and weight vector $\boldsymbol{w}$ with $\mathrm{tr}(\rho(\boldsymbol{x})O) = u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle) \in \mathcal{H}$, i.e., $\mathbb{E}_{\boldsymbol{x}}[\xi(\boldsymbol{x})^2] = 0$, Algorithm 1 will output a hypothesis $h \in \mathcal{H}$ such that*

$$R_{\mathrm{expl}}(h) \leq c_1\sqrt{\frac{1}{N_1}} + c_2\sqrt{\frac{1}{N_1 N_s}} + c_3\sqrt{\frac{1}{N_1}}, \tag{34}$$

where $c_1 = \mathcal{O}(LB\Delta)$, $c_2 = \mathcal{O}\left(LB\sqrt{\bar{\sigma}\log\left(\frac{1}{\delta}\right)}\right)$, $c_3 = \mathcal{O}\left(\Delta^2 \log\left(\frac{1}{\delta}\right)\right)$, and N_1 and N_s contribute asymmetrically to $R(h)$. That is, for a constant N_1, $R(h) \not\to 0$ when $N_s \to \infty$, but $R(h) \to 0$ when $N_1 \to \infty$ regardless of the value of N_s. Note that $\epsilon_1 = 0$ implies $M = 0$ by definition.

The overall analysis shows that for a sufficiently large N_1, classical models can learn quantum models that have efficient classical representation even when target labels are estimated with limited measurement shots, e.g., $N_s = 1$. Conversely, when such efficient classical representation cannot be found, $\mathrm{tr}(\rho(\boldsymbol{x})O)$ is not learnable even when N_1 and N_s are infinite. Corollary 1 further shows that N_s plays a less significant role than N_1 in the classical learning of quantum models. In other words, shot noise is not a fundamental concern in classical learning of quantum models as its role can be easily substituted by N_1.

C. Trade-offs between N_1 and N_s

In an ideal world, one would choose N_1 and N_s as large as possible to minimize the explicit risk. However, external constraints like financial budgets and time limitations might significantly restrict the total number of queries to a quantum model. Thus, a more realistic setting is to first consider a fixed number of queries to quantum models, and N_1 and N_s are subsequently decided.

In general, producing more samples for a fixed parameter setting in an experiment is much cheaper and faster than changing the parameter settings each time. Changing parameters incurs an additional cost that may stem from preprocessing subroutines, classical transpilation and optimization of the circuits or platform-dependent factors regarding the hardware we are executing the quantum circuits on. For example, the penalty cost for superconducting quantum computers would be larger than for trapped-ion quantum computers, as it is relatively cheaper to produce more samples for a fixed parameter set than to change the parameter setting each time in the former platform [32]. To quantify such costs for easier discussion, we assume that these costs can be quantitatively evaluated to be some multiple $\gamma \in \mathbb{R}_+$ of the cost to run a repetition of quantum circuits that have already been configured. That is, we assume changing the parameter setting once will incur extra cost of γ shots.

Considering the total measurement budget for training, we find that $N_{\mathrm{tot}} = N_1 \cdot (N_s + \gamma)$. Fixing the total measurement budget N_{tot} implies a trade-off between N_1 and N_s: increasing N_1 will reduce N_s and vice versa. This poses an interesting learning-theoretic question: *given a fixed N_{tot}, will classical machines learn better with training datasets consisting of more inputs/parameters with noisier labels (larger N_1 but smaller N_s) or fewer inputs with cleaner labels (smaller N_1 but larger N_s)?* As shown in Corollary 2, when N_1 and N_s are treated equally ($\gamma = 0$), asymptotically, it is generally better to sample more inputs, i.e., $(N_1^*, N_s^*) = (N_{tot}, 1)$. When there is an extra cost for changing the parameter settings, i.e., $\gamma > 0$, there exists a pair of optimal input size N_1^* and the shot number N_s^* that minimize the explicit risk. These observations are numerically illustrated in Figure 3 (b). For simplicity, we assume $\delta = 0.01$, and $\bar{\sigma} = L = B = \Delta = 1$.

Corollary 2 (Trade-off between N_1 and N_s)**.** *Consider the setting as per Corollary 1. For a given fix total measurement budget for training $N_{\mathrm{tot}} \in \mathbb{N}$ and a fix penalty cost $\gamma \in \mathbb{R}_+$, N_1 and N_s are determined by $N_{\mathrm{tot}} = N_1 \cdot (N_s + \gamma)$. Respecting this constraint, Algorithm 1 will output a hypothesis $h \in \mathcal{H}$ such that*

$$R_{\mathrm{expl}}(h) \leq c_1\sqrt{\frac{N_s + \gamma}{N_{\mathrm{tot}}}} + c_2\sqrt{\frac{N_s + \gamma}{N_{\mathrm{tot}} N_s}} + c_3\sqrt{\frac{N_s + \gamma}{N_{\mathrm{tot}}}}. \tag{35}$$

When $\gamma = 0$, the upper bound of the explicit risk $R_{\mathrm{expl}}(h)$ reduces to

$$R_{\mathrm{expl}}(h) \leq c_1\sqrt{\frac{N_s}{N_{\mathrm{tot}}}} + c_2\sqrt{\frac{1}{N_{\mathrm{tot}}}} + c_3\sqrt{\frac{N_s}{N_{\mathrm{tot}}}} \tag{36}$$

which is minimized when $N_s = 1$. When $\gamma > 0$, there exists a pair of optimal input data size and shot number (N_1^*, N_s^*) where

$$N_1^* = \frac{N_{tot}}{N_s^* + \gamma} \quad \textit{and} \quad N_s^* = \left(\frac{c_2 \gamma}{c_1 + c_3}\right)^{\frac{2}{3}} \tag{37}$$

that minimizes our upper bound of $R_{\mathrm{expl}}(h)$.

Note that the optimal value of N_s does not correlate with N_{tot}, but depends on the constant penalty cost γ. Hence, setting $N_s = 1$ regardless of the value of γ would only increase $R_{\mathrm{expl}}(h)$ by a factor of $\sqrt{1+\gamma}$, retaining learnability up to a constant factor for single measurement learning.

Taking a closer examination at N_s, we check whether other factors apart from the device-dependent cost γ affect the value of N_s. Delving into the definitions of the terms c_1, c_2, and c_3, we note that the terms L, Δ, and δ are constants that either depend on the problem setting or can be set arbitrarily. B, on the other hand, is directly

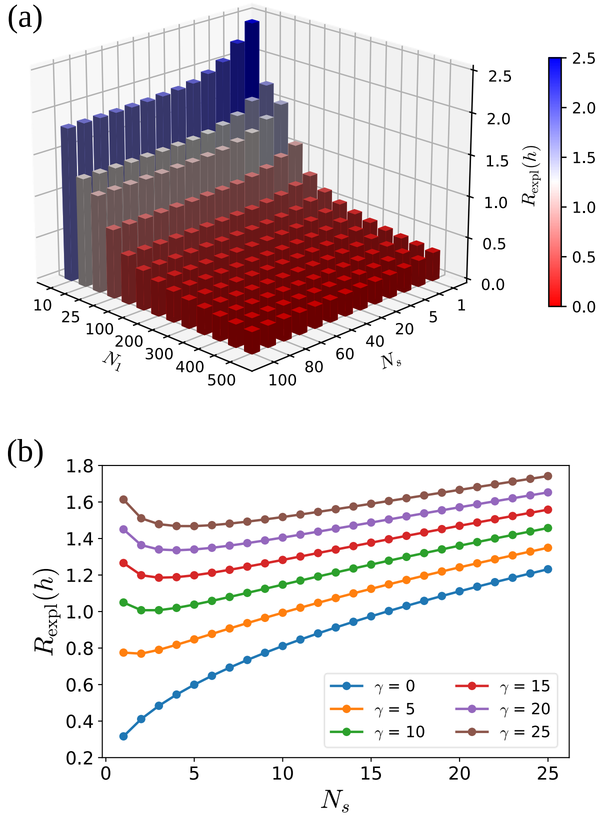

FIG. 3. The respective numerical illustrations of Corollary 1 and Corollary 2 with $\delta = 0.01$, and $\bar{\sigma} = L = B = \Delta = 1$. (a) The plot shows the asymmetrical effect of the number of training samples N_1 and the number of measurement shots N_s to the explicit risk $R_{\mathrm{expl}}(h)$. (b) For a fixed total measurement budget N_{tot}, the optimal pair of N_1 and N_s will change with γ. When $\gamma = 0$, the optimal shot number is $N_s = 1$ but it depends on γ when $\gamma > 0$. All curves are computed with $N_{tot} = 600$ and $N_s = \{1, 2, 3, \ldots, 24, 25\}$.

related to the expressibility of the hypothesis h used to model the quantum model. *Does the expressibility B of the hypothesis h affect the number of shots N_s required?*

Plugging in $c_1 = \mathcal{O}(B)$, $c_2 = \mathcal{O}(B)$, $c_3 = \mathcal{O}(1)$, we note that in terms of B, $N_s = \mathcal{O}\left(\frac{B}{B+K}\right)$, where K is a constant. While N_s is indeed dependent on B, its dependency can be upper bounded by a constant as $N_s \to \mathcal{O}(1)$ as B grows. Hence, even in cases where the expressibility of the hypothesis h we use to exactly model the quantum model scales exponentially, the number of shots required to sample each data is still limited to a constant value.

D. Shot-noise dependent bias-variance trade-off

An alternative framework for analyzing the occurrences of different error terms commonly seen in machine learning analysis is the bias-variance-noise decomposition. Here, we provide a summary with the full introduction deferred to Appendix C.

Optimizing the empirical risk $\widehat{R}(h)$ using different training datasets $\mathcal{S}$ would yield different trained models $h_{\mathcal{S}}(\boldsymbol{x})$. The bias then measures, on average, how much $h_{\mathcal{S}}$ deviates from the ground truth f

$$\mathbf{Bias}_{\mathcal{S}} := \mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - f(\boldsymbol{x}), \tag{38}$$

while the variance

$$\mathbf{Var}_{\mathcal{S}} := \mathbb{E}_{\mathcal{S}}\left[(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - h_{\mathcal{S}}(\boldsymbol{x}))^2\right] \tag{39}$$

measures the fluctuations among the trained models. As the expectation is taken over all possible training datasets of the same size, therefore, the bias and variance will be dependent on the complexity of the hypothesis class, the number of training data points N_1 and the number of random labels N_s.

The average of the explicit risk over all possible training datasets will then have the following decomposition, whose derivation is also found in Appendix C:

$$\mathbb{E}_{\mathcal{S}}[R_{\mathrm{expl}}(h_{\mathcal{S}})] = \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Bias}^2_{\mathcal{S}}\right] + \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Var}_{\mathcal{S}}\right]. \tag{40}$$

where

$$\mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Bias}^2_{\mathcal{S}}\right] := \mathbb{E}_{\boldsymbol{x}}\left[(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - f(\boldsymbol{x}))^2\right] \quad \text{and} \tag{41}$$

$$\mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Var}_{\mathcal{S}}\right] := \mathbb{E}_{\boldsymbol{x},\mathcal{S}}\left[(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - h_{\mathcal{S}}(\boldsymbol{x}))^2\right] \tag{42}$$

are the averaged bias squared and averaged variance, respectively. This decomposition shows that the shot noise has an indirect impact on the performance of classical machine learning models and this impact can be studied by analysing the statistical quantities $\mathbf{Bias}^2_{\mathcal{S}}$ and $\mathbf{Var}_{\mathcal{S}}$. Intuitively, high shot noise implies high variance in the labels, indirectly leading to high variance in the models, and further induces overfitting. We will provide a simple example in Section IV to illustrate how shot noise affects the bias-variance trade-off.

Equation (33) and Equation (40) appear to be unrelated to each other. On the one hand, the algorithm-specific Equation (33) gives a probabilistic guarantee on the performance of each trained model. On the other hand, the algorithm-agnostic Equation (40) provides an understanding of the average behaviour of the overall hypothesis class. One can however observe the similarities between the two by directly comparing Equation (33) and Equation (40). Specifically, the first term in Equation (33) can be understood as the bias of the models since it quantifies the asymptotic error that is achievable by the models while the second term captures the finite sampling noise of the bias; the other three terms inform on the variance of the model. Interestingly, the shot-noise dependent variance is captured by ϵ_4 and Figure 3 essentially captures the variance dependence on the number of training data points and number of measurement shots.

IV. CLASSICAL SURROGATES OF PQC MODELS AS PROBABILISTIC CONCEPTS

As a direct example, we apply our theoretical framework to create a classical surrogate of parameterized quantum circuit (PQC) models [8]. Treating PQC models as p-concepts enables us to study the impact of shot noise on constructing their corresponding classical surrogates. In particular, we observed asymmetrical effects from both the number of training data points and the number of measurement shots, as well as the potential for using a relatively small number of measurement shots to surrogate PQC models. As predicted by our theoretical analysis, the bias and variance of the classical surrogates are highly dependent on the strength of the shot noise. Finally, we highlight the role of the link function in our surrogate models in suppressing their variance in the presence of the shot noise.

We wish to emphasize that our work aims to provide a generic framework to analyse the learnability of PQMs in the presence of shot noise. Therefore, in this example, we will consider the feature map proposed in the literature [29, 30], but our framework is readily adaptable to future proposals of efficient feature maps. In addition, our results can be easily extended to other types of PQMs by replacing the quantum channel with appropriate substitutes.

A. Classical approximation of PQC models

In this section, we will briefly discuss the existing methods for approximating PQC models classically. As described in Section II B 1, PQC models can be written as $f_{\boldsymbol{\theta}}(\boldsymbol{x}) = \langle \boldsymbol{w}_F(\boldsymbol{\theta}), \boldsymbol{\phi}_F(\boldsymbol{x})\rangle$. Therefore, the immediate choice of feature map for modelling PQC models classically is the full trigonometric polynomial feature map $\boldsymbol{\phi}_F(\boldsymbol{x})$. However, the associated model class could be too expressive thus it might overfit the training data points [8]. In addition, the size of the frequency spectrum could be exponential in the data dimension, which becomes intractable for classical computers. Instead, one could hope to exploit some structure of the PQC to construct an efficient feature map $\boldsymbol{\phi}(\boldsymbol{x})$ to approximate the PQC models

$$\langle \mathbf{0}| U^\dagger(\boldsymbol{x},\boldsymbol{\theta}) O U(\boldsymbol{x},\boldsymbol{\theta}) |\mathbf{0}\rangle \approx \langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle. \tag{43}$$

According to our notation above, we would use the noise function $\xi(\boldsymbol{x})$ to refer to the approximation error $\xi(\boldsymbol{x}) = \langle \boldsymbol{w}_F, \boldsymbol{\phi}_F(\boldsymbol{x})\rangle - \langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle$. We drop the explicit $\boldsymbol{\theta}$ dependence of $\boldsymbol{w}_F$ and ξ for ease of notation.

One approach would be to construct $\boldsymbol{\phi}$ as a truncated version of $\boldsymbol{\phi}_F$. This would take advantage of the fact that the high-frequency components of PQC models that are subjected to Pauli noise [27] typically make smaller contributions than lower frequency terms. Thus, Fourier series with an appropriate level of truncation can be used to model PQC models without compromising much of the accuracy. This approach assumes that we know which components to truncate ahead of time, though, and that might be unrealistic for practical scenarios.

As an alternative, one can utilize a popular technique from machine learning called Random Fourier Features (RFF) [33], used to efficiently approximate the high-dimensional inner product $\langle \boldsymbol{w}_F(\boldsymbol{\theta}), \boldsymbol{\phi}_F(\boldsymbol{x})\rangle$ by randomly selecting only a few of its dominant terms [25, 26]. Using RFF amounts to performing a truncation of the Hilbert space, with the only difference being that the selection of components that are kept is probabilistic. RFF has been proposed as an approach to "dequantize" PQC-based quantum machine learning models by exploiting the efficient low-dimensional feature map $\boldsymbol{\phi}$ in Ref. [25]. On the other hand, Ref. [26] discusses the applicability of RFF in terms of which PQCs are likely to admit the efficient approximation. In both these references, the task is not to *learn* the classically efficient representation of the PQC but rather to show that a given downstream task can be learned efficiently classically, without ever running the PQC. Even though the specific task is not the same, we observe that the main limitation in learning quantum models comes from an efficient classical representation, which deeply aligns with the use of RFF. In Appendix D we formally discuss how the performance guarantees of RFF bring about learnability in the sense introduced in Sections II and III. Also, we wish to emphasize that the efficient classical representation of PQCs is still under active research, but our work could be directly adapted if efficient feature maps were found.

B. Modelling PQCs with and without link functions

In this section, we will discuss the operational role of the link function u in the surrogation of PQC models. Without loss of generality, we let $O = |\mathbf{0}\rangle\langle\mathbf{0}|$, hence we have

$$f_{\boldsymbol{\theta}}(\boldsymbol{x}) = |\langle \mathbf{0}| U(\boldsymbol{x},\boldsymbol{\theta}) |\mathbf{0}\rangle|^2 = \langle \boldsymbol{w}, \boldsymbol{\phi}_{\mathrm{RFF}}(\boldsymbol{x})\rangle + \xi(\boldsymbol{x}), \tag{44}$$

and $f_{\boldsymbol{\theta}}(\cdot) \in \mathcal{F}_{U,|\mathbf{0}\rangle\langle\mathbf{0}|}$. To model the probabilistic function $f_{\boldsymbol{\theta}}(\boldsymbol{x})$, we consider the following hypothesis class

$$\mathcal{H}_{\mathrm{RFF}} = \{h(\boldsymbol{x}) = u(\langle \boldsymbol{w}, \boldsymbol{\phi}_{\mathrm{RFF}}(\boldsymbol{x})\rangle), \|\boldsymbol{w}\|_2 \leq B\} \tag{45}$$

where u is the clipping function

$$u(x) = \begin{cases} 0, & x < 0 \\ x, & 0 \leq x \leq 1 \\ 1, & x > 1 \end{cases}, \tag{46}$$

a 1-Lipschitz function that enforces the matching of co-domains of the hypothesis class $\mathcal{H}$ and $|\langle \mathbf{0}| U(\boldsymbol{x},\boldsymbol{\theta}) |\mathbf{0}\rangle|^2$ while ensuring the output of the linear hypothesis h within range $[0,1]$ is not distorted. Note that the link function has no impact on $f_{\boldsymbol{\theta}}(\boldsymbol{x})$ since $f_{\boldsymbol{\theta}}(\boldsymbol{x}) \in [0,1]$.

To provide context regarding the value of B, we note that similar to the full Fourier representation of PQC models, the weight vectors of the RFF feature map can also be written as

$$\boldsymbol{w} = \sqrt{D} \begin{pmatrix} a_{\tilde{\boldsymbol{\omega}}_1}(\boldsymbol{\theta}) \\ b_{\tilde{\boldsymbol{\omega}}_1}(\boldsymbol{\theta}) \\ \vdots \\ a_{\tilde{\boldsymbol{\omega}}_D}(\boldsymbol{\theta}) \\ b_{\tilde{\boldsymbol{\omega}}_D}(\boldsymbol{\theta}) \end{pmatrix}^{\intercal} \tag{47}$$

where D is the dimension of the random Fourier feature map $\boldsymbol{\phi}_{\text{RFF}}$ and $\tilde{\boldsymbol{\omega}}_i \in \Omega$ are the sampled frequencies from the original Fourier spectrum Ω. Following general algorithm-independent results in statistical learning theory on RFFs [34, 35], we assume that the value $|a_{\tilde{\boldsymbol{\omega}}_i}(\boldsymbol{\theta})|$ and $|b_{\tilde{\boldsymbol{\omega}}_i}(\boldsymbol{\theta})|$ are bounded by some constant K. Note that $\|\boldsymbol{w}\|_2 \leq KD \in \mathcal{O}(D)$.

Combining Theorem 1 with the results from the RFF approximation yield Corollary 3.

Corollary 3. *Consider the hypothesis class $\mathcal{H}_{\text{RFF}}$ as defined in Equation (45), a target function $f(\boldsymbol{x}) \in \mathcal{F}_{U,|\mathbf{0}\rangle\langle\mathbf{0}|}$, and variables as defined in Theorem 1. Let $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$ be the training dataset with $\bar{y}_i$ estimated with N_s measurement shots. Running Algorithm 1 with $\mathcal{S}$ will yield $h \in \mathcal{H}_{\text{RFF}}$ such that*

$$R_{\text{expl}}(h) \leq \mathcal{O}\left(\sqrt{\epsilon_1} + M\epsilon_2 + D\left[\epsilon_3 + \epsilon_4\right] + \epsilon_5\right), \tag{48}$$

where $\epsilon_2 = \sqrt[4]{\frac{\log\left(\frac{1}{\delta}\right)}{N_1}}$, $\epsilon_3 = \sqrt{\frac{1}{N_1}}$, $\epsilon_4 = \sqrt{\frac{\bar{\sigma}\log\left(\frac{1}{\delta}\right)}{N_1 N_s}}$, $\epsilon_5 = \sqrt{\frac{\log\left(\frac{1}{\delta}\right)}{N_1}}$, *and* $\bar{\sigma} = \mathbb{E}_{\boldsymbol{x}}[\sigma^2_{\lambda|\boldsymbol{x}}]$.

Here, we exploited the information about the co-domain of the target p-concepts to design an appropriate link function u that restricts the size of the hypothesis class. To illustrate the impact of limiting the hypothesis class size, we relax the co-domains matching constraint, i.e., set u to be the identity map, hence the hypothesis class considered becomes

$$\mathcal{G}_{\text{RFF}} = \left\{g(\boldsymbol{x}) = \langle \boldsymbol{w}, \boldsymbol{\phi}_{\text{RFF}}(\boldsymbol{x})\rangle, \|\boldsymbol{w}\|_2 \leq B\right\}. \tag{49}$$

The most straightforward method to learn $f_{\boldsymbol{\theta}}(\boldsymbol{x})$ under this relaxed formulation is to directly minimize the empirical risk $\widehat{R}(h)$ given a sample $\mathcal{S}$ sampled from the distribution $\mathcal{D}$, which we call empirical risk minimization (ERM).

We can formulate the above as a quadratically constrained quadratic program as follows:

$$\boldsymbol{w}^* = \underset{\boldsymbol{w}, \|\boldsymbol{w}\|_2 \leq B}{\arg\min} \frac{1}{|\mathcal{S}|} \sum_{(\boldsymbol{x}, \bar{y}) \in \mathcal{S}} |\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle - \bar{y}|^2, \tag{50}$$

which can be efficiently solved by convex optimization methods such as interior point methods [36] or projected gradient descent. Alternatively, by including the constraint in the loss with Lagrangian multipliers, the problem can be formulated as a ridge regression task. Various prior work use this formulation to tackle learning problems involving PQCs [8, 25, 26].

Lemma 1. *Consider the hypothesis class $\mathcal{G}_{\text{RFF}}$ as defined in Equation (49), a target function $f(\boldsymbol{x}) \in \mathcal{F}_{U,|\mathbf{0}\rangle\langle\mathbf{0}|}$, and variables as defined in Theorem 1. Let $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$ be the training dataset with $\bar{y}_i$ estimated with N_s measurement shots. Optimizing Equation (50) with $\mathcal{S}$ will yield $g_{\mathcal{S}}^{\text{ERM}} \in \mathcal{G}_{\text{RFF}}$ such that*

$$R_{\text{expl}}(g_{\mathcal{S}}^{\text{ERM}}) \leq \mathcal{O}\left(\epsilon_1 + D^2\sqrt{\frac{\log\frac{1}{\delta}}{N_1}}\right). \tag{51}$$

The proof of this lemma can be found in Appendix E. Similar to Equation (48), one could understand Equation (51) from the bias and variance perspective, i.e., the first term informs the bias of the model while the second term tells us about the model's variance. Firstly, the inclusion of the link function u in the hypothesis class $\mathcal{H}$ results in a class of model that has higher bias as compared to hypothesis class $\mathcal{G}$ hence leads to a quadratic increase in error ϵ_1. Consequently, $\mathcal{H}$ that is higher in bias will have a lower variance, and we can observe the separate and asymmetrical effects of the data sampling and shot noises on the explicit risk. Removing the link function leads to higher variance in $\mathcal{G}$, and the sensitivity to shot and data sampling noises becomes indistinguishable. The relationship between errors in these two generalization bounds essentially manifests the bias-variance trade-off. Further, such results showcase the fact the ERM-based hypothesis selection can still generalize with a constant number of measurements provided that we have abundant data points.

We note that without the application of the link function u in our modelling, classical models are much more susceptible to shot noise. Our theoretical results of Corollary 2 and Lemma 1 imply that in order to learn labels obtained from constant number measurements, without the link function u, classical algorithms may require up to data points N_1 that are square of what is needed for models with the link function u. In the following section, we numerically showcase this property.

V. NUMERICAL VALIDATION ON THE ROLE OF SHOT NOISE

In this section, we will provide numerical verifications of our theoretical results, validating the operational roles of shot noise in learning quantum models.

A. Numerical settings

We consider the data re-uploading model [37] for one-dimensional data points x in our numerical demonstra-

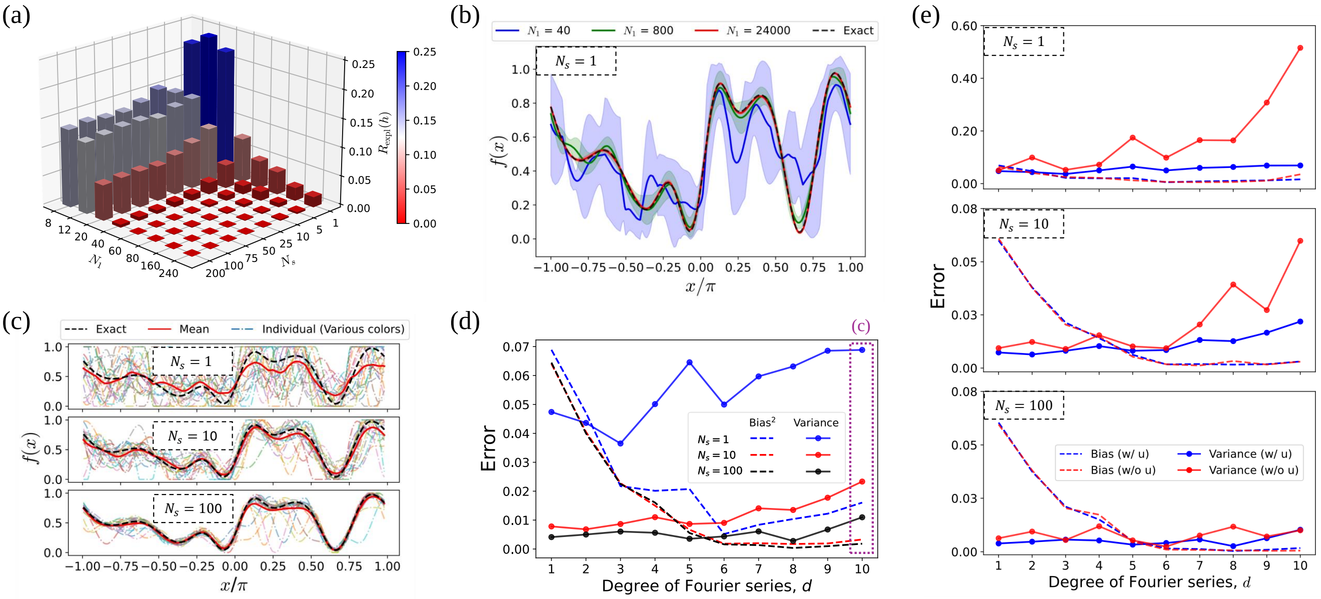

FIG. 4. (a) The averaged explicit risk for different numbers of training data points N_1 and number of measurement shots N_s. The overall trends agreed with the theoretical prediction in Figure 3: for a fixed N_1, the explicit risk saturated after some threshold value of N_s, but the explicit risk can be reduced by increasing N_1 regardless of the value of N_s. (b) When the model in $\mathcal{H}_{10}$ are presented with a sufficiently large dataset, i.e., $N_1 = 24000$, the exact function (black dashed line) can be learned even if the labels are estimated with one measurement shot. (c) Twenty different trained models (dotted dashed line of various colours) from $\mathcal{H}_{10}$ and their mean predictors (solid red line) for $N_1 = 1, 10, 100$. Increasing N_s reduces the shot noise, hence reducing the spread of the trained models. (d) The bias-variance trade-off curve. The bias and variance of the trained models in (c) are calculated and plotted in the purple dotted box. The rest of the values are computed using similar procedures as per (c) for $\mathcal{H}_d$ with $d = \{1, 2, 3, 4, 5, 6, 7, 8, 9\}$. Both the bias and variance decrease when N_s increases, illustrating the shot-noise dependent bias-variance trade-off. (e) Bias and variance for models with and without the link function u. The models without the link function are more expressive, hence they are more susceptible to the shot noise, i.e., they have a higher tendency to overfit the shot noise. Increasing N_s will reduce the shot noise, hence suppressing the shot-noise-induced variance. Note that the same target function is considered in all these numerical experiments.

tion

$$f_{\boldsymbol{\theta}}(x) = \left|\langle 0|\,\mathrm{Rot}\left(\boldsymbol{\theta}^{L_r+1}\right)\,\Pi_{l=1}^{L_r}\left[R_X(x)\mathrm{Rot}\left(\boldsymbol{\theta}^{l}\right)\right]|0\rangle\right|^2, \tag{52}$$

where $\boldsymbol{\theta} = (\boldsymbol{\theta}^1, \ldots, \boldsymbol{\theta}^{L_r+1})$ is the set of rotational angles, $\mathrm{Rot}(\boldsymbol{\theta}^l) = R_Z(\theta_3^l)R_Y(\theta_2^l)R_Z(\theta_1^l)$ is the universal single qubit unitary gate, L_r is the number of layer repetitions, and $R_P(\cdot)$ are the Pauli rotation unitary gates with $P \in \{X, Y, Z\}$. While we considered only the single qubit data re-uploading model with one-dimensional data points, it is straightforward to generalize our results to the multi-qubit model or with multi-dimensional data points. As described, the data re-uploading model can be expressed as a truncated Fourier series

$$f_{\boldsymbol{\theta}}(x) = c_0(\boldsymbol{\theta}) + \sum_{\omega=1}^{L_r} a_\omega(\boldsymbol{\theta})\cos(\omega x) + b_\omega(\boldsymbol{\theta})\sin(\omega x), \tag{53}$$

with Fourier spectrum $\Omega_{L_r}^+ = \{1, \ldots, L_r\}$ while the Fourier coefficients are dependent solely on $\boldsymbol{\theta}$ and their associated unitaries.

Now, we will describe our numerical setting. Firstly, we considered fixed randomly generated angles $\boldsymbol{\theta}$ in our numerical demonstrations, and this set of angles is used for all numerical experiments. Therefore, we will drop the dependency on $\boldsymbol{\theta}$ from now on. In addition, we set $L_r = 10$ for the data re-uploading model to generate a degree 10 Fourier series. Such a target function is sufficiently complex for us to observe various impacts of shot noise in learning $f(x)$. Finally, this numerical example does not require the utilization of random Fourier features, as the model under consideration is rather straightforward; therefore, the truncation method suffices. Specifically, we consider the following truncated Fourier series as our hypothesis class

$$\mathcal{H}_d = \left\{ h_d(x) = u\left(\nu_0 + \sum_{\omega=1}^{d} \alpha_\omega \cos(\omega x) + \beta_\omega \sin(\omega x)\right)\right\} \tag{54}$$

where $\nu_0, \alpha_\omega, \beta_\omega \in \mathbb{R}$, $u(\cdot)$ is the clipping function as defined in Equation (46) and $d \in \mathbb{N}$ controls the degree of the truncated Fourier series, hence the complexity of $\mathcal{H}_d$. For all numerical experiments, the number of training steps T is fixed as 50, and 500 testing data points are used to evaluate the performance of trained models. To distinguish the hypothesis class with and without the link function, we denote $\mathcal{H}_d$ with the identity link function as $\mathcal{G}_d$. Note that all datasets are extracted using the procedures described in Section II B 2.

B. Asymmetrical effects of N_1 and N_s

To begin with, we investigate the asymmetry dependent of the explicit risk on the number of training data points N_1 and the number of measurement shots N_s. In particular, we set $d = 10$ such that the approximation error $\epsilon_1 = 0$, i.e., when $\nu_0 = c_0$, $\alpha_\omega = a_\omega$, and $\beta_\omega = b_\omega$ for all $\omega \in \Omega_{10}^{+}$, enabling us to isolate the impact of these two attributes. In this example, the ratio of the number of training data points N_1 to the number of validation data points N_2 is N_1:N_2 = 8:2 with total data points $N = \{10, 15, 25, 50, 75, 100, 200, 300\}$. That is, we trained the model in $\mathcal{H}_{10}$ with different pairwise combinations of $N_1 = \{8, 12, 20, 40, 60, 80, 160, 240\}$ training data points and $N_s = \{1, 5, 10, 25, 50, 75, 100, 200\}$ measurement shots using Algorithm 1 under $T = 50$ training iterations, and the optimal model is chosen using $N_2 = \{2, 3, 5, 10, 15, 20, 40, 60\}$ validation data points for the respective value of N_1. Finally, the explicit risk is estimated with 500 testing data points and we averaged the explicit risk over 5 random instances of training and validation datasets.

The results shown in Figure 4 (a) agreed with our theoretical prediction in Figure 3, validating the asymmetrical effects of N_1 and N_s as described in Corollary 1. In particular, it shows the decreasing trend of explicit risk with the increase of N_1 while keeping $N_s = 1$. This observation is further validated by Figure 4 (b), where the exact function can be learned when the model is presented with sufficiently large training data points with labels estimated using one measurement repetition, i.e., $N_1 = 2.4 \times 10^4$ and $N_s = 1$. The three solid curves in Figure 4 (b) are the mean predictors obtained using training datasets of size $N_1 = \{40, 800, 24000\}$ and validation datasets of size $N_2 = \{10, 200, 600\}$ respectively. Each of these mean predictors is averaged over 5 different training instances and the shaded regions are the standard deviations of the predictions. As expected, increasing N_1 reduces the standard deviations of the predictors and improves the mean predictions.

C. Shot-noise dependent bias-variance trade-off

As discussed in Section III D, training models with different finite-size training datasets will yield different trained models. This phenomenon is observed in Figure 4 (c) where 20 distinct trained models from $\mathcal{H}_{10}$, i.e., dashed-dotted lines of different colours, each trained with different training datasets of size 40 are different across $N_s = 1, 10, 100$. In addition, the reducing fluctuations of the trained models with increasing N_s demonstrated the N_s-dependent relationship between these trained models. As N_1 is sufficiently large, the prediction accuracy can be improved by increasing N_s and this is reflected in Figure 4 (c) where the mean predictor is approaching the exact function as N_s increases. These two observations can otherwise be captured by computing two statistical quantities, the squared bias

$$\mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Bias}_{\mathcal{S}}^2\right] := \mathbb{E}_{\boldsymbol{x}}\left[\left(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - f(\boldsymbol{x})\right)^2\right] \tag{55}$$

and the variance

$$\mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Var}_{\mathcal{S}}\right] := \mathbb{E}_{\boldsymbol{x},\mathcal{S}}\left[\left(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - h_{\mathcal{S}}(\boldsymbol{x})\right)^2\right]. \tag{56}$$

In particular, we compute their empirical versions using the trained models as per Figure 4 (c) using 500 testing data points. The computed values are plotted in Figure 4 (d) at $d = 10$, i.e., the points in the purple dotted box. As expected the bias and variance reduce when N_s increases.

These exact settings and procedures as per Figure 4 (c) are repeated to obtain trained models from $\mathcal{H}_d$ for $d = \{1, 2, 3, 4, 5, 6, 7, 8, 9\}$, and these models are then used to compute their respective bias and variance. Plotting their bias and variance yields the bias-variance trade-off curve, as shown in Figure 4 (d). Across $N_s = 1, 10, 100$, the bias (variance) consistently decreases (increases) with increasing d. This observation is consistent with the bias-variance trade-off concept, where less complex models (in our case, $\mathcal{H}_d$ with lower d) will have higher bias but with lower variance. In contrast, the highly complicated models will have lower bias but with higher variance. The former type of model tends to underfit the training data while the latter is more likely to overfit the training data. In addition, Figure 4 (d) illustrates the shot-noise dependent bias-variance trade-off as described in Section III D: Increase N_s will reduce the bias and variance of the models.

Using the same settings as per Figure 4 (d) but a different training procedure, we extract the bias and variance of the hypothesis without the link function u, i.e., $\mathcal{G}_d$. Specifically, there is an exact analytical solution if we solve Equation (50) using kernel ridge regression and we use the validation dataset to choose the optimal regularization strength out of $C = \{0.006, 0.015, 0.03, 0.0625, 0.125, 0.25, 0.5, 1.0, 2.0, 5.0, 8.0, 16.0, 32.0, 64.0, 128.0, 256, 512, 1024\}$. Then, their bias and variance are compared against the hypothesis equipped with the link function in Figure 4 (e) and these numerical results are in agreement with the theoretical analysis in Section IV B. That is, the variance of $\mathcal{G}_d$ is significantly higher than their counterpart when N_s is low. High shot noise implies that the estimated labels would be very different from their exact values and a more expressive model class like $\mathcal{G}_d$ will have a higher tendency to overfit the shot noise, lending to a higher

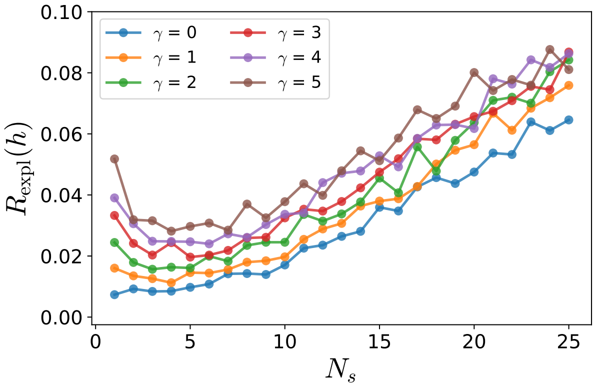

FIG. 5. The trade-off between N_1 and N_s is considered under a fixed total measurement budget of $N_{\mathrm{tot}} = 600$ for $\gamma = \{0, 1, 2, 3, 4, 5\}$ and $N_s = \{1, 2, 3, \ldots, 24, 25\}$. When N_1 and N_s are treated equally, i.e., $\gamma = 0$, the optimal pair of N_1 and N_s is given by $(N_1^*, N_s^*) = (600, 1)$. As γ increases, more measurement shots are required, hence smaller N_1, to achieve better model performance. However, there will be a threshold beyond which the performance of models worsens.

variance. Increasing N_s reduces the shot noise but the finite data sampling noise remains. This explains the reducing but non-vanishing variance for both $\mathcal{H}_d$ and $\mathcal{G}_d$ when N_s increases as well as the success of current learning protocol using $\mathcal{G}_d$ [8, 10, 11]. Interestingly, the model's bias with the link function matches well with the one without. In summary, the link function helps suppress the shot noise-induced variance by restricting the expressivity of the hypothesis class.

D. Trade-off between N_1 and N_s

Finally, we numerically investigate the trade-off between N_1 and N_s under a fixed total measurement budget of N_{tot}. Recall that the relationship between N_{tot}, N_1, and N_s is given by $N_{\mathrm{tot}} = (N_1 + N_2)(N_s + \gamma)$, where γ is the penalty cost and N_2 is the size of validation dataset. The inclusion of N_2 captures the resource constraint for choosing the optimal time step T^*. Here, we let $N_{\mathrm{tot}} = 600$, $\gamma = \{0, 1, 2, 3, 4, 5\}$, and the ratio of N_1 to N_2 be 8:2. Furthermore, we set $N_s = \{1, 2, 3, \ldots, 24, 25\}$ giving different combinations of N_1 and N_2. Repeating the similar procedures as per Figure 4 (a) over 60 random instances of training and validation datasets for the above-mentioned settings yields Figure 5. As predicted by Corollary 2, for a fixed N_{tot} and when $\gamma = 0$, the performance of classical machines can be enhanced by reducing N_s, and the optimality is achieved when $N_s = 1$. On the other hand, the optimal pair of N_1 and N_s depends on the penalty cost when $\gamma > 0$; the larger the γ, the higher the N_s required to achieve optimal model performance.

VI. DISCUSSION

Finite measurement or shot noise is an intrinsic quantum phenomenon. Such noise is always present in the estimation of quantum models; hence, classical machines will unavoidably encounter shot noise when learning quantum models. Therefore, it is crucial to understand whether shot noise could increase the difficulty for classical machines to learn quantum models, or if it is just a statistical feature that can be well-handled by classical models.

By formulating parameterized quantum models as probabilistic concepts, we show that classical machines can learn quantum models with efficient classical representation in the presence of shot noise. Said otherwise, the fundamental hardness of learning quantum models depends on the existence of efficient classical representation, while the impact of shot noise is only prominent when there is an insufficient number of training data points. When sufficient training data points are provided, classical learning of quantum models is possible even when the labels are estimated with limited measurement shots. This asymmetrical effect of the number of training data and measurement repetitions arises from the differences in information gained when sampling each component. That is, one effectively samples across various labels when sampling across the training points but increasing the resolution of the labels does not provide extra information on other data points.

Each quantum measurement, be it on a fixed or different parameter setting, counts as a query to quantum models. While unlimited queries to quantum models are desired, our limited time and monetary resources force us to wisely distribute our budget to maximize the information extracted from quantum models. That is, one has to choose to train the classical machines with datasets consisting of either more inputs with noisier labels or fewer inputs with cleaner labels. If sampling across parameter settings does not incur extra cost compared to sampling quantum models with the same parameter setting, then the classical machine would learn better with datasets consisting of more inputs but with the noisiest labels. Otherwise, the optimal budget partition would depend on the cost differences between measurements with fixed and different parameter settings.

While the hardness of learning quantum models classically is not dictated by the shot noise, it has an impact on the actual training of classical machines. For a given set of training data points $\{\boldsymbol{x}_i\}_{i=1}^{N_1}$, different label sampling instances will yield different training datasets, i.e., $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$ or $\mathcal{S}' = (\boldsymbol{x}_i, \bar{y}'_i)_{i=1}^{N_1}$. Each dataset will produce an associated trained model. We capture this model's sensitivity to variation of labels through the bias-variance-noise decomposition and show that the link function can suppress this undesired sensitivity by restricting the size of the hypothesis class. Finally, we use our framework for the classical surrogation of parameterized quantum circuit models, and our theoretical analysis correctly predicts the behaviours of classical surrogates in the presence of shot noise.

Viewed from other angles, our work provides a framework to study the impact of classical approximation and shot noise on learning quantum models classically. Future works could focus on searching for good classical approximations, and our framework could be directly adapted to handle shot noise. An interesting direction is to combine our framework with the analysis in Ref. [38] to investigate the classical learnability of the parameterized quantum circuit models that are free of barren plateaus. This will provide an alternative perspective on the relationship between classical simulability and learnability of parameterized quantum models [39]. Shallow parameterized quantum circuits usually admit efficient classical representation, yet they might experience exponential concentration if observables are not chosen carefully [40]. This setting is suitable to push the limits of our framework to check if classical machines can still learn such models under the influence of exponential concentration.

Finally, the core of our framework is the assumption that the parameterized quantum models represent the conditional unbiased expectation of their unbiased estimators. However, estimators might not be unbiased after some post-processing operations. An example of such post-processing operations is quantum error mitigation. It will be interesting to investigate the role of shot noise in the biased regime.

Appendix A: Sampling and estimation methods on PQMs

1. Direct sampling-based estimation

The most straightforward method is to generate estimations by directly conducting measurements on the target observable. Plugging in the eigendecomposition of the observable O, i.e., $O = \sum_{k=1}^{K} \lambda^{(k)} \left|\lambda^{(k)}\right\rangle \left\langle\lambda^{(k)}\right|$ in $f(\boldsymbol{x}) =$

$\mathrm{tr}(\rho(\boldsymbol{x})O)$ yields

$$f(\boldsymbol{x}) = \sum_{k=1}^{K} \lambda^{(k)} \left\langle \lambda^{(k)} \right| \rho(\boldsymbol{x}) \left| \lambda^{(k)} \right\rangle , \tag{A1}$$

where $0 \leq \left\langle \lambda^{(k)} \right| \rho(\boldsymbol{x}) \left| \lambda^{(k)} \right\rangle \leq 1 \ \forall k$, $\lambda^{(k)} \in \mathbb{R}$, and $\sum_{k=1}^{K} \left\langle \lambda^{(k)} \right| \rho(\boldsymbol{x}) \left| \lambda^{(k)} \right\rangle = 1$. The random measurement processes of $\rho(\boldsymbol{x})$ in the eigenbasis $\left| \lambda^{(k)} \right\rangle$ can be modelled as sampling of eigenvalue $\lambda^{(k)}$ from the associated probability distribution, i.e., $\lambda \sim p_{\boldsymbol{x}}(\lambda)$ with $\lambda \in \Lambda = \{\lambda^{(k)}\}_{k=1}^{K}$ and $p_{\boldsymbol{x}}(\lambda) = \langle \lambda | \rho(\boldsymbol{x}) | \lambda \rangle$.

Given N_s i.i.d. measurement outcomes $\{\lambda_i\}_{i=1}^{N_s}$, one could estimate $f(\boldsymbol{x})$ by the empirical mean

$$\bar{y}_D = \frac{1}{N_s} \sum_{i=1}^{N_s} \lambda_i . \tag{A2}$$

where we have implictly assumed the dependence of $\bar{y}_D$ on $\boldsymbol{x}$, i.e., $\bar{y}_D \equiv \bar{y}_D(\boldsymbol{x})$. The finite-measurement-outcome mean $\bar{y}_D$ is an unbiased estimator of $f(\boldsymbol{x})$

$$f(\boldsymbol{x}) = \mathbb{E}_{\bar{y}_D} \left[\bar{y}_D | \boldsymbol{x} \right] \tag{A3}$$

with variance $\sigma^2_{\bar{y}_D|\boldsymbol{x}} = \sigma^2_{\lambda|\boldsymbol{x}} / N_s$.

It is however generally hard to measure $\rho(\boldsymbol{x})$ in the eigenbasis of the observable. In typical scenarios, one would normally consider a linear combination of M Pauli observables P_i, i.e., $O = \sum_{i=1}^{M} a_i P_i$ with $a_i \in \mathbb{R}$, and the eigenbasis of such an observable is non-trivial to find. To estimate the original observable expectation value, one will typically measure the expectation value of $\rho(\boldsymbol{x})$ against each Pauli observable and then linearly combine them with the associated weights a_i

$$\mathrm{tr}(\rho(\boldsymbol{x})O) = \sum_{i=1}^{M} a_i \, \mathrm{tr}(\rho(\boldsymbol{x}) P_i). \tag{A4}$$

While each Pauli estimator is unbiased for the associated Pauli observable, the joint estimators of $\mathrm{tr}(\rho(\boldsymbol{x})O)$ constructed by summing these Pauli estimators need not be unbiased.

2. Shadow-based estimation

Alternatively, estimating measurement results using classical shadows [41] also introduces structural noise to our framework, allowing training based on random measurements as opposed to direct measurements, which may be much more costly in practice.

Recall that in the classical shadows protocol, to estimate properties of a quantum state ρ, one first evolves the quantum state using a unitary U sampled from a tomographically complete unitary ensemble $\mathcal{U}$ and performs measurements on the computational basis $|\hat{b}\rangle \in \{0,1\}^n$ and the bit-string b is observed with probability $\Pr\left[\hat{b} = b\right] = \langle b | U \rho U^\dagger | b \rangle$. From the measurement outcome, one can construct a classical snapshot $\hat{\rho} = \mathcal{M}_{\mathcal{U}}^{-1}(U^\dagger |\hat{b}\rangle\langle\hat{b}| U)$ where we apply an inverted quantum channel $\mathcal{M}_{\mathcal{U}}^{-1}$ determined by the unitary ensemble $\mathcal{U}$. This classical snapshot is an unbiased estimator for the density matrix, i.e., $\rho = \mathbb{E}_{U,|\hat{b}\rangle}[\hat{\rho}]$.

The classical snapshot serves as a good estimator for the parameterized quantum state when applied to a suitable set of Hermitian observables $\{H_1, H_2, \cdots, H_M\}$. For example, the classical snapshots can be used to estimate the function $f(\boldsymbol{x}) = \mathrm{tr}(\rho(\boldsymbol{x})O)$ with $O = \sum_{i=1}^{M} a_i P_i$, i.e., $\bar{y}_{CS} = \mathrm{tr}(\bar{\rho}(\boldsymbol{x})O)$ where $\bar{\rho} = \frac{1}{N_s} \sum_{i=1}^{N_s} \hat{\rho}_i$ is the averaged sum of N_s classical snapshots. It is straightforward to show that such an estimator is an unbiased estimator of $f(\boldsymbol{x})$

$$f(\boldsymbol{x}) = \mathbb{E}_{\bar{y}_{CS}} \left[\bar{y}_{CS} | \boldsymbol{x} \right] . \tag{A5}$$

Other unbiased shadow estimation techniques based on random sampling such as operator shadows [42] can also be used to produce the unbiased estimators for the quantum models.

Appendix B: Details on the learning algorithm

1. Intuitive understanding on the working principle of Algorithm 1

Algorithm 1 works similarly to gradient descent algorithm. Take the following empirical risk

$$\widehat{R} = \frac{1}{2N_1}\sum_{j=1}^{N_1} |y_j - u\left(\langle w, \boldsymbol{\phi}(\boldsymbol{x_j})\rangle\right)|^2 \tag{B1}$$

We can then upper bound the gradient as follows:

$$\frac{\partial \widehat{R}}{\partial \boldsymbol{w}} \leq \frac{L}{N_1}\sum_{j=1}^{N_1}(u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x_j})\rangle) - y_j)\boldsymbol{\phi}(\boldsymbol{x_j}) \tag{B2}$$

By introducing kernelization to linear models, one can set $\boldsymbol{w} = \sum_{i=1}^{N_1} \alpha_i \boldsymbol{\phi}(\boldsymbol{x_i})$. Setting the upper bound as the gradient step with a learning rate of $\frac{1}{L^2}$, we see that in each step, the value of α_j has an update of

$$\Delta\alpha_j = \frac{u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x_j})\rangle) - y_j}{LN_1} = \frac{u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x_j})\rangle) - y_j}{LN_1} = \frac{u\left(\sum_{i=1}^{N_1} \alpha_i k(\boldsymbol{x_i}, \boldsymbol{x_j})\right) - y_j}{LN_1}, \tag{B3}$$

giving us the update in Algorithm 1.

Due to initialization of parameters to zero, which is akin to interior point methods, the algorithm provides implicit norm regularization of the parameters. This property, in addition to the limitation of gradient steps taken, provides the theoretical guarantees as shown in Theorem 1, which we show in the following section.

2. Proof of Theorem 1

We are given the output range $\mathcal{Y} = [-\Delta, \Delta]$. Let $\bar{\Gamma} := \frac{1}{N_1}\sum_{i=1}^{N_1}(\bar{y}_i - u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x}_i)\rangle + \xi(\boldsymbol{x}_i)))\boldsymbol{\phi}(\boldsymbol{x}_i)$, $\bar{\Gamma}^t := \frac{1}{N_1}\sum_{i=1}^{N_1}(\bar{y}_i - u(\langle \boldsymbol{w}^t, \boldsymbol{\phi}(\boldsymbol{x}_i)\rangle))\boldsymbol{\phi}(\boldsymbol{x}_i)$ and $\chi := \frac{1}{N_1}\sum_{i=1}^{N_1}\xi(\boldsymbol{x}_i)^2$. We apply the Lemma 11 from Ref. [31] to the empirical mean $\bar{y}$.

Lemma B.1. *At iterative t in Algorithm 1, suppose $\|\boldsymbol{w}^t - \boldsymbol{w}\| \leq B$ for $B > 1$, then if $\|\bar{\Gamma}\| \leq \epsilon_4 < 1$, then*

$$\|\boldsymbol{w}^t - \boldsymbol{w}\|^2 - \|\boldsymbol{w}^{t+1} - \boldsymbol{w}\|^2 \geq \lambda\left(\left(\frac{2}{L} - \lambda\right)\hat{R}(h^t) - 2\Delta\sqrt{\chi} - 2B\epsilon_4 - \lambda\epsilon_4^2 - 2\Delta\lambda\epsilon_4\right), \tag{B4}$$

where λ is the regularization parameter.

Using Lemma B.1 with $\lambda = 1/L$, we have

$$\|\boldsymbol{w}^t - \boldsymbol{w}\|^2 - \|\boldsymbol{w}^{t+1} - \boldsymbol{w}\|^2 \geq \frac{1}{L}\left(\frac{\hat{R}(h^t)}{L} - 2\Delta\sqrt{\chi} - 2B\epsilon_4 - \frac{\epsilon_4^2}{L} - \frac{2\Delta\epsilon_4}{L}\right). \tag{B5}$$

For each iteration t of Algorithm 1, one of the following two cases needs to be satisfied

$$\text{Case 1: } \|\boldsymbol{w}^t - \boldsymbol{w}\|^2 - \|\boldsymbol{w}^{t+1} - \boldsymbol{w}\|^2 > \frac{B\epsilon_4}{L} \tag{B6}$$

$$\text{Case 2: } \|\boldsymbol{w}^t - \boldsymbol{w}\|^2 - \|\boldsymbol{w}^{t+1} - \boldsymbol{w}\|^2 \leq \frac{B\epsilon_4}{L}. \tag{B7}$$

Let t^* be the first iteration where Case 2 holds. We show that such an iteration exists. Assume the contradictory, that is, Case 2 fails for each iteration. Since $\|\boldsymbol{w}^0 - \boldsymbol{w}\|_2^2 = \|\boldsymbol{0} - \boldsymbol{w}\|_2^2 \leq B^2$ by assumption, however,

$$B^2 \geq \|\boldsymbol{w}^0 - \boldsymbol{w}\|_2^2 \geq \|\boldsymbol{w}^0 - \boldsymbol{w}\|_2^2 - \|\boldsymbol{w}^k - \boldsymbol{w}\|_2^2 \tag{B8}$$

$$= \sum_{t=0}^{k-1}\left(\|\boldsymbol{w}^t - \boldsymbol{w}\|_2^2 - \|\boldsymbol{w}^{t+1} - \boldsymbol{w}\|_2^2\right) \geq \frac{kB\epsilon_4}{L}, \tag{B9}$$

for k iterations. Hence, in at most $T \geq \frac{BL}{\epsilon_4}$ iterations Case 1 will be violated and Case 2 will have to be true. Combining Equation (B5) and Case 2 yield

$$\hat{R}(h^t) \leq 2L\Delta\sqrt{\chi} + 3BL\epsilon_4 + \epsilon_4^2 + 2\Delta\epsilon_4 \tag{B10}$$

What remains to be done is to bound χ and to obtain N_s in terms of ϵ_4. Similar to Ref. [31], we could bound χ using Hoeffding's inequality

$$\sqrt{\chi} \leq \sqrt{\epsilon_1} + \mathcal{O}\left(M\sqrt[4]{\frac{\log(1/\delta)}{N_1}}\right), \tag{B11}$$

and therefore by observing that $B \propto \Delta$, we have

$$\hat{R}(h^t) \leq \mathcal{O}\left(L\Delta\sqrt{\epsilon_1} + LM\sqrt[4]{\frac{\log(1/\delta)}{N_1}} + BL\epsilon_4\right). \tag{B12}$$

By definition, we have that $(\bar{y}_i - u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x}_i)\rangle + \xi(\boldsymbol{x}_i)))\boldsymbol{\phi}(\boldsymbol{x}_i)$ are zero mean i.i.d. random variables with bounded norm, so we can use the following vector Bernstein inequality to bound the norm of $\bar{\Gamma}$.

Lemma B.2 (Vector Bernstein inequality (Lemma 18 from [43]))**.** *Let $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N$ be independent zero-mean vector-valued random variables with common dimension d and they are uniformly bounded and also the variance is bounded above $\mathbb{E}[\|\boldsymbol{x}_i\|^2] \leq \sigma^2$. Let*

$$\boldsymbol{z} = \frac{1}{N}\left\|\sum_{i=1}^{N}\boldsymbol{x}_i\right\|_2. \tag{B13}$$

Then we have for $0 \leq \epsilon \leq \sigma^2/\mu$

$$P[\|\boldsymbol{z}\| \geq \epsilon] \leq \exp\left(-\frac{N\epsilon^2}{8\sigma^2} + \frac{1}{4}\right). \tag{B14}$$

Before using the vector Bernstein inequality, we need to compute the variance of $\|(\bar{y} - \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}])\boldsymbol{\phi}(\boldsymbol{x})\|$ where $\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}] = u(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle + \xi(\boldsymbol{x}))$, i.e., $\mathbb{E}_{\bar{\mathcal{D}}}[\|(\bar{y} - \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}])\boldsymbol{\phi}(\boldsymbol{x})\|^2]$ as $\mathbb{E}_{\bar{\mathcal{D}}}[\|(\bar{y} - \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}])\boldsymbol{\phi}(\boldsymbol{x})\|] = 0$ by definition. Therefore,

$$\begin{aligned}
\mathbb{E}_{\bar{\mathcal{D}}}\left[\|(\bar{y} - \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}])\boldsymbol{\phi}(\boldsymbol{x})\|^2\right] &= \mathbb{E}_{\bar{\mathcal{D}}}\left[(\bar{y} - \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}])^2\|\boldsymbol{\phi}(\boldsymbol{x})\|^2\right] && \text{(B15)}\\
&\leq \mathbb{E}_{\bar{\mathcal{D}}}\left[(\bar{y} - \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}])^2\right] && \text{(B16)}\\
&= \mathbb{E}_{\bar{\mathcal{D}}}\left[\bar{y}^2 - 2\bar{y}\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}] + \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]^2\right] && \text{(B17)}\\
&= \mathbb{E}_{\boldsymbol{x}}\mathbb{E}_{\bar{y}|\boldsymbol{x}}\left[\bar{y}^2 - 2\bar{y}\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}] + \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]^2\right] && \text{(B18)}\\
&= \mathbb{E}_{\boldsymbol{x}}\left[\mathbb{E}_{\bar{y}}[\bar{y}^2|\boldsymbol{x}] - \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]^2\right] && \text{(B19)}\\
&= \mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{\bar{y}|\boldsymbol{x}}\right] && \text{(B20)}\\
&= \frac{\mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{y|\boldsymbol{x}}\right]}{N_s} && \text{(B21)}
\end{aligned}$$

We can therefore bound $\|\bar{\Gamma}\|$ by letting $\sigma = \frac{\mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{y|\boldsymbol{x}}\right]}{N_s}$

$$P(\|\bar{\Gamma}\| \leq \epsilon_4) \geq 1 - \exp\left(-\frac{N_1 N_s \epsilon_4^2}{8\mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{y|\boldsymbol{x}}\right]} + \frac{1}{4}\right). \tag{B22}$$

For a probability of $1 - \delta$, number of training samples N_1, and number of measurement repetitions N_s, we can achieve $\|\bar{\Gamma}\| \leq \epsilon_4$ with

$$\epsilon_4 = \sqrt{\frac{8\mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{y|\boldsymbol{x}}\right]}{N_1 N_s}\left(\log\left(\frac{1}{\delta}\right) + \frac{1}{4}\right)}. \tag{B23}$$

To bound $R(h^{t^*})$ with $\hat{R}(h^{t^*})$, we require the following results:

Theorem B.1 (Theorem 8, [44]; Formulation of Theorem 21, [31]). *Let $\mathcal{L} : \mathcal{Y}' \times \mathcal{Y} \to \mathbb{R}_+$ be a loss function upper bounded by $b > 0$ and such that for any fixed y, $y' \to \mathcal{L}(y', y)$ is L-Lipschitz for some $L > 0$. Given function class $\mathcal{F} \subset (\mathcal{Y}')^{\mathcal{X}}$, for any $f : \mathcal{X} \to \mathcal{Y}' \in \mathcal{F}$, and for any sample $\mathcal{S}$ from distribution $\mathcal{D}$ of size N,*

$$\left| \mathbb{E}_{\mathcal{D}} \left[\mathcal{L}(f(x), y)\right] - \frac{1}{N} \sum_{(x,y)\in\mathcal{S}} \mathcal{L}(f(x), y) \right| \leq 4L\mathfrak{R}_N(\mathcal{F}) + 2b\sqrt{\frac{\log 2/\delta}{2N}}, \tag{B24}$$

where $\mathfrak{R}_N(\mathcal{H})$ is the expected value of the empirical Rademacher complexity of the function class $\mathcal{F}$ over all samples of size N.

Plugging the generalization, we have the following result for all hypotheses $h \in \mathcal{H}$.

$$R_{\text{expl}}(h) \leq \hat{R}(h) + 8\Delta\mathfrak{R}_{N_1}(\mathcal{H}) + 2\Delta^2\sqrt{\frac{\log(\frac{2}{\delta})}{2N_1}}. \tag{B25}$$

Next, to compute the empirical Rademacher complexity of $\mathcal{H}$, we use the following results:

Theorem B.2 (Lemma 22, [44] or Theorem 1, [45]; Formulation of Theorem 22, [31]). *Let $\mathcal{X}$ be a subset of an inner product space such that for all $\boldsymbol{x} \in \mathcal{X}$, $\|\boldsymbol{x}\|_2 \leq X$, and let $\mathcal{W} = \{\boldsymbol{x} \to \langle \boldsymbol{w}, \boldsymbol{x} \rangle, \|\boldsymbol{w}\|_2 \leq W\}$. Then it holds that*

$$\mathfrak{R}_N(\mathcal{W}) \leq \frac{XW}{\sqrt{N}}, \tag{B26}$$

Lemma B.3 (Talagrand's lemma, Corollary 3.17, [46]; Formulation of Lemma 5.7, [47]). *Let $\Phi : \mathbb{R} \to \mathbb{R}$ be a L-Lipschitz function. Then for any hypothesis set $\mathcal{F}$ of real-valued functions, the following holds:*

$$\mathfrak{R}_N(\Psi \circ \mathcal{F}) \leq L\mathfrak{R}_N(\mathcal{F}), \tag{B27}$$

Noting that our hypothesis class $\mathcal{H}$ in question is a linear class with a L-Lipschitz function applied to it, with the constraints $\|\boldsymbol{w}\|_2 \leq B$ and $\|\boldsymbol{\phi(x)}\|_2 \leq 1$ combining the above two results, we get

$$\mathfrak{R}_{N_1}(\mathcal{H}) \leq \frac{BL}{\sqrt{N_1}}, \tag{B28}$$

Finally, we can make use of Rademacher complexity to bound $R(h^t)$

$$R_{\text{expl}}(h^{t^*}) \leq \hat{R}(h^{t^*}) + \mathcal{O}\left(BL\Delta\sqrt{\frac{1}{N_1}} + \Delta^2\sqrt{\frac{\log(1/\delta)}{N_1}} \right) \tag{B29}$$

$$= \mathcal{O}\left(L\Delta\sqrt{\epsilon_1} + L\Delta M\sqrt[4]{\frac{\log(1/\delta)}{N_1}} + BL\Delta\sqrt{\frac{1}{N_1}} + BL\sqrt{\frac{\bar{\sigma}}{N_1 N_s}\left(\log\left(\frac{1}{\delta}\right)\right)} + \Delta^2\sqrt{\frac{\log(1/\delta)}{N_1}} \right) \tag{B30}$$

where $\bar{\sigma} = \mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{y|\boldsymbol{x}}\right]$. The last step is to show that we can indeed find a hypothesis satisfying the above guarantee. Using the Hoeffding inequality and union bound, one could show that $N_2 \geq O\left(N_1\Delta^2 \log(\frac{T}{\delta^2})\right)$ validation data points suffice to choose the optimal hypothesis h^{t^*} at time step t^* that satisfies Equation (B30).

Appendix C: Bias-variance-noise decomposition

For a given training dataset $\mathcal{S} = (\boldsymbol{x}_i, \bar{y}_i)_{i=1}^{N_1}$, one would obtain an associated trained model $h_{\mathcal{S}}(\boldsymbol{x})$ by optimizing the empirical risk $\widehat{R}(h)$ using some optimization methods such as the gradient descent algorithm. Further, different training datasets $\mathcal{S}'$ would yield different trained models $h_{\mathcal{S}'}(\boldsymbol{x})$, each associated with explicit risk $R_{\text{expl}}(h_{\mathcal{S}})$ and $R_{\text{expl}}(h_{\mathcal{S}'})$, respectively. This observation begs the question of how these trained models are related to each other and the target concept $c(\boldsymbol{x}) = \mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]$.

To address the above-mentioned questions, we introduce a machine learning concept known as the bias-variance trade-off. The bias of machine learning models informs their consistent errors and it is defined as

$$\mathbf{Bias}_{\mathcal{S}} := \mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - f(\boldsymbol{x}). \tag{C1}$$

Since $f(\boldsymbol{x})$ is independent of $\mathcal{S}$, one could express the bias as $\mathbf{Bias}_{\mathcal{S}} = \mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x}) - f(\boldsymbol{x})]$. Low bias suggests that on average the trained models $h_{\mathcal{S}}(\boldsymbol{x})$ are close to the target function, and typically machine learning models with larger model class sizes will have lower bias. Yet, models with low bias need not be optimal as they tend to be more sensitive to variations in training data; such models are said to have high variance where the variance of the model is defined as

$$\mathbf{Var}_{\mathcal{S}} := \mathbb{E}_{\mathcal{S}}\left[\left(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - h_{\mathcal{S}}(\boldsymbol{x})\right)^2\right]. \tag{C2}$$

It should be clear from the definition that the bias and variance are dependent on the complexity of the hypothesis class, the number of training data points N_1 and the number of random labels N_s.

The above-mentioned bias-variance trade-off can be studied by analysing the average behaviour of the trained models under the constraints of finite training data points and labels, which we capture by taking the expectation value over all possible training data sets $\mathcal{S}$ with the same N_1 and N_s, which we denote $\mathbb{E}_{\mathcal{S}|N_1,N_s}[R_{\text{impl}}(h_{\mathcal{S}})]$ where $R_{\text{impl}}(h_{\mathcal{S}}) = \mathbb{E}_{\bar{\mathcal{D}}}[(h_{\mathcal{S}}(\boldsymbol{x}) - \bar{y})^2]$ is the implicit risk of $h_{\mathcal{S}}(\cdot)$ as defined in Equation (8).

This averaged risk quantifies the overall performance of the hypothesis class $\mathcal{H}$ under all realization of training datasets of size N_1, with empirical means estimated using N_s random labels. Furthermore, $R_{\text{impl}}(h) = R_{\text{expl}}(h) + \bar{\sigma}_{N_S}$ implies

$$\mathbb{E}_{\mathcal{S}|N_1,N_s}[R_{\text{impl}}(h_{\mathcal{S}})] = \mathbb{E}_{\mathcal{S}|N_1,N_s}[R_{\text{expl}}(h_{\mathcal{S}})] + \bar{\sigma}_{N_S}, \tag{C3}$$

where $\mathbb{E}_{\mathcal{S}|N_1,N_s}[R_{\text{expl}}(h_{\mathcal{S}})]$ is the averaged explicit risk and $R_{\text{impl}}(\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}]) := \bar{\sigma}_{N_S} = \mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{\bar{y}|\boldsymbol{x}}\right] = \frac{1}{N_s}\mathbb{E}_{\boldsymbol{x}}\left[\sigma^2_{y|\boldsymbol{x}}\right]$ is the irreducible error that lower bounds the implicit risk on unseen sample. Note that in the asymptotic regime ($N_1 \to \infty$), the variance goes to 0 as the finite data sampling noise diminishes, and one would consistently obtain the optimal model in $\mathcal{H}$ that achieves the optimal explicit risk $R_{\text{expl}}(h)$. In addition, the strength of the irreducible error is controllable by the number of random samples N_s. In particular, $\bar{\sigma}_{N_S} \to 0$ as $N_s \to \infty$ and therefore $\mathbb{E}_{\mathcal{S}|N_1,N_s\to\infty}[R_{\text{impl}}(h_{\mathcal{S}})] \to \mathbb{E}_{\mathcal{S}|N_1,N_s\to\infty}[R_{\text{expl}}(h_{\mathcal{S}})]$.

We can then further decompose the explicit risk averaged over all dataset.

$$\begin{aligned}
\mathbb{E}_{\mathcal{S}}[R_{\text{expl}}(h_{\mathcal{S}})] &= \mathbb{E}_{\boldsymbol{x},\mathcal{S}}\left[\left(h_{\mathcal{S}}(\boldsymbol{x}) - c(\boldsymbol{x})\right)^2\right] && \text{(C4)}\\
&= \mathbb{E}_{\boldsymbol{x},\mathcal{S}}\left[\left(h_{\mathcal{S}}(\boldsymbol{x}) - \mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] + \mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - c(\boldsymbol{x})\right)^2\right] && \text{(C5)}\\
&= \mathbb{E}_{\boldsymbol{x}}\left[\left(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - c(\boldsymbol{x})\right)^2\right] + \mathbb{E}_{\boldsymbol{x},\mathcal{S}}\left[\left(\mathbb{E}_{\mathcal{S}}[h_{\mathcal{S}}(\boldsymbol{x})] - h_{\mathcal{S}}(\boldsymbol{x})]\right)^2\right] && \text{(C6)}\\
&= \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Bias}^2_{\mathcal{S}}\right] + \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Var}_{\mathcal{S}}\right]. && \text{(C7)}
\end{aligned}$$

In summary, we have

$$\begin{aligned}
\mathbb{E}_{\mathcal{S}|N_1,N_s}[R_{\text{expl}}(h_{\mathcal{S}})] &= \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Bias}^2_{\mathcal{S}}\right] + \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Var}_{\mathcal{S}}\right], \quad \text{and} && \text{(C8)}\\
\mathbb{E}_{\mathcal{S}|N_1,N_s}[R_{\text{impl}}(h_{\mathcal{S}})] &= \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Bias}^2_{\mathcal{S}}\right] + \mathbb{E}_{\boldsymbol{x}}\left[\mathbf{Var}_{\mathcal{S}}\right] + \bar{\sigma}_{N_s}. && \text{(C9)}
\end{aligned}$$

Appendix D: Random Fourier feature models

1. Classical approximation of PQC functions

Let $\mathcal{F}_{U,O}$ and $\boldsymbol{\phi}_F(\boldsymbol{x})$ be the PQC concept class and feature map as defined in Equation (21) and Equation (28), respectively. In addition, let $k_F(\boldsymbol{x},\boldsymbol{x}') = \langle\boldsymbol{\phi}_F(\boldsymbol{x}),\boldsymbol{\phi}_F(\boldsymbol{x}')\rangle$ be the kernel of $\boldsymbol{\phi}_F(\boldsymbol{x})$.

Our goal of learning PQCs corresponds to taking $\mathcal{F}_{U,O}$ as our concept class. It is a still-unresolved question which PQCs provably give rise to function families that can or cannot be well approximated by kernel-based function families, but it is known that PQCs exist which cannot. Nonetheless, we offer a generic PQC construction whose functions are guaranteed to be well-approximated by a kernel-based hypothesis family. The recipe we propose does not exactly match the typical PQCs used by practitioners, but it is generic enough that it may become useful in the future. The construction relies on the Linear Combination of Unitaries (LCU) framework [48] and resembles constructions proposed in e.g. Refs. [49, 50].

Let k_F be a kernel that can be well-approximated as an Embedding Quantum Kernel (EQK) [49] on n qubits, meaning there exists a data-dependent unitary gate $U(\boldsymbol{x})$ such that

$$\sup_{\boldsymbol{x},\boldsymbol{x}'\in\mathcal{X}}\left|k_F(\boldsymbol{x},\boldsymbol{x}') - |\langle\mathbf{0}|U^\dagger(\boldsymbol{x})U(\boldsymbol{x}')|\mathbf{0}\rangle|^2\right|^2 \leq \epsilon \tag{D1}$$

for almost every $\boldsymbol{x}, \boldsymbol{x}' \in \mathcal{X}$. Then, given $N \in \mathbb{N}$, a vector of real numbers $\boldsymbol{\alpha} = (\alpha_i)_{i=1}^N$, and a set of inputs $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N$, consider a PQC over $n + \lceil \log(N) \rceil$ qubits. The circuit starts on the all-0 state, and the unitary $U(\boldsymbol{x})$ is applied on the first n-qubits. In parallel, we perform amplitude encoding of $\boldsymbol{\alpha}$ on the other $\lceil \log(N) \rceil$ qubits of the auxiliary register. Next, we define a controlled operation CU_i which, conditional on the auxiliary register being in state $|i\rangle$ for $i \in \{1, \ldots, N\}$ applies $U^\dagger(\boldsymbol{x}_i)$ on the main register. It follows that these controlled operations commute $[CU_i, CU_j] = 0$. We need only apply all such controlled gates in sequence, then: $\prod_{i=1}^N CU_i$, and measure the probability of the first n-qubits being in the all-0 state at the end (together with a diagonal observable on the auxiliary register that takes care of the negative signs in $\boldsymbol{\alpha}$). For notational ease, we do not explicitly write the extra observable on the auxiliary register, and we write only the projector on the all-0 state. This means that the functions can take negative values even though they are defined as the absolute square of a complex number. This way, given $\boldsymbol{\alpha}$ and $\boldsymbol{x}, \boldsymbol{x}_1, \ldots, \boldsymbol{x}_N$ we have defined a PQC in the form of a unitary $W(\boldsymbol{\alpha}, \boldsymbol{x}, (\boldsymbol{x}_i)_i)$, and produces as output a function in the kernel-based hypothesis family:

$$|\langle \mathbf{0} | W(\boldsymbol{\alpha}, \boldsymbol{x}, (\boldsymbol{x}_i)_i) | \mathbf{0} \rangle|^2 = \sum_{i=1}^N \alpha_i |\langle \mathbf{0} | U^\dagger(\boldsymbol{x}) U(\boldsymbol{x}') | \mathbf{0} \rangle|^2. \tag{D2}$$

From the ϵ-approximation of the initial kernel k_F via the EQK defined by U, it follows that each function of the form $\sum_{i=1}^N \alpha_i k(\boldsymbol{x}, \boldsymbol{x}_i)$ can be approximated by a function in $\mathcal{F}_{W, |\mathbf{0}\rangle\langle\mathbf{0}|}$, by taking the same $\boldsymbol{\alpha}$ vector and the same set of inputs $(\boldsymbol{x}_i)_i$. Without loss of generality, we assume the parameter vector $\boldsymbol{\alpha}$ has bounded norm $\|\boldsymbol{\alpha}\|_2^2 \leq B$:

$$\begin{aligned}
&\sup_{\boldsymbol{x} \in \mathcal{X}} \left| \left(\sum_{i=1}^N \alpha_i k_F(\boldsymbol{x}, \boldsymbol{x}_i) \right) - |\langle \mathbf{0} | W(\boldsymbol{\alpha}, \boldsymbol{x}, (\boldsymbol{x}_i)_i) | \mathbf{0} \rangle|^2 \right|^2 && \text{(D3)}\\
&= \sup_{\boldsymbol{x} \in \mathcal{X}} \left| \sum_{i=1}^N \alpha_i \left(k_F(\boldsymbol{x}, \boldsymbol{x}_i) - |\langle \mathbf{0} | U^\dagger(\boldsymbol{x}) U(\boldsymbol{x}_i) | \mathbf{0} \rangle|^2 \right) \right|^2 && \text{(D4)}\\
&\leq \|\boldsymbol{\alpha}\|^2 \sum_{i=1}^N \sup_{x \in \mathcal{X}} \left| k_F(\boldsymbol{x}, \boldsymbol{x}_i) - |\langle \mathbf{0} | U^\dagger(\boldsymbol{x}) U(\boldsymbol{x}_i) | \mathbf{0} \rangle|^2 \right|^2 && \text{(D5)}\\
&\leq B^2 \epsilon && \text{(D6)}
\end{aligned}$$

Altogether, this recipe allows us to construct a PQC whose associated function family is the same as a given kernel-based function family. For Algorithm 1 to succeed as a classical learner of this function family, then, we need only be able to evaluate the kernel k_F efficiently classically. It is known that the complexity of evaluating the trigonometric kernels that result from quantum embeddings is upper-bounded by the cardinality of the frequency spectrum $\tilde{\Omega}$ arising from the encoding strategy.

2. Approximating PQCs with random Fourier features

If the PQC $U(\boldsymbol{x}, \boldsymbol{\theta})$ is such that its corresponding feature map is of polynomial dimension $|\tilde{\Omega}| \in \mathcal{O}(\mathrm{poly}(m))$, then we know we can classically express the corresponding function exactly: $\langle \mathbf{0} | U^\dagger(\boldsymbol{x}, \boldsymbol{\theta}) O U(\boldsymbol{x}, \boldsymbol{\theta}) | \mathbf{0} \rangle = \langle \boldsymbol{w}_F, \boldsymbol{\phi}_F(\boldsymbol{x}) \rangle$, where the real-valued vector $\boldsymbol{w}_F$ is efficiently storable in classical memory. Refs. [8, 51] offer a discussion on what encoding strategies connected to families of PQCs will result in Fourier spectra of polynomial size. It is nevertheless known that many natural encoding strategies result in an exponentially large Fourier spectrum, where we cannot rely on an exact realization of the PQC function as a classical linear map. Some of these cases have been recently analyzed in Refs. [26, 27] under the lens of Random Fourier Features (RFF) [33]. The main idea in RFF is to efficiently approximate the high-dimensional inner product $\langle \boldsymbol{w}_F, \boldsymbol{\phi}_F(\boldsymbol{x}) \rangle$ by sampling a few of its dominant terms.

For instance, consider an encoding strategy which gives rise to an exponentially large Fourier spectrum $|\Omega| \propto \exp(m)$. Then, the inner product

$$\langle \boldsymbol{w}, \boldsymbol{\phi}_F(\boldsymbol{x}) \rangle = \sum_{j=1}^{2|\Omega|-1} w_j \phi_{F,j}(\boldsymbol{x}) \tag{D7}$$

cannot be classically evaluated in general due to its containing many terms. Now consider a specific PQC $U(\boldsymbol{x}, \boldsymbol{\theta})$ with this encoding strategy, but which is structured enough that we know that some entries of the weight vector are more dominant than others, in that they contribute more to the sum. One way to capture this would be by considering a probability distribution over the Fourier spectrum $P(\Omega)$, where the probability associated with a specific frequency is proportional to the magnitude squared of its coefficients $p(\boldsymbol{\omega}) = a_{\boldsymbol{\omega}}^2 + b_{\boldsymbol{\omega}}^2$. Without loss of generality, we assume the coefficients are alreadyproperly normalized. Then, what the RFF algorithm prescribes we do is sample a number D of frequencies from such a distribution $\tilde{\boldsymbol{\omega}} \sim P^D$, and then consider the classical efficient feature map $\boldsymbol{\phi}_{\mathrm{RFF}}(\boldsymbol{x})$ consisting of only those frequencies:

$$\boldsymbol{\phi}_{\mathrm{RFF}}(\boldsymbol{x}) = \frac{1}{\sqrt{D}} \begin{pmatrix} \cos\langle \tilde{\boldsymbol{\omega}}_1, \boldsymbol{x}\rangle \\ \sin\langle \tilde{\boldsymbol{\omega}}_1, \boldsymbol{x}\rangle \\ \vdots \\ \cos\langle \tilde{\boldsymbol{\omega}}_D, \boldsymbol{x}\rangle \\ \sin\langle \tilde{\boldsymbol{\omega}}_D, \boldsymbol{x}\rangle \end{pmatrix}. \tag{D8}$$

The sampled frequencies $\tilde{\boldsymbol{\omega}}$ are all in the original Fourier spectrum $\tilde{\boldsymbol{\omega}}_i \in \Omega$, so $\boldsymbol{\phi}_{\mathrm{RFF}}(\boldsymbol{x})$ is just an appropriately renormalized subvector of the full $\boldsymbol{\phi}_F(\boldsymbol{x})$. This smaller feature map gives rise to the hypothesis family:

$$\mathcal{H}_{\mathrm{RFF}} = \{u(\langle \boldsymbol{w}, \boldsymbol{\phi}_{\mathrm{RFF}}(\boldsymbol{x})\rangle) \,|\, \boldsymbol{w} \in \mathbb{R}^D\}. \tag{D9}$$

Then, if the PQC function is such that it can in principle be approximated as a linear map of rank D [52], it follows from Refs. [25, 26, 33] that the RFF hypothesis family should contain a good approximation to the function. In the context of this work, this means that Algorithm 1 should be able to learn the initial PQC function by using $\mathcal{H}_{\mathrm{RFF}}$ as a hypothesis class.

The remaining question is, again, how to specify the right $\mathcal{H}_{\mathrm{RFF}}$ for a given PQC of interest, modelled by the function family $\mathcal{F}_{U,O}$. The ultimate general-case answer is not fully resolved [26], but we provide a recipe to, given an RFF-approximable EQK k, construct a corresponding PQC.

Let k be a kernel that can be approximated as the inner product of a feature map $\boldsymbol{\phi}$ of polynomial size (in particular, this could be the randomized feature map produced by the RFF algorithm):

$$\sup_{\boldsymbol{x},\boldsymbol{x}' \in \mathcal{X}} \left| k(\boldsymbol{x}, \boldsymbol{x}') - \langle \boldsymbol{\phi}(\boldsymbol{x}), \boldsymbol{\phi}(\boldsymbol{x}')\rangle \right|^2 \leq \epsilon, \tag{D10}$$

for almost every $\boldsymbol{x}, \boldsymbol{x}' \in \mathcal{X}$. Let further $U(\boldsymbol{x})$ be a quantum embedding that implements the feature map $\boldsymbol{\phi}(\boldsymbol{x})$ (w.l.o.g. we take $\boldsymbol{\phi}$ to be properly normalized):

$$\sup_{\boldsymbol{x},\boldsymbol{x}' \in \mathcal{X}} \left| |\langle \mathbf{0} | U^\dagger(\boldsymbol{x}) U(\boldsymbol{x}') | \mathbf{0}\rangle|^2 - \langle \boldsymbol{\phi}(\boldsymbol{x}), \boldsymbol{\phi}(\boldsymbol{x}')\rangle \right|^2 \leq \epsilon'. \tag{D11}$$

Then the same LCU construction we used before also results in a PQC whose function family approximates the function family of the RFF-based kernel, which in turn approximates the function family of the original kernel. With triangular inequality, it follows that this PQC construction approximates the original kernel-based function family. Since Algorithm 1 can provably learn the kernel-based function family, it follows it can also learn this PQC family.

Appendix E: Proof of Lemma 1

To discuss the explicit risk of the ERM given the hypothesis class $\mathcal{H}$ in Equation (45), we use the following result in statistical learning theory:

Proposition E.1 (Proposition 4.1, [47])**.** *Let $\mathcal{D}$ be a distribution over $\mathcal{X} \times \mathcal{Y}$. Let $\mathcal{L} : \mathcal{Y}' \times \mathcal{Y} \to \mathbb{R}_+$ be a loss function. Considering a hypothesis class $\mathcal{F}$ that maps $\mathcal{X}$ to $\mathcal{Y}'$, For any sample $\mathcal{S}$ from distribution $\mathcal{D}$, for hypotheses $f \in \mathcal{F}$, the following holds:*

$$\mathbb{E}_{\mathcal{D}}[\mathcal{L}(f_{\mathcal{S}}^{\mathrm{ERM}}(\boldsymbol{x}), y)] - \inf_{f \in \mathcal{F}} \mathbb{E}_{\mathcal{D}}[\mathcal{L}(f(\boldsymbol{x}), y)] \leq 2 \sup_{f \in \mathcal{F}} \left| \mathbb{E}_{\mathcal{D}}[\mathcal{L}(f(\boldsymbol{x}), y)] - \frac{1}{|\mathcal{S}|} \sum_{(\boldsymbol{x}, y) \in \mathcal{S}} \mathcal{L}(f(\boldsymbol{x}), y) \right|. \tag{E1}$$

Considering the implicit loss function ℓ_{impl} for the loss function $\mathcal{L}$ in the above proposition, we get

$$R_{\mathrm{impl}}(h_{\mathcal{S}}^{\mathrm{ERM}}) - \inf_{h \in \mathcal{H}} R_{\mathrm{impl}}(h) \leq 2 \sup_{h \in \mathcal{H}} |R_{\mathrm{impl}}(h) - \widehat{R}(h)|. \tag{E2}$$

Noting that $R_{\text{impl}}(h) = R_{\text{expl}}(h) + R_{\text{impl}}(\mathbb{E}_{\bar{y}}[\bar{y}|\boldsymbol{x}])$, we can see that

$$R_{\text{expl}}(h_{\mathcal{S}}^{\text{ERM}}) - \inf_{h\in\mathcal{H}} R_{\text{expl}}(h) \leq 2 \sup_{h\in\mathcal{H}} |R_{\text{impl}}(h) - \widehat{R}(h)|. \tag{E3}$$

By definition, we know that

$$\inf_{h\in\mathcal{H}} R_{\text{expl}}(h) = \inf_{h\in\mathcal{H}} \mathbb{E}_{\bar{\mathcal{D}}}[(h(\boldsymbol{x}) - c(\boldsymbol{x}))^2] \leq \mathbb{E}_{\bar{\mathcal{D}}}[(\langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle - \langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle + \xi(\boldsymbol{x}))^2] = \mathbb{E}_{\bar{\mathcal{D}}}[\xi(\boldsymbol{x})^2] \leq \epsilon_1. \tag{E4}$$

Hence we see that

$$R_{\text{expl}}(h_{\mathcal{S}}^{\text{ERM}}) \leq \epsilon_1 + 2 \sup_{h\in\mathcal{H}} |R_{\text{impl}}(h) - \widehat{R}(h)|. \tag{E5}$$

We now find error bounds on the right-hand side of the previous proposition. To do so, we require the following results obtainable by combining Theorem 8 and Lemma 22 from [44]:

Theorem E.1 (Theorem 11.11, [47])**.** *Given distribution $\mathcal{D}$ over $\mathcal{X} \times \mathcal{Y}$, let $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be a positive semidefinite kernel, $\Phi : \mathcal{X} \to \mathbb{H}$ be the feature map associated with kernel k, and hypothesis class $\mathcal{H} = \{\boldsymbol{x} \to \langle \boldsymbol{w}, \boldsymbol{\phi}(\boldsymbol{x})\rangle, \|\boldsymbol{w}\|_{\mathbb{H}} \leq \Lambda\}$. Assume there exists $r, M > 0$ such that $k(\boldsymbol{x}, \boldsymbol{x}) \leq r^2$ and for all hypotheses $h : \mathcal{X} \to \mathcal{Y}' \in \mathcal{H}$ and all $(\boldsymbol{x}, y) \in \mathcal{D}$, $|h(\boldsymbol{x}) - y| \leq M$. Then for any sample $\mathcal{S}$ from $\mathcal{D}$ of size N, the generalization bound is as follows:*

$$\left| \mathop{\mathbb{E}}_{(\boldsymbol{x},y)\sim\mathcal{D}} \left[|h(\boldsymbol{x}) - y|^2\right] - \frac{1}{N} \sum_{(\boldsymbol{x},y)\in\mathcal{S}} |h(\boldsymbol{x}) - y|^2 \right| \in \mathcal{O}\left(\frac{M\Lambda r}{\sqrt{N}} + M^2 \sqrt{\frac{\log\frac{1}{\delta}}{N}} \right). \tag{E6}$$

Plugging in our error losses and range of $\mathcal{H}$, we note that $\Lambda, M \in \mathcal{O}(D)$ and $r = 1$. We then obtain the following generalization bound for $\mathcal{H}$.

$$|R_{\text{impl}}(h) - \widehat{R}(h)| \in \mathcal{O}\left(D^2 \sqrt{\frac{\log\frac{1}{\delta}}{N_1}} \right), \tag{E7}$$

Note that this result yields a better result than the Rademacher-based generalization bound proposed by Caro *et al.* [51] by a logarithmic factor if we use the entire Fourier spectrum instead of RFF. We can then write the explicit risk for the ERM as follows:

$$R_{\text{expl}}(h_{\mathcal{S}}^{\text{ERM}}) \in \mathcal{O}\left(\epsilon_1 + D^2 \sqrt{\frac{\log\frac{1}{\delta}}{N_1}} \right). \tag{E8}$$

Advantage of Quantum Machine Learning from General Computational Advantages

Abstract. A key milestone of quantum machine learning (QML) is to demonstrate its advantage over classical methods in accelerating supervised learning with classical data. Previously, QML's proven advantages were limited to learning tasks constructed based on Shor's algorithms. We here construct supervised learning tasks with provable advantage based on general quantum computational advantages beyond Shor's algorithms. We construct a polynomial-time QML algorithm for solving these tasks even though these tasks have exponentially many candidates of functions to be learned. At the same time, we prove the hardness of achieving these tasks for any polynomial-time classical method. We also clarify protocols for preparing classical data of this learning task for its experimental demonstration. These results pave the way to exploit various quantum advantages in computing functions for demonstrating QML's advantages.

Keywords: Quantum machine learning, PAC learning, Quantum advantage, Supervised learning

1 Introduction

Machine learning supervised by big data supports our daily lives in today's world. Quantum machine learning (QML) attracts growing attention as an emerging field of research to further accelerate and scale up the learning by taking advantage of quantum computation [1, 2]. Due to its importance and potential, QML has gathered substantial attention among the community of recent AQIS conferences [3–5]. Quantum computation is believed to achieve significant speedup in solving various computational problems over conventional classical computation [6, 7]. The central goal of supervised learning is, however, not solving the computational problems themselves but finding and making a correct prediction on unseen data under the supervision of given sample data [8–11]. A far-reaching milestone in the field of QML is to demonstrate the advantage of QML, i.e., an end-to-end acceleration in accomplishing this goal of learning in such a way that any possible classical learning method would never be able to achieve.

However, it has been challenging to realize this milestone due to our limited theoretical understanding of the learning tasks with the advantage of QML. Representative QML algorithms such as those in Refs. [12–17] have theoretically guaranteed upper bounds of their runtime, and it is indeed hard for existing classical algorithms to achieve the same learning tasks as these QML algorithms within a comparable runtime; nevertheless, these facts are insufficient to provably rule out the possibility of the potential existence of classical learning methods achieving the comparable runtime. For example, the quantum algorithm for recommendation systems was initially claimed to achieve an exponential speedup compared to the existing classical algorithms at the time [13], but it turned out in later research that the quantum algorithm achieves only a polynomial speedup compared to the best possible classical algorithm due to a breakthrough in designing a quantum-inspired classical algorithm for solving the same task [18]. Prior to our work, the advantage of QML based on general types of quantum computational advantages has only shown for a limited class of learning problems that can be simply solved by a brute-force algorithm trying each solution candidate one by one [19, 20]; however, in practice, machine learning algorithms never try all the possible candidates of the functions to be learned, which is infeasible in many cases. Of interest here are more difficult yet common learning problems where the number of candidates is exponential. In this regime, the advantage of QML in accelerating supervised learning with classical data has been proven only based on the quantum computational advantage of Shor's algorithms [21–23] to solve integer factoring and discrete logarithms [19, 20, 24–26]. The existing techniques to prove the hardness of learning for all possible classical methods use a cryptographic argument essentially depending on the specific mathematical structure of discrete logarithms and integer factoring [8, 9, 19, 20, 24–27], which do not straightforwardly generalize. A fundamental open question in the theory of QML has been what types of quantum computational advantages, beyond that of Shor's algorithms, lead to learning tasks to demonstrate the end-to-end acceleration of the learning; to address this question, novel techniques need to be established to prove the classical hardness of learning beyond the realm of Shor's algorithms.

Also from a practical perspective, toward the experimental demonstration of the advantages of QML, Shor's algorithms are challenging to realize with near-term quantum technologies [28], confronting as an obstacle to the demonstration. One reason for this practical challenge is rooted in the fact that Shor's algorithms need to compete with the well-established classical algorithms for integer factoring that run only within subexponential time, which is much shorter than exponential time [29–31]. For this reason, a milestone in realizing Shor's algorithms is often set to factorize a relatively

*hayata.yamasaki@gmail.com
†natsuto.isogai@phys.s.u-tokyo.ac.jp
‡murao@phys.s.u-tokyo.ac.jp

large integer, such as a 2048-bit integer [28]. On the other hand, apart from Shor's algorithms, polynomial-time quantum algorithms can also solve other types of computational problems that are potentially harder for classical algorithms, such as those relevant to topological data analysis (TDA) [32–36], Pell's equation [37, 38], and BQP-complete problems [39–45]. For the classically hard problems, one could potentially use a much smaller size of the problem instance, e.g., with much less than 2048-bit inputs, to demonstrate the quantum computational advantages. In view of this, the solution to the above open question on the relation between quantum computational advantages and the advantage of QML will also constitute a significant step to the practical demonstration as well as the fundamental understanding of QML.

2 Summary of Main Result

In this work, we address this open question by showing that quantum advantages in computing functions *in general* lead to the provable end-to-end advantage of QML in conducting supervised learning with classical data, without specifically depending on Shor's algorithms. Significantly, our results hold for learning problems with exponentially many candidates of the functions to be learned in terms of the problem size.

To address the above question, we explicitly construct a family of classification tasks in a conventional setting of supervised learning with classical sample data, i.e., in a probably approximately correct (PAC) learning model [8, 9, 46], using a general class of functions that can be computed efficiently in polynomial time for a large fraction of inputs by quantum algorithms but not by any classical algorithm (even under the supervision of data). In a classification task, for an unknown function c to be learned (called a concept), one is initially given sample data of inputs x from a target distribution $x \sim \mathcal{D}$ and the corresponding outputs $c(x) = 0$ or $c(x) = 1$ of binary labels. Using these samples, the classification task aims to find and make a correct prediction (called a hypothesis) that should coincide with $c(x)$ for a large fraction of $x \sim \mathcal{D}$. We study classification tasks that have a common structure to those widely appearing in conventional machine learning; in particular, we consider tasks that can be solved by a commonly used learning method called feature mapping and linear separation (see Fig. 1 of Technical Manuscript). In this approach, the learning algorithm first maps an input x to another vector $f(x)$ and subsequently classifies x in the space of $f(x)$. This mapping f is known as a feature map, transforming x in the input space into the corresponding feature $f(x)$ in the feature space that encapsulates essential information for the classification. The sets of x satisfying $c(x) = 0$ and $c(x) = 1$ are mapped into $\mathcal{F}_0$ and $\mathcal{F}_1$ of $f(x)$, respectively. The feature map here should be designed so that $\mathcal{F}_0$ and $\mathcal{F}_1$ have linear separability, i.e, the property that a hyperplane in the feature space should be able to distinguish between $\mathcal{F}_0$ and $\mathcal{F}_1$ [47]. The goal of the learning task is to find the hyperplane and use it to make a correct prediction for $x \sim \mathcal{D}$.

Our key discovery is that the advantage of QML stems from the feature mapping that makes the learning feasible for quantum computation but hard for classical computation; in our QML framework, we convert the input x into a bit string representing their feature $f(x)$ by a feature map f that can be computed efficiently by quantum computation but not by classical computation. The feature space for these bit strings is represented as a vector space over a finite field (see Technical Manuscript for details). Remarkably, for our learning task, we show that f can be arbitrarily chosen from a general class of functions that can be, roughly speaking, computed efficiently within a polynomial time by quantum algorithms (for a large fraction of inputs $x \sim \mathcal{D}$ with a high probability) but not by classical algorithms (even with a polynomial-size advice string, e.g., sample data). We call a function in this class a *quantumly advantageous function* (see also Technical Manuscript for the precise definition). In the previous work on the provable advantage of QML, the choice of such a feature map was limited to those computed by Shor's algorithms, which has been undermining the applicability of QML. By contrast, our results make it possible to use arbitrary quantumly advantageous functions as feature maps in QML to obtain the following theorem.

Theorem 1 *(informal, see also Technical Manuscript): Advantage of QML from general computational advantages. For any quantumly advantageous function f under any target distribution $\mathcal{D}$, we construct a quantum algorithm that can find and make a correct prediction in our learning task within a polynomial time; by contrast, we prove that no polynomial-time classical algorithm can achieve this.*

Construction of polynomial-time QML algorithm. We construct a polynomial-time quantum algorithm for solving our learning task using a polynomial amount of classical sample data. This quantum algorithm is simply implementable by a variant of the conventional learning method: feature mapping by quantum computation to map the input classical data into the corresponding bit strings representing their features, followed by linear separation by classical computation to find an appropriate hyperplane in the feature space to achieve the classification. While the feature space of these bit strings is discrete, our algorithm finds a hyperplane by solving a system of linear equations using Gaussian elimination. A technical challenge in constructing our algorithm is that the learning algorithm does not necessarily find the true hyperplane of the unknown concept c to be learned but may output an approximate estimate of the hyperplane; nevertheless, our analysis shows that any hyperplane learned by our algorithm leads to a correct prediction for a large fraction of $x \sim \mathcal{D}$ with a high probability to achieve the learning task (see Technical Manuscript for details).

Provable classical hardness At the same time, under the assumption that no polynomial-time classical algorithm can compute the quantumly advantageous function used in our construction (yet, importantly, without any cryptographic assumption specifically depending on Shor's algorithms), we prove that no polynomial-time classical algorithm can accomplish this learning task. The feature mapping and the linear separation may also be applicable to some of the previous works on the advantage of QML [24], but a more crucial difference arises from the techniques for proving the classical hardness. In particular, a feature map constructed in Ref. [24] used Shor's algorithms to transform an input into a feature in a feature space, which was taken as a space of functions called the reproducing kernel Hilbert space (RKHS) in the kernel method [10, 11] to show a polynomial-time quantum learning algorithm. However, the existing techniques for proving the classical hardness of such learning tasks needed to use a cryptographic argument on the hardness of solving computational problems depending on the specific mathematical structure of discrete logarithms and integer factoring [8, 9, 19, 20, 24–27] and do not straightforwardly generalize. By contrast, we develop techniques for analyzing our learning task with its feature space formulated as the vector space of bit strings (i.e., the vector space over a finite field), making it possible to prove the classical hardness for any quantumly advantageous function in general (see Technical Manuscript for details).

Protocol for demonstrating the provable advantage of QML Furthermore, we clarify a protocol for preparing the classical sample data to demonstrate this provable advantage of QML in the experiments. For the demonstration, we propose a two-party setup, where a party A is in charge of preparing the classical sample data, and the other party B receives the data from A to perform the learning (see also Fig. 2 of Technical Manuscript). We here put A and B on equal footing by allowing both to compute the feature map f by quantum computation. Note that in the previous work on the advantage of QML based on Shor's algorithms [19, 20, 24–26], the data for their learning tasks were able to be prepared by classical computation, but this classical data preparation was possible by assuming a special property of cryptographic primitives (i.e., *classically one-way* permutation, which is hard to invert efficiently by classical computation but is invertible efficiently by quantum computation). We also show that A's data preparation for our task is possible in the same way by only using classical computation if we use the classically one-way permutations for f (see Technical Manuscript for details). These results pave the way to the practical demonstration of the provable advantage of QML in experiments, via realizing any quantum algorithms for computing quantumly advantageous functions without necessarily depending on Shor's algorithms.

3 Impact

In conclusion, our work successfully bridges the gap between the advantage of QML (in finding and making a correct prediction from given samples) and quantum computational advantages (in computing functions), disclosing the origin of the advantage of QML stemming from the computation of *any* quantumly advantageous functions. The existing works on the provable advantages of QML were limited to the realm of Shor's algorithms [19, 20, 24–26] or to that of brute-force algorithms that are not applicable to the super-polynomial number of candidates [19, 20]. By contrast, our results open vast opportunities to use a general class of quantum algorithms beyond Shor's algorithms to enjoy the provable advantage of QML, such as those relevant to topological data analysis (TDA) [32–36], Pell's equation [37, 38], and BQP-complete problems [39–45] (see Technical Manuscript for details of these examples). In different settings from ours, advantages of using quantum computation have been shown in a learning setting with quantum data obtained from quantum experiments [48–53] and also in a distribution learning setting [54–56]; still, it is not straightforward to apply these quantum algorithms to accelerate the common learning tasks in the era of big data, as represented by supervised learning with classical data. By contrast, our approach offers a QML framework that can address this common type of learning task. A merit of our QML framework is that it is simply implementable by using any quantumly advantageous function for feature mapping, followed by classically performing linear separation in the feature space.

Also from a broader perspective, in applications of machine learning, state-of-the-art classical learning methods such as deep learning heuristically design the feature maps, e.g., by adapting the architectures of deep neural networks [57]. The theoretical analysis of optimized choices of feature maps for given data is challenging even in classical cases, but empirical facts suggest that the classification tasks for real-world data often reduce to applying feature maps designed by such artificial neural networks followed by linear separation [57]. In view of the success of the artificially designed feature maps, it is crucial to allow as large classes of functions as possible to create more room for the heuristic optimization of the feature maps. Advancing ahead, our QML framework makes it possible to design the feature maps flexibly, using arbitrary quantumly advantageous functions to attain the provable advantage of QML. Toward the demonstration of the advantage of QML, an experimental challenge still remains in seeking how to realize quantum computation to surpass the capability of classical computation, and yet our QML framework opens a way to transcend all possible classical learning methods by exploiting *any* realization of quantumly advantageous functions for the feature maps.

Note: After this work had appeared in arXiv, Ref. [58] also showed a result in a similar direction, i.e., shows a provable advantage of QML over any classical methods for learning problems with exponentially many candidates, using another technique. We believe that this fact also supports a common interest and a high impact of our results in the field of QML.

An overarching milestone of quantum machine learning (QML) is to demonstrate the advantage of QML over all possible classical learning methods in accelerating a common type of learning task as represented by supervised learning from classical data. However, the provable advantages of QML in supervised learning have been known so far only for the learning tasks designed for using the advantage of specific quantum algorithms, i.e., Shor's algorithms. Here we explicitly construct an unprecedentedly broader family of supervised learning tasks with classical data to offer the provable advantage of QML based on general quantum computational advantages, progressing beyond Shor's algorithms. Our learning task is feasibly achievable by executing a general class of functions that can be computed efficiently in polynomial time for a large fraction of inputs by arbitrary quantum algorithms but not by any classical algorithm. We prove the hardness of achieving this learning task for any possible polynomial-time classical learning method. We also clarify protocols for preparing the classical data to demonstrate this learning task in experiments. These results open vast opportunities to exploit a variety of quantum advantages in computing functions for the realization of provably advantageous QML.

Introduction.— Machine learning technologies supervised by big data serve as one of the core infrastructures to support our daily lives. Quantum machine learning (QML) attracts growing attention as an emerging field of research to further accelerate and scale up the learning by taking advantage of quantum computation [1, 2]. Quantum computation is believed to achieve significant speedup in solving various computational problems over conventional classical computation [3, 4]. The central goal of supervised learning is, however, not solving the computational problems themselves but finding and making a correct prediction on unseen data under the supervision of given sample data [5–8]. A far-reaching milestone in the field of QML is to demonstrate the advantage of QML, i.e., an end-to-end acceleration in accomplishing this goal of learning in such a way that any possible classical learning method would never be able to achieve.

However, it has been challenging to realize this milestone due to our limited theoretical understanding of the learning tasks with the advantage of QML. Representative QML algorithms such as those in Refs. [9–14] have theoretically guaranteed upper bounds of their runtime, and it is indeed hard for existing classical algorithms to achieve the same learning tasks as these QML algorithms within a comparable runtime; nevertheless, these facts are insufficient to provably rule out the possibility of the potential existence of classical learning methods achieving the comparable runtime. For example, the quantum algorithm for recommendation systems was initially claimed to achieve an exponential speedup compared to the existing classical algorithms at the time [10], but it turned out in later research that the quantum algorithm achieves only a polynomial speedup compared to the best possible classical algorithm due to a breakthrough in designing a quantum-inspired classical algorithm for solving the same task [15]. It is possible to prove the advantage of QML in accelerating particular types of supervised learning with classical data, as shown in Refs. [16–20]; yet problematically, such learning tasks are mostly based on the quantum computational advantage of Shor's algorithms to solve integer factoring and discrete logarithms [21–23], and the techniques to prove the hardness of learning for all possible classical methods use a cryptographic argument essentially depending on the specific mathematical structure of discrete logarithms and integer factoring [5, 6, 16–20, 24], which do not straightforwardly generalize. References [18, 19] also study the advantage of QML based on more general quantum computational advantages than that of Shor's algorithms, but this technique was limited to learning problems with only polynomially many possible functions to be learned, which are learnable just by a brute-force algorithm. By contrast, of interest here are the learning problems with exponentially many possible functions to be learned, which require more efficient learning algorithms than such a brute-force approach yet commonly appear in practical machine learning. A fundamental open question in the theory of QML has been what types of quantum computational advantages, beyond that of Shor's algorithms, lead to the end-to-end quantum acceleration in solving such learning problems with exponentially many possibilities; to address this question, novel techniques need to be established to prove the classical hardness of learning beyond the realm of Shor's algorithms.

Also from a practical perspective, toward the experimental demonstration of the advantages of QML, Shor's algorithms are challenging to realize with near-term quantum technologies [25], confronting as an obstacle to the demonstration. One reason for this practical challenge is rooted in the fact that Shor's algorithms need

[*] hayata.yamasaki@gmail.com

to compete with the well-established classical algorithms for integer factoring that run only within subexponential time, which is much shorter than exponential time [26–28]. For this reason, a milestone in realizing Shor's algorithms is often set to factorize a relatively large integer, such as a 2048-bit integer [25]. On the other hand, apart from Shor's algorithms, polynomial-time quantum algorithms can also solve other types of computational problems that are potentially harder for classical algorithms, such as those relevant to topological data analysis (TDA) [29–33], BQP-complete problems [34–40], and Pell's equation [41, 42]. For the classically hard problems, one could potentially use a much smaller size of the problem instance, e.g., with much less than 2048-bit inputs, to demonstrate the quantum computational advantages. In view of this, the solution to the above open question on the relation between quantum computational advantages and the advantage of QML will also constitute a significant step to the practical demonstration as well as the fundamental understanding of QML.

In this work, we address this open question by showing that quantum advantages in computing functions *in general* lead to the provable end-to-end advantage of QML in supervised learning with classical data, even for exponentially many possible functions to be learned. Our results do not specifically depend on Shor's algorithms. In particular, using a general class of functions that can be computed efficiently in polynomial time for a large fraction of inputs by quantum algorithms but not by any classical algorithm (even under the supervision of data), we explicitly construct a family of classification tasks in a conventional setting of supervised learning from classical sample data, i.e., in a probably approximately correct (PAC) learning model [5, 6, 43]. This classification task may require finding a correct classifier function among exponentially many possibilities for labeling the input data. We construct a polynomial-time quantum algorithm for solving our learning task using a polynomial amount of classical sample data. This quantum algorithm is simply implementable by a variant of the conventional learning method: feature mapping by quantum computation to map the input classical data into the corresponding bit strings representing their features, followed by linear separation by classical computation to find an appropriate hyperplane in the feature space to achieve the classification. At the same time, we prove that no polynomial-time classical algorithm can accomplish this learning task. Furthermore, we provide a protocol for preparing the classical sample data to demonstrate this advantage of QML in the experiments. These results open vast opportunities for anyone to use a general class of quantum algorithms of their favorite to achieve provably advantageous QML over any classical learning method even for the learning problems with exponentially many possibilities, progressing beyond the previous approach in Refs. [16–20].

Formulation of learning tasks.— We describe the setting of learning and the formulation of our learning task. Our analysis is based on a conventional setting of supervised learning, i.e., the PAC learning model [5, 6, 43]. See Methods on the definition of the PAC learning model.

Following the convention of the PAC learning, we formulate our concept class $\mathcal{C}_N$, i.e., a set of functions $c \in \mathcal{C}_N$ to be learned, which classify an N-bit input x coming from a target probability distribution $\mathcal{D}_N$ into binary-labeled categories specified by $c(x) = 0$ or $c(x) = 1$. Our formulation is in line with a conventional learning approach based on feature mapping and linear separation (Fig. 1). In this approach, the learning algorithm first maps an input x to another vector $f(x)$ and subsequently classifies x in the space of $f(x)$. This mapping f is known as a feature map, transforming x in the input space into the corresponding feature $f(x)$ in the feature space that encapsulates essential information for the classification. The sets of x satisfying $c(x) = 0$ and $c(x) = 1$ are mapped into $\mathcal{F}_0$ and $\mathcal{F}_1$ of $f(x)$, respectively. The feature map here should be designed so that $\mathcal{F}_0$ and $\mathcal{F}_1$ have linear separability, i.e, the property that a hyperplane in the feature space should be able to distinguish between $\mathcal{F}_0$ and $\mathcal{F}_1$ [44]. More formally, there should exist a vector s in the feature space and a threshold t such that

$$f(x) \cdot s \leq t \text{ for } c(x) = 0; \quad f(x) \cdot s > t \text{ for } c(x) = 1. \tag{1}$$

The equation $f(x) \cdot s = t$ represents the hyperplane to separate $\mathcal{F}_0$ and $\mathcal{F}_1$ specified by the unknown target concept c to be learned. The concept class of c is learnable by converting the given input samples using the feature map, followed by finding this hyperplane, i.e., its parameter s, using the corresponding output samples. Once we find s, for a new input x drawn from $\mathcal{D}_N$, we can make a correct prediction of $c(x)$ by evaluating a hypothesis $h(x)$ in a hypothesis class, which classifies x based on the value of $f(x) \cdot s$.

Based on this approach, we construct our concept class $\mathcal{C}_N = \{c_s\}_s$ parameterized by s in the vector space $\mathbb{F}_2^D$ over a finite field, where $\mathbb{F}_2 = \{0, 1\}$ is the finite field representing a bit, and D is the dimension of the feature space $\mathbb{F}_2^D$. Each concept c_s is a function from the input space $\{0, 1\}^N$ to binary labels $\{0, 1\}$. With some choice of the feature map $f_N : \{0, 1\}^N \to \mathbb{F}_2^D$, we here define c_s as

$$c_s(x) := f_N(x) \cdot s \in \mathbb{F}_2 = \{0, 1\}, \tag{2}$$

where $f_N(x) \cdot s$ is the bitwise inner product in $\mathbb{F}_2^D$. This concept class is designed in accordance with the convention in machine learning based on feature mapping and linear separation as in (1), yet using the finite fields as the feature space (i.e., $f_N(x) \cdot s = t := 0$ or $f_N(x) \cdot s = 1$).

Advantage of QML from general quantum computational advantages.— To seek the advantage of QML, we study our concept class in (2) with an appropriate choice of the feature map f_N. Remarkably, for our concept class, we show that f_N can be arbitrarily chosen from, roughly speaking, a general class of functions that can be computed efficiently within a polynomial time by quantum

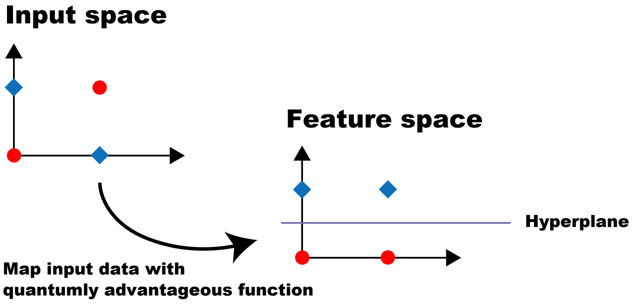

FIG. 1. A conventional learning approach based on feature mapping and linear separation, which our work also follows. Inputs x in the input space (red circles with output labels $c(x)=0$ and blue squares with $c(x)=1$) are mapped into the corresponding features $f(x)$ in the feature space by a feature map f. Then, using the features $f(x)$ of the input samples and the corresponding output samples $c(x)$, we find a hyperplane linearly separating the sets of features for $c(x)=0$ and $c(x)=1$ as in (1) to achieve the learning. In our learning tasks, we use quantumly advantageous functions as f.

algorithms but not by classical algorithms. In the following, we introduce this general class of functions for f_N, followed by describing how the advantage of QML emerges from this general quantum advantage in computing f_N.

Under a target distribution $\mathcal{D}_N$, we choose the feature map f_N to be any function in a general class denoted by

$$\{(f_N,\mathcal{D}_N)\}_N \in \mathsf{HeurFBQP}\setminus(\mathsf{HeurFBPP/rpoly}), \qquad (3)$$

as defined more precisely in the following (see also Supplementary Information for more details). We call a function in this class a *quantumly advantageous function* under $\mathcal{D}_N$.

In (3), we require that $f_N(x)$ should be efficiently computable by a quantum algorithm for a large fraction of x drawn from $\mathcal{D}_N$, and the set $\mathsf{HeurFBQP}$ of pairs of the function f_N and the distribution $\mathcal{D}_N$ represents those satisfying this requirement. In the computational complexity theory, a (worst-case) complexity class FBQP [45] conventionally represents a set of functions $f_N(x)$ that is efficiently computable by a quantum algorithm for all x even for the worst-case input [1], but for PAC learning, it suffices to work on a *heuristic* complexity class $\mathsf{HeurFBQP}$ that requires the efficiency not all but only a large fraction of x [46, 47]. More precisely, $\{(f_N,\mathcal{D}_N)\}_N \in \mathsf{HeurFBQP}$ requires that there exists a quantum algorithm $\mathcal{A}(x,\mu,\nu)$ that should run, for any N and $0<\mu,\nu<1$, within a polynomial runtime $O(\mathsf{poly}(N,1/\mu,1/\nu))$ to output $f_N(x)$ correctly for a large fraction $1-\mu$ of inputs x drawn from $\mathcal{D}_N$ with a high probability at least $1-\nu$, i.e.,

$$\Pr_{x\sim\mathcal{D}_N}\left[\Pr\left[\mathcal{A}(x,\mu,\nu)=f_N(x)\right]\geq 1-\nu\right]\geq 1-\mu, \qquad (4)$$

where the inner probability is taken over the randomness of $\mathcal{A}$.

At the same time, in (3), we require that $f_N(x)$ should not be efficiently computable by any classical (randomized) algorithm for the large fraction of x even with the help of the sample data, and to meet this requirement, it suffices to consider the relative complement of the set $\mathsf{HeurFBPP/rpoly}$ as in (3). In the complexity theory, $\mathsf{HeurFBPP}$ can be considered to be the classical analog of $\mathsf{HeurFBQP}$ while FBPP the classical analog of FBQP, indicating that the functions $f_N(x)$ are efficiently computable from the given input x by a classical randomized algorithm. Additionally, in the setting of PAC learning, the sample data are also initially given apart from x. The use of the sample data is not necessarily limited to the learning, but the data may also potentially help the classical algorithm to compute $f_N(x)$ itself more efficiently [18, 19, 48]. The parameters of hypotheses learned from the data given according to a data distribution can be seen as a random bit string of polynomial length $O(\mathsf{poly}(N,1/\mu,1/\nu,1/\xi))$ that could potentially make the computation more efficient with a high probability at least $1-\xi$, known as the randomized advice string α in the complexity theory [49]. To address this issue, we require that $f_N(x)$ should remain hard to compute by any classical algorithm even with an arbitrary polynomial-length randomized advice string α. More precisely, $\{(f_N,\mathcal{D}_N)\}_N \notin \mathsf{HeurFBPP/rpoly}$ requires that no classical (randomized) algorithm $\mathcal{A}(x,\alpha,\mu,\nu,\xi)$ with a randomized advice $\alpha\sim\mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}$ of length $O(\mathsf{poly}(N,1/\mu,1/\nu,1/\xi))$ sampled from an advice distribution $\mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}$ should run, for any N and $0<\mu,\nu,\xi<1$, in a polynomial time $O(\mathsf{poly}(N,1/\mu,1/\nu,1/\xi))$ to output $f_N(x)$ correctly with a high probability at least $1-\nu$ for a large fraction $1-\xi$ of α for a large fraction $1-\mu$ of x from $\mathcal{D}_N$, i.e.,

$$\Pr_{x\sim\mathcal{D}_N}\left[\Pr_{\alpha\sim\mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}}\left[\Pr\left[\mathcal{A}(x,\alpha,\mu,\nu,\xi)=f_N(x)\right]\right.\right.$$
$$\left.\left.\geq 1-\nu\right]\geq 1-\xi\right]\geq 1-\mu, \qquad (5)$$

where the most inner probability is taken over the randomness of $\mathcal{A}$. The previous work on the advantage of QML [16–20] used a cryptographic argument specifically depending on discrete logarithms and integer factoring to prove the classical hardness of their learning tasks, but we here identify that we can use the heuristic complexity class $\mathsf{HeurFBPP/rpoly}$ to rule out the existence of polynomial-time classical learning algorithms for our learning tasks. Note that the heuristic complexity class was also used in Refs. [18, 19] for providing conditions

[1] Note that Ref. [45] defines FBQP as a class of search problems, i.e., computation of functions having a set of multiple outputs for each input, but we consider f_N to have a single output $f_N(x)$ for each input x.

of the concept classes that offer the advantage of QML, but their results were limited to polynomial-size concept classes learnable by a brute-force algorithm that just tries all the concepts in the concept class; by contrast, we here apply the heuristic complexity class to the computation of feature maps, which makes it possible to construct exponential-size concept classes beyond the reach of such a brute-force approach.

Our main result proves that for *any* choice of the quantumly advantageous functions f_N in (3), our exponential-size concept class in (2) leads to the advantage of QML. In particular, the main result is summarized as follows. (See also Methods for the more precise definitions of the efficient learnability of the concept and the efficient evaluatability of the hypothesis.)

Theorem 1 (Advantage of QML from general computational advantages)**.** *Under any target distribution $\mathcal{D}_N$ over N-bit inputs, for any quantumly advantageous function f_N under $\mathcal{D}_N$, the concept class $\mathcal{C}_N$ defined in (2) with f_N is quantumly efficiently learnable, and for this $\mathcal{C}_N$, we can construct a quantumly efficiently evaluatable hypothesis class. By contrast, $\mathcal{C}_N$ is not classically efficiently learnable by any classically efficiently evaluatable hypothesis class.*

Importantly, Theorem 1 establishes the advantage of QML in supervised learning with exponential-size concept classes using arbitrary quantumly advantageous functions, in contrast with the fact that the existing techniques for proving the advantage of QML [16–20] were limited to using the advantage of Shor's algorithms. In Methods, to prove Theorem 1, we explicitly construct polynomial-time quantum algorithms for learning the concept and evaluating the hypothesis; at the same time, we prove that no classical algorithm can evaluate hypotheses that correctly predict the concepts in our concept class.

For our concept, the quantum algorithms for the learning and the evaluation are implementable by the simple approach of feature mapping and linear separation: in our case, the feature mapping uses the quantum algorithm in (4), and the linear separation is performed only by classical computing. A technical challenge in constructing our algorithms is that the learning algorithm does not necessarily find the true parameter s of the target concept c_s but may output an estimate $\tilde{s}$ with $\tilde{s} \neq s$; nevertheless, our analysis shows that the parameter $\tilde{s}$ learned by our algorithm leads to a correct hypothesis $h_{\tilde{s}}$ satisfying $h_{\tilde{s}}(x) = c_s(x)$ for a large fraction of x with high probability (see Methods for details).

The feature mapping and the linear separation may also be applicable to some of the previous works on the advantage of QML [16], but a more crucial difference arises from the techniques for proving the classical hardness. In particular, a feature map constructed in Ref. [16] used Shor's algorithms to transform an N-bit input into a feature in a feature space, which was taken as a space of functions called the reproducing kernel Hilbert space (RKHS) in the kernel method [7, 8] to show a polynomial-time quantum learning algorithm. However, the existing techniques for proving the classical hardness of such learning tasks needed to use a cryptographic argument on the hardness of solving computational problems depending on the specific mathematical structure of discrete logarithms and integer factoring [5, 6, 16–20, 24] and do not straightforwardly generalize. By contrast, we develop techniques for analyzing our learning task with its feature space formulated as the vector space over a finite field, making it possible to prove the classical hardness for any quantumly advantageous function in general (see Methods for details).

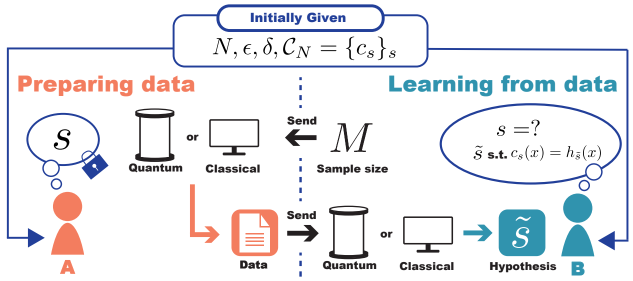

FIG. 2. A setup for demonstrating the advantage of QML in supervised learning by two parties A and B, where A is in charge of preparing the classical sample data, and B receives the data from A to perform the learning. The parties A and B are initially given the problem size N, the error parameter ϵ, the significance parameter δ, and the concept class $\mathcal{C}_N = \{c_s\}_s$ in (2) by choosing the feature map as a quantumly advantageous function f_N. The party A chooses a D-bit parameter s of the target concept c_s, which is kept as A's secret. To learn c_s, the party B decides the number M of sample data to be used for B's learning and lets A know M. Then, A prepares M input-output sample data as described in the main text and sends the data to B. Using the given data, B performs the algorithms in Theorem 1 to find a D-bit string $\tilde{s}$ and make a prediction for new inputs x by the hypothesis $h_{\tilde{s}}(x) = f_N(x) \cdot \tilde{s}$ so that the error in estimating true $c_s(x)$ should be below ϵ with high probability at least $1 - \delta$.

Lastly, due to the generality of the quantumly advantageous functions, Theorem 1 opens unprecedented opportunities for realizing the provable advantages of QML in supervised learning beyond the realm of Shor's algorithms, e.g., in the fields relevant to TDA [29–33], BQP-complete problems [34–40], and Pell's equation [41, 42]. See Methods for more details.

Protocol for preparing classical sample data for the experimental demonstration.— To embody the opportunities of demonstrating the advantage of QML in experiments, we clarify the protocol for preparing the classical sample data for our concept class $\mathcal{C}_N$ in (2).

For the demonstration, we consider a two-party setting, where a party A is in charge of preparing the classical sample data, and the other party B receives the data from A to perform the learning (Fig. 2). Initially, A and B are given the problem size N, the error parameter ϵ, and the significance parameter δ. Let $\mathcal{D}_N$ be a target distribution, and suppose that A can load a sequence of inputs x sampled from $\mathcal{D}_N$ (e.g., from some input data storage), with each x loadable in a unit time. Note that the exact description of the true distribution $\mathcal{D}_N$ may be unknown to both A and B throughout the learning. In addition, A and B are given the concept class $\mathcal{C}_N$ determined by choosing the feature map f_N as a quantumly advantageous function under $\mathcal{D}_N$. Given this initial setup, B decides the number $M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ of sample data to be used for B's learning and lets A know M (see Supplementary Information for the precise choice of M). Then, A chooses the parameter $s \in \mathbb{F}_2^D$ of the target concept $c_s \in \mathcal{C}_N$ arbitrarily (e.g., by sampling s uniformly at random). For the given M and this choice of c_s, A is in charge of preparing M input-output pairs of sample data and giving the data to B while keeping s as A's secret. The task for B is to find a vector $\tilde{s} \in \mathbb{F}_2^D$ using the M data sent from A and make a prediction for new inputs x drawn from $\mathcal{D}_N$ by the hypothesis $h_{\tilde{s}}(x) = f_N(x) \cdot \tilde{s}$ so that the error in estimating true $c_s(x)$ should be below ϵ with high probability at least $1 - \delta$.

For A, we propose a data-preparation protocol using quantum computation in the same way as B using quantum computation for learning, while we will also discuss another protocol using only classical computation later. To prepare the data, A first loads M inputs $x_1, \ldots, x_M$ drawn from $\mathcal{D}_N$. Then, using the quantum algorithm (4) for computing f_N, A prepares the corresponding M outputs denoted by $\mathcal{A}(x_1), \ldots, \mathcal{A}(x_M)$. While the outputs $\mathcal{A}(x)$ may not always be the same as $f_N(x)$ due to the randomness of the quantum algorithm, our analysis shows that, with an appropriate choice of parameters μ and ν in (4), A can make the error in these M outputs negligibly small by only using a polynomial time of quantum computation (see Supplementary Information for details). Finally, A send $\{x_m, \mathcal{A}(x_m)\}_{m=1}^{M}$ to B as the M data.

Note that in the previous work on the advantage of QML based on Shor's algorithms [16–20], the data for their learning tasks were able to be prepared by classical computation, but we here put A and B on equal footing by allowing both to compute f_N by quantum computation. In the previous work, the data were prepared by assuming a special property of cryptographic primitives (i.e., *classically one-way* permutation, which is hard to invert efficiently by classical computation but is invertible efficiently by quantum computation). In Supplementary Information, we show that the data preparation for our concept class is also possible by only using classical computation if we construct f_N using the classically one-way permutations.

Then, the protocol for achieving B's task reduces to running the quantum learning and evaluation algorithms in Theorem 1. To compare these quantum algorithms with classical algorithms, we also propose to perform B's task by only using classical computation for several small problem sizes N. In particular, from the (superpolynomial) runtimes of classically computing f_N for the several choices of small N, we propose to perform extrapolation to estimate the constant factors in the (superpolynomial, potentially exponential) scaling of the runtime of this classical method for larger N. The demonstration of the advantage of QML is successfully achieved by realizing the polynomial-time quantum algorithms in experiments for an appropriate choice of N to outperform the classical algorithms with the estimated superpolynomial runtime.

Discussion and outlook.— In this work, we have proved that a general class of quantum advantages in computing functions, characterized by $\mathsf{HeurFBQP} \setminus (\mathsf{HeurFBPP/rpoly})$ in (3), lead to the end-to-end advantage of QML in a task of supervised learning with classical data, even for exponentially many possible functions to be learned. We have clarified the polynomial-time quantum algorithms to find and make a correct prediction and have also proved the hardness of this learning task for any possible polynomial-time classical method. Whereas such advantage of QML was shown only for specific cases of using the advantage of Shor's algorithms in previous research [16–20], our results make it possible to use the general quantum advantages in computing functions beyond that of Shor's algorithms, such as those relevant to topological data analysis (TDA), BQP-complete problems, and Pell's equation. Furthermore, we propose protocols to prepare the classical sample data for the experimental demonstration of this advantage of QML. These results solve the fundamental open question about characterizing which types of quantum computational advantages lead to the advantage of QML in accelerating supervised learning, making it possible to exploit all the quantumly advantageous functions for QML.

Our results also constitute a significant step toward the practical demonstration of the advantage of QML in experiments. For implementation with near-term quantum technologies, heuristic QML algorithms have been studied widely [50–53], but no analysis provides a classically hard (yet quantumly feasible) instance of the learning tasks; even more problematically, no analysis provides bounds of the runtime and the success probability of these heuristic QML algorithms. In different settings, advantages of using quantum computation have been shown in a learning setting with quantum data obtained from quantum experiments [54–59] and also in a distribution learning setting [60–62]; still, it is not straightforward to apply these quantum algorithms to accelerate the common learning tasks in the era of big data, as represented by supervised learning from classical data. By contrast, our approach offers a QML framework that can address this type of learning task. A merit of our QML framework is that it is simply implementable by using any quantumly advantageous function for feature mapping, followed by classically performing linear separation in the feature space, which our framework takes as the space of bit strings representing features.

Also from a broader perspective, in applications of machine learning, state-of-the-art classical learning methods such as deep learning heuristically design the feature maps, e.g., by adapting the architectures of deep neural networks [63]. The theoretical analysis of optimized choices of feature maps for given data is challenging even in classical cases, but empirical facts suggest that the classification tasks for real-world data often reduce to applying feature maps designed by such artificial neural networks followed by linear separation [63]. In view of the success of the artificially designed feature maps, it is crucial to allow as large classes of functions as possible to create more room for the heuristic optimization of the feature maps. Advancing ahead, our QML framework makes it possible to design the feature maps flexibly, using arbitrary quantumly advantageous functions to attain the provable advantage of QML. It also turns out that a large dimension of the feature space is not even a prerequisite for the advantage of QML in our framework, as opposed to a common yet unproven folklore on the potential relevance of large dimension [50–53]; after all, we have proved that the advantage of QML stems solely from the quantum advantages in computing functions without any further requirement for their mathematical structure. Toward the demonstration of the advantage of QML, an experimental challenge still remains in seeking how to realize quantum computation to surpass the capability of classical computation, and yet our QML framework opens a way to transcend all possible classical learning methods by exploiting *any* realization of quantumly advantageous functions for the feature maps.

METHODS

In Methods, we summarize the probabilistically approximately correct (PAC) learning model, sketch the proof of our main result, i.e., Theorem 1 in the main text, and provide examples of new directions of quantum machine learning (QML) based on Theorem 1.

Throughout the paper, we use the following notations. Let $\mathbb{N}$ be the set of all natural numbers $1, 2, \ldots$. Let $\mathbb{F}_2 = \{0, 1\}$ denote the finite field of order 2, i.e., for $0, 1 \in \mathbb{F}_2$,

$$\begin{aligned} 0+0&=0, & 0\times 0&=0,\\ 0+1&=1, & 0\times 1&=0,\\ 1+0&=1, & 1\times 0&=0,\\ 1+1&=0, & 1\times 1&=1. \end{aligned} \tag{6}$$

Note that $\{0, 1\}$ and $\mathbb{F}_2$ may be the same set, but we will use $\mathbb{F}_2$ for representing the feature space, where we use the bitwise arithmetics in (6), while we will use $\{0, 1\}$ in the other cases. Let $\mathsf{poly}(x)$ denote a polynomial of x. Unless otherwise stated, we use N as the length of input bit strings for a family of computational problems. For a probability distribution $\mathcal{D}$ over the set $\mathcal{X}$, we denote by $x \sim \mathcal{D}$ to mean that x is drawn from the distribution $\mathcal{D}$. A probability $\mathbf{Pr}_{x\sim\mathcal{D}}[\cdots]$ indicates that the probability is taken for the random draw of x according to distribution $\mathcal{D}$.

PAC learning model.— We summarize the definition of the PAC learning model based on Ref. [6]. See also Supplementary Information for further details.

In the PAC learning model, for a problem size N, a specification of a set of functions $\mathcal{C}_N$, called a concept class, is initially given. Each function $c \in \mathcal{C}_N$ is called a concept, which maps an N-bit input x to a Boolean-valued output $c(x) \in \{0, 1\}$ (i.e., a label of x in classification). For some unknown choice of a concept $c \in \mathcal{C}_N$ called the target concept, the learning algorithm is given a polynomial number of samples $\{x_m, c(x_m)\}_{m=1}^{M}$, which are pairs of inputs with each x_m drawn from a target probability distribution $\mathcal{D}_N$ and the corresponding outputs $c(x_m)$. Note that the previous work [16–19] on the advantage of QML studied a restricted setting that only allows for uniform distribution in the choice of the target distribution $\mathcal{D}_N$, but in our work, $\mathcal{D}_N$ can be an arbitrary distribution over the N bits without this restriction. Using the given sample data, the learning algorithm is designed to find a function, termed a hypothesis h, from a set $\mathcal{H}_N$ of functions called a hypothesis class, so as to make a correct prediction on c by h.

In the PAC learning model, the ability to find the correct hypothesis for the target concept using the given samples is called the learnability of a concept class under a target distribution [6]. In particular, for the problem size N, the error parameter $\epsilon > 0$, and a confidence parameter $\delta > 0$, a concept class $\mathcal{C}_N$ is *quantumly (classically) efficiently learnable* under $\mathcal{D}_N$ if there exists a quantum (classical randomized) learning algorithm $\mathcal{A}$ that finds a hypothesis h such that

$$\mathrm{error}(h) \coloneqq \mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}[h(x) \neq c(x)] < \epsilon. \tag{7}$$

with high probability at least $1-\delta$, using a polynomial number of samples $\{x_m, c(x_m)\}_{i=1}^{M}$ ($M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$) within a polynomial time complexity $t_{\mathcal{A}} = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ (see also Supplementary Information for more details).

The ability to efficiently evaluate the hypothesis identified from the samples is also crucial in the PAC learning model, which is called evaluatability [6]. By definition of the learnability, the learned hypothesis may inevitably have some error on a nonzero fraction ϵ of x drawn from $\mathcal{D}_N$, and the definition of evaluatability here also inherits this point. In particular, for $\epsilon, \delta > 0$, we say that a hypothesis class $\mathcal{H}_N$ is *quantumly (classically) efficiently evaluatable* under $\mathcal{D}_N$ if, given a hypothesis h, there exists a quantum (classical randomized) evaluation algorithm $\mathcal{A}$ that can compute $h(x)$ for a large fraction $1-\epsilon$ of new inputs x drawn from $\mathcal{D}_N$ with high probability at least $1-\delta$ in terms of the randomness of the (randomized) algorithm $\mathcal{A}$, within a polynomial time complexity $t_{\mathcal{A}} = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ (see also Supplementary Information for more details).

Quantum learning and evaluation algorithms and classical hardness for our concept class.— Within the PAC learning model, we sketch the proof of our main result, i.e., Theorem 1 in the main text. In particular, for our concept class, we construct a polynomial-time quantum algorithm for learning the concept to output the corresponding hypothesis in a hypothesis class. Then, we also construct a polynomial-time quantum algorithm for evaluating the hypothesis in the hypothesis class. Finally, we prove the hardness of the evaluation of the hypotheses in the hypothesis class for any possible polynomial-time classical algorithm. See also Supplementary Information for more details.

Our quantum learning algorithm starts with using a quantum algorithm $\mathcal{A}$ in (4) to compute the feature map $f_N(x_m)$ for each of the given samples $\{(x_m, c_s(x_m))\}_{m=1}^{M}$. Note that the features output by $\mathcal{A}$, denoted by $\{\mathcal{A}(x_m)\}_{m=1}^{M}$, may not exactly coincide with the features $\{f_N(x_m)\}_{m=1}^{M}$ in general due to the randomness of the quantum algorithm, but our analysis shows that the learning algorithm can feasibly make the failure probability negligibly small. Our learning algorithm then classically performs Gaussian elimination to solve a system of linear equations for a variable $\tilde{s} \in \mathbb{F}_2^D$

$$\begin{aligned} \mathcal{A}(x_1)\cdot\tilde{s} &= c_s(x_1),\\ \mathcal{A}(x_2)\cdot\tilde{s} &= c_s(x_2),\\ &\vdots\\ \mathcal{A}(x_M)\cdot\tilde{s} &= c_s(x_M), \end{aligned} \tag{8}$$

subsequently outputting a solution $\tilde{s}$ as an estimate of the parameter of the hypothesis. For $\tilde{s}$, we construct the hypothesis $h_{\tilde{s}}$ by

$$h_{\tilde{s}}(x) \coloneqq f_N(x)\cdot\tilde{s}. \tag{9}$$

A technical challenge in our construction of the learning algorithm arises from the fact that the solutions $\tilde{s}$ of the system of the linear equations in (8) may not be unique. After all, we work on a general setting allowing any target distribution $\mathcal{D}_N$, any quantumly advantageous function f_N, and any quantum algorithm $\mathcal{A}$ to compute f_N approximately as in (4); thus, it may happen that

$$\tilde{s} \neq s. \tag{10}$$

For the worst-case input $x \in \{0,1\}^N$, it may indeed happen that

$$h_{\tilde{s}}(x) \neq c_s(x). \tag{11}$$

It is thus nontrivial to prove that the hypothesis $h_{\tilde{s}}$ given by (9) can predict the target concept c_s correctly as required for the learnability. We nevertheless prove that any of the solutions $\tilde{s}$ of (8) (even if (10) is the case) leads to a correct hypothesis

$$h_{\tilde{s}}(x) = c_s(x) \tag{12}$$

for a large fraction of input x drawn from $\mathcal{D}_N$ with a high probability. In other words, our analysis proves that the fraction of x causing (11) can be made negligibly small by our polynomial-time quantum learning algorithm, leading to the quantumly efficient learnability of our concept class (see Supplementary Information for details).

As for the quantum algorithm for evaluating the hypothesis, with the parameter $\tilde{s}$ learned, the evaluation algorithm aims to estimate $f_N(x)\cdot\tilde{s}$ in (9). For a new input x drawn from $\mathcal{D}_N$, our evaluation algorithm simply uses the quantum algorithm $\mathcal{A}$ in (4) to compute $\mathcal{A}(x)$, i.e., an estimate of $f_N(x)$. The output $\mathcal{A}(x)$ of $\mathcal{A}$ may be different from $f_N(x)$ in general due to the randomness of the quantum algorithm, but we show that the error can be made negligibly small within a polynomial time. Then, our algorithm takes the (bitwise) inner product of $\mathcal{A}(x)$ and the given parameter $\tilde{s}$, which we prove leads to a correct evaluation of $h(x)$ for a large fraction of input x with a high probability, leading to the quantumly efficient evaluatability (see Supplementary Information for details).

Finally, the classical hardness is proved by contradiction, as with the established arguments in the computational learning theory [5, 6]. In particular, we prove that if all concepts $c_s(x)$ ($s \in \mathbb{F}_2^D$) of our concept class in (2) were classically efficiently learnable by some hypotheses $h_s(x)$ that are classically efficiently evaluatable by polynomial-time classical algorithms, then the feature map $f_N(x)$ in (2) would be computed by a polynomial-time classical algorithm using these classical evaluation algorithms, contradicting to the assumption that f_N is a quantumly advantageous function. To prove the classical hardness of learning for the exponential-size concept classes as in our case, the previous work on the advantage of QML relied on a cryptographic argument that specifically depends on Shor's algorithms [16–20]; by contrast, our proof technique developed here does not depend on such a specific property of Shor's algorithms but is applicable to any quantumly advantageous function in general.

For this development, our key idea is to use the property of the vector space $\mathbb{F}_2^D$ over the finite field used as the feature space in our construction. In particular, for the standard basis $\{s_d\}_{d=1}^D$ of this D-dimensional vector space $\mathbb{F}_2^D$ (i.e., $s_1 = (1,0,\ldots,0,0)^\top, \ldots, s_D = (0,0,\ldots,0,1)^\top$), suppose that the concepts $c_{s_d}(x)$ for $d = 1,\ldots,D$ are efficiently learnable by classically efficiently evaluatable hypotheses $h_{s_d}(x)$. Then, observing that the bitwise inner product $c_{s_d}(x) = f_N(x) \cdot s_d$ yields the dth bit of $f_N(x)$, we use the corresponding hypotheses $h_{s_d}(x)$ to construct an estimate of $f_N(x)$ as

$$\tilde{f}_N(x) = \begin{pmatrix} h_{s_1}(x) \\ h_{s_2}(x) \\ \vdots \\ h_{s_D}(x) \end{pmatrix} \in \mathbb{F}_2^D. \tag{13}$$

Thus, the polynomial-time classical algorithms for evaluating the hypotheses would be able to compute each element of this vector and thus approximate $f_N(x)$ well with high probability, which contradicts the fact that f_N is a quantumly advantageous function. Therefore, our concept class that includes the concepts $c_{s_d}(x)$ for $d = 1,\ldots,D$ is not classically efficiently learnable by any classically efficiently evaluatable hypothesis class (see Supplementary Information for details).

New directions of QML based on quantumly advantageous functions.— Our results in Theorem 1 of the main text open unprecedented opportunities for using a variety of quantum algorithms to demonstrate the advantage of QML, progressing beyond Shor's algorithms. We here propose several promising candidates of such quantum algorithms relevant to the following different areas.

1. *Topological data analysis (TDA).*— Quantum algorithms for computing an estimation of normalized Betti numbers and other topological invariants [29–33] gather considerable attention due to their potential applications to TDA, an area of data science using mathematical tools on topology. The functions computed by these quantum algorithms are leading candidates of the quantumly advantageous functions since techniques for proving the computational hardness are also known in multiple relevant cases under conventional assumptions in the complexity theory [64–69]. Classical sample data given in terms of bit strings can also be used as the input to some of these quantum algorithms, without necessarily using oracles for the input to these algorithms; for example, given N input points constituting a Vietoris-Rips (VR) complex, the quantum algorithm in Ref. [30] computes an approximation of the normalized persistent Betti number with accuracy $O(1/\mathsf{poly}(N))$ with probability at least $1-O(1/\mathsf{poly}(N))$. In this case, the function that this quantum algorithm computes can be used as a feature map $f_N : \{0,1\}^{O(\mathsf{poly}(N))} \to \mathbb{F}_2^{O(\log(N))}$, from which we can construct our concept class according to (2). Note that the normalized persistent Betti number may have a different value from the (original) persistent Betti number due to the normalization factor, but independently of such mathematical structure, our results lead to the advantage of QML for our concept class.

2. *BQP-complete problems.*— It is indeed a variant of long-standing open problems in the complexity theory to prove the existence of the quantumly advantageous functions unconditionally without any computational hardness assumption; however, a natural candidate for the quantumly advantageous functions is the functions relevant to the hardest problems in the scope of the polynomial-time quantum algorithms, known as BQP-complete problems [34–40]. For instance, the function used for the local unitary-matrix average eigenvalue (LUAE) problem in Ref. [35] yields such a candidate. Given an N-bit string b and a $O(\mathsf{poly}(N))$-bit string representing an $O(\mathsf{poly}(N))$-size quantum circuit to implement a $2^N \times 2^N$ unitary matrix U, let $\{\lambda_j\}_j$ denote the set of eigenvalues of U with the corresponding set $\{|\nu_j\rangle\}_j$ of eigenvectors. Then, the LUAE problem involves computation of an estimate of the average eigenvalue $\bar{\lambda} = \sum_{j=1}^{2^N} |\langle b|\nu_j\rangle|^2 \lambda_j$ up to precision $O(1/\mathsf{poly}(N))$ with probability at least $1 - O(1/\mathsf{poly}(N))$ [35]. Thus, the function to be computed in the LUAE problem provides a feature map $f_N : \{0,1\}^{O(\mathsf{poly}(N))} \to \mathbb{F}_2^{O(\log(N))}$, from which we can construct our concept class according to (2). We remark that this construction is based on the worst-case complexity class BQP, but for our concept class, we can indeed choose f_N based on the hardest problems in the heuristic complexity class HeurFBQP, which is potentially even broader than the worst-case complexity class. Also note that Refs. [18, 19] considered using instances of BQP-

complete problems themselves as the polynomial-size concept classes that provide the advantage of QML, but since their construction uses BQP-complete problems directly as the concept classes, the connection between quantum advantages in the learning of concept classes and the computation of functions was elusive; by contrast, our contribution is to bridge this connection by using quantumly advantageous functions appearing in the BQP-complete problems to introduce new, different concept classes.

3. *Cryptographic problems beyond the scope of Shor's algorithms.*— Shor's algorithms [21–23] stand as polynomial-time quantum algorithms to solve integer factoring and discrete logarithms relevant to Rivest–Shamir–Adleman (RSA) cryptosystem [70], and no existing classical algorithm can solve these problems within a polynomial time. But it still remains an unsolved open problem whether these are hard to compute for any possible polynomial-time classical algorithm apart from the existing ones. If an efficient classical algorithm for solving these problems were found in the future, the previously known advantage of QML depending on Shor's algorithms would also cease to survive. Even in such a case, our results open a chance that the advantage of QML can still survive based on another cryptographic problem that can be harder than those solved by Shor's algorithms. For example, given an N-bit nonsquare positive integer d for Pell's equation $x^2 - dy^2 = 1$, the first $O(\mathsf{poly}(N))$ digits of $\ln\left(x_1 + y_1\sqrt{d}\right)$ for its least positive solution (x_1, y_1) can be computed with a high probability exponentially close to one by a polynomial-time quantum algorithm [41, 42]; at the same time, even if one has a polynomial-time classical algorithm for solving integer factoring and discrete logarithms, it is unknown if one can obtain a polynomial-time classical algorithm for this computation, which is relevant to a key exchange system based on the principal ideal problem [71] (see Refs. [41, 42] for details). This computations yields a feature map $f_N : \{0,1\}^N \to \mathbb{F}_2^{O(\mathsf{poly}(N))}$, from which we can construct our concept class according to (2). This construction provides an example of exponential-size concept classes in N leading to the advantage of QML without depending on the computational advantage of Shor's algorithms, which has been challenging to establish as long as one uses techniques in the existing work [16–20].

SUPPLEMENTARY INFORMATION

Supplementary Information of "Advantage of Quantum Machine Learning from General Computational Advantages" is organized as follows. Section A gives settings and definitions of a learning model and quantum computational advantage. Section B provides our learning task and proof of the advantage of quantum machine learning (QML) in solving our learning task. Section C describes a setup for demonstrating this advantage of QML and presents protocols for preparing the classical sample data for the demonstration.

Appendix A: Setting and definition

In this section, we present settings and definitions relevant to our work. In Section A 1, we define a model of probably and approximately correct (PAC) learning [5, 6, 43] to be analyzed in this work and also define the advantage of QML. In Section A 2, we define quantum advantages in computing a function, which we will use to show the advantage of QML.

1. PAC learning model

The analysis in our work will be based on a conventional model of learning called the PAC learning model in Ref. [6]. Let $\mathcal{D}_N$ be any unknown target probability distribution supported on an input space $\mathcal{X}_N \subseteq \{0,1\}^N$ of N bits. In our work, a concept class $\mathcal{C}_N$ over $\mathcal{X}_N$ is a set of functions from the input space to the set of binary labels. Consequently, a concept $c \in \mathcal{C}_N$ is a function such that $c : \mathcal{X}_N \to \{0,1\}$. A sample is denoted as $(x, c(x))$, which is a pair of the input and the output for the concept. Let $\mathbf{EX}(c, \mathcal{D}_N)$ be a procedure (oracle) that returns a labeled sample $(x, c(x))$ within a unit time upon each call, where x is drawn randomly and independently according to $\mathcal{D}_N$. Note that the samples $(x, c(x))$ from $\mathbf{EX}(c, \mathcal{D}_N)$ are given in terms of classical bit strings throughout this paper. In this setting, we can consider $\mathcal{X} = \bigcup_{N\geq 1} \mathcal{X}_N$ and $\mathcal{C} = \bigcup_{N\geq 1} \mathcal{C}_N$ to define an infinite family of learning problems of increasing input lengths.

In the PAC learning model, a learning algorithm will have access to samples from $\mathbf{EX}(c, \mathcal{D}_N)$ for an unknown target concept c, which is chosen from a given concept class $\mathcal{C}_N$. Using the samples, the learning algorithm will find a hypothesis h from a hypothesis class $\mathcal{H}_N$ so that h should approximate c. We define a measure of approximation error between hypothesis h and unknown concept c as

$$\mathrm{error}(h) = \mathbf{Pr}_{x\sim\mathcal{D}_N}[c(x) \neq h(x)]. \tag{A1}$$

The learning algorithm only sees input-output samples of the unknown target concept c. The algorithm may not have to directly deal with the representation of true c, i.e., a symbolic encoding of c in terms of a bit string. However, it still matters which representation the algorithm chooses for its hypothesis h since the learning algorithm needs to output the representation of h. To deal with these representations more formally, consider a representation scheme $\mathcal{R}$ for a concept class $\mathcal{C}_N$, which is a function $\mathcal{R} : \Sigma^* \to \mathcal{C}_N$ with $\Sigma = \{0,1\}$ denoting a bit and $\Sigma^* := \bigcup_{N\geq 1} \Sigma^N$ denoting the set of bit strings. We call any string $\sigma \in \Sigma^*$ such that $\mathcal{R}(\sigma) = c$ a representation of c. For $\mathcal{R}$, we here consider the length of the bit string $\sigma \in \Sigma^*$ to be the size of each representation σ, which we write $\mathrm{size}(\sigma)$. A representation of hypothesis h can be formulated in the same way by replacing c with h and $\mathcal{C}_N$ with $\mathcal{H}_N$.

The learning task is divided into two main parts. One is to find, using the samples, a representation of the hypothesis h that approximates the target concept c well, and the other is to make a prediction by evaluating $h(x)$ correctly for a new input $x \in \mathcal{X}_N$ and the learned representation of h. First, we define efficient learnability as shown below. This definition requires that the algorithm find and output the representation of the appropriate hypothesis h for the target concept c within a polynomial time. Note that this definition implies that the representation of the hypotheses h should also be of at most polynomial length. Conventionally, the PAC learning model may require that it be learnable for all distributions [6], but we can here observe that learning tasks in practice usually deal with data given from a particular distribution; for example, in the classification of images of dogs and cats, the learning algorithm does not have to work for any distribution over the images, but it suffices to deal with a given distribution supported on the meaningful images such as those of dogs and cats. Based on this observation, our model requires that it be learnable for a given (unknown) target distribution. Note that throughout the learning, the learning algorithm does not have to estimate the description of the target distribution itself, but it only suffices to learn the target concept c by the hypothesis h.

Definition S1 (Efficient learnability). *For any problem size $N \in \mathbb{N}$, let $\mathcal{C}_N$ be a concept class and $\mathcal{D}_N$ be a target distribution over an input space $\mathcal{X}_N \subseteq \{0,1\}^N$ of N bits. We say that $\mathcal{C}_N$ is quantumly (classically) efficiently learnable under the target distribution $\mathcal{D}_N$ if there exists a hypothesis class $\mathcal{H}_N$ and a quantum (classical randomized) algorithm $\mathcal{A}$ with the following property: for every concept $c \in \mathcal{C}_N$, and for all $0 < \epsilon, \delta < 1$, if $\mathcal{A}$ is given access to $\mathbf{EX}(c, \mathcal{D}_N)$ in addition to ϵ and δ, then $\mathcal{A}$ runs in a polynomial time*

$$t_{\mathcal{A}}(\mathbf{EX}, \epsilon, \delta) = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta)), \tag{A2}$$

to output a representation of hypothesis $h \in \mathcal{H}_N$ satisfying, with probability at least $1 - \delta$,

$$\mathrm{error}(h) \leq \epsilon, \tag{A3}$$

where the left-hand side is given by (A1). The probability is taken over the random examples drawn from the *calls of* $\mathbf{EX}(c, \mathcal{D}_N)$ *and the randomness used in the randomized algorithm* $\mathcal{A}$*. The number of calls of* $\mathbf{EX}(c, \mathcal{D}_N)$ *(i.e., the number of samples) and the size of the output representation of the hypothesis are bounded by the runtime.*

As for the evaluation of the learned hypothesis, we give a definition of efficient evaluatability below. This definition requires that, given an input x and a representation σ_h of a hypothesis h, the algorithm should evaluate $h(x)$ correctly in a polynomial time for a large fraction of x with high probability. The representation of a hypothesis used in this definition can be, in general, an arbitrary polynomial-length bit string representing the hypothesis. In particular, in the case of the previous work [16–20] on the advantage of QML using Shor's algorithms for solving integer factoring and discrete logarithms [21–23], a classical algorithm may be able to prepare samples on its own; by contrast, in our general setting, samples are given from the oracle **EX** as in Definition S1, and we do not necessarily require that the evaluation algorithms should be able to simulate **EX** to prepare the samples on their own. (For example, in Section C 2, we will discuss the preparation of samples by quantum computation rather than classical computation, so the classical algorithm may not be able to prepare the samples on its own.) In this learning setting, at best, an evaluation algorithm may be able to use the given samples encoded in the polynomial-length representation of the hypothesis as an extra input to the algorithm, which may not be prepared by the algorithm on its own but can be used for the algorithm to compute $h(x)$ more efficiently [18, 19, 48]. In addition to this encoding of a polynomial amount of sample data used in the learning, the representation of the hypothesis can even include any polynomial-length bit string to help the evaluation algorithm compute the hypothesis even more efficiently (which may be prepared potentially using an exponential runtime if we do not assume efficient learnability). In complexity theory, such an extra probabilistic input (apart from x) to make the computation potentially more efficient is known as a randomized advice string [49], as described in more detail in Section A 2. Note that it would be more conventional in the computational complexity theory to use an advice string given deterministically [4], but we here consider the samples and the representation of the hypothesis obtained from the samples as special instances of the randomized advice string since the samples in the PAC learning are given probabilistically from a data distribution. Also, in a conventional setting, efficient evaluation in the PAC model may mean that the hypothesis can be evaluated in worst-case polynomial time [6]. However, recalling the above observation that practical learning tasks deal with data from a more specific target distribution, we see that it may be too demanding to require that the hypothesis h should be evaluated efficiently for all possible $x \in \mathcal{X}_N$ even in the worst case; rather, it makes more sense to require that we should be able to evaluate $h(x)$ efficiently for x drawn from the target distribution of interest with a sufficiently high probability. In the complexity theoretical terms, this requirement can be captured by the notion of heuristic polynomial time [46, 47]; accordingly, we define efficient evaluatability based on heuristic complexity, as shown below. Since the heuristic hardness implies the worst-case hardness, proving the hardness of efficient evaluation for our learning model immediately leads to the conventional worst-case hardness of efficient evaluation in the learning (see also Section A 2 for more discussion on the difference and relation between these hardness results).

Definition S2 (Efficient evaluatability)**.** *For any problem size* $N \in \mathbb{N}$*, let* $\mathcal{C}_N$ *be a concept class and* $\mathcal{D}_N$ *be a target distribution over an input space* $\mathcal{X}_N \subseteq \{0,1\}^N$ *of* N *bits. We say that the hypothesis class* $\mathcal{H}_N$ *is quantumly (classically) efficiently evaluatable under the target distribution* $\mathcal{D}_N$ *if there exists a quantum (classical randomized) algorithm* $\mathcal{A}$ *such that for all* $N \in \mathbb{N}$, $0 < \epsilon, \delta < 1$, *and a* $O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$*-length bit string* σ_h *representing any hypothesis* $h \in \mathcal{H}_N$*,* $\mathcal{A}$ *runs in a polynomial time for all* $x \in \mathcal{X}_N$

$$t_{\mathcal{A}}(x, \sigma_h, \epsilon, \delta) = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta)), \tag{A4}$$

to output $\mathcal{A}(x, \sigma_h, \epsilon, \delta)$ *satisfying*

$$\Pr_{x \sim \mathcal{D}_N} \left[\Pr\left[\mathcal{A}(x, \sigma_h, \epsilon, \delta) = h(x)\right] \geq 1 - \delta\right] \geq 1 - \epsilon, \tag{A5}$$

where the inner probability is taken over the randomness of the randomized algorithm $\mathcal{A}$*.*

From Definitions S1 and S2, a learning task can be divided into four categories CC, CQ, QC, and QQ [18, 19], which means that whether the learning task is classically or quantumly efficiently learnable and whether it is classically or quantumly efficiently evaluatable, respectively. It is known that the categories CQ and QQ are equivalent unless the hypothesis class is fixed [19]. Note that Refs. [19] defined these categories based on the worst-case complexity, but the categories for our definitions may be different in that Definitions S1 and S2 are given based on the heuristic complexity. In our work, we will study the advantage of QML in the sense of $\mathsf{CC}\,/\,\mathsf{QQ}$ separation, following the previous work [16, 17] on the advantage of QML; i.e., we will construct a learning task in QQ but not in CC.

Finally, we remark that the learnability and the evaluatability are different in that Definition S1 requires that the hypothesis h should be found in polynomial time with a high probability, and Definition S2 requires that h should be evaluated. Efficient learnability itself does not require that the learned hypothesis should be efficiently used for making a prediction via its evaluation, and efficient evaluatability itself does not require that the representation of the hypothesis should be obtained efficiently in learning from the samples. However, to achieve the end-to-end acceleration of QML, we eventually need both quantumly efficient learnability and quantumly efficient evaluatability simultaneously, which our analysis aims at. Correspondingly, for the classical hardness of the learning tasks, our interest is to rule out the possibility that the best classical method achieves efficient learnability and efficient evaluatability simultaneously.

2. Quantum computational advantage

In this section, we present the computational complexity classes relevant to our analysis of the advantage of QML. Our analysis will use a general class of functions that are efficient to compute by quantum computation but hard by classical computation, based on the complexity classes defined here.

In the following, we will start by presenting the worst-case, average-case, and heuristic computational complexity classes [46, 47], whose difference arises from the fraction of the inputs for which the problem can be solved in polynomial time. Then, we will present the complexity classes for computing functions by classical randomized algorithms and quantum algorithms. Finally, we will explain advice strings, which are, roughly speaking, bit strings given to the algorithm in addition to the input to help solve the problem efficiently.

We introduce three cases of complexity classes: worst-case, average-case, and heuristic polynomial time. A complexity class is conventionally defined as a worst-case class; for example, the class P of (worst-case) polynomial time is a family of decision problems such that all the inputs of the problems in the family can be solved within a polynomial time in terms of the length of the input bit strings (even for the worst-case choice of the input) [4]. Accordingly, the existing analyses of the advantage of QML in previous research were also based on the worst-case complexity classes, requiring that the algorithm should be able to evaluate the hypothesis $h(x)$ for all $x \in \mathcal{X}_N$ [16–19]. However, this requirement is too demanding in our setting; after all, the PAC learning model allows for errors depending on a given target distribution. In the learning as in Definitions S1 and S2, it suffices to learn and evaluate $h(x)$ efficiently only for a sufficiently large fraction of x on the support of the given target distribution, rather than all x. Intuitively, in the classification of images for example, it suffices to learn and evaluate $h(x)$ efficiently for meaningful images on the support of the true probability distribution of samples, and whether $h(x)$ can be evaluated for all possible images including those never appearing in the real-world data is irrelevant in practice. To capture this difference, we here take into account average-case and heuristic complexity classes [46, 47]. The class of worst-case polynomial time is the class of decision problems that are solvable in polynomial time. Whereas P is a class of decision problems, average-case polynomial time AvgP and heuristic polynomial time HeurP are the classes of *distributional* decision problems that consist not only of decision problems but also of the target probability distributions of the input. In solving the distributional problems, the runtime of an algorithm may probabilistically change depending on the input given from the distribution. The runtime of solving the problem in AvgP should be polynomial in input length on average over inputs given from the distribution [72], which may allow, e.g., an exponentially long runtime to obtain a correct answer for an exponentially small fraction of the inputs. On the other hand, HeurP requires that the runtime of correctly solving the problem should be polynomial only for a sufficiently large fraction of (yet not all) the inputs from the distribution, and for the rest of the small fraction of the inputs, the algorithm may output a wrong answer [46, 47]. Note that in the heuristic class, the average runtime of correctly solving the problem is not necessarily bounded. By definition, the worst-case complexity class is contained in the average-case class, and the average-case class in the heuristic class; i.e., it is shown that $\mathsf{P} \subseteq \mathsf{AvgP} \subseteq \mathsf{HeurP}$ [73]. More formally, we define the worst-case, average-case, and heuristic classes with reference to P as follows. Note that for our analysis of learning, only the worst-case and heuristic classes are relevant, while the average-case classes are discussed here for clarity of presentation; thus, we may stop mentioning the average-case classes after this definition.

Definition S3 (Worst-case, average-case, and heuristic polynomial time [46, 47, 72])**.** *We define the worst-case, average-case, and heuristic complexity classes, namely,* P*,* AvgP*, and* HeurP*, respectively, as follows.*

1. *A decision problem, i.e., a function $L : \{0,1\}^* \to \{0,1\}$ with a single-bit output, is in P if there exists a deterministic classical algorithm $\mathcal{A}$ such that for every N and every input $x \in \{0,1\}^N$, $\mathcal{A}$ outputs $L(x)$ in $\mathsf{poly}(N)$ time.*

2. *A distributional problem $(L, \mathcal{D})$ is in AvgP if there exists a deterministic classical algorithm $\mathcal{A}$ and a constant d such that for every N*
$$\mathbb{E}_{x\sim\mathcal{D}_N}\left[\frac{t_{\mathcal{A}}(x)^{\frac{1}{d}}}{N}\right] = O(1), \tag{A6}$$
where $t_{\mathcal{A}}(x)$ is the time taken to calculate $L(x)$ by $\mathcal{A}$, and $\mathbb{E}_{x\sim\mathcal{D}_N}[\cdots]$ is the expected value over x drawn from $\mathcal{D}_N$.

3. *A distributional problem $(L, \mathcal{D})$ is in HeurP if there exists a deterministic classical algorithm $\mathcal{A}$ such that for every N and all $0 < \mu < 1$, the runtime $t_{\mathcal{A}}(x, \mu)$ of $\mathcal{A}$ for every input x in the support of $\mathcal{D}_N$ is $t_{\mathcal{A}}(x, \mu) = O(\mathsf{poly}(N, 1/\mu))$, and the output $\mathcal{A}(x, \mu)$ of $\mathcal{A}$ satisfies*
$$\mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}[\mathcal{A}(x,\mu) = L(x)] \geq 1 - \mu. \tag{A7}$$

Next, we define the classes of problems solvable by a (classical) randomized algorithm. In Definition S3, we use a deterministic classical algorithm to solve problems.

By contrast, in the randomized algorithms, we need to take into account errors arising from the randomization. Corresponding to P and HeurP, we define the two classes of problems for randomized algorithms as follows.

Definition S4 (Worst- and heuristic bounded-error probabilistic polynomial time [46, 47]). *We define a worst-case class* BPP *and a heuristic class* $\mathsf{HeurBPP}$ *for classical randomized algorithms as follows.*

1. *A decision problem L is in BPP if there exists a classical randomized algorithm $\mathcal{A}$ such that for every N and every input $x \in \{0,1\}^N$, the runtime $t_{\mathcal{A}}(x)$ of $\mathcal{A}$ is $t_{\mathcal{A}}(x) = O(\mathsf{poly}(N))$, and the output $\mathcal{A}(x)$ of $\mathcal{A}$ satisfies*
$$\mathbf{Pr}[\mathcal{A}(x) = L(x)] \geq 2/3, \tag{A8}$$
where the probability is taken over the randomness of $\mathcal{A}$.

2. *A distributional problem $(L, \mathcal{D})$ is in $\mathsf{HeurBPP}$ if there exists a classical randomized algorithm such that for every N and all $0 < \mu < 1$, the runtime $t_{\mathcal{A}}(x,\mu)$ of $\mathcal{A}$ for every input x in the support of $\mathcal{D}_N$ is $t_{\mathcal{A}}(x,\mu) = O(\mathsf{poly}(N, 1/\mu))$, and the output $\mathcal{A}(x,\mu)$ of $\mathcal{A}$ satisfies*
$$\mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}[\mathbf{Pr}[\mathcal{A}(x,\mu) = L(x)] \geq 2/3] \geq 1-\mu, \tag{A9}$$
where the inner probability of $\mathcal{A}(x,\mu) = L(x)$ is taken over randomness of $\mathcal{A}$.

Whereas we have so far explained complexity classes of decision problems, i.e., those for computing functions with a single-bit output, our analysis will use a Boolean function with a single multi-bit output for each N-bit input
$$f_N : \{0,1\}^N \to \{0,1\}^{D(N)}, \tag{A10}$$
where $D : \mathbb{N} \to \mathbb{N}$ is any function satisfying $D(N) = O(\mathsf{poly}(N))$, and we may abbreviate $D(N)$ as D in the following of this paper. Accordingly, we define the complexity classes of function problems, i.e., problems of computing such multi-bit output functions f_N. For the heuristic complexity class, we also refer to a family of problems $\{(f_N, \mathcal{D}_N)\}_{N\in\mathbb{N}}$ as distributional function problems. Whenever f_N is used in the following of this paper, it refers to a function with a single multi-bit output for each input. Note that the complexity classes of function problems may also be defined as those of search problems, which can be considered to be the problems of computing functions with many possible outputs for each input, and the algorithms aim to search for one of the possible outputs for a given input. But even if one considers such a more general definition, functions f_N relevant to our analysis are those with a single output for each input; correspondingly, we here present the definitions using the single-output functions for simplicity.

Definition S5 (Worst-case and heuristic distributional function bounded-error polynomial time). *We define a worst-case class* FBPP *and a heuristic class* $\mathsf{HeurFBPP}$ *for computing multi-bit output functions as follows.*

1. *Given $R_N := \{(x, f_N(x))\}_{x\in\{0,1\}^N}$ and $R := \bigcup_N R_N$, the relation R is in FBPP if there exists a randomized classical algorithm $\mathcal{A}$ such that for all N, every input $x \in \{0,1\}^N$, and all $0 < \nu < 1$, the runtime $t_{\mathcal{A}}(x,\nu)$ of $\mathcal{A}$ is $t_{\mathcal{A}}(x,\nu) = O(\mathsf{poly}(N, 1/\nu))$, and the output $\mathcal{A}(x,\nu)$ of $\mathcal{A}$ satisfies*
$$\mathbf{Pr}[(x, \mathcal{A}(x,\nu)) \in R_N] \geq 1-\nu, \tag{A11}$$
where the probability is taken over the randomness of $\mathcal{A}$.

2. *A distributional function problem $F = \{(f_N, \mathcal{D}_N)\}_{N\in\mathbb{N}}$ is in $\mathsf{HeurFBPP}$ if there exists a classical randomized algorithm $\mathcal{A}$ such that for all N and all $0 < \mu, \nu < 1$, the runtime $t_{\mathcal{A}}(x,\mu,\nu)$ of $\mathcal{A}$ for every input $x \in \{0,1\}^N$ in the support of $\mathcal{D}_N$ is $t_{\mathcal{A}}(x,\mu,\nu) = O(\mathsf{poly}(N, 1/\mu, 1/\nu))$, and the output $\mathcal{A}(x,\mu,\nu)$ of $\mathcal{A}$ satisfies*
$$\mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}[\mathbf{Pr}[\mathcal{A}(x,\mu,\nu) = f_N(x)] \geq 1-\nu] \geq 1-\mu, \tag{A12}$$
where the inner probability of $\mathcal{A}(x,\mu,\nu) = f_N(x)$ is taken over randomness of $\mathcal{A}$.

We next define the classes FBQP and $\mathsf{HeurFBQP}$ of problems efficiently solvable by quantum algorithms. The classes defined so far are the computational complexity classes for deterministic or randomized classical algorithms, but we here define FBQP and $\mathsf{HeurFBQP}$ using quantum algorithms in place of the classical algorithms. The class $\mathsf{HeurFBQP}$ will be used for our construction of learning tasks in Definition S8 of Section B 1 to prove the advantage of QML. Note that we have $\mathsf{FBQP} \subseteq \mathsf{HeurFBQP}$ in the same way as $\mathsf{P} \subseteq \mathsf{HeurP}$. Working on $\mathsf{HeurFBQP}$, we aim to make it possible to use a potentially larger class of computational advantages of heuristic quantum algorithms captured by $\mathsf{HeurFBQP}$ rather than FBQP, so as to achieve a wider class of learning tasks more efficiently.

Definition S6 (Worst-case and heuristic distributional function bounded-error quantum polynomial time). *We define a worst-case class* FBQP *and a heuristic class* $\mathsf{HeurFBQP}$ *for quantum algorithms as follows.*

1. *Given $R_N = \{(x, f_N(x))\}_{x\in\{0,1\}^N}$ and $R = \bigcup_N R_N$, the relation R is in FBQP if there exists a quantum algorithm $\mathcal{A}$ such that for all N, every input $x \in \{0,1\}^N$, all $0 < \nu < 1$, the runtime $t_{\mathcal{A}}(x,\nu)$ of $\mathcal{A}$ is $t_{\mathcal{A}}(x,\nu) = O(\mathsf{poly}(N, 1/\nu))$, and the output $\mathcal{A}(x,\nu)$ of $\mathcal{A}$ satisfies*
$$\mathbf{Pr}[(x, \mathcal{A}(x,\nu)) \in R_N] \geq 1-\nu, \tag{A13}$$
where the probability is taken over the randomness of $\mathcal{A}$.

2. *A distributional function problem $F = \{(f_N, \mathcal{D}_N)\}_{N\in\mathbb{N}}$ is in* HeurFBQP *if there exists a quantum algorithm $\mathcal{A}$ such that for all N and all $0 < \mu, \nu < 1$, the runtime $t_{\mathcal{A}}(x, \mu, \nu)$ of $\mathcal{A}$ for every input $x \in \{0,1\}^N$ in the support of $\mathcal{D}_N$ is $t_{\mathcal{A}}(x, \mu, \nu) = O(\mathsf{poly}(N, 1/\mu, 1/\nu))$, and the output $\mathcal{A}(x, \mu, \nu)$ of $\mathcal{A}$ satisfies*

$$\mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}[\mathbf{Pr}[\mathcal{A}(x, \mu, \nu) = f_N(x)] \geq 1-\nu] \geq 1-\mu, \quad \text{(A14)}$$

where the inner probability of $\mathcal{A}(x, \mu, \nu) = f_N(x)$ is taken over randomness of $\mathcal{A}$.

Finally, we introduce the complexity classes with randomized advice strings [49]. As discussed in Section A 1, the analysis of the efficient evaluatability in the PAC learning model needs to take into account the randomized advice strings of at most $O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ length [18, 19, 48]. To capture the power of the bit strings representing the hypotheses to be evaluated, we consider the complexity classes with a polynomial-length randomized advice string as follows.

Definition S7 (Worst-case and heuristic distributional function bounded-error polynomial time with randomized advice)**.** *We define a worst-case class* FBPP/rpoly *and a heuristic class* HeurFBPP/rpoly *with advice as follows.*

1. *Given $R_N = \{(x, f_N(x))\}_{x\in\{0,1\}^N}$ and $R = \bigcup_N R_N$, the relation R is in* FBPP/rpoly *if there exists a randomized classical algorithm $\mathcal{A}$ such that for all N, every input $x \in \{0,1\}^N$, and all $0 < \nu, \xi < 1$, there exists an advice distribution $\mathcal{D}^{\mathrm{adv}}_{N,\nu,\xi}$ over $\{0,1\}^{O(\mathsf{poly}(N,1/\nu,1/\xi))}$ such that the runtime $t_{\mathcal{A}}(x, \alpha, \nu, \xi)$ of $\mathcal{A}$ is $t_{\mathcal{A}}(x, \alpha, \nu, \xi) = O(\mathsf{poly}(N, 1/\nu, 1/\xi))$, and the output $\mathcal{A}(x, \alpha, \nu, \xi)$ of $\mathcal{A}$ satisfies*

$$\mathop{\mathbf{Pr}}_{\alpha\sim\mathcal{D}^{\mathrm{adv}}_{N,\nu,\xi}}[\mathbf{Pr}[(x, \mathcal{A}(x, \alpha, \nu, \xi)) \in R_N] \geq 1-\nu] \geq 1-\xi, \quad \text{(A15)}$$

where the inner probability is taken over the randomness of $\mathcal{A}$.

2. *A distributional function problem $F = \{(f_N, \mathcal{D}_N)\}_{N\in\mathbb{N}}$ is in* HeurFBPP/rpoly *if there exists a randomized classical algorithm $\mathcal{A}$ such that for all N and all $0 < \mu, \nu, \xi < 1$, there exists an advice distribution $\mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}$ over $\{0,1\}^{O(\mathsf{poly}(N,1/\mu,1/\nu,1/\xi))}$ such that the runtime $t_{\mathcal{A}}(x, \alpha, \mu, \nu, \xi)$ of $\mathcal{A}$ for every input $x \in \{0,1\}^N$ in the support of $\mathcal{D}_N$ is $t_{\mathcal{A}}(x, \alpha, \mu, \nu, \xi) = O(\mathsf{poly}(N, 1/\mu, 1/\nu, 1/\xi))$, and the output $\mathcal{A}(x, \alpha, \mu, \nu, \xi)$ of $\mathcal{A}$ satisfies*

$$\mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}\left[\mathop{\mathbf{Pr}}_{\alpha\sim\mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}}[\mathbf{Pr}[\mathcal{A}(x, \alpha, \mu, \nu, \xi) = f_N(x)] \geq 1-\nu] \geq 1-\xi\right] \geq 1-\mu, \quad \text{(A16)}$$

where the probability of $\mathcal{A}(x, \alpha, \mu, \nu, \xi) = f_N(x)$ is taken over randomness of $\mathcal{A}$.

We similarly define other possible classes such as FP by combining the above definitions.

Appendix B: Advantage of QML from general quantum computational advantages

In this section, we prove that, for general quantum computational advantages, we can correspondingly construct learning tasks that are hard for classical computation but can be efficiently solved by quantum computation, within the conventional framework of supervised learning (i.e., in the PAC model formulated in Section A 1). In previous work [16–20], the advantage of QML was observed under the computational hardness assumption for a specific type of problem, such as that solved by Shor's algorithms. References [18, 19] also provide a learning problem with the advantage of QML based on more general quantum computational advantages than that of Shor's algorithms, but the concept class therein was limited to be polynomial-size ones, which can be straightforwardly solved by a brute-force algorithm. In contrast, the learning tasks introduced here will have exponential-size concept classes and yet will still be based on general types of quantum computational advantages, i.e., arbitrary functions in HeurFBQP \(HeurFBPP/rpoly) rather than just that of Shor's algorithms. In Section B 1, we explicitly give the concept class of these learning tasks as linear separation problems in the space of bits. In Section B 2, we construct polynomial-time quantum algorithms for learning and evaluation in our learning tasks. In Section B 3, we rigorously prove the classical hardness of the learning tasks.

1. Formulation of learning tasks

In this section, we construct learning tasks using general types of quantum advantages based on complexity classes introduced in Section A 2.

First, we define the general complexity class of functions to be used for formulating our learning task. Although Refs. [18, 19] studied conditions on the complexity classes that potentially lead to the advantage of QML, the analyses in Refs. [18, 19] were based on worst-case complexity [18, 19] and were not able to explicitly construct the learning tasks satisfying their conditions in general. By contrast, we here identify an appropriate class of functions using the heuristic complexity classes, so that we can use any functions in this class for our explicit construction of the learning tasks with the provable advantage of QML. The class that we use is given as follows.

Definition S8 (Quantumly advantageous functions)**.** *For a distributional functions problem $\{(f_N, \mathcal{D}_N)\}_{N\in\mathbb{N}}$ in*

$$\{(f_N, \mathcal{D}_N)\}_N \in \textsf{\textit{HeurFBQP}}\backslash(\textsf{\textit{HeurFBPP/rpoly}}), \tag{B1}$$

we call f_N a quantumly advantageous function under the target distribution $\mathcal{D}_N$.

As presented in the main text, the quantumly advantageous functions may include various functions beyond those computed by Shor's algorithms. Since we use heuristic complexity classes, the class of functions in Definition S8 is even larger than the class defined by the worst-case complexity classes, as discussed in Section A 2. For example, our definition does not rule out the possibility of using heuristic quantum algorithms such as the variational quantum algorithms (VQAs) for seeking evidence of the utility of QML based on the heuristic complexity class [74], in case one finds a variant of such quantum algorithms that are faster than classical algorithms for most of the inputs.

We define our concept class using the quantumly advantageous functions below. In the existing work [16–19] on the advantage of QML, the target distribution was limited to the uniform distribution, and the task was dependent on the specific mathematical structure of the functions computed by Shor's algorithms; by contrast, we allow for an arbitrary target distribution $\mathcal{D}_N$ over N bits, and we can use an arbitrary quantumly advantageous function without specifically depending on Shor's algorithms.

Definition S9 (Concept class for the advantage of QML from general computational advantages)**.** *For any N, $D = O(\mathsf{poly}(N))$, any target distribution $\mathcal{D}_N$ over an input space $\mathcal{X}_N \subseteq \{0,1\}^N$ of N bits, and any quantumly advantageous function $f_N : \{0,1\}^N \to \mathbb{F}_2^D$ under $\mathcal{D}_N$, we define a concept class $\mathcal{C}_N$ over the input space $\mathcal{X}_N$ as $\mathcal{C}_N = \{c_s\}_{s\in\mathbb{F}_2^D}$ with its concept c_s for each parameter $s \in \mathbb{F}_2^D$ given by*

$$c_s(x) := f_N(x) \cdot s \in \mathbb{F}_2 = \{0,1\}, \tag{B2}$$

where $f_N(x) \cdot s$ for $f_N(x), s \in \mathbb{F}_2^D = \{0,1\}^D$ is a bitwise inner product in the vector space $\mathbb{F}_2^D$ over the finite field.

2. Construction of polynomial-time quantum algorithms for learning and evaluation

In this section, we show polynomial-time quantum algorithms for learning concepts in the concept class in Definition S9 and for evaluating hypotheses in the hypothesis class for this concept class. A challenge here arises from the fact that our concept class $\mathcal{C}_N$ in Definition S9 may have an exponential size in N. To see the importance of addressing this challenge, recall that, for example, Refs. [18, 19] also analyzed the advantage of QML based on general quantum computational advantages, but their results were only applicable to polynomial-size concept classes so that their concept classes should be efficiently learnable by a brute-force quantum algorithm that just tries all the concepts in the concept class. However, our interest here is whether QML can learn concepts without such a brute-force approach. Advancing ahead, our results overcome such limitations by constructing QML algorithms achieving efficient learning and evaluation for the exponential-size concept classes, of which we will also prove the hardness for any classical learning methods in Sec. B 3. Below, we first describe our learning algorithm (Algorithm S1) and prove the quantum efficient learnability for our concept class. We then describe our evaluation algorithm (Algorithm S2) and prove the quantum efficient evaluatability for the hypothesis class constructed for our concept class.

We first describe our quantum algorithm for learning. Our algorithm for learning a target concept in our concept class is given by Algorithm S1. The concept class $\mathcal{C}_N = \{c_s : s \in \mathbb{F}_2^D\}$ is defined in Definition S9 for any (unknown) target distribution $\mathcal{D}_N$ over $\mathcal{X}_N \subseteq \mathbb{F}_2^N$ and any quantumly advantageous function $f_N : \{0,1\}^N \to \mathbb{F}_2^D$. Let c_s denote the unknown target concept to be learned from the samples by the algorithm, where s is the true parameter of the target concept. For any $\epsilon > 0$ and $\delta > 0$, our algorithm aims to achieve the learning in Definition S1, i.e., to output $\tilde{s}$ so that a hypothesis $h_{\tilde{s}}$ represented by $\tilde{s}$ should satisfy

$$\underset{x\sim\mathcal{D}_N}{\mathbf{Pr}}\left[h_{\tilde{s}}(x) \neq c_s(x)\right] \leq \epsilon \tag{B3}$$

with a high probability greater than or equal to $1-\delta$. To this goal, we set the internal parameters in Algorithm S1 as

$$M = \left\lceil \frac{D}{\epsilon} - 1 \right\rceil, \tag{B4}$$

$$\mu = \frac{\delta}{2M}, \tag{B5}$$

$$\nu = \frac{\delta}{2M}, \tag{B6}$$

where $\lceil x \rceil$ is the ceiling function, i.e., the smallest integer greater than or equal to x.

In Algorithm S1, M samples are initially loaded as the input, obtained from the oracle **EX** in the setting of the PAC learning model described in Section A 1. The M samples are denoted by $\{(x_m, c_s(x_m))\}_{m=1}^M$, where c_s is the (unknown) target concept to be learned from the samples by the algorithm. Then, the algorithm probabilistically computes the quantumly advantageous function f_N for each of the M input samples $x_1, \ldots, x_M$. By definition of the quantumly advantageous function f_N in $\mathsf{HeurFBQP}$ of (A14), we have a quantum algorithm $\mathcal{A}$ to achieve

$$\underset{x\sim\mathcal{D}_N}{\mathbf{Pr}}\left[\mathbf{Pr}\left[\mathcal{A}(x,\mu,\nu) = f_N(x)\right] \geq 1-\nu\right] \geq 1-\mu, \tag{B7}$$

with runtime

$$t_{\mathcal{A}}(x,\mu,\nu) = O\left(\left(\frac{N}{\mu\nu}\right)^{\alpha}\right), \tag{B8}$$

where $\alpha > 0$ is an upper bound of the degree of the polynomial runtime. To compute f_N, Algorithm S1 applies the quantum algorithm $\mathcal{A}$ to each of $x_1, \ldots, x_M$. We write the outputs of $\mathcal{A}$ as $\mathcal{A}(x_1), \ldots, \mathcal{A}(x_M) \in \mathbb{F}_2^D$, respectively, where we will omit μ and ν for simplicity of notation if it is obvious from the context. Note that $\mathcal{A}$ may not be a deterministic algorithm, and thus, we may have $\mathcal{A}(x_m) = f_N(x_m)$ only probabilistically. Using $\mathcal{A}(x_1), \ldots, \mathcal{A}(x_M)$ obtained from these computations, the algorithm performs Gaussian elimination by classical computation to solve a system of linear equations

$$\begin{aligned} \mathcal{A}(x_1) \cdot \tilde{s} &= c_s(x_1), \\ \mathcal{A}(x_2) \cdot \tilde{s} &= c_s(x_2), \\ &\vdots \\ \mathcal{A}(x_M) \cdot \tilde{s} &= c_s(x_M), \end{aligned} \tag{B9}$$

where the left-hand sides of the system of linear equations are the bitwise inner product in the space $\mathbb{F}_2^D$ of the D-dimensional vectors over the finite field. This step provides a solution

$$\tilde{s} = \begin{pmatrix} \tilde{s}_1 \\ \tilde{s}_2 \\ \vdots \\ \tilde{s}_D \end{pmatrix} \in \mathbb{F}_2^D \tag{B10}$$

of the system of linear equations. This system of linear equations always has the true parameter s of the target concept c_s as a solution but may have more than one solution if the set $\{\mathcal{A}(x_1), \ldots, \mathcal{A}(x_M)\}$ does not include a spanning set of D vectors in the D-dimensional vector space $\mathbb{F}_2^D$. The non-spanning cases indeed occur in our setting, especially when the support of $\mathcal{D}_N$ or the range of f_N is small, on which we impose no assumption for the generality of our learning task. Even if the system of linear equations has more than one solution, the algorithm can nevertheless adopt any solution of (B9) as $\tilde{s}$ in (B10). The learning algorithm outputs this parameter $\tilde{s}$ as a representation of the hypothesis given by

$$h_{\tilde{s}}(x) = f_N(x) \cdot \tilde{s}, \tag{B11}$$

where the right-hand side is the bitwise inner product in $\mathbb{F}_2^D$. The hypothesis class is then given by

$$\mathcal{H}_N := \{h_{\tilde{s}} : \tilde{s} \in \mathbb{F}_2^D\}. \tag{B12}$$

In the following, we will prove the efficient learnability of our concept class $\mathcal{C}_N$ by Algorithm S1. The proof is nontrivial since the parameter $\tilde{s}$ in (B10) output by our learning algorithm may not be exactly equal to true s of the target concept c_s but can be any of multiple possible solutions of the system of linear equations in (B9); i.e., we need to take into account the cases of

$$\tilde{s} \neq s. \tag{B13}$$

```
Algorithm S1 Quantum algorithm for learning a concept in the concept class in Definition S9
Input: Samples loaded from the oracle EX, $\epsilon > 0$, and $\delta > 0$.
Output: A $D$-bit representation $\tilde{s} \in \mathbb{F}_2^D$ of the hypothesis
    $h_{\tilde{s}}$ in (B11) in the hypothesis class in (B12) achieving
    the error below $\epsilon$ with high probability at least $1 - \delta$, as in (B3).
1: Load $M$ samples $(x_1, c_s(x_1)), \ldots, (x_M, c_s(x_M))$ from the
   oracle EX with $M$ given in (B4).
2: for $m = 1, \ldots, M$ do
3:     Perform the quantum algorithm $\mathcal{A}$ in (B7) for the input
       $x_m$ with the parameters $\mu$ and $\nu$ in (B5) and (B6),
       respectively, to obtain $\mathcal{A}(x_m)$.
4: end for
5: Perform Gaussian elimination by classical computation
   for solving the system of linear equations in (B9), using
   $\mathcal{A}(x_1), \ldots, \mathcal{A}(x_M)$ obtained in the previous steps and the
   output samples $c_s(x_1), \ldots, c_s(x_M)$ loaded initially, to obtain a solution $\tilde{s}$ in (B10).
6: return $\tilde{s}$.
```

```
Algorithm S2 Quantum algorithm for evaluating a hypothesis in the hypothesis class for the concept class in Definition S9
Input: A new input $x \in \mathcal{X}_N$ sampled from the target distribution $\mathcal{D}_N$,
    a parameter $\tilde{s} \in \mathbb{F}_2^D$ of the hypothesis $h_{\tilde{s}}$
    in (B11) in the hypothesis class (B12), $\epsilon > 0$, and $\delta > 0$.
Output: An estimate $\tilde{h} \in \{0, 1\}$ of the hypothesis $h_{\tilde{s}}(x)$ for
    the input $x$ achieving the error below $\epsilon$ with high probability at least $1 - \delta$, as in (B41).
1: Perform the quantum algorithm $\mathcal{A}$ in (B7) for the input
   $x$ with the parameters $\mu$ and $\nu$ in (B42) and (B43), respectively, to obtain $\mathcal{A}(x)$.
2: return $\tilde{h} = A_N(x) \cdot \tilde{s}$ in (B44).
```

We will nevertheless prove that we have

$$h_{\tilde{s}}(x) = c_s(x) \tag{B14}$$

for a large fraction of x with a high probability as required for the efficient learnability in Definition S1.

To achieve this proof, our key technique is to use the lemma below, which indicates that if we have sufficiently many samples $x_1, \ldots, x_M$, then for a new $(M+1)$th input x_{M+1} to be given in the future, we will be able to represent its feature $y_{M+1} = f_N(x) \in \mathbb{F}_2^D$ as a linear combination of those of the M samples, $y_1 = f_N(x_1), \ldots, y_M = f_N(x_M) \in \mathbb{F}_2^D$, with a high probability. Using this lemma, in our proof of efficient learnability, we will show that the learned hypothesis $h_{\tilde{s}}(x) = f_N(x) \cdot \tilde{s}$ with $\tilde{s}$ estimated from $y_1, \ldots, y_M$ will coincide with the target concept $c_s(x) = f_N(x) \cdot s$ with true s, by expanding $f_N(x)$ therein as the linear combination of $f_N(x_1), \ldots, f_N(x_M)$. In particular, we here give the following lemma.

Lemma S10 (Probability of linear combination)**.** *Suppose that M vectors $y_1,\ldots,y_M\in\mathbb{F}_2^D$ are sampled from any probability distribution on a D-dimensional vector space $\mathbb{F}_2^D$ over the finite field in an identically and identically distributed (IID) way. If the $(M+1)$th vector y is sampled from the same distribution, then y can be represented by a linear combination of the other M vectors $y_1,\ldots,y_M$, i.e.,*

$$y=\sum_{m=1}^{M}\alpha_m y_m \quad \text{for some } \alpha_m\in\mathbb{F}_2=\{0,1\}, \tag{B15}$$

with a high probability greater than or equal to

$$1-\frac{D}{M+1}. \tag{B16}$$

Proof. We write $y_{M+1}:=y$. Given any sequence $y_1,\ldots,y_{M+1}$ of the $M+1$ vectors, let m' be the number of nonzero vectors in $(y_1,\ldots,y_{M+1})$ such that the vector cannot be represented by a linear combination of the other M vectors. Let $p(m')$ denote the probability that the sequence $y_1,\ldots,y_{M+1}$ randomly chosen by the IID sampling includes exactly m' vectors that cannot be represented by a linear combination of the other M. Since the space $\mathbb{F}_2^D$ is D-dimensional, we always have

$$m'\leq D, \tag{B17}$$

that is,

$$\sum_{m'=0}^{D}p(m')=1. \tag{B18}$$

For example, we may have $m'=D$ in the cases where the sequence includes the D vectors that form a basis of the vector space $\mathbb{F}_2^D$, and the other $N-D$ vectors are zero vectors.

Conditioned on having these m' vectors in the sequence of $M+1$ vectors, the probability of (B15) is bounded by the probability of having one of the m' vectors out of the $M+1$ vectors as the $(M+1)$th vector, i.e.,

$$\begin{aligned}&\mathbf{Pr}\left[y_{M+1}\neq\sum_{m=1}^{M}\alpha_m y_m\quad\forall\alpha_m\in\mathbb{F}_2\middle|m'\right]\\ &=\frac{m'}{M+1} &\text{(B19)}\\ &\leq\frac{D}{M+1}, &\text{(B20)}\end{aligned}$$

where the first equality follows from the assumption of IID sampling, and the inequality in the last line from (B17). Therefore, it holds that

$$\begin{aligned}&\mathbf{Pr}\left[y_{M+1}\neq\sum_{m=1}^{M}\alpha_m y_m\quad\forall\alpha_m\in\mathbb{F}_2\right]\\ &=\sum_{m'=0}^{M}p(m')\,\mathbf{Pr}\left[y_{M+1}\neq\sum_{m=1}^{M}\alpha_m y_m\quad\forall\alpha_m\in\{0,1\}\middle|m'\right]\\ &\leq\left(\sum_{m'=0}^{M}p(m')\right)\frac{D}{M+1} &\text{(B21)}\\ &=\frac{D}{M+1}, &\text{(B22)}\end{aligned}$$

which yields the conclusion. □

Using Lemma S10, we prove that the concept class $\mathcal{C}_N$ in Definition S9 is quantumly efficiently learnable as follows.

Theorem S11 (Quantumly efficient learnability)**.** *For any N, $D=O(\mathsf{poly}(N))$, any target distribution $\mathcal{D}_N$ over the N-bit input space $\mathcal{X}_N\subseteq\{0,1\}^N$, and any quantumly advantageous function $f_N:\{0,1\}^N\to\mathbb{F}_2^D$ under $\mathcal{D}_N$, the concept class $\mathcal{C}_N$ in Definition S9 with f_N is quantumly efficiently learnable by Algorithm S1.*

Proof. In the following, we will first discuss the success probability of our algorithm and then analyze the error in the learning. Finally, we will provide an upper bound of the runtime.

Regarding the success probability of Algorithm S1, the probabilistic parts of the learning algorithm are the loading of the M samples $(x_1,c_s(x_1)),\ldots,(x_M,c_s(x_M))$ from the oracle **EX** and the computations of $f_N(x)$ for all $x\in\{x_1,\ldots,x_M\}$ by the quantum algorithm $\mathcal{A}$. The other parts, such as the Gaussian elimination, are deterministic, as shown in Algorithm S1. In loading the M samples, based on Lemma S10, we require that the feature map $f_N(x)$ for the next $(M+1)$th sample x from the same target distribution $\mathcal{D}_N$, which is to be evaluated after the learning from the M samples, should be represented as a linear combination of those of the M samples, $f_N(x_1),\ldots,f_N(x_M)$, with a high probability at least $1-\epsilon$; i.e., it should hold that

$$\mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}\left[f_N(x)=\sum_{m=1}^{M}\alpha_m f_N(x_m)\right]\geq1-\epsilon. \tag{B23}$$

Using Lemma S10 with $y_1=f_N(x_1),\ldots,y_M=f_N(x_M)$, and $y=f_N(x)$, we see that, with M given by (B4), this requirement is fulfilled. Also, in the computations of f_N, we require that the probabilistic quantum algorithm $\mathcal{A}$ should simultaneously achieve

$$\mathcal{A}(x_1)=f_N(x_1),\ldots,\mathcal{A}(x_M)=f_N(x_M), \tag{B24}$$

with a high probability of at least $1-\delta$. For each $m\in\{1,\ldots,M\}$, due to (B7) and the union bound, we have $\mathcal{A}(x_m)=f_N(x_m)$ with a probability at least

$$1-(\mu+\nu); \tag{B25}$$

then, due to the union bound, the probability of having (B24) simultaneously is at least

$$1-M(\mu+\nu). \tag{B26}$$

Thus, with μ chosen as (B5) and ν as (B6), the requirement in (B24) is fulfilled. As a whole, the requirement in (B23) is always satisfied for our choice of M, and the requirement in (B24) is satisfied with a high probability at least $1-\delta$ for our choice of μ and ν, which guarantees that the overall success probability of the learning algorithm is lower bounded by $1-\delta$.

Given that the requirements in (B23) and (B24) are fulfilled, the error in learning as in Definition S1 is bounded as follows. Under (B23) and (B24), for any x satisfying

$$f_N(x) = \sum_{m=1}^{M} \alpha_m f_N(x_m), \tag{B27}$$

the hypothesis $h_{\tilde{s}}$ in (B11) parameterized by $\tilde{s} \in \mathbb{F}_2^D$ output by Algorithm S1 can correctly classify x as

$$\begin{aligned}
h_{\tilde{s}}(x) &= f_N(x) \cdot \tilde{s} && \text{(B28)}\\
&= \sum_{m=1}^{M} \alpha_m f_N(x_m) \cdot \tilde{s} && \text{(B29)}\\
&= \sum_{m=1}^{M} \alpha_m \mathcal{A}(x_m) \cdot \tilde{s} && \text{(B30)}\\
&= \sum_{m=1}^{M} \alpha_m c_s(x_m) && \text{(B31)}\\
&= \sum_{m=1}^{M} \alpha_m f_N(x_m) \cdot s && \text{(B32)}\\
&= f_N(x) \cdot s && \text{(B33)}\\
&= c_s(x), && \text{(B34)}
\end{aligned}$$

where (B29) follows from (B27), (B30) from (B24), and (B31) from (B9). Therefore, due to the requirement of (B23), we have

$$\mathbf{Pr}\left[h(x) = c_s(x)\right] \geq 1-\epsilon; \tag{B35}$$

that is, the error in (A1) is bounded by

$$\mathrm{error}(h) = \mathbf{Pr}\left[h(x) \neq c_s(x)\right] \leq \epsilon, \tag{B36}$$

as required for the learnability in Definition S1.

The runtime of Algorithm S1 is dominated by the computations of f_N by $\mathcal{A}$ and the Gaussian elimination. We first consider the runtime of computing f_M for the M samples $x_1, \ldots, x_M$. For each x_m with $m \in \{1, \ldots, M\}$, the runtime of the quantum algorithm $\mathcal{A}$ for computing f_N is given by $t_{\mathcal{A}}(x_m)$ in (B8); thus, the runtime of the M calculations is

$$\sum_{m=1}^{M} t_{\mathcal{A}}(x_m) = O\left(M\left(\frac{N}{\mu\nu}\right)^{\alpha}\right). \tag{B37}$$

In addition, the runtime of performing the Gaussian elimination to find a solution $\tilde{s} \in \mathbb{F}_2^D$ of the system of M linear equations in (B9) (with $D \leq M$ due to (B4)) is

$$O(M^3). \tag{B38}$$

In total, for M in (B4), μ in (B5), ν in (B6), and $D = O(\mathsf{poly}(N)) = O(N^{\beta})$ with some $\beta > 0$, the overall runtime of Algorithm S1 is upper bounded by

$$\begin{aligned}
&O\left(M\left(\frac{N}{\mu\nu}\right)^{\alpha}\right) + O(M^3)\\
&= O\left(\frac{N^{2\alpha\beta+\alpha+\beta}}{\delta^{2\alpha}\epsilon^{2\alpha+1}} + \frac{N^{3\beta}}{\epsilon^3}\right) && \text{(B39)}\\
&= O\left(\mathsf{poly}\left(N, \frac{1}{\epsilon}, \frac{1}{\delta}\right)\right), && \text{(B40)}
\end{aligned}$$

as required for efficient learnability in Definition S1. □

Next, we describe our quantum algorithm for evaluating the hypotheses for our concept class. Our quantum algorithm for evaluating a hypothesis $h_{\tilde{s}}$ in (B11) with the learned parameter $\tilde{s}$ is given by Algorithm S2, where the hypothesis class is in (B12). In our case, the parameter $\tilde{s}$ serves as the D-bit representation of the hypothesis, corresponding to σ_h in Definition S2 of the efficient evaluatability. For any $\epsilon > 0$ and $\delta > 0$, our evaluation algorithm aims to achieve the efficient evaluation in Definition S2; in particular, the evaluation algorithm aims to output an estimate $\tilde{h} \in \{0,1\}$ of the hypothesis $h_{\tilde{s}}(x)$ for the input x so as to satisfy

$$\mathop{\mathbf{Pr}}_{x\sim\mathcal{D}_N}\left[\mathbf{Pr}\left[\tilde{h} = h_{\tilde{s}}(x)\right] \geq 1-\delta\right] \geq 1-\epsilon, \tag{B41}$$

where the inner probability is taken over the randomness of the evaluation algorithm. To this goal, we set the internal parameters in Algorithm S2 as

$$\begin{aligned}
\mu &= \epsilon && \text{(B42)}\\
\nu &= \delta. && \text{(B43)}
\end{aligned}$$

In algorithm S2, an unseen input x is initially given by sampling from the target distribution $\mathcal{D}_N$. Then, the algorithm probabilistically computes the quantumly advantageous function f_N for the input x, using the same quantum algorithm $\mathcal{A}$ as that used in our learning algorithm, i.e., that in (B7) and (B8), yet with the parameters μ in (B42) and ν in (B43). We let $\mathcal{A}(x)$ denote the output of $\mathcal{A}$ in (B7) for the input x, where we will omit μ and ν for simplicity of notation if it is obvious from the context. Note that $\mathcal{A}$ may not be a deterministic algorithm; that is, we may have $\mathcal{A}(x) = f_N(x)$ only probabilistically, as shown in (B7). Finally, using the given parameter $\tilde{s}$ of the hypothesis $h_{\tilde{s}}$, the evaluation algorithm calculates the bitwise inner product of $\mathcal{A}(x)$ obtained from the above computation and $\tilde{s}$, so as to output

$$\tilde{h} \coloneqq \mathcal{A}(x) \cdot \tilde{s}. \tag{B44}$$

We now prove the quantumly efficient evaluatability of the hypothesis class $\mathcal{H}_N$ in (B12) by Algorithm S2 as follows.

Theorem S12 (Quantumly efficient evaluatability)**.** *For any N, $D = O(\mathsf{poly}(N))$, any target distribution $\mathcal{D}_N$ over the N-bit input space $\mathcal{X}_N \subseteq \{0,1\}^N$, and any quantumly advantageous function $f_N : \{0,1\}^N \to \mathbb{F}_2^D$ under $\mathcal{D}_N$, the hypothesis class $\mathcal{H}_N$ in* (B12) *with f_N, parameterized by $\tilde{s} \in \mathbb{F}^D$, is quantumly efficiently evaluatable by Algorithm S2.*

Proof. In the following, we will first discuss the success probability of our evaluation algorithm and then provide an upper bound of the runtime.

The probabilistic part of Algorithm S2 is confined solely to the computation of $f_N(x)$ by the quantum algorithm $\mathcal{A}$, and the other parts, such as the bitwise inner product, are deterministic. The requirement for this probabilistic part is that the quantum algorithm $\mathcal{A}$ should compute $f_N(x)$ correctly for a large fraction $1-\epsilon$ of the given input x with high probability at least $1-\delta$, i.e.,

$$\Pr_{x\sim\mathcal{D}_N}\left[\Pr\left[\mathcal{A}(x) = f_N(x)\right] \geq 1-\delta\right] \geq 1-\epsilon. \tag{B45}$$

Using $\mathcal{A}$ in (B7) with μ chosen as (B42) and ν as (B43), we fulfill this requirement. Conditioned on having

$$\mathcal{A}(x) = f_N(x), \tag{B46}$$

the output $\tilde{h}$ in (B44) becomes

$$\tilde{h} = \mathcal{A}(x)\cdot\tilde{s} = f_N(x)\cdot\tilde{s} = h_{\tilde{s}}(x). \tag{B47}$$

Consequently, Algorithm S2 outputs $\tilde{h}$ satisfying

$$\Pr_{x\sim\mathcal{D}_N}\left[\Pr\left[\tilde{h} = h_{\tilde{s}}(x)\right] \geq 1-\delta\right] \geq 1-\epsilon, \tag{B48}$$

as required for the evaulatability in Definition S2.

The runtime of Algorithm S2 is dominated by the computation of f_N by $\mathcal{A}$ and the bitwise inner product. We first consider the runtime $t_{\mathcal{A}}$ of $\mathcal{A}$ for the input x. We have the algorithm $\mathcal{A}$ satisfying (B8). Accordingly, with μ chosen as (B42) and ν as (B43), we have

$$t_{\mathcal{A}}(x) = O\left(\left(\frac{N}{\mu\nu}\right)^{\alpha}\right) \tag{B49}$$

$$= O\left(\left(\frac{N}{\epsilon\delta}\right)^{\alpha}\right). \tag{B50}$$

Also, the runtime of the bitwise inner product of vector in the D-dimensional vector space $\mathbb{F}_2^D$ over the finite field in (B44) is

$$O(D). \tag{B51}$$

Thus, for μ in (B42), ν in (B43), and $D = O(\mathsf{poly}(N)) = O(N^{\beta})$ with some $\beta > 0$, the overall runtime of Algorithm S2 is upper bounded by

$$O\left(\left(\frac{N}{\epsilon\delta}\right)^{\alpha}\right) + O(D) \tag{B52}$$

$$= O\left(\left(\frac{N}{\epsilon\delta}\right)^{\alpha}\right) + O\left(N^{\beta}\right) \tag{B53}$$

$$= O\left(\mathsf{poly}\left(N, \frac{1}{\epsilon}, \frac{1}{\delta}\right)\right), \tag{B54}$$

as required for the efficient evaluatablity in Definition S2. □

3. Provable hardness for any polynomial-time classical algorithm

In this section, we prove the classical hardness of efficient learning and efficient evaluation for our concept class in Definition S9. Our proof is given by contradiction; that is, we will prove that, assuming that there exists a classically efficient evaluatable hypothesis class (Definition S2) for classically efficient learnability (Definition S1) of our concept class, one would be able to construct a polynomial-time classical algorithm to compute a quantumly advantageous function f_N in Definition S8 using the polynomial-time classical algorithms for evaluating the hypotheses in this hypothesis class. This classical algorithm is presented in Algorithm S3. The rest of this section first describes this classical algorithm for the reduction of evaluating hypotheses to computing f_N and then provides the full proof of the classical hardness.

To see the significance of our construction of this classical algorithm for the reduction, recall that it has been challenging to prove the classical hardness of learning without relying on discrete logarithms or integer factoring, which are solved by Shor's algorithms; by contrast, our proof of the classical hardness is applicable to any quantumly advantageous function beyond the scope of Shor's algorithms. Note that, in this direction, Refs. [18, 19] have also considered a concept class to show the advantage of QML based on general quantum computational advantages, but their results were applicable only to polynomial-size concept classes that can be learned by a brute-force algorithm, and our interest here is exponential-size concept classes that cannot be learned in such a brute-force approach. The technique of the proof by contradiction itself may be well established in the complexity theory and also used info showing the classical hardness of learning in the previous works [5, 6, 16–20, 24]. However, the existing proofs of the classical hardness in these previous works essentially depend on a specific mathematical structure of discrete logarithms and integer factoring, so as to go through a cryptographic argument based on these computational problems. To go beyond the realm of Shor's algorithms, novel techniques without relying on the existing cryptographic approach need to be developed. In contrast with these existing works, for our exponential-size concept class with its feature space formulated as the space of bit strings, which is quantumly efficiently learnable and evaluatable as shown in Sec. B 2, we prove the classical hardness based on any quantumly advantageous func-

Algorithm S3 Classical algorithm for the reduction of evaluating the hypotheses for the concept class in Definition S9 to computing the quantumly advantageous function in Definition S8

```
Input: A new input $x \in \mathcal{X}_N$ sampled from the target distribution $\mathcal{D}_N$, $\mu, \nu, \xi > 0$, a randomized advice string $\alpha \sim \mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}$ in (B67) providing the representations $\alpha = (\sigma_{h_{s_1}}, \ldots, \sigma_{h_{s_D}})$ of $D$ hypotheses $h_{s_1}, \ldots, h_{s_D}$ in (B62) for the concept class $\mathcal{C}_N$ in Definition S9.
Output: An estimate $\tilde{f}$ of a quantumly advantageous function $\tilde{f}_N(x)$ for $\mathcal{C}_N$ achieving (B55) and (B56).
for $d = 1, \ldots, D$ do
    Perform the quantum algorithm $\mathcal{A}$ in (B64) and (B65) for $x$, $\sigma_{h_{s_1}}$, $\epsilon$ in (B59), and $\delta$ in (B60), to compute an estimate $\tilde{h}_{s_d} \in \{0,1\}$ of $h_{s_d}(x)$.
end for
return $\tilde{f} = \left(\tilde{h}_{s_1}, \ldots, \tilde{h}_{s_1}\right)^\top$ in (B66).
```

tions in Definition S8, without depending on any specific quantum algorithm such as Shor's algorithms.

To show this, for any target distribution $\mathcal{D}_N$, any quantumly advantageous function $f_N : \{0,1\}^N \to \mathbb{F}_2^D$ under $\mathcal{D}_N$ in Definition S8 with $D = O(\mathsf{poly}(N))$, and our concept class $\mathcal{C}_N$ in Definition S9, we assume that $\mathcal{C}_N$ is classically efficiently learnable as in Definition S2 by a hypothesis class $\mathcal{H}_N$, and the hypothesis class $\mathcal{H}_N$ is classically efficiently evaluatable as in Definition S2. Under this assumption, we construct a polynomial-time classical algorithm for the reduction of the efficient evaluation of the hypotheses in $\mathcal{H}_N$ to the computation of f_N, as shown in Algorithm S3, which will lead to the contradiction. Given an input x drawn from $\mathcal{D}_N$ and an appropriate choice of a polynomial-length randomized advice string α sampled from a advice distribution $\mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}$ as in the definition of $\mathsf{HeurFBPP/rpoly}$ in (A16), the goal of Algorithm S3 is, for all $0 < \mu < 1$, $0 < \nu < 1$, and $0 < \xi < 1$, to output an estimate $\tilde{f} \in \mathbb{F}_2^D$ of $f_N(x)$ satisfying

$$\underset{x\sim\mathcal{D}_N}{\mathbf{Pr}}\left[\underset{\alpha\sim\mathcal{D}^{\mathrm{adv}}_{N,\mu,\nu,\xi}}{\mathbf{Pr}}\left[\mathbf{Pr}[\mathcal{A}(x,\alpha,\mu,\nu,\xi) = f_N(x)]\right.\right.$$
$$\left.\left.\geq 1-\nu\right] \geq 1-\xi\right] \geq 1-\mu, \tag{B55}$$

within runtime

$$t_{\mathcal{A}}(x,\alpha,\mu,\nu,\xi) = O\left(\mathsf{poly}\left(N, \frac{1}{\mu}, \frac{1}{\nu}, \frac{1}{\xi}\right)\right), \tag{B56}$$

where α will be given from distributions of the representations of D hypotheses in $\mathcal{H}_N$ as described below. To this goal, we set the internal parameters in Algorithm S3 as

$$\epsilon_{\mathrm{learn}} = \frac{\mu}{2D}, \tag{B57}$$

$$\delta_{\mathrm{learn}} = \frac{\xi}{D}, \tag{B58}$$

$$\epsilon_{\mathrm{eval}} = \frac{\mu}{2D}, \tag{B59}$$

$$\delta_{\mathrm{eval}} = \frac{\nu}{D}. \tag{B60}$$

In Algorithm S3, an input x drawn from the distribution $\mathcal{D}_N$ is initially given, and the representations of hypotheses for D concepts in our concept class $\mathcal{C}_N$ are also initially given. In particular, let

$$\{s_d \in \mathbb{F}_2^D\}_{d=1,\ldots,D} \tag{B61}$$

denote the standard basis of the D-dimensional vector space $\mathbb{F}_2^D$, where the dth element of the vector $s_d \in \mathbb{F}_2^D$ is 1, and all the other elements of s_d are 0. Then, under the assumption of the classically efficient learnability of $\mathcal{C}_N$, for each s_d and all $0 < \epsilon_{\mathrm{learn}}, \delta_{\mathrm{learn}} < 1$, there should exist a classical algorithm that outputs, with a high probability of at least $1 - \delta_{\mathrm{learn}}$, a representation $\sigma_{h_{s_d}}$ of a hypothesis h_{s_d} such that

$$\underset{x\sim\mathcal{D}_N}{\mathbf{Pr}}\left[h_{s_d}(x) \neq c_{s_d}(x)\right] \leq \epsilon_{\mathrm{learn}}, \tag{B62}$$

and $\sigma_{h_{s_d}}$ should be of polynomial length

$$\mathrm{size}\left(\sigma_{h_{s_d}}\right) = O\left(\left(\frac{N}{\epsilon_{\mathrm{learn}}\delta_{\mathrm{learn}}}\right)^{\eta}\right), \tag{B63}$$

where $\eta > 0$ is an upper bound of the degree of the polynomial length. Note that our proof of the hardness does not use the learning algorithm directly in Algorithm S3, but the assumption of classically efficient learnability is used to guarantee the existence of the hypotheses that approximate the concepts well and have polynomial-length representations, as in (B62) and (B63).

Furthermore, under the assumption of the classically efficient evaluatability of this hypothesis class, there should exist a classical (randomized) algorithm $\mathcal{A}$ such that for the representation $\sigma_{h_{s_d}}$ of each hypothesis h_{s_d} with s_d in (B61), and all $0 < \epsilon_{\mathrm{eval}}, \delta_{\mathrm{eval}} < 1$, the algorithm $\mathcal{A}$ outputs an estimate $\tilde{h}_{s_d} \in \{0,1\}$ of $h_{s_d}(x)$ satisfying

$$\underset{x\sim\mathcal{D}_N}{\mathbf{Pr}}\left[\mathbf{Pr}\left[\tilde{h}_{s_d} = h_{s_d}(x)\right] \geq 1 - \delta_{\mathrm{eval}}\right] \geq 1 - \epsilon_{\mathrm{eval}}, \tag{B64}$$

within polynomial runtime for all x in the support of $\mathcal{D}_N$

$$t_{\mathcal{A}}\left(x, \sigma_{h_{s_d}}, \epsilon_{\mathrm{eval}}, \delta_{\mathrm{eval}}\right) = O\left(\left(\frac{N}{\epsilon_{\mathrm{eval}}\delta_{\mathrm{eval}}}\right)^{\gamma}\right), \tag{B65}$$

where $\gamma > 0$ is an upper bound of the degree of the polynomial runtime.

Under this assumption on the classically efficient learnability and the classically efficient evaluatability, Algorithm S3 uses the classical evaluation algorithm $\mathcal{A}$ to compute each of the D hypotheses $h_{s_1}(x), \ldots, h_{s_D}(x)$ for the input x, to obtain $\tilde{h}_{s_1}, \ldots, \tilde{h}_{s_D}$. Note that $\mathcal{A}$ may not be a deterministic algorithm, and thus, we may have $\tilde{h}_{s_d} = h_{s_d}(x)$ only probabilistically. But if it holds that $\tilde{h}_{s_d} = h_{s_d}(x) = c_{s_d}(x)$, then $\tilde{h}_{s_d}$ is the dth bit of $f_N(x) \in \mathbb{F}_2^D$, as can be seen from (B2). Using this property of the vector space of bit strings, from the computed values $\tilde{h}_{s_1}, \ldots, \tilde{h}_{s_D} \in \{0,1\}$, Algorithm S3 outputs

$$\tilde{f} := \begin{pmatrix} \tilde{h}_{s_1} \\ \tilde{h}_{s_2} \\ \vdots \\ \tilde{h}_{s_D} \end{pmatrix} \in \mathbb{F}_2^D \tag{B66}$$

as an estimate of $f_N(x)$.

Using the reduction achieved by Algorithm S3, we prove that our concept class $\mathcal{C}_N$ is not classically efficiently learnable by any classically efficiently evaluatable hypothesis class. We also note that, in previous works [5, 16, 17, 24] of the classical hardness of learning tasks, efficient evaluatability was defined in terms of worst-case complexity; by contrast, motivated by the practical applicability as discussed in Section A 1, our definition of efficient evaluatablity in Definition S2 is in terms of heuristic complexity. Since the heuristic complexity classes include the corresponding worst-case complexity classes as discussed in Section A 2, our proof of the classical hardness of our learning tasks for the heuristic complexity implies the more conventional classical hardness for the worst-case complexity as well.

Theorem S13 (Classical hardness)**.** *For any N, $D = O(\mathsf{poly}(N))$, any target distribution $\mathcal{D}_N$ over the N-bit input space $\mathcal{X}_N \subseteq \{0,1\}^N$, and any quantumly advantageous function $f_N : \{0,1\}^N \to \mathbb{F}_2^D$ under $\mathcal{D}_N$, the concept class $\mathcal{C}_N$ in Definition S9 with f_N is not classically efficiently learnable by any classically efficiently evaluatable hypothesis class.*

Proof. We prove the statement by contradiction; i.e., we show that, under the assumption that $\mathcal{C}_N$ is classically efficiently learnable by some classically efficiently evaluatable hypothesis class, there should exist a classical randomized algorithm (Algorithm S3) with a polynomial-length randomized advice string α achieving (B55) and (B56) for the reduction to computing the quantum advantageous function f_N. In the following, we first analyze the length of α. Then, we consider the success probability of our algorithm for the reduction. Finally, we discuss the runtime of our algorithm for the reduction.

The length of the randomized advice string α is bounded as follows. We let the advice distribution $\mathcal{D}_{N,\mu,\nu,\xi}^{\mathrm{adv}}$ be the output distribution of the classical randomized algorithm for efficient learning that outputs the representations of the D hypothesis satisfying (B62) and (B63), and we use these representations as the randomized advice string

$$\alpha := \left(\sigma_{h_{s_1}}, \ldots, \sigma_{h_{s_D}}\right). \tag{B67}$$

Due to (B63), (B57), (B58), and $D = O(\mathsf{poly}(N)) = N^\beta$ for some $\beta > 0$, the total length of α is

$$\sum_{d=1}^{D} \mathrm{size}(\sigma_{h_{s_d}}) = O\left(D \times \left(\frac{N}{\epsilon_{\mathrm{learn}}\delta_{\mathrm{learn}}}\right)^\eta\right) \tag{B68}$$

$$= O\left(\frac{N^{\beta\eta+\beta+\eta}}{\mu^\eta}\right), \tag{B69}$$

as required for $\mathsf{HeurFBPP/rpoly}$ in (A16).

Regarding the success probability of Algorithm S3, conditioned on having α in (B67) with (B62) satisfied for all $d \in \{1, \ldots, D\}$ as in (B72), the remaining probabilistic parts of the algorithm are the input x from $\mathcal{D}_N$ inducing the error between the hypotheses $h_{s_1}(x), \ldots, h_{s_D}(x)$ and the true concepts $c_{s_1}(x), \ldots, c_{s_D}(x)$ in (B62), and the computations of the estimates $\tilde{h}_{s_1}, \ldots, \tilde{h}_{s_D}$ of the hypotheses $h_{s_1}(x), \ldots, h_{s_D}(x)$ by the evaluation algorithm $\mathcal{A}$ in (B64). The other parts, such as the output of $\tilde{f}$ from $\tilde{h}_{s_1}, \ldots, \tilde{h}_{s_D}$ in (B66), are deterministic, as shown in Algorithm S3. In Algorithm S3, we require that the representation α in (B67) of the D hypothesis $h_{s_1}(x), \ldots, h_{s_D}(x)$ sampled from $\mathcal{D}_{N,\mu,\nu,\xi}^{\mathrm{adv}}$ should simultaneously coincide with the true concepts $c_{s_1}(x), \ldots, c_{s_D}(x)$, i.e.,

$$h_{s_1}(x) = c_{s_1}(x), \ldots, h_{s_D}(x) = c_{s_D}(x). \tag{B70}$$

With our choice of $\epsilon_{\mathrm{learn}}$ in (B57) and δ_{learn} in (B58), due to (B62) and the union bound, this requirement is fulfilled for a large fraction of x at least

$$1 - D\epsilon_{\mathrm{learn}} = 1 - \frac{\mu}{2}, \tag{B71}$$

for a large fraction of the randomized advice string at least

$$1 - D\delta_{\mathrm{learn}} = 1 - \xi. \tag{B72}$$

In addition, we require that the estimates $\tilde{h}_{s_1}, \ldots, \tilde{h}_{s_D}$ simultaneously coincides with these hypotheses $h_{s_1}(x), \ldots, h_{s_D}(x)$, i.e.

$$\tilde{h}_{s_1} = h_{s_1}(x), \ldots, \tilde{h}_{s_D} = h_{s_D}(x). \tag{B73}$$

With our choice of ϵ_{eval} in (B59) and δ_{eval} in (B60), due to (B64) and the union bound, this requirement is fulfilled for a large fraction of x at least

$$1 - D\epsilon_{\mathrm{eval}} = 1 - \frac{\mu}{2}, \tag{B74}$$

with a high probability of at least

$$1 - D\delta_{\mathrm{eval}} = 1 - \nu. \tag{B75}$$

Given the requirements in (B70) and (B73), due to (B66), the output of Algorithm S3 is

$$\tilde{f} = \begin{pmatrix} \tilde{h}_{s_1} \\ \tilde{h}_{s_2} \\ \vdots \\ \tilde{h}_{s_D} \end{pmatrix} = \begin{pmatrix} c_{s_1}(x) \\ c_{s_2}(x) \\ \vdots \\ c_{s_D}(x) \end{pmatrix} = f_N(x), \tag{B76}$$

where the last equality follows from (B2) since $\{s_d\}_d$ is the standard basis of the D-dimensioanl vector space $\mathbb{F}_2^D$. Consequently, due to (B71), (B72), (B74), (B75), and the union bound, the requirements in (B70) and (B73) are simultaneously fulfilled for a large fraction of x at least

$$1-\mu, \tag{B77}$$

for a large fraction of α at least

$$1-\xi, \tag{B78}$$

with a high probability of at least

$$1-\nu, \tag{B79}$$

which yields the success probability of our algorithm as required for HeurFBPP/rpoly in (A16).

The runtime of Algorithm S3 is determined by the evaluations of the D hypotheses and the bitwise inner product. For any x and every $d \in 1, \ldots, D$, the runtime of the classical algorithm $\mathcal{A}$ for computing h_{s_d} is given by

$$t_{\mathcal{A}}\left(x, \sigma_{h_{s_d}}, \epsilon_{\text{eval}}, \delta_{\text{eval}}\right) = O\left(\left(\frac{N}{\epsilon_{\text{eval}}\delta_{\text{eval}}}\right)^{\gamma}\right), \tag{B80}$$

as shown in (B65). Thus, the runtime of the D evaluations is

$$\sum_{d=1}^{D} t_{\mathcal{A}}\left(x, \sigma_{h_{s_d}}, \epsilon_{\text{eval}}, \delta_{\text{eval}}\right) = O\left(D\left(\frac{N}{\epsilon_{\text{eval}}\delta_{\text{eval}}}\right)^{\gamma}\right). \tag{B81}$$

In addition, the runtime of the output of the D-dimensional vector $\tilde{f}$ in (B66) is

$$O(D). \tag{B82}$$

Due to (B81) and (B82), for ϵ_{eval} in (B59), δ_{eval} in (B60), and $D = O(N^{\beta})$ with some constant $\beta > 0$, the overall runtime of Algorithm S3 is upper bounded by

$$\begin{aligned} &O\left(D\left(\frac{N}{\epsilon_{\text{eval}}\delta_{\text{eval}}}\right)^{\gamma}\right) + O(D) \\ &= O\left(N^{\beta}\left(\frac{N^{\gamma}N^{\beta\gamma}N^{\beta\gamma}}{\mu^{\gamma}\nu^{\gamma}}\right)\right) \\ &= O\left(\frac{N^{2\beta\gamma+\beta+\gamma}}{\mu^{\gamma}\nu^{\gamma}}\right) \\ &= O\left(\mathsf{poly}\left(N, \frac{1}{\mu}, \frac{1}{\nu}\right)\right), \end{aligned} \tag{B83}$$

as required for HeurFBPP/rpoly in (A16).

Consequently, under the assumption that $\mathcal{C}_N$ is classically efficiently learnable by some classically efficiently evaluatable hypothesis class, one would be able to construct Algorithm S3 achieving (B55) and (B56); that is, the problem $\{(f_N, \mathcal{D}_N)\}$ would be in HeurFBPP/rpoly. This contradicts Definition S8 of the quantum advantageous function f_N. □

Appendix C: Data-preparation protocols for demonstrating advantage of QML from general computational advantages

In this section, we propose protocols for preparing the sample data for our learning tasks studied in Section B so as to demonstrate the advantage of QML using our learning tasks. A nontrivial part of our analysis of this data preparation is that the sample data can be prepared only probabilistically in our general setting; after all, the quantumly advantageous functions used for our concept class in Definition S9 are defined for probabilistic algorithms and heuristic complexity classes in general. Nevertheless, we provide feasible conditions for the correct data preparation. The rest of this section is organized as follows. In Section C 1, we provide a two-party setup for demonstrating the advantage of QML with one party preparing the data and the other learning from the data. In Section C 2, we describe a protocol using quantum computation to prepare the correct sample data with a high success probability for the demonstration. In Section C 3, we describe another protocol using classical computation to prepare the sample data with a high success probability for the demonstration, in special cases where the quantumly advantageous function is constructed based on a class of one-way permutation that is hard to invert by a polynomial-time classical algorithm but can be inverted by a polynomial-time quantum algorithm.

1. Setup for demonstrating advantage of QML from general computational advantages

This section provides a setup for demonstrating the advantage of QML. In other words, we propose a learning setting including data preparation.

In our setup, we consider two parties; a party A is in charge of data preparation, and the other party B receives sample data from A to perform learning. The party A uses either quantum or classical computers to prepare the data while B does not know how A has prepared the data. The data should be prepared in such a way that B can achieve the learning if B uses the quantum learning algorithm in Section B 2 but cannot if B is limited to any polynomial-time classical learning method as in Section B 3. See also the main text for an illustration of the setup.

The overall protocol for A and B demonstrating the advantage of QML in this setup is as follows. First, two parties A and B are given the problem size N, the concept class $\mathcal{C}_N = \{c_s\}_{s\in\mathbb{F}_2^D}$ specified by the quantumly advantageous function $f_N : \mathbb{F}_2^N \to \mathbb{F}_2^D$ under a target distribution $\mathcal{D}_N$ in Definition S9, the error parameter ϵ and the confidence parameter δ, where $D = O(\mathsf{poly}(N))$. Note that the description of $\mathcal{D}_N$ may be unknown to A and B throughout the protocol, but A has access to (an oracle to load) an $O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ amount of the inputs x sampled from $\mathcal{D}_N$ within a unit time per loading each input. Given these parameters, based on (B4), B determines the number of samples for learning as

$$M = \left\lceil \frac{D}{\epsilon} - 1 \right\rceil, \tag{C1}$$

where $\lceil \cdots \rceil$ is the ceiling function, and send M to A. Then, A decides the parameter s of the target concept c_s arbitrarily and keeps s as A's secret. For M and s, the task of A is to correctly prepare the M sample data

$$\{(x_m, c_s(x_m))\}_{m=1}^{M}, \tag{C2}$$

using a quantum or classical computer. After preparing the M data in (C2), A sends the data to B. Using the given sample data, the task of B is to find a parameter $\tilde{s} \in \mathbb{F}_2^D$ and make a prediction for new input x drawn from $\mathcal{D}_N$ by the hypothesis $h_{\tilde{s}}(x) = f(x) \cdot \tilde{s}$ so that the error should satisfy

$$\mathop{\mathbf{Pr}}_{x \sim \mathcal{D}_N} [h_{\tilde{s}}(x) \neq c_s(x)] \leq \epsilon \tag{C3}$$

with a high probability of at least $1 - \delta$.

Using Algorithm S1 and Algorithm S2, B can achieve this task with quantum computation within a polynomial time

$$O(\mathsf{poly}(N, 1/\epsilon, 1/\delta), \tag{C4}$$

and our analysis in Section B 3 shows that B cannot achieve this task with any polynomial-time classical method. In the following sections, we will construct A's algorithms for preparing the data in (C2) with a high probability of at least $1 - \delta$ within a polynomial time

$$O(\mathsf{poly}(N, 1/\epsilon, 1/\delta)). \tag{C5}$$

With a sufficient amount of correct data, one can conduct the learning and test the learned hypothesis. Thus, with A's data-preparation algorithm and B's learning and evaluation algorithms, our protocol in the above setup can demonstrate the advantage of QML.

2. Quantum algorithm for preparing data

In this section, we show how to prepare the sample data in (C2) for the concept class in Definition S9 based on a quantumly advantageous function f_N in Definition S8, using a quantum algorithm.

Algorithm S4 Quantum algorithm for data preparation

```
Input: The problem size $N$, the concept class $\mathcal{C}_N$ in Definition S9 with a quantumly advantageous function $f_N$, $\epsilon > 0$, $\delta > 0$, the number $M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ of samples to be prepared (e.g., given by (C1)), the true parameter $s$ of the target concept, inputs sampled from a target distribution $\mathcal{D}_N$ to be loaded from an oracle.
Output: An estimate $\{(x_m, \tilde{c}_m)\}_{m=1}^{M}$ of the $M$ sample data $\{(x_m, c_s(x_m))\}_{m=1}^{M}$ satisfying (C6) with a high probability at least $1 - \delta$.
for $m = 1, \ldots, M$ do
    Load an input $x_m$ sampled from the target distribution $\mathcal{D}_N$ (with access to the oracle).
    Perform the quantum algorithm $\mathcal{A}$ in (B7) for computing $f_N$ for the input $x_m$ with the parameters $\mu$ and $\nu$ in (C7) and (C8), respectively, to obtain $\mathcal{A}(x_m)$.
    Compute $\tilde{c}_m = \mathcal{A}(x_m) \cdot s$ in (C9).
end for
return $\{(x_m, \tilde{c}_m)\}_{m=1}^{M}$.
```

The data-preparation algorithm is shown in Algorithm S4. As described in Section C 1, given the problem size N, the concept class $\mathcal{C}_N$ in Definition S9 with a quantumly advantageous function f_N, the error parameter ϵ, the significance parameter δ, the number $M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ of samples to be prepared (e.g., given by (C1), yet we here describe the algorithm for general M), and the true parameter s of the target concept, we assume that Algorithm S4 has access to (an oracle to load) an $O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ amount of the inputs x sampled from $\mathcal{D}_N$ within a unit time per loading each input. Then, the goal of Algorithm S4 is to output an estimate $\{(x_m, \tilde{c}_m)\}_{m=1}^{M}$ of the data $\{(x_m, c_s(x_m))\}_{m=1}^{M}$ in (C2) with x_m drawn from the target distribution $\mathcal{D}_N$, so that it should hold with a high probability at least $1 - \delta$ that, for all m,

$$\tilde{c}_m = c_s(x_m). \tag{C6}$$

Note that the error parameter ϵ is not explicitly relevant to Algorithm S4 except for the possibility of M depending on ϵ. To this goal, we set the internal parameters in Algorithm S4 as

$$\mu = \frac{\delta}{2M}, \tag{C7}$$

$$\nu = \frac{\delta}{2M}. \tag{C8}$$

In Algorithm S4, for each $m = 1, \ldots, M$, we start with sampling x_m from the target distribution $\mathcal{D}_N$. Then, we use the quantum algorithm $\mathcal{A}$ in (B7) to compute the quantumly advantageous function f_N with μ in (C7) and ν in (C8), to obtain $\mathcal{A}(x_m)$ within a polynomial runtime in (B8), where μ and ν in (B7) may be omitted for simplicity of the presentation if obvious from the context. Finally, Algorithm S4 computes an estimate $\tilde{c}_m$ of $c_s(x_m)$ by

$$\tilde{c}_m \coloneqq \mathcal{A}(x_m) \cdot s, \tag{C9}$$

in accordance with the definition of c_s in (B2). After performing these computations for all m, the algorithm outputs

$$\{(x_m, \tilde{c}_m)\}_{m=1}^{M} \tag{C10}$$

as an estimate of the data $\{(x_m, c_s(x_m))\}_{m=1}^{M}$ in (C2).

The following theorem shows that this algorithm prepares the data in (C2) correctly with a high probability $1-\delta$ within a polynomial time.

Theorem S14 (The polynomial-time data preparation with a quantum algorithm)**.** *Given any N, ϵ, and δ, for any $M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$, Algorithm S4 outputs the M sample data $\{(x_m, c_s(x_m))\}_{m=1}^{M}$ in (C2) with a high probability at least $1-\delta$ within a polynomial time*

$$O(\mathsf{poly}(N, 1/\epsilon, 1/\delta)). \tag{C11}$$

Proof. We will first discuss the success probability of Algorithm S4 and then provide an upper bound of the runtime.

The probabilistic parts of Algorithm S4 are the computations of f_N by the quantum algorithm $\mathcal{A}$. We require that for all $m \in \{1, \ldots, M\}$, the output $\mathcal{A}(x_m)$ of this quantum algorithm should coincide with $f_N(x_m)$ simultaneously, i.e.

$$\mathcal{A}(x_1) = f_N(x_1), \ldots, \mathcal{A}(x_M) = f_N(x_M). \tag{C12}$$

Given this requirement, the output of Algorithm S4 coincides with the data in (C2); that is, $\tilde{c}_m$ in (C9) satisfies

$$\tilde{c}_m = \mathcal{A}(x_m) \cdot s = f_N(x_m) \cdot s = c_s(x_m), \tag{C13}$$

by definition of c_s in (B2). With our choice of μ in (C7) and ν in (C8), due to the union bound, this requirement is fulfilled with a high probability at least

$$1 - M(\mu + \nu) = 1 - \delta, \tag{C14}$$

which yields the desired success probability.

The runtime of Algorithm S4 is determined by the computations of f_N and the bitwise inner product. Due to (B8) with the choice of μ in (C7) and ν in (C8), for $D = O(N^{\beta})$ with $\beta > 0$ and $M = O((\frac{N}{\epsilon\delta})^{\lambda})$ with $\lambda > 0$, we have the overall runtime

$$O\left(M\left(\left(\frac{N}{\mu\nu}\right)^{\alpha} + D\right)\right) \tag{C15}$$

$$= O\left(\frac{N^{\alpha+2\alpha\lambda+\lambda}}{\epsilon^{(2\alpha+1)\lambda}\delta^{2\alpha\lambda+2\alpha+\lambda}} + \frac{N^{\beta+\lambda}}{\epsilon^{\lambda}\delta^{\lambda}}\right) \tag{C16}$$

$$= O\left(\mathsf{poly}\left(N, 1/\epsilon, 1/\delta\right)\right), \tag{C17}$$

which yields the conclusion. □

3. Classical algorithm for preparing data based on classically one-way permutation

In this section, we show how to prepare the sample data in (C2) using a classical algorithm, for a concept class derived by replacing the quantumly advantageous function used in Definition S9 with an inverse of a classically one-way permutation introduced in the following.

We define the classically one-way permutation to derive the concept class for preparing the data with the classical algorithm.

Definition S15 (Classically one-way permutation)**.** *For N, let $f_N^{\mathrm{OWP}} : \{0,1\}^N \to \{0,1\}^N$ be a permutation (i.e., an N-bit one-to-one function), where we may write $\mathbb{F}_2^N = \{0,1\}^N$. We write*

$$x = f_N^{\mathrm{OWP}}(y), \tag{C18}$$

where sampling x from a probability distribution $\mathcal{D}_N$ with computing $y = f_N^{\mathrm{OWP}^{-1}}(x)$ is equivalent to sampling y from a probability distribution $\mathcal{D}_N^Y$ with computing (C18) under the condition that

$$\mathcal{D}_N = f_N^{\mathrm{OWP}}(\mathcal{D}_N^Y). \tag{C19}$$

We say that a permutation f_N^{OWP} is a classically one-way permutation f_N^{OWP} under $\mathcal{D}_N$ if the relation $R := \{R_N\}_{N\in\mathbb{N}}$ with $R_N := \{(y, f_N^{\mathrm{OWP}}(y))\}_{y\in\{0,1\}^N}$ is in FP*, and the distributional function problem $\{(f_N^{\mathrm{OWP}^{-1}}, \mathcal{D}_N)\}_{N\in\mathbb{N}}$ is in* HeurFBQP *but not in* HeurFBPP/rpoly*.*

We then introduce the following concept class by replacing the quantumly advantageous function in the concept class of Definition S9 with the classically one-way permutation in Definition S15.

Definition S16 (Concept class based on classically one-way permutation)**.** *For any N, any probability distribution $\mathcal{D}_N$ over $\mathbb{F}_2^N$, and any classically one-way permutation $f_N^{\mathrm{OWP}} : \mathbb{F}_2^N \to \{0,1\}^N$ under $\mathcal{D}_N$ in Definition S15, we define a concept class $\mathcal{C}_N^{\mathrm{OWP}}$ over the input space $\mathcal{X}_N$ as $\mathcal{C}_N^{\mathrm{OWP}} := \{c_s\}_{s\in\mathbb{F}_2^N}$, where $\mathcal{X}_N$ is the support of $\mathcal{D}_N$ in (C19), and c_s is a concept given by*

$$c_s(x) := f_N^{\mathrm{OWP}^{-1}}(x) \cdot s \in \mathbb{F}_2 = \{0,1\}, \tag{C20}$$

with $f_N^{\mathrm{OWP}^{-1}}(x) \cdot s$ denoting a bitwise inner product in the vector space $\mathbb{F}_2^N$ over the finite field.

By definition, the inverse $f_N^{\mathrm{OWP}^{-1}}$ of the classically one-way permutation f_N^{OWP} in Definition S16 is a special case of the quantumly advantageous functions in Definition S9. Therefore, the quantum efficient learnability, the quantum efficient evaluatability, and the classical hardness for this concept class follow from the same argument as Section B. Note that particular variants of classically one-way permutations f_N^{OWP} that can be inverted by Shor's algorithms are used in the previous work on the advantage of QML [16–19]. Since f_N^{OWP} is a permutation, if the target distribution $\mathcal{D}_N$ is uniform, then Algorithm S5 simply samples from the uniform distribution, which is assumed in Refs. [16–19]. By contrast, our analysis does not assume the uniform distribution, generalizing the settings in Refs. [16–19]. And even more importantly, the concept class in Definition S16 does not depend on specific cryptographic techniques for the classically one-way permutation f_N^{OWP} such as those invertible by Shor's algorithms, in the same way as the concept class in Definition S9 without depending on the specific

Algorithm S5 Classical algorithm for data preparation with classically one-way function

```
Input: The problem size $N$, the concept class $\mathcal{C}_N$ in Definition S16 with a classically one-way permutation $f_N^{\mathrm{OWP}}$,
    $\epsilon > 0$, $\delta > 0$, the number $M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ of samples to be prepared (e.g., given by (C1)), the true
    parameter $s$ of the target concept, and parameters $y$ sampled from a probability distribution $\mathcal{D}_N^Y$ in (C19) to be
    loaded from an oracle.
Output: The $M$ sample data $\{(x_m, c_s(x_m))\}_{m=1}^M$ in (C21).
for $m = 1, \ldots, M$ do
    Load a parameter $y_m$ sampled from the distribution $\mathcal{D}_N^Y$ (with access to the oracle).
    Perform the deterministic classical algorithm in (C22) to compute $f_N^{\mathrm{OWP}}$ for $y_m$, to obtain $x_m = f_N^{\mathrm{OWP}}(y_m)$.
    Compute $c_s(x_m) = y_m \cdot s$ in (C24).
end for
return $\{(x_m, c_s(x_m))\}_{m=1}^M$.
```

mathematical structure of quantumly advantageous functions.

In the following, based on the setup described in Section C 1, we modify the protocol in such a way that the concept class is replaced with the above concept class based on a classically one-way permutation, and the party A has access to (an oracle to load) an $O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ amount of the parameters y in (C18) sampled from $\mathcal{D}_N^Y$ in (C19), in place of loading x, within a unit time per loading each y.

The classical data-preparation algorithm is shown in Algorithm S5. Given the problem size N, the concept class $\mathcal{C}_N$ in Definition S16 with a classically one-way permutation f_N^{OWP} under the probability distribution $\mathcal{D}_N$ in Definition S15, the error parameter ϵ, the significance parameter δ, the number $M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$ of samples to be prepared (e.g., given by (C1), yet we here describe the algorithm for general M), the true parameter s of the target concept, and the parameters y to be loaded as assumed above, the goal of Algorithm S5 is to output M pairs of data

$$\{(x_m, c_s(x_m))\}_{m=1}^M, \tag{C21}$$

with each x_m drawn from the distribution $\mathcal{D}_N$, where (C21) is a variant of (C2) up to the change of the concept class to (C20). Note that the error parameter ϵ and the significance parameter δ are not explicitly relevant to Algorithm S5 except for the possibility of M depending on ϵ and δ. In Algorithm S5, for each $m = 1, \ldots, M$, we start with loading y_m sampled from the distribution $\mathcal{D}_N^Y$. Then, the algorithm computes the classically one-way permutation f_N^{OWP} for y_m. By definition of the classically one-way permutation $\{f_N^{\mathrm{OWP}}\}_{N \in \mathbb{N}} \in \mathsf{FP}$, we have a polynomial-time deterministic classical algorithm $\mathcal{A}$ to compute

$$x_m = \mathcal{A}(y_m) = f_N^{\mathrm{OWP}}(y_m) \tag{C22}$$

within runtime

$$t_{\mathcal{A}}(y_m) = O\left(N^{\zeta}\right), \tag{C23}$$

where $\zeta > 0$ is an upper bound of the degree of the polynomial runtime. Finally, Algorithm S5 computes $c_s(x_m)$ by

$$c_s(x_m) = y_m \cdot s, \tag{C24}$$

following the definition of c_s in (C20). After performing these computations for all m, Algorithm S5 outputs the data in (C21), i.e.,

$$\{(x_m, c_s(x_m))\}_{m=1}^M. \tag{C25}$$

The following theorem shows that Algorithm S5 prepares the data in (C21) correctly within a polynomial time.

Theorem S17 (The polynomial-time data preparation with a classical algorithm based on classically one-way functions)**.** *Given any N, ϵ, and δ, for any $M = O(\mathsf{poly}(N, 1/\epsilon, 1/\delta))$, Algorithm S5 outputs the M sample data $\{(x_m, c_s(x_m))\}_{m=1}^M$ in (C21) within a polynomial time*

$$O(\mathsf{poly}(N, 1/\epsilon, 1/\delta)). \tag{C26}$$

Proof. Algorithm S5 is a deterministic algorithm and has no error; thus, it suffices to discuss the runtime. The runtime of Algorithm S5 is determined by computing the classically one-way permutation f_N^{OWP} in Definition S15 for M inputs $y_1, \ldots y_M$ and bitwise inner product. Due to (C23), for $M = O((\frac{N}{\epsilon\delta})^{\lambda})$ with $\lambda > 0$, we have the overall runtime

$$O\left(M\left(N^{\zeta} + N\right)\right) \tag{C27}$$

$$= O\left(\frac{N^{\zeta+\lambda}}{\epsilon^{\lambda}\delta^{\lambda}}\right) \tag{C28}$$

$$= O\left(\mathsf{poly}\left(\frac{N}{\epsilon\delta}\right)\right), \tag{C29}$$

which yields the conclusion. □

(Dated: May 14, 2024)

This is an extended, non-technical abstract for AQIS.2024. It is for a presentation aimed to be an birds-eye overview on a generalized recipe for reverse processes via Bayesian inference. It takes most from PRX Quantum.5.010332 [1]. Some figures are also appended to the end of the document.

I. QUESTIONS TO SET THE STAGE

Reversibility is a central concept in physics and information science, from entropy to state recovery, noise and dissipation [2–8]. That said, there exists a plurality of approaches for characterizing it, some of which only apply in strictly defined, classical contexts. Given reversibility's fundamentality, a question arises: can we formalize the definition of reverse processes for any processes, classical or quantum?

This question is enhanced by a further puzzle: introducing an ancillary system, every irreversible process can always be seen as a marginal of a larger reversible global process [9, 10]. This is sometimes called the *dilation* of a channel (as in Stinespring dilations).

$$\mathcal{E}[\bullet] = \mathrm{Tr}_B\left[U(\bullet \otimes \beta)U^\dagger\right] \tag{1}$$

How, then, does reversal on marginal level compare to that in the global, dilated picture? Does "reversal and marginalization commute"? This has implications in physical implementation of recovery protocols, as it relates to the question of when can I reverse a process $\mathcal{R}[\mathcal{E}]$ with the same global dynamics (i.e. some unitary U) I used for the forward process $\mathcal{E}$. That is,

$$\mathcal{R}[\mathcal{E}][\bullet] \overset{!}{=} \mathrm{Tr}_B[U^\dagger(\bullet \otimes \beta')U]. \tag{2}$$

We may call this condition **tabletop time-reversibility.** Most notably, this is satisfied by Gibbs-preserving maps in **thermal operations** [2]. The question is where else does this hold? Put another way, "how special are thermal operations, with regard to reversibility?"

II. RESPONSES & RESULTS

In this work, we answer these three questions. Firstly, we adopt the perspective that the physically viable, universally applicable and axiomatically valid characterization of classical and quantum reversibility lies in **Bayes' rule** [11, 12]]

$$\hat{\varphi}_\gamma(a|a') = \varphi(a'|a)\frac{\gamma(a)}{\varphi[\gamma](a')}, \tag{3}$$

and the **Petz Recovery map** [13–15]

$$\hat{\mathcal{E}}_\alpha[\bullet] = \sqrt{\alpha}\,\mathcal{E}^\dagger\left[\frac{1}{\sqrt{\mathcal{E}[\alpha]}}\bullet\frac{1}{\sqrt{\mathcal{E}[\alpha]}}\right]\sqrt{\alpha}. \tag{4}$$

respectively, which has been fruitful in comparing reversal across regimes and the derivation of fluctuation relations [16, 17]. Noting that the Petz Map has been seen as the prime candidate for the quantum generalization of Bayes' rule [18–23].

Doing so, we show by using these Bayesian tools to define reverse processes, this approach

1. **Recovers the typical examples of reverse processes** (eg. bijections and reversible processes go to inversions, bistochastic and unital processes go to their transpose and adjoint respectively and so on). Furthermore, it gives insights to why these forward maps give reverse processes they do.

2. Shows that reversal and marginalization (in both classical and quantum regimes) *do commute* as long as one takes into propagated correlations formed between the ancillary system and the reference of the reversal. **In other words, the Bayesian and open system perspectives on irreversibility coincide.** This is proven through the decomposition of these forward maps

$$\varphi(a'|a) = \sum_{bb'}\Phi(a',b'|a,b)\beta(b), \qquad \varphi = \Sigma_B\circ\Phi\circ\hat{\Sigma}_{B,\square\otimes\beta} \tag{5}$$

$$\mathcal{E}[\bullet] = \mathrm{Tr}_B\left[U(\bullet\otimes\beta)U^\dagger\right] = \mathrm{Tr}_B\circ\mathcal{U}\circ\hat{\mathrm{Tr}}_{B,\square\otimes\beta}[\bullet], \tag{6}$$

in terms of *assignment maps*:

$$\hat{\Sigma}_{B,\Lambda}[\bullet_A] = \bullet_A\cdot\left(\frac{\Lambda}{\Sigma_B[\Lambda]}\right)_{B|A}, \tag{7}$$

$$\hat{\mathrm{Tr}}_{B,\Omega}[\bullet_A] = \sqrt{\Omega}\left[\left(\frac{1}{\sqrt{\mathrm{Tr}_B[\Omega]}}\bullet_A\frac{1}{\sqrt{\mathrm{Tr}_B[\Omega]}}\right)\otimes\mathbb{1}_B\right]\sqrt{\Omega} \tag{8}$$

The proofs, theorems and technical details can be found in the main text [1].

3. Finally, we show that **tabletop time-reversibility is a remarkably special condition**, identifying families of this condition for qubit channels and beyond. We also find physically insightful theorems [1] pertaining to a generalization of thermal operations, its relationship with correlations and its implications on energetics in the quantum regime.

III. IMPACT

Finally, we make some qualitative remarks on the impacts of this work.

1. It provides a practical benefit by identifying scenarios where reversal (and thus, information recovery) can be done with the same unitary that defines the dilation of the transformation. This is significant as it is well known that, in general, this is an extremely complex process to implement.

2. It gives a conceptual basis for the definition of reverse processes for quantum fluctuation theorems, giving a quantum informational perspective [8, 16, 17, 24].

3. It helps quantify how irreversibility can be seen as a function of the reverse process' dependence on reference prior. In other words, it gives a quantitative meaning to the connection of irreversibility (and entropy) to prior information. Something illustrated by famous physics puzzles like Landauer Erasure and even Laplace's and Maxwell's Demons.

FIG. 2: An illustration of tabletop time-reversibility. Any channel $\mathcal{E}$ can be dilated to on a global $\mathcal{U}$ and a bath. Bayesian retrodiction associates a reverse channel $\hat{\mathcal{E}}_\alpha$ to $\mathcal{E}$, which can itself be dilated into a larger unitary process $\mathcal{V}$. However, $\mathcal{V} \neq \mathcal{U}^\dagger$ is in general—informally speaking, such that "a different experimental setup" would be required to implement the forward and reverse channels. Tabletop reversible channels are when $\mathcal{V} = \mathcal{U}^\dagger$: informally, when we can "run the experimental setup backwards" to implement the reverse channel.

Tsirelson's Precession Protocol: A Theory-independent Bound Saturated by Quantum Mechanics, and Other Generalisations

Lin Htoo Zaw[1] * Mirjam Weilenmann[2] Valerio Scarani[2] [3]

[3] *Department of Physics, National University of Singapore, 2 Science Drive 3, Singapore 117542*

Abstract. Tsirelson's precession protocol certifies the nonclassicality of a system by asking how often a uniformly-precessing variable is positive at one of three equally-spaced points in time [1]. It does not require simultaneous or sequential measurements like other nonclassicality tests, and has also been shown to be useful for detecting Wigner negativity and entanglement. Here, we present two recent results about the protocol. The first result is a theory-independent bound for systems with finitely many outcomes [2]. We show that, unlike Bell and noncontextuality inequalities, quantum theory saturates the general bound. As such, the precession protocol falsifies any general theory that does not also saturate this bound. The second result involves previously-proposed generalisations of the protocol. We characterise all such protocols with three probing times for the quantum harmonic oscillator. An open question about the maximum violation of these generalised protocols is partially answered, the exact relationship between violating states of different protocols is also found. This characterises the wider class of states whose Wigner negativity and entanglement can be detected by the precession protocol.

Keywords: harmonic oscillator, spin angular momentum, theory-independent bound, general probabilistic theories

Background and Motivation. The time evolution of uniformly-precessing variables $(A_x(t), A_y(t))$—like the position and momentum of the harmonic oscillator, or components of a vector rotating with a fixed angular momentum—is the same in both classical and quantum theory. Both the classical observables and the corresponding quantum operators in the Heisenberg representation satisfy

$$\begin{aligned} A_x(t) &= \cos(\tfrac{2\pi t}{T})A_x(0) + \sin(\tfrac{2\pi t}{T})A_y(0) \\ A_y(t) &= \cos(\tfrac{2\pi t}{T})A_y(0) - \sin(\tfrac{2\pi t}{T})A_x(0) \end{aligned} \tag{1}$$

for the period T. As the dynamics are the same in both classical and quantum theory, one does not expect to find quantumness in the dynamics of the harmonic oscillator.

Tsirelson showed that, on the contrary, the nonclassicality of a system can be certified by simply asking how often a uniformly-precessing variable is positive [1]. The precession protocol involves many rounds, where $A_x(t)$ is measured at a randomly-chosen time $t_k = kT/3$ for $k \in \{0, 1, 2\}$ in each round, and after many rounds, the score

$$P_3 := \frac{1}{3}\sum_{k=0}^{2}\left\{\Pr\left[A_x(\tfrac{kT}{3}) > 0\right] + \frac{1}{2}\Pr\left[A_x(\tfrac{kT}{3}) = 0\right]\right\} \tag{2}$$

is calculated. The nonclassicality of the system is certified if the observed value P_3 violates the classical bound $P_3 > 2/3 =: \mathbf{P}_3^c$ [1].

Violations of the classical bound have been shown for specific examples of quantum systems. The maximum quantum violation is $P_3 \approx 0.709$ for the quantum harmonic oscillator, and conjectured to be $P_3 = 0.75$ for spin systems [4]. An open question here is the maximum violation by quantum theory: is $P_3 = 0.75$ the best that quantum theory can do, or are there uniformly-precessing quantum variables that do better?

Since the first few works on Tsirelson's precession protocol, some generalisations have also been proposed. They include probing the system at $k\tilde{T}/3$ for some $\tilde{T} \neq T$ [5], which captures the situation where the period of the prcession is not precisely known, and studying the classical bound as a facet in a constrained conditional probability polytope [6], which gives rise to the so-called Type I inequality (nonclassical when $P_{\mathrm{I}} > 2/3$) and Type II inequality (nonclassical when $P_{\mathrm{II}} > 1/3$), where

$$\begin{aligned} P_{\mathrm{I}} &:= \frac{1}{3}\sum_{k=0}^{2}\left\{\Pr\left[A_x(\tfrac{2kT}{5}) > 0\right] + \frac{1}{2}\Pr\left[A_x(\tfrac{2kT}{5}) = 0\right]\right\} \\ P_{\mathrm{II}} &:= \frac{1}{3}\sum_{k=0}^{2}(-1)^k\left\{\Pr\left[A_x(\tfrac{kT}{5}) > 0\right] + \frac{1}{2}\Pr\left[A_x(\tfrac{kT}{5}) = 0\right]\right\}. \end{aligned} \tag{3}$$

An open question here is the maximum possible violation of these generalised protocols: unlike the original precession protocol, estimates of the maximum score have yet to be found for specific quantum systems, let alone quantum theory in general.

Practical Applications. The precession protocol bounds the Wigner negativity volume [4], which is a measure of the amount of non-Gaussian resource required for quantum information processing [7, 8]. As the protocol only requires quadrature measurements, it is straightforward to perform in optical systems with homodyne measurements and optomechanics with position measurements at different times. When applied to collective modes of coupled oscillators, it has also been shown to witness non-Gaussian entanglement between coupled os-

*htoo@zaw.li

cillators [9]. Finally, for spin ensembles, it solves an open problem about the detection of the genuine multipartite entanglement of GHZ states using only measurements of the total angular momentum of the system [10].

Foundational Applications. Unlike other nonclassicality tests like noncontextual or Leggett–Garg inequalities [11, 12], the precession protocol does not require simultaneous or sequential measurements. Furthermore, the precession protocol is not susceptible to the so-called "*clumsiness loophole*" [13]. As such, it offers a more straightforward experimental test of nonclassicality in situations where the measured variable is certain to be uniformly-precessing.

Contributions. There are several related open questions for the precession protocol: *What is the maximum possible violation of the original protocol (or its extensions) for a specific quantum system (or quantum theory in general)*? Our contributions answer one open question, and partially answer another.

Our first contribution is to derive a theory-independent bound for the original precession protocol for systems with a finitely many outcomes [2]. The derivation relies only on the linearity of the expectation value with respect to the observables, which is an assumption satisfied by all general probabilistic theories [14]. The derived general bound depends only on the spectrum of the measured observable, where spectrum is defined in a purely theory-independent manner as the set of all possible outcomes.

We then prove by construction that the general bound is saturated by quantum mechanics, which answers the question about the maximum possible violation of the original precession protocol by quantum theory. This means that no general theory can outperform quantum theory in the precession protocol. As the cat state of a spin-3/2 particle saturates this bound, and the cat state is commonly prepared for its metrological properties [15], this provides a simple test that can experimentally falsify general theories that do not also saturate this bound.

Our second contribution is to characterise the family of precession protocols with three probing times, which include the type I and type II inequalities [3]. For the quantum harmonic oscillator, we not only show how the maximum quantum violation for every such protocol is related to the violation of the original precession protocol, but also derive the exact unitary relationship between violating states of different protocols.

In particular, denoting $\mathbf{P}_3^\infty$, $\mathbf{P}_\mathrm{I}^\infty$, and $\mathbf{P}_\mathrm{II}^\infty$ as the maximum quantum score for the quantum harmonic oscillator with the original, type I, and type II inequalities respectively, we show that $\mathbf{P}_\mathrm{I}^\infty = \mathbf{P}_3^\infty$ and $\mathbf{P}_\mathrm{II}^\infty = \mathbf{P}_3^\infty - 1/3$. This partially answers the open question about the maximum quantum violation for generalisations of the precession protocol for the quantum harmonic oscillator.

In terms of applications, our results expand the class of states that can be detected by the family of precession protocols. From the derived relationship between the different protocols, we can show that if a state is detected by one protocol, a squeezed version of that state will be detected by another protocol. This is particularly useful when information is encoded in superpositions of coherent states, as is common in the field of continuous variable quantum information processing, where squeezing has been recently introduced as a technique to protect the encoded state against photon loss [16, 17]. As previous work has shown that the entanglement of the three-headed cat state can be detected by the original precession protocol [9], our results therefore imply that the same state, protected via squeezing, can be detected by other members of the family of precession protocols with three probing times.

Abstract. Although the similarity between non-stabilizer states—also known as magic states—in discrete-variable systems and non-Gaussian states in continuous-variable systems has widely been recognized, the precise connections between these two notions have still been unclear. We establish a fundamental link between these two quantum resources via the Gottesman-Kitaev-Preskill (GKP) encoding. We show that the negativity of the continuous-variable Wigner function for an encoded GKP state coincides with a magic measure we introduce, which matches the negativity of the discrete Wigner function for odd dimensions. We also provide a continuous-variable representation of the stabilizer Rényi entropy—a recent proposal for a magic measure for multi-qubit states. With this in hand, we give a classical simulation algorithm with runtime scaling with the resource contents, quantified by our magic measures. We also employ our results to prove that implementing a multi-qubit logical non-Clifford operation in the GKP code subspace requires a non-Gaussian operation even at the limit of perfect encoding, despite the fact that the ideal GKP states already come with much non-Gaussianity.

Keywords: resource theories, magic states, non-Gaussianity, GKP encoding

1 Background and motivation

Quantum computing is predicted to give a computational speed-up compared to classical computation. It is still an open problem to find and pinpoint the origins of the speed-up or what manifestation would allow for such phenomena. This fact becomes even more important, as in reality every quantum information processing task will be restricted in a certain way given that they will be implemented in a physical system.

One of the promising platforms for quantum information processing is to utilize a quantum optical system, which is equipped with an infinite-dimensional Hilbert space accommodating continuous-variable systems. There, the non-Gaussian states have been identified as necessary resources for quantum computational advantages [1], as computation solely run by Gaussian resources can be efficiently simulated classically. The most prominent measure that quantifies non-Gaussian features [2–7] is the negativity of Wigner function [4, 8, 9] that also captures the hardness of classical simulability. Other natural platforms, such as superconducting and ion-trap-based architectures, assume discrete-variable systems, in which quantum information is encoded in finite-dimensional Hilbert spaces. Among many relevant quantum resources needed for efficient quantum information processing, one peculiar quantity necessary for quantum speedup is the non-stabilizerness, also known as quantum magic, as quantum circuits only consisting of stabilizer states and Clifford operations can be efficiently simulatable by classical computers. Interestingly, the magicness of discrete-variable states can also be studied by looking at a discrete version of the Wigner function [10, 11]. Indeed, the negativity of the discrete Wigner function [12] has been shown to be a valid magic measure when the underlying Hilbert space has odd dimensions.

Although it has been pointed out that there is a conceptual similarity between non-Gaussianity and magic in terms of necessary resources for universal quantum computation, the direct quantitative connection between these two resources has still been elusive. In particular, constructing a map between non-Gaussianity and magic will not only solidify the relation between two main operational frameworks that are important for quantum computing but also provide a novel approach where one resource could be analyzed by employing a tool developed for analyzing the other.

2 Bridging magic and non-Gaussianity

In this work, we accomplish this by finding a fundamental relation between the discrete and continuous-variable distributions via the Gottesman-Kitaev-Preskill (GKP) encoding [13], which is one of the standard error-correcting codes for continuous-variable systems. Our results therefore recover and significantly extend a recent finding of the relation between multi-qubit systems and continuous-variable systems [14]. We accomplish this by introducing a new operator basis for qudit systems. For $l, m \in \mathbb{Z}_{2d}$, let $O_{l,m}$ be an operator defined by

$$O_{l,m} = \omega_d^{-ml/2} M_l Z_d^m \tag{1}$$

*oliver.hahn@chalmers.se
†ryujitakagi.pat@gmail.com

where $M_l = \sum_{\substack{u,v\in\mathbb{Z}_d \\ u+v \mod d=l}} |u\rangle\langle v|$ and Z_d the d-dimensional Pauli Z operator. This can easily be extended to n-qudit systems, where we define $O_{\boldsymbol{l},\boldsymbol{m}} = \prod O_{l_i,m_i}$ for $\boldsymbol{l},\boldsymbol{m} \in \mathbb{Z}_{2d}^n$. The newly defined operators are hermitian and unitary operators that are orthogonal in the Hilbert-Schmidt inner product $\mathrm{Tr}\left(O_{l,m}O_{l',m'}\right) = \delta_{mm'}\delta_{ll'}d$. Let us now define the distribution

$$x_\rho(\boldsymbol{l},\boldsymbol{m}) := d^{-n}\,\mathrm{Tr}(O_{\boldsymbol{l},\boldsymbol{m}}\rho) \tag{2}$$

which corresponds to the coefficients for $O_{\boldsymbol{l},\boldsymbol{m}}$ when expanding the state ρ with this operator basis.

This distribution is inherently connected to GKP states, which form an error correction code for bosonic systems. The peculiar property of the Wigner function of GKP states is that it comes with an atomic form, where the Dirac distribution has disjoint support

$$W_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}(\boldsymbol{r}) = \frac{\sqrt{d}^n}{\sqrt{8\pi}^n}\sum_{\boldsymbol{l},\boldsymbol{m}} c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m}) \times \delta\left(\boldsymbol{r_p} - \boldsymbol{m}\sqrt{\frac{\pi}{2d}}\right)\delta\left(\boldsymbol{r_q} - \boldsymbol{l}\sqrt{\frac{\pi}{2d}}\right) \tag{3}$$

where ρ_{GKP} refers to a GKP state that encodes a qudit state ρ, and $c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m})$ is a coefficient serving as a weight for each peak in the Wigner function of a GKP state ρ_{GKP}. We show that this coefficient exactly coincides with the distribution introduced above, i.e.,

$$c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m}) = x_\rho(\boldsymbol{l},\boldsymbol{m}). \tag{4}$$

Using this connection we can now state the first theorem. We will use the periodicity of the GKP Wigner function and only consider one unit cell of the lattice and are thus restricting to a hypercube $r_{q_i} \in [0,\sqrt{2d\pi}), r_{p_i} \in [0,\sqrt{2d\pi})$ in the phase space. This motivates us to consider an l_p-norm of a function f defined for a unit cell $\|f\|_{p,\mathrm{cell}} := \left(\int_{\mathrm{cell}} d\boldsymbol{r}|f(\boldsymbol{r})|^p\right)^{1/p}$ where $\int_{\mathrm{cell}}$ refers to the integral over the unit hypercube. We then obtain the following result that directly connects discrete- and continuous-variable quantum resources.

Theorem 1. *For an n-qudit state ρ on a d^n-dimensional space and for an arbitrary $p > 0$, it holds that*

$$d^{n(1-1/p)}\|x_\rho\|_p = \frac{\|W_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}}{\|W_{\mathrm{STAB}_n,\mathrm{GKP}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}}, \tag{5}$$

where $\|W_{\mathrm{STAB}_n,\mathrm{GKP}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}$ is the quantity that takes the same value for every n-qudit pure stabilizer state ϕ. When d is odd, we further have

$$d^{n(1-1/p)}\|W_\rho^{\mathrm{DV}}\|_p = \frac{\|W_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}}{\|W_{\mathrm{STAB}_n,\mathrm{GKP}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}}. \tag{6}$$

with W_ρ^{DV} being the discrete Wigner function.

Theorem 1 relates the l_p-norm of GKP states to the l_p-norm of x_ρ for a discrete-variable state ρ, which quantifies the magicness in ρ, and therefore establishes a direct connection between the Wigner negativity of a qudit encoded in GKP and a magic quantifier in finite dimensions. The case of $p = 1$, i.e.,

$$\|x_\rho\|_1 = \frac{\|W_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}}{\|W_{\mathrm{STAB}_n,\mathrm{GKP}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}}, \tag{7}$$

is particularly insightful. In this case, the 1-norm of the continuous-variable Wigner function coincides with the continuous-variable Wigner negativity, which is known to be a valid measure of non-Gaussianity [4, 9]. The quantity in Theorem 1 is then the amount of non-Gaussianity renormalized by the negativity of the GKP states encoding stabilizer states. This renormalization is necessary, as even stabilizer states encoded in GKP have non-zero continuous Wigner negativity.

Its property as a magic quantifier depends on whether the dimension of the discrete-variable systems is odd or even. For odd dimensions, $\|x_\rho\|_1$ coincides with the discrete Wigner negativity [12]. On the other hand, for the case of even dimensions, $\|x_\rho\|_p$ does not reduce to known magic measures in general. However, for the special case of $d = 2$, it is equivalent to the stabilizer Rényi entropy [15], a recent proposal for computable magic measures for multi-qubit systems. We discuss further properties of this quantity in the technical manuscript.

In addition to the Wigner function, we also find that l_p-norm of the discrete-variable characteristic function χ_ρ^{DV} (which corresponds to the coefficients of the generalized Pauli operators) exactly corresponds to that of continuous-variable characteristic functions. This particularly provides a new interpretation of the stabilizer Rényi entropy—which is precisely defined by the l_p norm of the Pauli coefficients—in terms of GKP encoding, and naturally extends it to all dimensions.

Theorem 2. *Let ρ be an n-qudit state on a d^n-dimensional space. Then,*

$$d^{n(1-1/p)}\|\chi_\rho^{\mathrm{DV}}\|_p = \frac{\|\chi_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}}{\|\chi_{\mathrm{STAB},\mathrm{GKP}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}} \tag{8}$$

where $\chi_\rho^{\mathrm{DV,CV}}$ is the discrete- and continuous-variable characteristic functions, and $\|\chi_{\mathrm{STAB},\mathrm{GKP}}^{\mathrm{CV}}\|_{p,\mathrm{cell}}$ is the quantity that takes the same value for every pure stabilizer state ϕ.

This result particularly establishes an insightful relation between continuous characteristic functions and stabilizer Rényi entropies [15]

$$M_\alpha(\rho) = \frac{2\alpha}{1-\alpha}\log\frac{\|\chi_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{2\alpha,\mathrm{cell}}}{\|\chi_{\mathrm{STAB},\mathrm{GKP}}^{\mathrm{CV}}\|_{2\alpha,\mathrm{cell}}} - \frac{\alpha\, n\log d}{1-\alpha} \tag{9}$$

where $M_\alpha(\rho) := \alpha(1-\alpha)^{-1}\log\|\Xi(\rho)\|_\alpha - n\log d$ with $\Xi_P(\rho) = \frac{1}{d^n}\,\mathrm{Tr}\left(\rho P\right)^2$ is α-stabilizer Rényi entropy.

3 Applications

Simulation algorithms Employing our framework, we introduce a classical simulation algorithm that runs with the cost quantified by the magic quantifiers we introduce, extending the previous approaches of classical simulation based on quasiprobability distributions [16, 17] to all dimensions. See technical manuscript for details of the algorithm.

The simulation time scales with the amount of negativity in the entire circuit defined as

$$\mathcal{M}_{\rightarrow} = \|x_\rho\|_1 \prod_{t=1}^{T} \max_{\boldsymbol{\lambda_t}} \|x_{U_t}(\boldsymbol{\lambda_t})\|_1 \max_{\boldsymbol{\lambda_T}} |x_\Pi(\boldsymbol{\lambda_T})| \tag{10}$$

where the maximum is taken over all trajectories and

$$x_\rho(\lambda) = \mathrm{Tr}\left(\rho \frac{O_{\boldsymbol{\lambda}}}{d^n}\right) \tag{11}$$

$$x_U(\lambda', \lambda) = \mathrm{Tr}\left(\frac{O_{\boldsymbol{\lambda'}}}{d^n} U O_{\boldsymbol{\lambda}} U^\dagger\right) \tag{12}$$

$$x_\Pi(\lambda) = \mathrm{Tr}\left(\Pi O_{\boldsymbol{\lambda}}\right). \tag{13}$$

are the coefficients related to the input state ρ, the unitary evolution U and the measurement effect Π with $\lambda = (\boldsymbol{l}, \boldsymbol{m}) \in \mathbb{Z}_d^{2n}$. The number of samples K that achieves precision ϵ with a failure probability p_f is given by

$$K \geq 2\mathcal{M}_{\rightarrow}^2 \frac{1}{\epsilon^2} \ln\left(\frac{2}{p_f}\right). \tag{14}$$

This shows that the number of samples directly scales with the resourcefulness of the input state $\|x_\rho\|_1$ if we evolve using the free operations of our magic quantifiers like Clifford unitaries. This result gives a nice operational interpretation of the quantifiers discussed in this work, as already noted in the case for the discrete Wigner negativity [16].

Magic needs non-Gaussianity It has been known since the original GKP paper [13] that one can implement the logical T-gate and thus get an H-type magic state by using a cubic phase state or cubic interaction e^{icQ^3}. However, this is merely one possibility for implementing a non-Gaussian interaction, and this does not show the necessity of non-Gaussianity to implement a non-Clifford operation on the code subspace. This is a widely held belief based on the correspondence between a pair of Pauli and displacement operators and that of Clifford and Gaussian operations, where displacement operators and Pauli operators are both Heisenberg-Weyl operators. However, this "belief" has not been proven in general, beyond specific scenarios in qubit systems [18]. Indeed, GKP states have much Wigner negativity and thus *a priori* additional non-Gaussianity may not be required, making the necessity of non-Gaussian operation to implement a non-Clifford operation nontrivial.

Nevertheless, the results established above allow us to show that non-Gaussian operations are essential to implement non-stabilizer operations in the GKP code space. In fact, we find that the Gaussian *protocols* [9]—a class of quantum channels larger than Gaussian operations, which also admits feed-forwarded Gaussian operations conditioned on the outcomes of Gaussian measurements—are not able to implement non-stabilizer operations in the GKP code space. Importantly, Gaussian protocols include a gate teleportation circuit involving a Gaussian measurement and a feed-forwarded Gaussian unitary, which itself is not a Gaussian operation. An immediate consequence of this result is that a Gaussian protocol cannot implement non-Clifford unitary gates deterministically.

Theorem 3. *Let Λ be a quantum channel with n-qubit input and output systems. If there exists a pure stabilizer state ϕ and a pure non-stabilizer state ψ such that $\Lambda(\phi) = \psi$, Λ cannot be implemented in a GKP code space by a Gaussian protocol. Also, for a quantum channel Λ with n-qudit input and output systems with odd local dimensions, the condition can be relaxed to the existence of a (potentially mixed) stabilizer state σ and a state ρ with $\|W_\rho^{\mathrm{DV}}\|_1 > 1$ such that $\Lambda(\sigma) = \rho$.*

4 Conclusions

We established a fundamental quantitative relation between discrete- and continuous-variable systems via the GKP encoding. We introduced a magic measure for discrete-variable systems and showed that it corresponds to the non-Gaussianity measure defined by the continuous-variable Wigner function that encodes the same qudit states via GKP encoding. Our distributions allow for a magic quantifier for all dimensions and extend the discrete Wigner negativity defined for odd dimensions in a unified manner. Furthermore, we present an analogous relation for characteristic functions, providing a new representation of the stabilizer Rényi entropy in terms of continuous-variable characteristic function.

Employing our framework, we introduced a classical simulation algorithm, where the run time scales with the magic quantifiers we introduced. We utilized our findings to demonstrate that achieving a deterministic implementation of a logical non-Clifford operation, with identical input and output dimensions within the GKP code subspace, necessitates a non-Gaussian operation, even when operating at the theoretical limit of ideal GKP state input.

Our work suggests various interesting future directions, including the extension of our results to realistic GKP states with finite squeezing, as well as the application of our framework to other bosonic codes.

Although the similarity between non-stabilizer states—also known as magic states—in discrete-variable systems and non-Gaussian states in continuous-variable systems has widely been recognized, the precise connections between these two notions have still been unclear. We establish a fundamental link between these two quantum resources via the Gottesman-Kitaev-Preskill (GKP) encoding. We show that the negativity of the continuous-variable Wigner function for an encoded GKP state coincides with a magic measure we introduce, which matches the negativity of the discrete Wigner function for odd dimensions. We also provide a continuous-variable representation of the stabilizer Rényi entropy—a recent proposal for a magic measure for multi-qubit states. With this in hand, we give a classical simulation algorithm with runtime scaling with the resource contents, quantified by our magic measures. We also employ our results to prove that implementing a multi-qubit logical non-Clifford operation in the GKP code subspace requires a non-Gaussian operation even at the limit of perfect encoding, despite the fact that the ideal GKP states already come with much non-Gaussianity.

I. INTRODUCTION

The difference between what constitutes quantum and classical physics is often hard to grasp. The hope is to leverage quantum mechanics in order to get a computational speed-up when using quantum computing compared to classical computation. Finding and pinpointing the origins of the speed-up or what property allows for such a phenomenon is still an open problem. Aside from an academic interest, this undertaking would allow us to identify and quantify what resources are required to do a certain computational task. This fact becomes even more important, as in reality every quantum information processing task will be restricted in a certain way given that they will be implemented in a physical system.

One of the promising platforms for quantum information processing consists of quantum optical systems [1], which is equipped with an infinite-dimensional Hilbert space associated with observable possessing a continuous-variable spectrum. In such systems, non-Gaussian components have been identified as necessary resources for quantum computational advantages [2], as computation solely run by Gaussian resources can be efficiently simulated classically. Such non-Gaussian features in e.g. quantum states can be quantified by several measures of non-Gaussianity [3–9], among which the negativity of Wigner function [5, 6, 10] has been known as the computable measure that also captures the hardness of classical simulability [11].

The other paradigm for quantum information processing assumes discrete-variable systems, in which quantum information is encoded in finite-dimensional Hilbert spaces. Promising platforms implementing discrete-variables systems include superconducting [12] and ion-trap-based [13] architectures. Among many relevant quantum resources needed for efficient quantum information processing in discrete-variable systems, one peculiar quantity necessary for quantum speedup is the non-stabilizerness [14], also known as quantum magic, which stems from the fact that quantum circuits only consisting of stabilizer states and Clifford operations can be efficiently simulable by classical computers [15]. Interestingly, the magicness of discrete-variable states can also be studied by looking at a discrete version of the Wigner function [16, 17] analogously to the case of continuous-variable systems. Indeed, the negativity of the discrete Wigner function [18, 19] has been shown to be a valid magic measure when the underlying Hilbert space has odd dimensions. For even dimensions, one needs to consider other quantifiers [20–33], as there is no known quasiprobability distribution that easily connects to magic.

Although some conceptual similarities between non-Gaussianity and magic resources have been observed [17, 33–35], the direct quantitative connection between these two resources has still been elusive. In particular, constructing a map between magic and non-Gaussianity would strengthen the relation between two main operational frameworks that are important for quantum computing and provide a novel approach where one resource could be analyzed by employing a tool developed for analyzing the other.

In this work, we accomplish this mapping by finding a fundamental relation between the discrete and continuous-variable systems via the Gottesman-Kitaev-Preskill (GKP) encoding [36], which is one of the most promising error-correcting codes for continuous-variable systems. We introduce a family of distributions for discrete-variable systems and show that their l_p-norm exactly corresponds to that of the continuous-variable Wigner function for the GKP state encoding the original discrete-variable qudit. Specifically for odd dimension, the l_1 norm of the qudit distributions yields the negativity of the associated Wigner function for both discrete and continuous-variable settings. The connection is even stronger as the continuous Wigner function can be directly represented using the discrete Wigner function of the encoded state. On the other hand, our distributions yield a magic quantifier for all dimensions, which encompasses the negativity of the discrete Wigner function defined for odd dimensions and the stabilizer Rényi entropy [28] defined for multi-qubit sys-

[*] oliver.hahn@chalmers.se
[†] ryujitakagi.pat@gmail.com

tems in a unified manner. Our results, therefore, allow for recovering and significantly extending a recent finding of the relation between multi-qubit systems and continuous-variable systems [29].

In addition to the Wigner function, we also find that l_p-norm of the discrete-variable characteristic function (which corresponds to the coefficients of the generalized Pauli operators) exactly corresponds to the one of continuous-variable characteristic functions of GKP-encoded states. This provides a new interpretation of the stabilizer Rényi entropy—which is precisely defined by the l_p norm of the Pauli coefficients—in terms of GKP encoding, and naturally extends it to all dimensions.

Employing our framework, we introduce a classical simulation algorithm that runs with the cost quantified by the magic measure we introduce, extending the previous approaches of classical simulation based on quasiprobability distributions [37, 38] to all dimensions. We also apply our results to prove that the deterministic implementation of a logical non-Clifford operation with the same input and output systems in the GKP code subspace requires a non-Gaussian operation even at the limit of ideal GKP state input. Since ideal GKP states have unbounded non-Gaussianity, it is not a priori obvious that more non-Gaussianity is needed to apply a logical non-Clifford operation. Our result shows that this is actually the case in general, extending an observation for specific non-Clifford gates in multi-qubit systems [39] to the general class of non-Clifford gates on all dimensions.

II. PRELIMINARIES

Here we briefly review the relevant formalism for discrete- and continuous-variable quantum computing.

A. Discrete variables

Qubits are ubiquitous in quantum information processing and are $d = 2$ level systems. Qudits are an intuitive generalizations to d dimensions. A general pure qudit state is defined as

$$|\psi\rangle = \sum_{i=0}^{d-1} \alpha_i |i\rangle \tag{1}$$

with normalization condition $\sum_{i=0}^{d-1} |\alpha_i|^2 = 1$ and $|i\rangle$ a computational basis state. The Pauli group can be defined for arbitrary dimensions in analogy to the qubit case as $\mathcal{P}_d = \{\omega_D^u X_d^v Z_d^w : v, w \in \mathbb{Z}_d, u \in \mathbb{Z}_D\}$ where $\omega_d = e^{2\pi i/d}$ is the dth root of unity and

$$D = \begin{cases} d: & \text{for } d \text{ odd} \\ 2d: & \text{for } d \text{ even} \end{cases} \tag{2}$$

with $\mathbb{Z}_d$ being the integers modulo d. The d dimensional Pauli operators Z_d, X_d, sometimes also called shift and clock operators, are a way to generalize the qubit Pauli operators Z_2, X_2 and are defined as

$$X_d = \sum_{j=0}^{d-1} |j+1\rangle \langle j| \tag{3}$$

$$Z_d = \sum_{j=0}^{d-1} \omega_d^j |j\rangle \langle j| \tag{4}$$

with the property $X_d^d = Z_d^d = \mathbb{1}$ [40].

We use the generalized Pauli operators X_d, Z_d to define the operators of the d-dimensional Heisenberg-Weyl group as [16, 17]

$$P_d(a,b) = \omega_d^{\frac{1}{2}ab} X_d^a Z_d^b \tag{5}$$

with $a, b \in \mathbb{Z}_d$. Then, the commutation relations are

$$P_d(a,b) P_d(c,d) = \omega_d^{(a,b)\Omega(c,d)^T} P_d(c,d) P_d(a,b), \tag{6}$$

where

$$\Omega = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \tag{7}$$

is the symplectic form.

For n-qudit systems, the Heisenberg-Weyl operators are written by

$$P_d(\boldsymbol{u}) = \otimes_{i=1}^n P_d(a_i, b_i) \tag{8}$$

with $\boldsymbol{u} = (\boldsymbol{a}, \boldsymbol{b}) \in \mathbb{Z}_d^{2n}$, which satisfy the orthogonality relation

$$\mathrm{Tr}\left[P_d(\boldsymbol{u}) P_d^\dagger(\boldsymbol{v})\right] = d^n \delta_{\boldsymbol{u},\boldsymbol{v}}. \tag{9}$$

The d dimensional n qudit Clifford group is generated by the following unitary operations

$$\begin{aligned} R &= \sum_{j,s=0}^{d-1} \omega_d^{js} |s\rangle \langle j| \\ P &= \sum_{j=0}^{d-1} \omega_d^{j^2/2} (\omega_D \omega_{2d}^{-1})^{-j} |j\rangle \langle j| \\ \mathrm{SUM} &= \sum_{i,j=0}^{d-1} |i\rangle \langle i| \otimes |i+j \mod d\rangle \langle j| . \end{aligned} \tag{10}$$

For $d = 2$, these operators reduce to the Hadamard, Phase, and CNOT gate [40] respectively. A Clifford unitary U_C acts on the Heisenberg-Weyl operator in a simple way

$$U_C P_d(\boldsymbol{u}) U_C^\dagger = P_d(S\boldsymbol{u}) \tag{11}$$

where $S \in \mathrm{SP}(2n, \mathbb{Z}_D)$ is a symplectic matrix [40] associated with the Clifford unitary U_C .

Using the discrete Heisenberg-Weyl operators, we define the characteristic function [17]

$$\chi_\rho^{\mathrm{DV}}(\boldsymbol{u}) = d^{-n}\, \mathrm{Tr}\left[\rho P_d(\boldsymbol{u})^\dagger\right]. \tag{12}$$

Odd-dimensional systems allow for a simple way to define the discrete Wigner function by the discrete symplectic Fourier transform of the characteristic function

$$W_\rho^{\mathrm{DV}}(\boldsymbol{u}) = d^{-n} \sum_{\boldsymbol{v}\in\mathbb{Z}_d^{2n}} \omega_d^{-\boldsymbol{u}\Omega_n\boldsymbol{v}^T} \chi_\rho^{\mathrm{DV}}(\boldsymbol{v}) \tag{13}$$

$$= d^{-n}\,\mathrm{Tr}\,[A(\boldsymbol{u})\rho], \tag{14}$$

where Ω_n now takes the form

$$\Omega = \begin{pmatrix} 0 & \mathbb{1}_n \\ -\mathbb{1}_n & 0 \end{pmatrix} \tag{15}$$

and $\mathbb{1}_n$ is the $n \times n$ identity matrix. The phase space point operator in (10) can be written by

$$A(\boldsymbol{u}) = d^{-n} \sum_{\boldsymbol{v}\in\mathbb{Z}_d^{2n}} \omega_d^{-\boldsymbol{u}\Omega_n\boldsymbol{v}^T} P_d(\boldsymbol{u})^\dagger. \tag{16}$$

The discrete Wigner function in odd dimensions has many useful properties. It is covariant under Clifford unitaries U_C meaning that

$$W^{\mathrm{DV}}_{U_C\rho U_C^\dagger}(\boldsymbol{u}) = W_\rho^{\mathrm{DV}}(S\boldsymbol{u}) \tag{17}$$

with $S \in \mathrm{Sp}(2n, \mathbb{Z}_d)$ being the symplectic matrix associated with Clifford unitary U_C. The discrete Wigner function $W_\rho(\boldsymbol{u})$ is a quasiprobability distribution and is thus not necessarily positive. Nevertheless, it constructs a valid probability distribution for an arbitrary stabilizer state. This property was utilized to introduce a magic measure— a quantifier for non-stabilizerness—given by

$$\|W_\rho^{\mathrm{DV}}\|_1 = \sum_{\boldsymbol{u}} \left|W_\rho^{\mathrm{DV}}(\boldsymbol{u})\right| \tag{18}$$

which is known as the negativity of the Wigner function [19]. This is a resource monotone under Clifford operations in the sense of resource theories [41], meaning that this does not increase under Clifford operations. The negativity of the Wigner function (18) can be considered as a l_1-norm of the function $W_\rho^{\mathrm{DV}} : \mathbb{Z}_d^{2n} \to \mathbb{R}$. In the following, we also consider the l_p-norm of a function $f : \mathbb{Z}_d^{2n} \to \mathbb{C}$ defined by

$$\|f\|_p = \left(\sum_{\boldsymbol{u}\in\mathbb{Z}_d^{2n}} |f(\boldsymbol{u})|^p \right)^{1/p} \tag{19}$$

for a real number $p > 0$.

B. Continuous variables

A related but inherently different paradigm in quantum information processing uses infinite dimensional systems. The central observables in these systems are commonly called position Q and momentum P operators that fulfill the canonical commutation relations

$$[Q, P] = i. \tag{20}$$

These operators have continuous spectra, which is why this type of quantum information processing is often called *continuous variables*, in contrast to *discrete-variable* systems described in the previous section. For a n-mode system, the infinite-dimensional Heisenberg-Weyl operators, also known as displacement operators, are defined by

$$D(\boldsymbol{r}) = \prod_{j=1}^{n} e^{-ir_{p_j}r_{q_j}/2} e^{-ir_{q_j}P_j} e^{ir_{p_j}Q_j} \tag{21}$$

where $\boldsymbol{r} = (r_{q_1}, ..., r_{q_n}, r_{p_1}, ..., r_{p_n}) = (\boldsymbol{r_q}, \boldsymbol{r_p})$ and Q_j, P_j are position and momentum operators for j th mode. Displacement operators fulfill the commutation relation

$$D(\boldsymbol{r})D(\boldsymbol{r'}) = e^{-i\boldsymbol{r}\Omega_n\boldsymbol{r'}^T} D(\boldsymbol{r'})D(\boldsymbol{r}). \tag{22}$$

Similarly to the discrete case, we can use the continuous Heisenberg-Weyl operators to define the characteristic function

$$\chi_\rho^{\mathrm{CV}}(\boldsymbol{r}) = \mathrm{Tr}\,[\rho D(-\boldsymbol{r})] \tag{23}$$

and the Wigner function as its symplectic Fourier transform

$$\begin{aligned} W_\rho^{\mathrm{CV}}(\boldsymbol{r}) &= \frac{1}{(2\pi)^n} \int \mathrm{d}\boldsymbol{r'} e^{i\boldsymbol{r}\Omega_n\boldsymbol{r'}} \chi_\rho(\boldsymbol{r'}) \\ &= \frac{1}{(2\pi)^n} \int_{-\infty}^{\infty} \mathrm{d}^n\boldsymbol{x} e^{i\boldsymbol{r_p}\boldsymbol{x}} \left\langle \boldsymbol{r_q} + \frac{\boldsymbol{x}}{2} \right| \rho \left| \boldsymbol{r_q} - \frac{\boldsymbol{x}}{2} \right\rangle_Q . \end{aligned} \tag{24}$$

The continuous Wigner function is a quasi-probability distribution and the Wigner negativity [10]

$$\|W_\rho^{\mathrm{CV}}\|_1 = \int \mathrm{d}\boldsymbol{r} \left|W_\rho^{\mathrm{CV}}(\boldsymbol{r})\right| \tag{25}$$

can be used as a valid quantifier for non-Gaussianity [5, 6]. Similarly to the case of discrete variables, we also consider a l_p-norm for a function $f : \mathbb{R}^{2n} \to \mathbb{C}$ defined by

$$\|f\|_p = \left(\int d\boldsymbol{r} |f(\boldsymbol{r})|^p \right)^{1/p}, \tag{26}$$

which gives back the Wigner negativity (25) as the l_1-norm of the Wigner function.

A family of states playing a major role in this work are the Gottesman-Kitaev-Preskill (GKP) states [36]. They were originally introduced as error correction codes for bosonic quantum systems. In this work, we employ this encoding as a platform to map magic and non-Gaussian resources, extending a prior attempt for multiqubit systems [29].

In the following, we use a subscript to denote a continuous-variable state that encodes a discrete-variable state. For instance, ρ_{GKP} refers to a continuous-variable state that encodes a qudit state ρ by the GKP encoding. The computational basis state $|j\rangle$ is encoded in the GKP code as an infinite superposition of position eigenstates as

$$|j\rangle_{\mathrm{GKP}} = \sum_{s=-\infty}^{\infty} |Q = \alpha(j + ds)\rangle\,, \tag{27}$$

which is equipped with a Wigner function

$$\begin{aligned} &W^{\mathrm{CV}}_{|j\rangle\langle j|_{\mathrm{GKP}}}(r_q, r_p) \\ &= \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{d}x e^{i r_p x}\psi^j\left(r_q + \frac{x}{2}\right)^* \psi^j\left(r_q - \frac{x}{2}\right) \\ &\propto \sum_{s,t=-\infty}^{\infty} (-1)^{st}\delta\left(r_p - \frac{\pi}{d\alpha}s\right)\delta\left(r_q - \alpha j - \frac{d\alpha}{2}t\right) \end{aligned} \tag{28}$$

with $\alpha = \sqrt{\frac{2\pi}{d}}$. A useful property of the GKP code is that all Clifford unitaries on the code subspace can be implemented using Gaussian unitaries.

As can be seen in (28), the Wigner function of a GKP state consists of a collection of delta functions. This comes with an unbounded negativity, which reflects the fact that an ideal GKP state is unnormalizable. Nevertheless, one can see that the delta peaks are periodically positioned with the unit cell of the size $\sqrt{2d\pi} \times \sqrt{2d\pi}$. This motivates us to consider an l_p-norm of a function f considered for a unit cell, defined by

$$\|f\|_{p,\mathrm{cell}} := \left(\int_{\mathrm{cell}} d\boldsymbol{r}|f(\boldsymbol{r})|^p\right)^{1/p} \tag{29}$$

where $\int_{\mathrm{cell}}$ refers to the integral over the domain restricted to a hypercube $r_{q_i} \in [0, \sqrt{2d\pi}), r_{p_i} \in [0, \sqrt{2d\pi})$ in the phase space.

We also note that there is a subtlety when we compute l_p-norm of a function that involves a delta function. We describe the procedure to perform such integrals in Appendix A.

III. BRIDGING MAGIC AND NON-GAUSSIANITY

In this section, we present our results that directly connect the resource content of the discrete-variable state with that of the continuous one, establishing a quantitative relation between magic and non-Gaussianity.

A. Via Wigner function

The first path to connect magic and non-Gaussianity uses the continuous Wigner function.

In order to make this connection, we start by introducing a new operator basis for qudit systems. For $l, m \in \mathbb{Z}_{2d}$, let $O_{l,m}$ be an operator defined by

$$O_{l,m} = \omega_d^{-ml/2} M_l Z_d^m \tag{30}$$

where

$$M_l = \sum_{\substack{u,v\in\mathbb{Z}_d \\ u+v \mod d=l}} |u\rangle\langle v| . \tag{31}$$

This can easily be extended to n-qudit systems, where we define $O_{\boldsymbol{l},\boldsymbol{m}} = \prod_{i=1}^n O_{l_i,m_i}$ for $\boldsymbol{l},\boldsymbol{m} \in \mathbb{Z}_{2d}^n$.

Let us now define the distribution

$$x_\rho(\boldsymbol{l},\boldsymbol{m}) := d^{-n}\,\mathrm{Tr}(O_{\boldsymbol{l},\boldsymbol{m}}\rho) \tag{32}$$

which corresponds to the coefficients for $O_{\boldsymbol{l},\boldsymbol{m}}$ when expanding the state ρ with this operator basis. Although $\boldsymbol{l},\boldsymbol{m}$ are elements of $\mathbb{Z}_{2d}$ in general, the operators $O_{\boldsymbol{l},\boldsymbol{m}}$, and correspondingly $x_\rho(\boldsymbol{l},\boldsymbol{m})$, can only gain a phase factor by a translation $l_i \to l_i + d$ and $m_i \to m_i + d$ for any $i = 1, \ldots, n$, and that the operators $\{O_{\boldsymbol{l},\boldsymbol{m}}\}_{l,m\in\mathbb{Z}_d^n}$ form an operator basis of a n-qudit system. We consider the l_p-norm for this distribution over the restricted domain $\boldsymbol{l},\boldsymbol{m} \in \mathbb{Z}_d^n$, i.e.,

$$\|x_\rho\|_p = \left(\sum_{\boldsymbol{l},\boldsymbol{m}\in\mathbb{Z}_d^n} |x_\rho(\boldsymbol{l},\boldsymbol{m})|^p\right)^{1/p} . \tag{33}$$

The following result connects the l_p-norm of the continuous Wigner function of a qudit encoded in GKP with the l_p norm of the distribution defined in (32).

Theorem 1. *For an n-qudit state ρ on a d^n-dimensional space and for an arbitrary real number $p > 0$, it holds that*

$$d^{n(1-1/p)}\|x_\rho\|_p = \frac{\|W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}\|_{p,\mathrm{cell}}}{\|W^{\mathrm{CV}}_{\mathrm{STAB}_n,\mathrm{GKP}}\|_{p,\mathrm{cell}}}, \tag{34}$$

where

$$\begin{aligned} \|W^{\mathrm{CV}}_{\mathrm{STAB}_n,\mathrm{GKP}}\|_{p,\mathrm{cell}} &:= \|W^{\mathrm{CV}}_{\phi_{\mathrm{GKP}}}\|_{p,\mathrm{cell}} \\ &= (4d)^{n/p}/(8\pi d)^{n/2} \end{aligned} \tag{35}$$

is a quantity that takes the same value for every n-qudit pure stabilizer state ϕ. When d is odd, an even stronger result holds

$$d^{n(1-1/p)}\|W^{\mathrm{DV}}_\rho\|_p = \frac{\|W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}\|_{p,\mathrm{cell}}}{\|W^{\mathrm{CV}}_{\mathrm{STAB}_n,\mathrm{GKP}}\|_{p,\mathrm{cell}}}. \tag{36}$$

We prove Theorem 1 later in this section using the following general relation between the discrete Wigner function of the corresponding encoded state and the continuous-variable Wigner function for GKP states, which may be of interest on its own. The peculiar property of the Wigner function of GKP states is that it comes with an atomic form, where the Dirac distribution has disjoint support

$$\begin{aligned} &W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(\boldsymbol{r}) \\ &= \frac{\sqrt{d}^n}{\sqrt{8\pi}^n}\sum_{\boldsymbol{l},\boldsymbol{m}} c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m})\delta\left(\boldsymbol{r_p} - \boldsymbol{m}\sqrt{\frac{\pi}{2d}}\right)\delta\left(\boldsymbol{r_q} - \boldsymbol{l}\sqrt{\frac{\pi}{2d}}\right) \end{aligned} \tag{37}$$

where $c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m})$ is a coefficient serving as a weight for each peak in the Wigner function of a GKP state ρ_{GKP}. We show how to derive Eq. (37) from (28) in Appendix B. This Wigner function forms a lattice, so we restrict it to one unit cell and focus on $l_i, m_i \in [0, 2d-1]$ or equivalently $l_i, m_i \in \mathbb{Z}_{2d}$ for each $i = 1, \ldots, n$.

The following result shows that the weight $c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m})$ in the domain $\boldsymbol{l},\boldsymbol{m} \in \mathbb{Z}_d^n$ exactly coincides with the distribution defined in (32).

Proposition 2. *For $\boldsymbol{l}, \boldsymbol{m} \in \mathbb{Z}_{2d}^n$, it holds that*

$$c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l}, \boldsymbol{m}) = x_\rho(\boldsymbol{l}, \boldsymbol{m}). \tag{38}$$

The proof of Proposition 2 can be found in Appendix B. This establishes the fundamental relation between discrete-variable and continuous-variable representations of an arbitrary state ρ. As we will see later in this section, for odd dimensions Proposition 2 directly connects the discrete Wigner function of an arbitrary state ρ and the continuous Wigner function of the GKP state that encodes ρ.

Theorem 1 relates the l_p-norm of GKP states to the l_p-norm of x_ρ for a discrete-variable state ρ, which quantifies the magicness in ρ, and therefore establishes a direct connection between the Wigner negativity of a qudit encoded in GKP and a finite-dimensional magic measure. The case of $p = 1$ is particularly insightful. In this case, the 1-norm of the continuous-variable Wigner function coincides with the continuous-variable Wigner negativity, which is known to be a valid measure of non-Gaussianity [5, 6]. The quantity in Theorem 1 is then the amount of non-Gaussianity renormalized by the negativity of the GKP states encoding stabilizer states. This renormalization is necessary, as even stabilizer states encoded in GKP have non-zero continuous Wigner negativity.

Its property as a magic measure depends on whether the dimension of the discrete-variable systems is odd or even. For odd dimensions, $\|x_\rho\|_1$ coincides with the discrete Wigner negativity [17, 19]. This is a magic measure defined for general mixed states that is monotonically non-increasing under stabilizer protocols [19], which consists of (1) Clifford unitaries (2) composition with stabilizer states (3) Pauli measurements (4) partial trace (5) the above operations conditioned on the outcomes of Pauli measurements or classical randomness. Moreover, it is faithful for pure states, i.e., $\|x_\psi\|_1 = 1$ if and only if ψ is a stabilizer state for an arbitrary pure state ψ [17].

On the other hand, for the case of even dimensions, $\|x_\rho\|_p$ does not reduce to known magic measures in general—the definition of a discrete Wigner function in even dimensions is more challenging and involves expanding the set of phase-space point operators to an over-complete basis [42]. In addition, the phase space point operators always have a unit trace [17, 42], while it is not the case for $O_{l,m}$ in even dimensions, indicating the subtlety of connecting it to Wigner functions. However, for the special case of $d = 2$, it is evident by definition that $\|x_\rho\|_p$ is equivalent to the stabilizer Rényi entropy [28], as the operator $\{O_{l,m}\}_{l,m}$ reduces to the Pauli operators. Indeed, the core properties that motivate the stabilizer Rényi entropy as "magic measures" can also be extended to $\|x_\rho\|_1$ for all dimensions as follows.

1. Invariance under Clifford unitaries U_C: $\left\|x_{U_C \rho U_C^\dagger}\right\|_1 = \|x_\rho\|_1$
2. Multiplicativity: $\|x_{\rho\otimes\sigma}\|_1 = \|x_\rho\|_1 \|x_\sigma\|_1$
3. Stabilizer states achieve the minimum value: $\|x_\phi\|_1 = 1$ for every pure stabilizer state ϕ, and $\|x_\psi\|_1 \geq 1$ for every pure state ψ.

The first two properties directly follow from the properties of the continuous Wigner function together with Theorem 1, or equivalently from the properties of the newly defined operators $O_{\boldsymbol{l},\boldsymbol{m}}$. We show the third property in Appendix C.

In addition, for odd dimensions and multi-qubit systems, we have the following property.

4. Faithfulness: For a pure state ϕ, $\|x_\phi\|_1 = 1$ if and only if ϕ is a stabilizer state.

This follows from the discrete Hudson's theorem [17] for odd dimensions and the faithfulness of stabilizer Rényi entropy [28] for multi-qubit systems.

The operators $O_{\boldsymbol{l},\boldsymbol{m}}$ are involutions that are orthogonal in the Hilbert-Schmidt inner product and therefore form a basis. Furthermore, they are closed under Clifford unitaries. We will delve more into the properties of the operators $O_{\boldsymbol{l},\boldsymbol{m}}$ in the next subsection.

Evidently, the major dividing line between even and odd dimensions for the above magic measures is the question of monotonicity under Pauli measurement and the inclusion of mixed states. The magic measures for odd dimensions are non-increasing under Pauli measurements, and they are valid magic measures for general mixed states. On the other hand, for even dimensions, they are designed solely for pure states, and the monotonicity under Pauli measurements does not hold in general [43]. In particular, it is an important problem to find a computable magic measure for multi-qubit systems that is non-increasing even under Pauli measurements. One such measure is known as stabilizer nullity [26], but it is a highly discontinuous measure unstable under an infinitesimally small perturbation. Finding a continuous computable measure with full monotonicity will thus make an interesting future direction. This problem also generalizes to all even dimensions in an equivalent way.

1. *Properties of operator basis*

Since the operators $O_{\boldsymbol{l},\boldsymbol{m}}$ defined in Eq. 30 are of interest in their own way and play a central role in connecting the continuous-variable and discrete-variable worlds as can be seen in Theorem 1 and Proposition 2, let us investigate their properties. A proof of the properties outlined here can be found in Appendix D.

In general, $l, m \in \mathbb{Z}_{2d}$ are defined over $\mod 2d$. However, for most applications, one can restrict to $\mathbb{Z}_d$. For a value above d, the operators are periodic in d

$$M_l = M_{l+d} \tag{39}$$
$$Z_d^m = Z_D^{m+d} \tag{40}$$

but can have different phases

$$\begin{aligned} O_{l+d,m} &= (-1)^m O_{l,m} \\ O_{l,m+d} &= (-1)^l O_{l,m} \\ O_{l+d,m+d} &= (-1)^{l+m+d} O_{l,m} \end{aligned} \tag{41}$$

Therefore, if one is only interested in the operators independent of the sign, one can restrict the domain of l, m.

In general, $O_{l,m}$ and Z_d are unitary, and M_l is Hermitian. Thus, it holds that

$$O_{l,m}O_{l,m}^{\dagger} = \mathbb{1}. \tag{42}$$

The operator $O_{l,m}$ is also Hermitian $O = O^{\dagger}$ and thus

$$O_{l,m}O_{l,m} = \mathbb{1}, \tag{43}$$

implying that the spectrum is ± 1.

These operators are orthogonal in the sense of the Hilbert-Schmidt inner product

$$\operatorname{Tr}\left(O_{l,m}O_{l'm'}\right) = \delta_{mm'}\delta_{ll'}d. \tag{44}$$

Furthermore, the action of Clifford unitaries on the operators $O_{\boldsymbol{l},\boldsymbol{m}}$ is equivalent to a symplectic linear transformation on the coordinates $(\boldsymbol{l}, \boldsymbol{m})$ and constant shifts. We show this in Appendix D 2. For $d = 2$, one recovers the standard Pauli operators. Therefore, $O_{l,m}$ can be seen as a Hermitian generalization of the Pauli operators to arbitrary dimensions.

M_l contains d 1s for any dimension, but they behave differently for even and odd dimensions. Whether the operator is traceless for even dimensions depends on whether l is even or odd—M_l is traceless for odd l, while it has trace 2 for even l. For odd dimensions, the matrices M_l have trace 1.

Using the properties of M_l and the known properties of Z_d, we can now give a summary of the properties of $O_{l,m}$

$$\operatorname{Tr}[O_{l,m}] = \begin{cases} 1 + (-1)^m & d, l \text{ even} \\ (-1)^{ml} & d \text{ odd} \end{cases} \tag{45}$$

$$O_{l,m} = O_{l,m}^{\dagger} \tag{46}$$

$$O_{l,m}^2 = \mathbb{1} \tag{47}$$

$$\operatorname{Tr}\left(O_{l,m}O_{l'm'}\right) = \delta_{mm'}\delta_{ll'}d \tag{48}$$

As we have seen that the operators are orthogonal under the Hilbert-Schmidt norm and form a basis, we can expand operators in that basis. We restrict to $\boldsymbol{l}, \boldsymbol{m} \in \mathbb{Z}_d$, since the operators for other $\boldsymbol{l}, \boldsymbol{m}$ are the same modulo a potentially different sign that can be absorbed in the coefficients.

We can represent every quantum state in basis the operators $O_{\boldsymbol{l},\boldsymbol{m}}$ such that

$$\begin{aligned}\rho &= \sum_{\boldsymbol{m},\boldsymbol{l}} \operatorname{Tr}\left[\rho\frac{O_{\boldsymbol{l},\boldsymbol{m}}}{d^n}\right]O_{\boldsymbol{l},\boldsymbol{m}} \\ &= \sum_{\boldsymbol{l},\boldsymbol{m}} x_\rho(\boldsymbol{l},\boldsymbol{m})O_{\boldsymbol{l},\boldsymbol{m}}\end{aligned} \tag{49}$$

Given by the spectrum of $O_{\boldsymbol{l},\boldsymbol{m}}$, we can bound the value of the coefficients

$$-\frac{1}{d^n} \leq x_\rho(\boldsymbol{l},\boldsymbol{m}) \leq \frac{1}{d^n}. \tag{50}$$

We can further bound $x_\rho(\boldsymbol{l},\boldsymbol{m})$ using $\operatorname{Tr}(\rho) = 1$ as

$$\begin{aligned}\operatorname{Tr}(\rho) &= \sum_{\boldsymbol{l},\boldsymbol{m}} x_\rho(\boldsymbol{l},\boldsymbol{m}) \operatorname{Tr}\left(O_{\boldsymbol{l},\boldsymbol{m}}\right) \\ &= \begin{cases} \sum_{\boldsymbol{l},\boldsymbol{m}} (-1)^{\boldsymbol{l}\cdot\boldsymbol{m}} x_\rho(\boldsymbol{l},\boldsymbol{m}) = 1 & \text{odd} \\ \sum_{\boldsymbol{l},\boldsymbol{m}:\text{even}} 2^n x_\rho(\boldsymbol{l},\boldsymbol{m}) = 1 & \text{even} \end{cases}\end{aligned} \tag{51}$$

where $\boldsymbol{l}\cdot\boldsymbol{m} = \sum_{i=1}^n l_i m_i$.

Interestingly, we find the following characterization of pure stabilizer states, which we prove in Appendix D 3.

Proposition 3. *For an arbitrary pure stabilizer state ϕ, $x_\rho(\boldsymbol{l},\boldsymbol{m})$ have the same magnitude $|x_\rho(\boldsymbol{l},\boldsymbol{m})| = \frac{1}{d^n}$ with d^n non-zero coefficients over $\boldsymbol{l},\boldsymbol{m} \in \mathbb{Z}_d^n$.*

We note that, because of the property (41), the non-zero coefficients in the larger domain $\boldsymbol{m},\boldsymbol{l} \in \mathbb{Z}_{2d}^n$ for a pure stabilizer state still solely takes the value d^{-n}, and the number of non-zero coefficients increases to $(4d)^n$.

We see that $x_\rho(\boldsymbol{l},\boldsymbol{m})$ is not directly a quasi-probability distribution but can easily be modified to be one for odd dimensions. In the case of odd dimensions, we can show a direct connection between the operators $O_{l,m}$ and the phase space operators $A(a_1, a_2)$. The precise connection is

$$O_{2a_2,-2a_1} = A(a_1, a_2), \tag{52}$$

where now the index $2a_2, -2a_1 \in \mathbb{Z}_{2d}$ go over numbers $\bmod 2d$, to get the sign correct. We can make the connection even more explicit by correcting the trace of $O_{l,m}$ and remembering that otherwise the phase space operators and $O_{l,m}$ are reordered versions of each other

$$(-1)^{a_1 a_2} O_{a_1,a_2} = A(\sigma[a_1, a_2]^T) \tag{53}$$

where σ is some permutation matrix over $\mathbb{Z}_d^2$. This result directly connects the discrete Wigner function W_ρ^{DV} with the distribution x_ρ via

$$x_\rho(\boldsymbol{a_1},\boldsymbol{a_2}) = (-1)^{\boldsymbol{a_1}\cdot\boldsymbol{a_2}} W_\rho^{\text{DV}}(\sigma[\boldsymbol{a_1},\boldsymbol{a_2}]^T). \tag{54}$$

2. *Proof of Theorem 1*

We are now ready to show Theorem 1.

Proof of Theorem 1. Using Propositions 2 and 3, we get for an arbitrary pure stabilizer state ϕ that

$$\begin{aligned}\|W_{\phi_{\text{GKP}}}^{\text{CV}}\|_{p,\text{cell}} &= \left[(4d)^n\left\{\left(\frac{d}{8\pi}\right)^{n/2} d^{-n}\right\}^p\right]^{1/p} \\ &= \frac{(4d)^{n/p}}{(8\pi d)^{n/2}}.\end{aligned} \tag{55}$$

Proposition 2 gives

$$\begin{aligned}\|W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}\|_{p,\mathrm{cell}} &= \left[\sum_{\boldsymbol{l},\boldsymbol{m}\in\mathbb{Z}^n_{2d}}\left\{\left(\frac{d}{8\pi}\right)^{n/2}|x_\rho(\boldsymbol{l},\boldsymbol{m})|\right\}^p\right]^{1/p}\\ &= \left[4^n\sum_{\boldsymbol{l},\boldsymbol{m}\in\mathbb{Z}^n_{d}}\left\{\left(\frac{d}{8\pi}\right)^{n/2}|x_\rho(\boldsymbol{l},\boldsymbol{m})|\right\}^p\right]^{1/p}\\ &= 4^{n/p}\left(\frac{d}{8\pi}\right)^{n/2}\|x_\rho\|_p\\ &= d^{n(1-1/p)}\|W^{\mathrm{CV}}_{\phi_{\mathrm{GKP}}}\|_{p,\mathrm{cell}}\|x_\rho\|_p,\end{aligned} \tag{56}$$

which shows (34).

For odd-dimensional cases, we can employ (53) to get

$$\begin{aligned}\rho &= \sum_{\boldsymbol{a}_1,\boldsymbol{a}_2} W^{\mathrm{DV}}_\rho(\boldsymbol{a}_1,\boldsymbol{a}_2)A(\boldsymbol{a}_1,\boldsymbol{a}_2)\\ &= \sum_{\boldsymbol{a}_1,\boldsymbol{a}_2} x_\rho(\boldsymbol{a}_1,\boldsymbol{a}_2)O_{\boldsymbol{a}_1,\boldsymbol{a}_2}\\ &= \sum_{\boldsymbol{a}_1,\boldsymbol{a}_2} x_\rho(\boldsymbol{a}_1,\boldsymbol{a}_2)(-1)^{\boldsymbol{a}_1\cdot\boldsymbol{a}_2}A(\sigma[\boldsymbol{a}_1,\boldsymbol{a}_2]^T).\end{aligned} \tag{57}$$

This particularly gives

$$\begin{aligned}\left\|W^{\mathrm{DV}}_\rho\right\|_p &= \left(\sum_{\boldsymbol{a}_1,\boldsymbol{a}_2}\left|W^{\mathrm{DV}}_\rho(\boldsymbol{a}_1,\boldsymbol{a}_2)\right|^p\right)^{1/p}\\ &= \left(\sum_{\boldsymbol{l},\boldsymbol{m}}\left|(-1)^{\boldsymbol{l}\cdot\boldsymbol{m}}x_\rho(\boldsymbol{l},\boldsymbol{m})\right|^p\right)^{1/p}\\ &= \|x_\rho\|_p.\end{aligned} \tag{58}$$

This, together with (34), shows (36), completing the proof. □

This concludes the section on establishing a connection between magic and non-Gaussianity with Wigner functions.

B. Via characteristic function

In this section, we use the formalism of characteristic functions to establish a connection between magic and non-Gaussianity similar to the one found in the previous section.

The characteristic function of a qudit state $\rho = \sum_{\boldsymbol{u},\boldsymbol{v}\in\mathbb{Z}^n_d}\rho_{\boldsymbol{u},\boldsymbol{v}}\left|\boldsymbol{u}\right\rangle\left\langle\boldsymbol{v}\right|$ encoded in GKP offers a striking connection to finite-dimensional systems as well. The characteristic function of a qudit encoded in GKP can then be written as

$$\begin{aligned}&\chi^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(\boldsymbol{r})\\ &= \sqrt{\frac{2\pi}{d}}\sum_{l,m=-\infty}^{\infty}\gamma_{\rho_{\mathrm{GKP}}}(l,m)\delta\left(p-m\sqrt{\frac{2\pi}{d}}\right)\delta\left(q-l\sqrt{\frac{2\pi}{d}}\right).\end{aligned} \tag{59}$$

We show the derivation in Appendix E.

The following result establishes the fundamental connection between the discrete characteristic function and the continuous-variable characteristic function of GKP states that encodes the discrete-variable state.

Theorem 4. *Let ρ be an n-qudit state on a d^n-dimensional space. For $\boldsymbol{l},\boldsymbol{m}\in\mathbb{Z}^n_{2d}$, it holds that*

$$\gamma_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m}) = d^n\omega_d^{-\boldsymbol{l}\cdot\boldsymbol{m}/2}\omega_D^{-\boldsymbol{l}\cdot\boldsymbol{m}/2}\chi^{\mathrm{DV}}_\rho(\boldsymbol{l},\boldsymbol{m})^* \tag{60}$$

In particular,

$$d^{n(1-1/p)}\|\chi^{\mathrm{DV}}_\rho\|_p = \frac{\|\chi^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}\|_{p,\mathrm{cell}}}{\|\chi^{\mathrm{CV}}_{\mathrm{STAB,GKP}}\|_{p,\mathrm{cell}}} \tag{61}$$

where

$$\begin{aligned}\|\chi^{\mathrm{CV}}_{\mathrm{STAB,GKP}}\|_{p,\mathrm{cell}} &\coloneqq \|\chi^{\mathrm{CV}}_{\phi_{\mathrm{GKP}}}\|_{p,\mathrm{cell}}\\ &= \left(\frac{2\pi}{d}\right)^{n/2}(4d)^{n/p}\end{aligned} \tag{62}$$

is a quantity that takes the same value for every pure stabilizer state ϕ.

The proof can be found in Appendix E. This gives us a direct connection to the $\alpha-$stabilizer Rényi entropy defined for multi-qubits [28], which has recently been shown to be a magic monotone under stabilizer protocols for $\alpha \geq 2$ [44]. Our result also provides an immediate generalization to all dimensions. The natural extension of the $\alpha-$stabilizer Rényi entropy to n-qudit state is

$$\begin{aligned}&M_\alpha(\rho)\\ &= (1-\alpha)^{-1}\log\left(d^{-n\alpha}\sum_{P\in\mathcal{P}^*_n}\left|\mathrm{Tr}\left(\rho P\right)\right|^{2\alpha}\right) - n\log d\\ &= \alpha(1-\alpha)^{-1}\log\left\|\Xi(\rho)\right\|_\alpha - n\log d\end{aligned} \tag{63}$$

where $\mathcal{P}^*_n$ is the projective generalized Pauli (Heisenberg-Weyl) group which only contains $+1$ phase, $\Xi_P(\rho) = \frac{1}{d^n}\,\mathrm{Tr}\left(\rho P\right)^2$ forms a probability distribution when ρ is pure.

Thus, we see immediately by comparison that we can write all α-stabilizer Rényi entropies with the $l_{2\alpha}$-norm of the continuous-variable characteristic function for the qudit state that the GKP state encodes. Specifically, we have

$$\begin{aligned}M_\alpha(\rho) &= \frac{2\alpha}{1-\alpha}\log\|\chi^{\mathrm{DV}}_\rho\|_{2\alpha} - n\log d\\ &= \frac{2\alpha}{1-\alpha}\log\frac{\|\chi^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}\|_{2\alpha,\mathrm{cell}}}{\|\chi^{\mathrm{CV}}_{\mathrm{STAB,GKP}}\|_{2\alpha,\mathrm{cell}}} - \frac{\alpha\, n\log d}{1-\alpha}\end{aligned} \tag{64}$$

where in the second equality we used Theorem 4.

IV. SIMULATION ALGORITHMS

In this section, we provide simulation algorithms that use magic measures based on the connections we established with the Wigner and characteristic functions. We give the technical details in Appendix F.

A. Wigner function

The magic measures that were inspired by the continuous Wigner function allow for a nice operational interpretation of the simulation cost of a quantum circuit. Pashayan *et al.* [37] introduced a simulation algorithm for quasi-probability distributions that strictly resemble the discrete Wigner functions in odd dimensions. These ideas were used to adapt the simulator to multi-qubit cases by Rall *et al.* [38]. Using our unified approach that works for all dimensions, we can extend the simulator by Pashayan *et al.* to all dimensions and recover the simulator of Rall *et al.* for $d = 2$ (see Appendix F). The simulation time scales with the amount of negativity in the entire circuit defined as

$$\mathcal{M}_{\rightarrow} = \|x_\rho\|_1 \prod_{t=1}^{T} \max_{\boldsymbol{\lambda_t}} \|x_{U_t}(\boldsymbol{\lambda_t})\|_1 \max_{\boldsymbol{\lambda_T}} |x_\Pi(\boldsymbol{\lambda_T})| \tag{65}$$

where the maximum is taken over all trajectories and

$$x_\rho(\lambda) = \mathrm{Tr}\left(\rho \frac{O_{\boldsymbol{\lambda}}}{d^n}\right) \tag{66}$$

$$x_U(\lambda', \lambda) = \mathrm{Tr}\left(\frac{O_{\boldsymbol{\lambda'}}}{d^n} U O_{\boldsymbol{\lambda}} U^\dagger\right) \tag{67}$$

$$x_\Pi(\lambda) = \mathrm{Tr}\,(\Pi O_{\boldsymbol{\lambda}}). \tag{68}$$

are the coefficients related to the input state ρ, the unitary evolution U and the measurement effect Π with $\lambda = (\boldsymbol{l}, \boldsymbol{m}) \in \mathbb{Z}_d^{2n}$. The number of samples K that achieves precision ϵ with a failure probability p_f is given by

$$K \geq 2\mathcal{M}_{\rightarrow}^2 \frac{1}{\epsilon^2} \ln\left(\frac{2}{p_f}\right). \tag{69}$$

This shows that the number of samples directly scales with the resourcefulness of the input state $\|x_\rho\|_1$ if we evolve using the free operations of our magic quantifiers like Clifford unitaries. This result gives a nice operational interpretation of the quantifiers discussed in this work, as already noted in the case for the discrete Wigner negativity [37].

A few comments on the difference between even and odd dimensional systems are in order. For odd dimensional systems, it holds $\|x_\rho\|_1 \geq 1$, whereas it is possible for qubits that $\|x_\rho\|_1 \leq 1$ for specific states which reduce the number of samples needed. These qubit states are discussed in [38] and are called hyperoctahedral states. We show that this phenomenon exists in all even dimensions and call these states hyperpolyhedral states. See Appendix G for details. However, for pure states, it holds that $\|x_\rho\|_1 \geq 1$.

Another interesting difference between even and odd dimensions when Pauli measurements are involved is that the simulator is less competitive in even dimensions. The cost of measurements is taken into account via the term

$$\max_{\lambda_T} |x_\Pi(\lambda_T)|. \tag{70}$$

Since for odd-dimensional systems $O_{\boldsymbol{l},\boldsymbol{m}}$ has trace 1, computational basis measurements do not increase the simulation time. This is not the case for even dimensions. In this case, the measurements increase simulation time, as was noted by Rall *et al.* [38].

Let us assume that we would like to measure k-qudits of our n-qudit system in a computational basis state $|\boldsymbol{i}\rangle$. The measurement effect then is given as $\Pi = \mathbb{1}_{n-k} \otimes |\boldsymbol{i}\rangle\langle\boldsymbol{i}|$. Without loss of generality, assume the measurement of the state $|\boldsymbol{1}\rangle\langle\boldsymbol{1}|$, the state with all measured qudit in the 1 state. The expansion of a qudit in the operators $O_{l,m}$ is $|1\rangle\langle 1| = \frac{1}{d}\sum_{i=1}^{d-1} O_{2,i}$. The cost inferred from the measurement is then

$$\max_{\lambda_T} |x_\Pi(\lambda_T)| = \max_{\boldsymbol{l},\boldsymbol{m}} |\mathrm{Tr}\,[O_{\boldsymbol{l},\boldsymbol{m}} \mathbb{1}_{n-k} \otimes |\boldsymbol{1}\rangle\langle\boldsymbol{1}|]| \tag{71}$$

$$= \max_{\boldsymbol{l_{n-k}},\boldsymbol{m_{n-k}}} \left|\mathrm{Tr}\left[O_{\boldsymbol{l_{n-k}},\boldsymbol{m_{n-k}}}\right]\right| \max_{\boldsymbol{l_k},\boldsymbol{m_k}} |\mathrm{Tr}\,[O_{\boldsymbol{l_k},\boldsymbol{m_k}} |\boldsymbol{1}\rangle\langle\boldsymbol{1}|]| \tag{72}$$

The maximum trace $|\mathrm{Tr}\,[O_{\boldsymbol{l_k},\boldsymbol{m_k}} |\boldsymbol{1}\rangle\langle\boldsymbol{1}|]|$ is 1 for both even and odd dimensions. However, for the first term there is a big difference between even and odd dimensions. For odd dimensions the trace of $O_{\boldsymbol{l},\boldsymbol{m}}$ is ± 1, so unmeasured qudits do not add to the simulation cost in any way. This is not the case for even dimensions. In even dimensions the trace of a single qudit operator $O_{l,m}$ is either 0 or 2. Therefore, the maximum of the first term $\left|\mathrm{Tr}\left[O_{\boldsymbol{l_{n-k}},\boldsymbol{m_{n-k}}}\right]\right|$ is 2^{n-k}, and thus the number of unmeasured qudits increase the number of samples required exponentially.

B. Characteristic function

The same ideas can be used to construct a simulator that is based on characteristic functions. It will reduce to the simulator by Rall *et al.* [38] for $d = 2$. The simulation cost scales with a resource quantified using magic measures based on the connection of the characteristic functions.

Instead of representing the quantum state in the basis of $O_{\boldsymbol{l},\boldsymbol{m}}$, we use the Heisenberg-Weyl operators $P_d(\boldsymbol{l}, \boldsymbol{m})$ defined in (8) as our basis. Since they are unitary and traceless (with the exception of the identity operator) a few small modification are in order. A qudit state ρ and its characteristic function χ_ρ^{DV} can be written as

$$\rho = \frac{1}{d}\sum_{\boldsymbol{l},\boldsymbol{m}} \chi_\rho^{\mathrm{DV}}(\boldsymbol{l}, \boldsymbol{m}) P_d(\boldsymbol{l}, \boldsymbol{m}) \tag{73}$$

with $\chi_\rho^{\mathrm{DV}}(\boldsymbol{0}, \boldsymbol{0}) = 1$, since $P_d(\boldsymbol{0}, \boldsymbol{0}) = \mathbb{1}$. Furthermore, since the density operator is Hermitian, it holds that

$$\sum_{\boldsymbol{l},\boldsymbol{m}} \chi_\rho^{\mathrm{DV}}(\boldsymbol{l}, \boldsymbol{m}) P_d(\boldsymbol{l}, \boldsymbol{m}) = \sum_{\boldsymbol{l},\boldsymbol{m}} \left[\chi_\rho^{\mathrm{DV}}(\boldsymbol{l}, \boldsymbol{m})\right]^* P_d(\boldsymbol{l}, \boldsymbol{m})^\dagger. \tag{74}$$

Therefore, many coefficients in the decomposition are redundant. For Heisenberg-Weyl operators it holds that

$$P^\dagger(\boldsymbol{l}, \boldsymbol{m}) = \omega_D^{\boldsymbol{l}\cdot\boldsymbol{m}} P(-\boldsymbol{l}, -\boldsymbol{m}) \tag{75}$$

and therefore

$$\left[\chi_\rho^{\mathrm{DV}}(\boldsymbol{l}, \boldsymbol{m})\right]^* = \omega_D^{\boldsymbol{l}\cdot\boldsymbol{m}} \chi_\rho^{\mathrm{DV}}(-\boldsymbol{l}, -\boldsymbol{m}). \tag{76}$$

This implies that we have only $\frac{d^2-1}{2}$ independent coefficients in the decomposition. Thus, we can only sample from the independent coefficients, since they are pairwise dependent.

The rest of the algorithm works equivalently. The simulation times scale with the negativity of the entire circuit which is here re-expressed as

$$\mathcal{M}_{\rightarrow}^{\chi} = \left\|\chi_{\rho}^{\mathrm{DV}}\right\|_1 \prod_{t=1} \max_{\lambda_t} \left\|\chi_{U_t}^{\mathrm{DV}}(\lambda_t)\right\|_1 \max_{\lambda_T} \left|\chi_{\Pi}^{\mathrm{DV}}(\lambda_T)\right| \tag{77}$$

with

$$\chi_{\rho}^{\mathrm{DV}}(\lambda) = \mathrm{Tr}\left(\rho \frac{P^{\dagger}(\lambda)}{d^n}\right) \tag{78}$$

$$\chi_{U}^{\mathrm{DV}}(\lambda', \lambda) = \mathrm{Tr}\left(\frac{P^{\dagger}(\lambda')}{d^n} U P(\lambda) U^{\dagger}\right) \tag{79}$$

$$\chi_{\Pi}^{\mathrm{DV}}(\lambda') = \mathrm{Tr}\left(\Pi P(\lambda)\right). \tag{80}$$

The simulator behaves similarly to the previous one for even dimensions. The same simulation time increase happens for unmeasured qudits, and the operations that do not increase the runtime are quite limited.

V. MAGIC NEEDS NON-GAUSSIANITY

It has been known since the original GKP paper [36] that one can implement the logical T-gate and thus get an H-type magic state by using a cubic phase state or cubic interaction e^{icQ^3}. However, this is merely one possibility for implementing a non-Gaussian interaction, and this does not show the necessity of non-Gaussianity to implement a non-Clifford operation on the code subspace. This is a widely held belief based on the correspondence between a pair of Pauli and displacement operators and that of Clifford and Gaussian operations, where displacement operators and Pauli operators are both Heisenberg-Weyl operators. However, this "belief" has not been proven in general, beyond specific scenarios in qubit systems [39]. Indeed, GKP states have much Wigner negativity and thus *a priori* additional non-Gaussianity may not be required, making the necessity of non-Gaussian operation to implement a non-Clifford operation nontrivial.

Nevertheless, the results established above allow us to show that non-Gaussian operations are essential to implement non-stabilizer operations in the GKP code space. In fact, we find that the Gaussian *protocols* [5]—a class of quantum channels larger than Gaussian operations, which also admits feed-forwarded Gaussian operations conditioned on the outcomes of Gaussian measurements—are not able to implement non-stabilizer operations in the GKP code space. Importantly, Gaussian protocols include a gate teleportation circuit involving a Gaussian measurement and a feed-forwarded Gaussian unitary, which itself is not a Gaussian operation [45].

Theorem 5. *Let Λ be a quantum channel with n-qubit input and output. If there exists a pure stabilizer state ϕ and a pure non-stabilizer state ψ such that $\Lambda(\phi) = \psi$, Λ cannot be implemented in a GKP code space by a Gaussian protocol. Also, for a quantum channel Λ with n-qudit input and output systems with odd local dimensions, the condition can be relaxed to the existence of a (potentially mixed) stabilizer state σ and a state ρ with $\|W_{\rho}^{\mathrm{DV}}\|_1 > 1$ such that $\Lambda(\sigma) = \rho$.*

Proof. Suppose that Λ can be implemented in the GKP code space by a Gaussian protocol $\mathcal{G}$, i.e., $\mathcal{G}(\sigma_{\mathrm{GKP}}) = \rho_{\mathrm{GKP}}$ for qudit states σ and ρ such that $\Lambda(\sigma) = \rho$. Since $\|W_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}$ does not increase under Gaussian protocols [5, 6, 29], we get

$$\|W_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{1,\mathrm{cell}} = \|W_{\mathcal{G}(\sigma_{\mathrm{GKP}})}^{\mathrm{CV}}\|_{1,\mathrm{cell}} \leq \|W_{\sigma_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}. \tag{81}$$

Because of the assumption that ρ is also an n-qudit state, Theorem 1 and (81) imply that

$$\begin{aligned} \|x_{\sigma}\|_1 &= \frac{\|W_{\sigma_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}}{\|W_{\mathrm{STAB}_n,\mathrm{GKP}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}} \\ &\geq \frac{\|W_{\rho_{\mathrm{GKP}}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}}{\|W_{\mathrm{STAB}_n,\mathrm{GKP}}^{\mathrm{CV}}\|_{1,\mathrm{cell}}} \\ &= \|x_{\rho}\|_1. \end{aligned} \tag{82}$$

Suppose that the input state σ is a pure stabilizer state denoted by ϕ and the output state ρ is a pure non-stabilizer state ψ. Since $\|x_{\xi}\|_1$ is faithful for pure states as shown in Sec. III A, i.e., for a pure state ξ, $\|x_{\xi}\|_1 = 1$ if and only if ξ is a stabilizer state, we get $\|x_{\phi}\|_1 = 0$ and $\|x_{\psi}\|_1 > 0$. This is a contradiction with (82), showing that such a channel Λ cannot be implemented by a Gaussian protocol.

The statement for odd dimensions follows by the same argument using the relation (36).

□

An immediate consequence is that a Gaussian protocol cannot implement non-Clifford unitary gates deterministically. This does not contradict the protocol by Baragiola *et al.* [46], which requires many auxiliary GKP states—making the whole operation involving the preparation of such ancillary states highly non-Gaussian—to apply a single non-Clifford gate. In addition, their protocol is probabilistic and, therefore, does not directly fall into the scope of our result, which is pertinent to deterministic operations.

VI. CONCLUSION AND OUTLOOK

In this work, we established a fundamental relation between discrete- and continuous-variable systems via the Gottesman-Kitaev-Preskill encoding. We introduced a family of distributions for discrete-variable systems and showed that their l_p-norm exactly corresponds to that of the continuous Wigner function that encodes the same qudit states via GKP encoding. Notably, the discrete-variable distribution coincides with the discrete Wigner function for odd dimensions, allowing us to connect the negativity of Wigner functions of discrete and continuous variables for $p = 1$. More generally, our distributions allow for defining a magic quantifier for all dimensions and extend the discrete Wigner negativity defined for odd dimensions and the stabilizer Rényi entropy defined for multiqubit systems in a unified manner. Furthermore, we showed that the l_p-norm of the discrete-variable characteristic function corresponds to the characteristic function of a GKP state that encodes the same qudit state. This provides a new interpretation of the stabilizer Rényi entropy in terms of the GKP encoding and naturally extends it to all dimensions. Employing this framework, we introduced a classical simulation algorithm, where the run time scales with the magic measures we introduced. The first algorithm is based on the magic measures connected to the continuous Wigner function and recovers the simulator in Ref. [37], while the second one is based on the magic measures connected to the continuous characteristic function. Both algorithms give a strong operational interpretation to the magic measures we introduced. We utilized our findings to demonstrate that achieving a deterministic implementation of a logical non-Clifford operation, with identical input and output dimensions within the GKP code subspace, necessitates a non-Gaussian operation, even when operating at the theoretical limit of ideal GKP state input.

Our framework offers a novel approach to analyzing magic and non-Gaussian resources by employing tools developed for the other. This begs the question of whether we can investigate more properties of finite-dimensional systems using infinite-dimensional ones or vice versa. Furthermore, we have seen that the magic measures defined in this work behave differently for even and odd dimensions. An interesting future direction is to further investigate the origin of this behavior. Finally, being able to investigate and see the dependence of the dimensionality could shed new light on the source of quantum speed-ups.

Note added.—During the completion of this manuscript, a related independent work by Lingxuan Feng and Shunlong Luo [47] was brought to our attention, where the authors found a complementary relation between the description of a qudit state and continuous-variable Wigner function of the corresponding GKP state.

Appendix A: l_p norm and renormalization

In this section, we formalize a way to compute the l_p norm of the characteristic function as well as the Wigner function of GKP states. Note here that the l_1 norm of the Wigner function is the Wigner negativity. The l_p norm is defined as

$$\|f\|_p = \left(\int \mathrm{d}\boldsymbol{x} |f(\boldsymbol{x})|^p\right)^{\frac{1}{p}}. \tag{A1}$$

We are interested in computing the l_p-norm of characteristic and Wigner functions of GKP states, so we deal with sums of Dirac distribution, where the distributions have disjoint support

$$\begin{aligned}&\left(\int_{-\infty}^{\infty} \mathrm{d}\boldsymbol{x} \left|\sum_i f_i(\boldsymbol{x})\delta(\boldsymbol{x}-\boldsymbol{x}_i)\right|^p\right)^{\frac{1}{p}} \\ &= \left(\sum_i |f_i(\boldsymbol{x}_i)|^p \delta(0)^{p-1}\right)^{\frac{1}{p}} = \left(\sum_i |f_i(\boldsymbol{x}_i)|^p\right)^{\frac{1}{p}} \delta(0)^{\frac{p-1}{p}}.\end{aligned} \tag{A2}$$

This integral evaluates to the same Dirac distribution $\delta(0)^{(p-1)/p}$ for all GKP states, which will be canceled by dividing it by the l_p-norm for another GKP state as in Theorems 1 and 4. Therefore, we will define the norm as

$$\begin{aligned}&\left(\int_{-\infty}^{\infty} \mathrm{d}\boldsymbol{x} \left|\sum_i f_i(\boldsymbol{x})\delta(\boldsymbol{x}-\boldsymbol{x}_i)\right|^p\right)^{\frac{1}{p}} \\ &= \left(\int_{-\infty}^{\infty} \mathrm{d}\boldsymbol{x} \left|\sum_i f_i(\boldsymbol{x})\right|^p \delta(\boldsymbol{x}-\boldsymbol{x}_i)\right)^{\frac{1}{p}} \\ &= \left(\sum_i |f_i(\boldsymbol{x}_i)|^p\right)^{\frac{1}{p}}\end{aligned} \tag{A3}$$

as a kind of regularization.

Appendix B: Proof of Proposition 2

In this section, we derive the atomic form of a n-qudit state encoded in the Gottesman-Kitaev-Preskill (GKP) code. We call the representation atomic if each Dirac distribution with different support appears only once in the summation, thus all Dirac distributions are distinct. We start deriving the atomic form for one qudit encoded in GKP and then generalize it to n-qudit systems.

1. One Qudit

For a single qudit, the Wigner function of a computational basis state $|j\rangle\langle j|$ encoded in GKP are

$$\begin{aligned}&W^{\mathrm{CV}}_{|j\rangle\langle j|_{\mathrm{GKP}}}(r_q, r_p) \\ &\propto \sum_{s,t=-\infty}^{\infty} (-1)^{st} \delta(r_p - \frac{\pi}{d\alpha} s)\delta(r_q - \alpha j - \frac{d\alpha}{2} t).\end{aligned} \tag{B1}$$

In order to derive the Wigner function of an arbitrary qudit state $\rho = \sum_{u,v\in\mathbb{Z}_d} \rho_{u,v} \left|u\right\rangle \left\langle v\right|$ encoded in the GKP code, we expand our state in the computational basis

$$W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(r_q,r_p) = \sum_{u,v\in\mathbb{Z}_d} \rho_{uv} \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathrm{d}x\, e^{ir_p x} \left[\sum_{s=-\infty}^{\infty} \delta\left(r_q + \frac{x}{2} - \sqrt{\frac{2\pi}{d}}(u+ds)\right)\right] \left[\sum_{t=-\infty}^{\infty} \delta\left(r_q - \frac{x}{2} - \sqrt{\frac{2\pi}{d}}(v+dt)\right)\right]. \tag{B2}$$

We then use the linearity of the Wigner function and get cross terms between the computational basis states j and k

$$\begin{aligned}
W^{\mathrm{CV}}_{|j\rangle\langle k|_{\mathrm{GKP}}}(r_q,r_p) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathrm{d}x e^{ir_p x} \left[\sum_{s=-\infty}^{\infty} \delta\left(r_q + \frac{x}{2} - \sqrt{\frac{2\pi}{d}}(j+ds)\right)\right] \left[\sum_{t=-\infty}^{\infty} \delta\left(r_q - \frac{x}{2} - \sqrt{\frac{2\pi}{d}}(k+dt)\right)\right] \\
&= \frac{1}{2\cdot 2\pi} \sum_{s,t} e^{2ir_p(r_q - \sqrt{\frac{2\pi}{d}}(k+dt))} \delta\left(r_q - \sqrt{\frac{\pi}{2d}}[j+k+ds+dt]\right) \\
&= \frac{1}{2\cdot 2\pi} \sum_{s,t} e^{2ir_p(q - \sqrt{\frac{2\pi}{d}}(k+dt-ds))} \delta\left(r_q - \sqrt{\frac{\pi}{2d}}[j+k+dt]\right) \\
&= \frac{1}{2\cdot 2\pi} \sum_{s,t} e^{2ir_p\sqrt{\frac{2\pi}{d}}ds} e^{2ir_p(r_q - \sqrt{\frac{2\pi}{d}}(k+dt))} \delta\left(r_q - \sqrt{\frac{\pi}{2d}}(j+k+dt)\right) \\
&= \frac{1}{2\cdot 2\pi} \sum_{s,t} \delta\left(\sqrt{\frac{2d}{\pi}} r_p - s\right) \delta\left(r_q - \sqrt{\frac{\pi}{2d}}(j+k+dt)\right) e^{2ir_p(\sqrt{\frac{\pi}{2d}}(j+k+dt) - \sqrt{\frac{2\pi}{d}}(k+dt))} \\
&= \frac{1}{2\sqrt{2\pi d}} \sum_{s,t} \delta\left(r_p - s\sqrt{\frac{\pi}{2d}}\right) \delta\left(r_q - \sqrt{\frac{\pi}{2d}}(j+k+dt)\right) e^{ir_p\sqrt{\frac{2\pi}{d}}(j-k-dt)},
\end{aligned} \tag{B3}$$

where we used the Poisson resummation formula

$$\sum_{n=-\infty}^{\infty} e^{i2\pi nx} = \sum_{k=-\infty}^{\infty} \delta(x-k). \tag{B4}$$

We simplify (B2) by using (B3) and arrive at

$$W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(r_q,r_p) = \frac{1}{\sqrt{8\pi d}} \sum_{u,v=0}^{d-1} \rho_{u,v} \sum_{s,t} (-1)^{s(u-v-dt)/d} \delta\left(r_p - s\sqrt{\frac{\pi}{2d}}\right) \delta\left(r_q - \sqrt{\frac{\pi}{2d}}(u+v+dt)\right). \tag{B5}$$

We need to find the coefficients $c_{\rho_{\mathrm{GKP}}}(l,m)$ such that

$$\begin{aligned}
&W_{\rho_{\mathrm{GKP}}}(r_q,r_p) \\
&= \frac{\sqrt{d}}{\sqrt{8\pi}} \sum_{l,m} c_{\rho_{\mathrm{GKP}}}(l,m) \delta\left(r_p - m\sqrt{\frac{\pi}{2d}}\right) \delta\left(r_q - l\sqrt{\frac{\pi}{2d}}\right)
\end{aligned} \tag{B6}$$

only has disjoint support for each Dirac distribution in the summation.

By inspection of Eq. (B5), we immediately see that $\delta\big(r_p - s\sqrt{\frac{\pi}{2d}}\big)$ is already in the correct form and thus will only contribute a phase with $s = m$. Furthermore, we restrict the GKP state to one until the cell of length $\sqrt{2d\pi}$, so each m, l can have $2d$ values $m, l \in \{0, 1, ..., 2d-1\}$. For now, let us consider $s = m = 0$. Then we get the same Dirac distribution for q if $u + v + dt = l$. This requirement can be simplified if we remember that we consider only a unit cell and thus $u+v \mod d = l$. Consequently the matrix element $c_{\rho_{\mathrm{GKP}}}(l,0)$ will be a sum of $\rho_{u,v}$ with $u+v \mod d = l$. We can write this as

$$c_{\rho_{\mathrm{GKP}}}(l,0) = d^{-1}\operatorname{Tr}(\rho M_l) \tag{B7}$$

with

$$M_l = \sum_{\substack{u,v\in\mathbb{Z}_d\\ u+v \bmod d = l}} |u\rangle\langle v| \,. \tag{B8}$$

As an example, if we take qubits $d=2$

$$M_0 = \begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix} \quad M_1 = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix} \tag{B9}$$

so we retrieve the identity and Pauli X. For qutrits $d=3$ we get

$$M_0 = \begin{pmatrix}1 & 0 & 0\\ 0 & 0 & 1\\ 0 & 1 & 0\end{pmatrix} \; M_1 = \begin{pmatrix}0 & 1 & 0\\ 1 & 0 & 0\\ 0 & 0 & 1\end{pmatrix} \; M_2 = \begin{pmatrix}0 & 0 & 1\\ 0 & 1 & 0\\ 1 & 0 & 0\end{pmatrix} \tag{B10}$$

We now consider the general case with $m \neq 0$. Recalling $l = u+v+dt$, the contribution for $m \neq 0$ is given by the phase factor

$$\begin{aligned}\sum_m (-1)^{m(u-v-dt)/d} &= \sum_m (-1)^{m(2u-l)/d}\\ &= \sum_m e^{i\pi m(2u-l)/d} = \omega_d^{-ml/2}\omega_d^{mu}\end{aligned} \tag{B11}$$

where $\omega_d = e^{2\pi i/d}$ is the d th root of unity. This allows us to obtain the general form of matrix elements in (B6) as

$$\begin{aligned} c_{\rho_{\mathrm{GKP}}}(l,m) &= d^{-1}\omega_d^{-ml/2}\operatorname{Tr}(M_l Z_d^m \rho) && \text{(B12)}\\ &= d^{-1}\operatorname{Tr}(O_\rho(l,m)\rho) && \text{(B13)}\\ &= x_\rho(l,m). && \text{(B14)}\end{aligned}$$

This shows Proposition 2 in the case of $n=1$.

2. n-Qudits

In this section, we will derive the multi-qudit atomic form of GKP states. The state of an arbitrary n-qudit state is given as $\rho = \sum_{\boldsymbol{u},\boldsymbol{v}\in\mathbb{Z}_d^n}\rho_{\boldsymbol{u},\boldsymbol{v}}|\boldsymbol{u}\rangle\langle\boldsymbol{v}|$. The Wigner function for the GKP state that encodes this n-qudit state is then

$$\begin{aligned} &W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(\boldsymbol{r})\\ &= \sum_{\boldsymbol{u},\boldsymbol{v}\in\mathbb{Z}_d^n}\rho_{\boldsymbol{u},\boldsymbol{v}}\prod_{i=1}^n \frac{1}{2\pi}\int_{-\infty}^{\infty}\mathrm{d}r_{x_i}\, e^{ir_{p_i}r_{x_i}}\left[\sum_{s_i=-\infty}^{\infty}\delta\left(r_{q_i}+\frac{r_{x_i}}{2}-\sqrt{\frac{2\pi}{d}}(u_i+ds_i)\right)\right]\left[\sum_{t_i=-\infty}^{\infty}\delta\left(r_{q_i}-\frac{r_{x_i}}{2}-\sqrt{\frac{2\pi}{d}}(v_i+dt_i)\right)\right]\\ &= \frac{1}{(\sqrt{8\pi d})^n}\sum_{\boldsymbol{u},\boldsymbol{v}\in\mathbb{Z}_d^n}\rho_{\boldsymbol{u},\boldsymbol{v}}\prod_{i=1}^n\left[\sum_{s_i,t_i}(-1)^{\frac{s_i}{d}(u_i-v_i-dt_i)}\delta\left(r_{p_i}-\sqrt{\frac{\pi}{2d}}s_i\right)\delta\left(r_{q_i}-\sqrt{\frac{\pi}{2d}}(dt_i+u_i+v_i)\right)\right].\end{aligned} \tag{B15}$$

We are now ready to show Proposition 2 by confirming that

$$\begin{aligned} W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(\boldsymbol{r}) = \frac{\sqrt{d}^n}{\sqrt{8\pi}^n}&\sum_{\boldsymbol{l},\boldsymbol{m}} c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m})\\ &\times\delta\left(\boldsymbol{r_p}-\boldsymbol{m}\sqrt{\frac{\pi}{2d}}\right)\delta\left(\boldsymbol{r_q}-\boldsymbol{l}\sqrt{\frac{\pi}{2d}}\right)\end{aligned} \tag{B16}$$

coincides with (B15) by taking $c_{\rho_{\mathrm{GKP}}}(\boldsymbol{l},\boldsymbol{m}) = x_\rho(\boldsymbol{l},\boldsymbol{m})$. We note that

$$\begin{aligned} &x_\rho(\boldsymbol{l},\boldsymbol{m})\\ &= d^{-n}\omega_d^{-\boldsymbol{m}\cdot\boldsymbol{l}/2}\operatorname{Tr}(M_{l_1}\otimes\ldots\otimes M_{l_n}Z_d^{m_1}\otimes\ldots\otimes Z_d^{m_n}\rho)\\ &= d^{-n}\omega_d^{-\boldsymbol{m}\cdot\boldsymbol{l}/2}\operatorname{Tr}(M_{\boldsymbol{l}}Z_d^{\boldsymbol{m}}\rho)\end{aligned} \tag{B17}$$

with

$$\begin{aligned} &\operatorname{Tr}(M_{\boldsymbol{l}}Z_d^{\boldsymbol{m}}\rho)\\ &\quad= \sum_{\boldsymbol{u},\boldsymbol{v}\in\mathbb{Z}_d^n}\rho_{\boldsymbol{u},\boldsymbol{v}}\langle\boldsymbol{v}|\,M_{l_1}\otimes\ldots\otimes M_{l_n}Z_d^{m_1}\otimes\ldots\otimes Z_d^{m_n}\,|\boldsymbol{u}\rangle\\ &\quad= \sum_{\boldsymbol{u},\boldsymbol{v}\in\mathbb{Z}_d^n}\rho_{\boldsymbol{u},\boldsymbol{v}}\omega_d^{m_1u_1}\ldots\omega_d^{m_nu_n}\langle\boldsymbol{v}|\,M_{l_1}\otimes\ldots\otimes M_{l_n}\,|\boldsymbol{u}\rangle\,.\end{aligned} \tag{B18}$$

Note that $\langle\boldsymbol{v}|\,M_{l_1}\otimes\ldots\otimes M_{l_n}\,|\boldsymbol{u}\rangle = 1$ when

$$u_i+v_i+dt_i = l_i \tag{B19}$$

and $\langle\boldsymbol{v}|\,M_{l_1}\otimes\ldots\otimes M_{l_n}\,|\boldsymbol{u}\rangle = 0$ otherwise. Consequently, the Wigner function (B16) with the coefficients (B17) becomes

$$\begin{aligned}
W^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(\boldsymbol{r}) &= \frac{\sqrt{d}^n}{\sqrt{8\pi}^n}\sum_{\boldsymbol{l},\boldsymbol{m}} x_\rho(\boldsymbol{l},\boldsymbol{m})\delta\Big(\boldsymbol{r_p}-\boldsymbol{m}\sqrt{\frac{\pi}{2d}}\Big)\delta\Big(\boldsymbol{r_q}-\boldsymbol{l}\sqrt{\frac{\pi}{2d}}\Big)\\
&= \frac{1}{\sqrt{8\pi d}^n}\sum_{\boldsymbol{l},\boldsymbol{m}}\sum_{u,v\in\mathbb{Z}_d^n}\rho_{uv}\omega_d^{-\boldsymbol{m}\cdot\boldsymbol{l}/2}\omega_d^{m_1u_1}...\omega_d^{m_nu_n}\,\langle v|\,M_{l_1}\otimes...\otimes M_{l_n}\,|u\rangle\,\Big(\boldsymbol{r_p}-\boldsymbol{m}\sqrt{\frac{\pi}{2d}}\Big)\delta\Big(\boldsymbol{r_q}-\boldsymbol{l}\sqrt{\frac{\pi}{2d}}\Big)\\
&= \frac{1}{\sqrt{8\pi d}^n}\sum_{u,v\in\mathbb{Z}_d^n}\rho_{uv}\prod_{i=1}^n\sum_{m_i,t_i}\omega_d^{-m_i(u_i+v_i+dt_i)/2}\omega_d^{m_iu_i}\Big(r_{p_i}-m_i\sqrt{\frac{\pi}{2d}}\Big)\delta\Big(r_{q_i}-\sqrt{\frac{\pi}{2d}}(u_i+v_i+dt_i)\Big)\\
&= \frac{1}{\sqrt{8\pi d}^n}\sum_{u,v\in\mathbb{Z}_d^n}\rho_{uv}\prod_{i=1}^n\sum_{m_i,t_i}(-1)^{m_i(u_i-v_i-dt_i)/d}\Big(r_{p_i}-m_i\sqrt{\frac{\pi}{2d}}\Big)\delta\Big(r_{q_i}-\sqrt{\frac{\pi}{2d}}(u_i+v_i+dt_i)\Big)
\end{aligned} \tag{B20}$$

which coincides with (B15). This completes the proof of Proposition 2.

Appendix C: Proof of Property 3 of $\|x_\rho\|_1$

In this section, we prove a property of $\|x_\rho\|_1$ among those listed in Sec. III, specifically that $\|x_\phi\|_1 = 1$ for every pure stabilizer state ϕ and $\|x_\psi\|_1 \geq 1$ for every pure state ψ.

We have the requirement for a pure state ψ that

$$\mathrm{Tr}(\psi^2) = \sum_{\boldsymbol{l},\boldsymbol{m}} x_\psi(\boldsymbol{l},\boldsymbol{m})^2 d^n = 1, \tag{C1}$$

which implies

$$\sum_{\boldsymbol{l},\boldsymbol{m}}\mathrm{Tr}(O_{\boldsymbol{l},\boldsymbol{m}}\psi)^2 = d^n. \tag{C2}$$

Recalling that $O_{\boldsymbol{l},\boldsymbol{m}}$ has eigenvalues ± 1, it holds that $|\,\mathrm{Tr}(O_{\boldsymbol{l},\boldsymbol{m}}\psi)| \leq 1,\ \forall \boldsymbol{l},\boldsymbol{m}$. This gives

$$\sum_{\boldsymbol{l},\boldsymbol{m}}|\,\mathrm{Tr}(O_{\boldsymbol{l},\boldsymbol{m}}\psi)| \geq \sum_{\boldsymbol{l},\boldsymbol{m}}\mathrm{Tr}(O_{\boldsymbol{l},\boldsymbol{m}}\psi)^2 = d^n, \tag{C3}$$

showing $\|x_\psi\|_1 \geq 1$ for every pure state ψ.

Let ϕ be an arbitrary pure stabilizer state. Proposition 3 ensures that $|x_\phi(\boldsymbol{l},\boldsymbol{m})| = 1/d^n$ for d^n elements, leading to

$$\|x_\phi\|_1 = \sum_{\boldsymbol{l},\boldsymbol{m}}|x_\phi(\boldsymbol{l},\boldsymbol{m})| = \frac{1}{d^n}\cdot d^n = 1, \tag{C4}$$

completing the proof.

Appendix D: Properties of the operator basis

1. Basic properties

In this section, we will show the properties of the operator

$$O_{l,m} = \omega_d^{-ml/2}M_lZ_d^m. \tag{D1}$$

As mentioned in the main text, the parameters are $l,m\in\mathbb{Z}_{2d}$. We will first show a property that involves all $l,m\in\mathbb{Z}_{2d}$. It holds that

$$\sum_{l,m\in\mathbb{Z}_{2d}} O_{l,m} = \sum_{l,m\in\mathbb{Z}_{2d}}\sum_{x=0}^{d-1}\omega_d^{-m(\frac{l}{2}-x)}\,|{-x}+l\rangle\langle x| \tag{D2}$$

$$= \sum_{l\in\mathbb{Z}_{2d}}\sum_{x=0}^{d-1}\sum_{m\in\mathbb{Z}_{2d}}\omega_d^{-m(\frac{l}{2}-x)}\,|{-x}+l\rangle\langle x| \tag{D3}$$

$$= \sum_{x=0}^{d-1}\sum_{l\in\mathbb{Z}_{2d}}\delta_{l,2x}\,|{-x}+l\rangle\langle x| \tag{D4}$$

$$= \mathbb{1}. \tag{D5}$$

Thus by summing over all $l,m\in\mathbb{Z}_{2d}$ we can resolve the identity using the operators $O_{l,m}$. Using the operators, however, as an operators basis we do not need all $l,m\in\mathbb{Z}_{2d}$. It suffices to restrict to $l,m\in\mathbb{Z}_d$. If we now have a value above d, we have

$$M_l = M_{l+d} \tag{D6}$$

$$Z_d^m = Z_d^{m+d}. \tag{D7}$$

However, the phases can be different

$$\begin{aligned}
O_{l+d,m} &= \omega_d^{-m(l+d)/2}M_lZ_d^m\\
&= (-1)^mO_{l,m}\\
O_{l,m+d} &= \omega_d^{-l(m+d)/2}M_lZ_d^m\\
&= (-1)^lO_{l,m}\\
O_{l+d,m+d} &= \omega_d^{-(l+d)(m+d)/2}M_lZ_d^m\\
&= (-1)^{l+m+d}O_{l,m}.
\end{aligned} \tag{D8}$$

So we get the same operators with a different sign.

It is easy to see that M_l is Hermitian. M_l is also an involution meaning $M_l^2 = \mathbb{1}$

$$M_lM_l = \sum_{\substack{u+v \bmod d=l\\ u'+v' \bmod d=l}} |u\rangle\,\langle v|u'\rangle\,\langle v'| \tag{D9}$$

$$= \sum_{\substack{u+v \bmod d=l \\ v+v' \bmod d=l}} |u\rangle\langle v'| \tag{D10}$$

$$= \sum_{u=v' \bmod d} |u\rangle\langle v'| \tag{D11}$$

$$= \sum_u |u\rangle\!\langle u|\,. \tag{D12}$$

Therefore,

$$\begin{aligned} O_{l,m}O_{l,m}^\dagger &= M_l Z_d^m \left(Z_d^m\right)^\dagger M_l^\dagger \\ &= M_l M_l \\ &= \mathbb{1}. \end{aligned} \tag{D13}$$

This confirms that $O_{l,m}$ is unitary. The operator $O_{l,m}$ is also Hermitian

$$\begin{aligned} O_{l,m}^\dagger &= \left[\omega_d^{-ml/2} M_l Z_d^m\right]^\dagger \\ &= \left[\omega_d^{-ml/2} \sum_{u+v \bmod d=l} \omega_d^{vm} |u\rangle\langle v|\right]^\dagger \\ &= \omega_d^{ml/2} \sum_{u+v \bmod d=l} \omega_d^{-vm} |v\rangle\langle u| \\ &= \omega_d^{-ml/2} \sum_{u+v \bmod d=l} \omega_d^{m(l-v)} |v\rangle\langle u| \\ &= \omega_d^{-ml/2} \sum_{u+v \bmod d=l} \omega_d^{um} |v\rangle\langle u| \\ &= O_{l,m} \end{aligned} \tag{D14}$$

and thus also an involution

$$O_{l,m}O_{l,m} = \mathbb{1} \tag{D15}$$

because of (D13). This implies that its eigenvalue is ±1.

The operators are orthogonal under the Hilbert-Schmidt inner product

$$\begin{aligned} \mathrm{Tr}\left(O_{l,m}O_{l',m'}\right) &= \omega_d^{-ml/2}\omega_d^{-m'l'/2}\,\mathrm{Tr}\left(M_l Z_d^m M_{l'} Z_d^{m'}\right) \\ &= \omega_d^{mv}\omega_d^{m'v'}\omega_d^{-ml/2}\omega_d^{-m'l'/2} \\ &\times \mathrm{Tr}\left(\sum_{\substack{u+v \bmod d=l \\ v'+v \bmod d=l'}} |u\rangle\langle v'|\right) \\ &= \sum_{\substack{u+v \bmod d=l \\ u+v \bmod d=l'}} \omega_d^{mv+m'u}\omega_d^{-ml/2}\omega_d^{-m'l'/2}. \end{aligned} \tag{D16}$$

This is 0 if $l \neq l'$ because $l, l' \in [0, d-1]$. Now assume $l = l'$, then we get

$$\begin{aligned} \mathrm{Tr}\left(O_{l,m}O_{l,m'}\right) &= \sum_{u+v \bmod d=l} \omega_d^{mv}\omega_d^{m'u}\omega_d^{-ml/2}\omega_d^{-m'l/2} \\ &= \sum_{u+v \bmod d=l} \omega_d^{(m-m')(v-u)/2} \\ &= \sum_{v\in\mathbb{Z}_d} \omega_d^{\tilde{m}v} e^{-i\pi\tilde{m}l/d} \\ &= e^{-i\pi\tilde{m}l/d} \sum_{v\in\mathbb{Z}_d} \omega_d^{\tilde{m}v} \end{aligned} \tag{D17}$$

where we set $\tilde{m} := m - m'$. This is 0 if $\tilde{m} \neq 0$, i.e., $m \neq m'$ because a sum over roots of unity is 0. On the other hand, when $l = l'$ and $m = m'$ we get

$$\mathrm{Tr}\left(O_{l,m}O_{l,m}\right) = \sum_{v\in\mathbb{Z}_d} 1 = d. \tag{D18}$$

In conclusion, we have

$$\mathrm{Tr}\left(O_{l,m}O_{l',m'}\right) = \delta_{mm'}\delta_{ll'}d. \tag{D19}$$

As we have seen earlier, $O_{l,m}$ are the standard Pauli operators for $d = 2$. So for $d > 2$ the operators $O_{l,m}$ are a generalization of the Pauli operators to arbitrary dimensions with the property of being an involution and Hermitian. In general, M_l and $O_{l,m}$ behave differently for even and odd dimensions, so we will separate the discussion.

a. *Odd dimensions*

In this section, we assume that the dimension d is odd. Then, the trace is

$$\mathrm{Tr}\left(O_{l,m}\right) = \sum_{2x \bmod d=l} \omega_d^{-ml/2}\omega_d^{mx}. \tag{D20}$$

When l is even, the solution for $2x \mod d = l$ is $x = l/2$ and gives $\mathrm{Tr}(O_{l,m}) = 1$. When l is odd, the solution for $2x \mod d = l$ is $x = (d+l)/2$, which gives $\mathrm{Tr}(O_{l,m}) = (-1)^m$. These can concisely be written as

$$\mathrm{Tr}\left(O_{l,m}\right) = (-1)^{ml}. \tag{D21}$$

The operator M_l has more structure, as seen in Eq. 31 which we report here for convenience

$$M_l = \sum_{u+v \bmod d=l} |u\rangle\langle v| \tag{D22}$$

There are d possibilities to fulfill this equation, so the matrix representation of M_l in computational basis will have d ones and the rest 0. Furthermore, the diagonal entries $2u \mod d = l$ have only one solution for every l. Therefore, the matrix M_l has one diagonal term 1 and is zero otherwise. Consequently $\mathrm{Tr}\left(M_l\right) = 1$.

Recall that we introduced the operators $O_{l,m}$ as the ones that connect the GKP state to the qudit state it encodes. Remarkably, we can establish a direct connection between this and the phase space point operators in odd dimensions, which a priori may not have anything to do with the operators $O_{l,m}$. The phase space point operators are defined as

$$\begin{aligned}A(a_1,a_2) &= d^{-1}\sum_{b_1,b_2=0}^{d-1} e^{-2i\frac{\pi}{d}(a_1,a_2)\Omega_d(b_1,b_2)^T} e^{i\frac{\pi}{d}b_1b_2} \\ &\quad\times \left(X_d^\dagger\right)^{b_2}\left(Z_d^\dagger\right)^{b_1} \\ &= d^{-1}\sum_{b_1,b_2}\omega_d^{a_2b_1}\omega_d^{b_2(\frac{1}{2}b_1-a_1)}\left(X_d^\dagger\right)^{b_2}\left(Z_d^\dagger\right)^{b_1}.\end{aligned} \tag{D23}$$

Using the expansion of Z_d and X_d in the computational basis

$$\begin{aligned}Z_d^b &= \sum_x \omega_d^{bx}|x\rangle\langle x| \\ Z_d^{b,\dagger} &= \sum_x \omega_d^{-bx}|x\rangle\langle x| = Z(-b) \\ X_d^b &= \sum_x |x+b\rangle\langle x| \\ X_d^{b\dagger} &= \sum_x |x\rangle\langle x+b| = X(-b)\end{aligned} \tag{D24}$$

we can write the phase space point operator as

$$\begin{aligned}A(a_1,a_2) &= d^{-1}\sum_x\sum_{b_1b_2}\omega_d^{b_1(a_2+\frac{1}{2}b_2)}\omega_d^{-a_1b_2}X_d^{-b_2}Z_d^{-b_1} \\ &= d^{-1}\sum_x\sum_{b_1b_2}\omega_d^{b_1(a_2-x+\frac{1}{2}b_2)}\omega_d^{-a_1b_2}|x-b_2\rangle\langle x|.\end{aligned} \tag{D25}$$

In order to further simplify, we need the discrete resummation formula

$$\frac{1}{d}\sum_{k=0}^{d-1}e^{2i\pi\frac{kn}{d}} = \delta_{0,n}. \tag{D26}$$

The phase space point operators can then be simplified to

$$\begin{aligned}&A(a_1,a_2) \\ &= d^{-1}\sum_x\sum_{b_1b_2}\omega_d^{b_1(a_2-x+\frac{1}{2}b_2)}\omega_d^{-a_1b_2}|x-b_2\rangle\langle x| \\ &= \sum_x\sum_{b_2}\delta_{0,a_2-x+\frac{1}{2}b_2}\omega_d^{-a_1b_2}|x-b_2\rangle\langle x| \\ &= \sum_x\sum_{b_2}\delta_{b_2,2(x-a_2)}\omega_d^{-a_1b_2}|x-b_2\rangle\langle x| \\ &= \sum_x\omega_d^{-2a_1(x-a_2)}|x-2(x-a_2)\rangle\langle x| \\ &= \sum_x\omega_d^{2a_1a_2}\omega_d^{-2a_1x}|-x+2a_2\rangle\langle x|.\end{aligned} \tag{D27}$$

Using the following substitutions

$$\begin{aligned}u &= -x+2a_2 \\ v &= x \\ u+v &= 2a_2 = l\end{aligned} \tag{D28}$$

we rewrite the phase space point operators as

$$\begin{aligned}A(a_1,l) &= \sum_{u+v \bmod d=l}\omega_d^{-a_1l}\omega_d^{-2a_1v}|u\rangle\langle v| \\ &= \sum_{u+v \bmod d=l}\omega_d^{a_1l}\omega_d^{-2a_1u}|u\rangle\langle v|.\end{aligned} \tag{D29}$$

By comparing this equation with the definition of $O_{l,m}$, we can identify $m = -2a_1$ and we get

$$A(a_1,a_2) = O_{2a_2,-2a_1}. \tag{D30}$$

This shows that the operator basis $\{O_{l,m}\}_{l,m\in\mathbb{Z}_d}$ is equivalent to the phase space point operators $\{A(a_1,a_2)\}_{a_1,a_2\in\mathbb{Z}_d}$ up to permutation and phase factors. Indeed, the oddness of d and (D8) ensure that there is a one-to-one correspondence between $a_1,a_2\in\mathbb{Z}_d$ and $l,m\in\mathbb{Z}_d$ such that $A(a_1,a_2) = O_{2a_2,-2a_1} \propto O_{l,m}$ up to phase, as $2a_2$ and $-2a_1$ respectively takes all values in $\mathbb{Z}_d$ by changing $a_1,a_2\in\mathbb{Z}_d$, and O_{l_1,m_1} and O_{l_2,m_2} coincide up to phase if $l_1 = l_2 \bmod d$ and $m_1 = m_2 \bmod d$.

b. Even dimensions

Now we investigate the operators $O_{l,m}$ for the case of even-dimensional systems. The trace is

$$\mathrm{Tr}\left(O_{l,m}\right) = \sum_x\omega^{-ml/2}\sum_{u+v \bmod d=l}\omega^{mu}\langle x|u\rangle\langle v|x\rangle \tag{D31}$$

$$= \sum_{2x \bmod d=l}\omega^{-ml/2}\omega^{mx}, \tag{D32}$$

which vanishes if l is odd. Suppose l is even and write $l = 2k$. Then we get

$$\mathrm{Tr}\left(O_{l,m}\right) = \sum_{2x \bmod d=l}\omega^{-ml/2}\omega^{mx} \tag{D33}$$

$$= \omega^{-mk}\left(\omega^{mk}+\omega^{m(k+\frac{d}{2})}\right) \tag{D34}$$

$$= 1+\omega^{m\frac{d}{2}} \tag{D35}$$

$$= 1+(-1)^m. \tag{D36}$$

We have the same behavior for the operators M_l. For odd dimensions the equation $u+v \mod d = l$ has d solutions. Therefore, the matrix representation in computational basis will have d 1's with the rest being 0. For odd l, the equation $2u \mod d = l$ has no solution, implying $\mathrm{Tr}\left(M_l\right) = 0$ for odd l. For even l, the equation $2u \bmod d = l$ has two solutions, $u = l/2$ and $u = l/2+d/2$. Therefore, we have $\mathrm{Tr}\left(M_l\right) = 2$.

We can make here an interesting observation. It is known that for odd dimensions the phase space point operator at the origin $A(0,0)$ acts as the parity operation

$$A(0,0)|x\rangle = |-x\rangle \tag{D37}$$

for a computational basis state x. The operators $O_{l,m}$ show the same behavior for even dimensions and thus for all dimensions

$$O_{0,0}\left|x\right\rangle = M_0\left|x\right\rangle = \left|-x\right\rangle. \tag{D38}$$

2. Clifford Covariance

This section investigates how the operators $O_{l,m}$ transform under Clifford unitaries. We will see that they behave almost equivalently to the Heisenberg-Weyl operators.

X_d, Z_d generate the $d-$dimensional Heisenberg-Weyl group and $R, P,$ SUM the $d-$dimensional Clifford unitaries. their action of computational basis state are [40]

$$X_d : \left|j\right\rangle \to \left|j+1\right\rangle \tag{D39}$$

$$Z_d : \left|j\right\rangle \to \omega_d^j \left|j\right\rangle \tag{D40}$$

$$R : \left|j\right\rangle \to \sum_{s=0}^{d-1} \omega_d^{js}\left|s\right\rangle \tag{D41}$$

$$P : \left|j\right\rangle \to \omega_d^{j^2/2}(\omega_D \omega_{2d}^{-1})^{-j}\left|j\right\rangle \tag{D42}$$

$$\text{SUM} : \left|i\right\rangle\left|j\right\rangle \to \left|i\right\rangle\left|i+j \mod d\right\rangle \tag{D43}$$

A Clifford unitary U_C maps the Heisenberg-Weyl operators

$$P_d(a,b) = \omega_d^{\frac{1}{2}ab} X_d^a Z_d^b \tag{D44}$$

in the following way

$$U_C P_d(u) U_C^\dagger = P_d(Su) \tag{D45}$$

where S is a $2n \times 2n$ matrix with entries over $\mathbb{Z}_D$ with $D = d$ for d odd and $D = 2d$ for d even. Heisenberg-Weyl operators have the following commutation relations

$$\left(X_d^a Z_d^b\right)\left(X_d^{a'} Z_d^{b'}\right) = \omega_d^{(a,b)\Omega(a',b')^T}\left(X_d^{a'} Z_d^{b'}\right)\left(X_d^a Z_d^b\right). \tag{D46}$$

We are now interested in how Clifford unitaries and Pauli operators transform

$$O_{l,m} = \sum_{x=0}^{d-1} \omega_d^{-m(\frac{l}{2}-x)}\left|-x+l\right\rangle\left\langle x\right| \tag{D47}$$

with $l, m \in [0, 2d-1]$ or equivalently $\mathbb{Z}_{2d}$. The values the computational basis states can have are $\mod d$ and the operators Z_d^m, M_l are repeating for $m, l \geq d$. The difference for $m, l \geq d$ is the phase factor $\omega_d^{-ml/2}$ that repeats after $2d$. This phase factor is important for the action of Clifford unitaries on the operators $O_{l,m}$, while it can be essentially neglected if we only want to use them as a basis. We expect by our construction through GKP that Clifford unitaries map $O_{\boldsymbol{l},\boldsymbol{m}}$ to another $O_{\boldsymbol{l'},\boldsymbol{m'}}$ and therefore keeps the negativity invariant.

The QFT gate R transforms the operator $O_{l,m}$ as

$$RO_{\boldsymbol{l},\boldsymbol{m}}R^\dagger = \sum_{x=0}^{d-1} \omega_d^{-m(\frac{l}{2}-x)} R\left|-x+l\right\rangle\left\langle x\right| R^\dagger \tag{D48}$$

$$= \sum_{s,s'} \omega_d^{-ml/2}\omega_d^{sl} \sum_x \omega_d^{x(m-s-s')}\left|s\right\rangle\left\langle s'\right| \tag{D49}$$

$$= \sum_{s,s'} \omega_d^{-ml/2}\omega_d^{sl}\delta_{s,m-s'}\left|s\right\rangle\left\langle s'\right| \tag{D50}$$

$$= \sum_{s'} \omega_d^{-ml/2}\omega_d^{ml}\omega_d^{-ls'}\left|m-s'\right\rangle\left\langle s'\right| \tag{D51}$$

$$= \sum_x \omega_d^{ml/2}\omega_d^{-lx}\left|m-x\right\rangle\left\langle x\right| \tag{D52}$$

and therefore transforms the coordinates like

$$m \to -l \tag{D53}$$

$$l \to m. \tag{D54}$$

The Phase gate P behaves differently for even and odd dimensions. For odd dimensions, we get

$$\begin{aligned} PO_{\boldsymbol{l},\boldsymbol{m}}P^\dagger &= \sum_x \omega_d^{-ml/2}\omega_d^{mx}\omega_d^{(-x+l)(-x+l-1)/2}\omega_d^{-x(x-1)/2} \\ &\quad \times\left|-x+l\right\rangle\left\langle x\right| \\ &= \sum_x \omega_d^{-ml/2}\omega_d^{mx}\omega_d^{(l^2-l)/2}\omega_d^{x(1-l)}\left|-x+l\right\rangle\left\langle x\right| \\ &= \sum_x \omega_d^{-l(m-l+1)/2}\omega_d^{x(m-l+1)}\left|-x+l\right\rangle\left\langle x\right| \end{aligned} \tag{D55}$$

with the coordinates transforming like

$$m \to m-l+1 \tag{D56}$$

$$l \to l. \tag{D57}$$

For even dimensions we nearly get the same result

$$PO_{\boldsymbol{l},\boldsymbol{m}}P^\dagger = \sum_x \omega_d^{-ml/2}\omega_d^{mx}\omega_d^{(-x+l)^2/2}\omega_d^{-x^2/2}\left|-x+l\right\rangle\left\langle x\right| \tag{D58}$$

$$= \sum_x \omega_d^{-ml/2}\omega_d^{mx}\omega_d^{(l^2)/2}\omega_d^{-xl}\left|-x+l\right\rangle\left\langle x\right| \tag{D59}$$

$$= \sum_x \omega_d^{-l(m-l)/2}\omega_d^{x(m-l)}\left|-x+l\right\rangle\left\langle x\right| \tag{D60}$$

and

$$m \to m-l \tag{D61}$$

$$l \to l. \tag{D62}$$

The action of Z_d transform $O_{l,m}$ as

$$Z_d O_{\boldsymbol{l},\boldsymbol{m}} Z_d^\dagger = \sum_x \omega_d^{-ml/2}\omega_d^{mx}\omega_d^{-x+l}\omega_d^{-x}\left|-x+l\right\rangle\left\langle x\right| \tag{D63}$$

$$= \sum_x \omega_d^{-l(m-2)/2}\omega_d^{x(m-2)}\left|-x+l\right\rangle\left\langle x\right| \tag{D64}$$

with the coordinates transforming as

$$m \to m-2 \tag{D65}$$

$$l \to l. \tag{D66}$$

Similarly for X_d we get

$$X_d O_{\boldsymbol{l},\boldsymbol{m}} X_d^\dagger = \sum_x \omega_d^{-ml/2} \omega_d^{mx} \left|-x+l+1\right\rangle \left\langle x+1\right| \tag{D67}$$

$$= \sum_x \omega_d^{-ml/2} \omega_d^{m(x-1)} \left|-x+l+2\right\rangle \left\langle x\right| \tag{D68}$$

$$= \sum_x \omega_d^{-m(l+2)/2} \omega_d^{mx} \left|-x+l+2\right\rangle \left\langle x\right| \tag{D69}$$

and

$$m \to m \tag{D70}$$

$$l \to l+2. \tag{D71}$$

The missing gate for the full Clifford group is the SUM gate

$$\mathrm{SUM} O_{\boldsymbol{l},\boldsymbol{m}} \otimes O_{\boldsymbol{l'},\boldsymbol{m'}} \mathrm{SUM}^\dagger = \sum_{x,y} \omega_d^{-ml/2} \omega_d^{-m'l'/2} \omega_d^{mx} \omega_d^{m'y} \left|-x+l,-y-x+l'\right\rangle \left\langle x,y+x\right| \tag{D72}$$

$$= \sum_{x,y'} \omega_d^{-ml/2} \omega_d^{-m'l'/2} \omega_d^{mx} \omega_d^{m'(y'-x)} \left|-x+l,-y'+l'+l\right\rangle \left\langle x,y'\right| \tag{D73}$$

$$= \sum_{x,y'} \omega_d^{-ml/2} \omega_d^{-m'l'/2} \omega_d^{x(m-m')} \omega_d^{m'y'} \left|-x+l,-y'+l'+l\right\rangle \left\langle x,y'\right| \tag{D74}$$

and

$$m \to m-m' \tag{D75}$$

$$l \to l \tag{D76}$$

$$m' \to m' \tag{D77}$$

$$l' \to l'+l. \tag{D78}$$

So we can write down the matrices that transform the coordinates under the action of Clifford unitaries $U_C O_{\boldsymbol{l},\boldsymbol{m}} U_C^\dagger = O_{M_{U_C}[l,l',m,m']^T}$. The matrices have the basis (l,m) or l,l',m,m', without the constant shifts and are given as

$$P : \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix} \tag{D79}$$

$$R : \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \tag{D80}$$

$$\mathrm{SUM} : \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{D81}$$

These matrices are all symplectic and therefore they fulfill the relation

$$M^T \Omega M = \Omega \tag{D82}$$

$$\Omega = \begin{pmatrix} 0 & \mathbb{1} \\ -\mathbb{1} & 0. \end{pmatrix} \tag{D83}$$

Interestingly, Clifford unitaries act on the Heisenberg-Weyl operators in a very similar way. The matrices S in the basis a,b and a_1,a_2,b_1,b_2 are given as [40]

$$P' : \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} \tag{D84}$$

$$R' : \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \tag{D85}$$

$$\mathrm{SUM} : \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{D86}$$

where these matrices are over $\mathbb{Z}_D$ ($D = d$ for odd $D = 2d$ for even). It was shown that these matrices generate the symplectic group over $\mathbb{Z}_D$. We can connect our matrices (up to constant shifts) to these matrices

$$R^3 = R' = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \tag{D87}$$

$$P^{d-1} = P' = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} \tag{D88}$$

while the SUM gate is already in the correct form. So the action of a Clifford unitary on $O_{\boldsymbol{l},\boldsymbol{m}}$ is a symplectic transformation over $\mathbb{Z}_{2d}$ of l,m. There is, however, a constant shift for P in the odd dimensional case.

3. Stabilizer states (Proof of Proposition 3)

This section shows that pure stabilizer states are flat when decomposing in the operators $O_{l,m}$ meaning all operators have the same weight modulo signs. We can write the zero state in all dimensions as

$$|0\rangle\!\langle 0| = |0\rangle\!\langle 0| + \frac{1}{d}\sum_{j}\sum_{\substack{u+v \mod d=0\\ v\neq 0}} w_d^{jv}\,|u\rangle\,\langle v| = \frac{1}{d}\sum_{j=0}^{d-1} O_{0,j} = \frac{1}{d}\sum_{j} M_0 Z_d^j = \frac{1}{d}\sum_{j}\sum_{u+v \mod d=0} \omega_d^{jv}\,|u\rangle\,\langle v| \tag{D89}$$

where we used that

$$\sum_{j=0}^{d-1}\omega_d^{jv} = 0 \tag{D90}$$

for $v \neq 0$. We see that all $O_{l,m}$ have the same weight. Using that the operators $O_{l,m}$ are covariant under Clifford unitaries as shown in Appendix D 2, we see that every pure stabilizer state has a flat weight.

Appendix E: Proof of Theorem 4

We compute the characteristic function for a qudit state ρ encoded in a GKP state. We need to use the following property of the displacement operator

$$D(\boldsymbol{r}) = \prod_{j=1}^{n} e^{ir_{q_j}r_{p_j}/2} e^{ir_{q_j}P_j} e^{-ir_{p_j}Q_j}; \tag{E1}$$

Then, the characteristic function of a qudit encoded in a GKP state is given as

$$\begin{aligned}
\chi^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(\boldsymbol{r}) &= \mathrm{Tr}\left[\rho D(-\boldsymbol{r})\right]\\
&= \sum_{u,v\in\mathbb{Z}_d} \rho_{u,v}\,\langle u|\,D(-\boldsymbol{r})\,|v\rangle\\
&= \sum_{u,v\in\mathbb{Z}_d} \rho_{u,v} \sum_{s,t=-\infty}^{\infty} \left\langle \sqrt{\frac{2\pi}{d}}(u+ds)\middle| D(-\boldsymbol{r}) \middle| \sqrt{\frac{2\pi}{d}}(v+dt)\right\rangle_q\\
&= \sum_{u,v}\sum_{s,t} \rho_{u,v} e^{ir_q r_p/2} e^{ir_p\sqrt{\frac{2\pi}{d}}(v+dt)} \left\langle \sqrt{\frac{2\pi}{d}}(u+ds)\middle| \sqrt{\frac{2\pi}{d}}(v+dt)+r_q\right\rangle_q\\
&= \sum_{u,v}\sum_{s,t} \rho_{u,v} e^{ir_q r_p/2} e^{ir_p\sqrt{\frac{2\pi}{d}}(v+dt)} \delta\left(r_q - \sqrt{\frac{2\pi}{d}}(u-v-d(t-s))\right)\\
&= \sum_{u,v}\sum_{s,t} \rho_{u,v} e^{i2\pi s(r_p\sqrt{\frac{d}{2\pi}})} e^{i\frac{r_p}{2}(r_q+2\sqrt{\frac{2\pi}{d}}(v+dt))} \delta\left(r_q - \sqrt{\frac{2\pi}{d}}(u-v-dt)\right)\\
&= \sqrt{\frac{2\pi}{d}}\sum_{u,v}\sum_{s,t} \rho_{u,v}\,\delta\left(r_p - \sqrt{\frac{2\pi}{d}}s\right)\delta\left(r_q - \sqrt{\frac{2\pi}{d}}(u-v-dt)\right) e^{i\frac{r_p}{2}(r_q+2\sqrt{\frac{2\pi}{d}}(v+dt))}\\
&= \sqrt{\frac{2\pi}{d}}\sum_{u,v}\sum_{s,t} \rho_{u,v} e^{i\frac{\pi}{d}s(u+v+dt)} \delta\left(r_p - \sqrt{\frac{2\pi}{d}}s\right)\delta\left(r_q - \sqrt{\frac{2\pi}{d}}(u-v-dt)\right).
\end{aligned} \tag{E2}$$

With this expression, we aim at finding the coefficient $\gamma_{\rho_{\mathrm{GKP}}}(l,m)$ for $l,m \in \mathbb{Z}_d$ such that

$$\begin{aligned}
&\chi^{\mathrm{CV}}_{\rho_{\mathrm{GKP}}}(\boldsymbol{r})\\
&= \sqrt{\frac{2\pi}{d}}\sum_{l,m=-\infty}^{\infty} \gamma_{\rho_{\mathrm{GKP}}}(l,m)\\
&\quad\times \delta\left(r_p - m\sqrt{\frac{2\pi}{d}}\right)\delta\left(r_q - l\sqrt{\frac{2\pi}{d}}\right).
\end{aligned} \tag{E3}$$

Similarly to the case for the Wigner function, we restrict to one unit cell. Thus, the requirement for l is

$$u - v - dt = l \tag{E4}$$

$$u - v \mod d = l \tag{E5}$$

and therefore

$$\gamma_{\rho_{\rm GKP}}(l,0) = \sum_{u-v \mod d=l} \langle v|\,\rho\,|u\rangle = \operatorname{Tr}\left[X_d^l \rho\right]. \tag{E6}$$

By simplifying the phase factor

$$e^{i\frac{\pi}{d}s(v+u+dt)} = e^{i\frac{\pi}{d}s(-l+2u)} = \omega_d^{-sl/2}\omega_d^{su} \tag{E7}$$

we can write the coefficients as

$$\gamma_{\rho_{\rm GKP}}(l,m) = \omega_d^{-lm/2} \operatorname{Tr}\left[\rho X_d^l Z_d^m\right]. \tag{E8}$$

Therefore, the coefficients are given by the trace over the Pauli operators in d dimensions. This can be generalized to n qudits as

$$\begin{aligned}\gamma_{\rho_{\rm GKP}}(\boldsymbol{l},\boldsymbol{m}) &= \omega_d^{-\boldsymbol{l}\cdot\boldsymbol{m}/2} \operatorname{Tr}\left[\rho X^{\boldsymbol{l}} Z^{\boldsymbol{m}}\right] \\ &= d^n \omega_d^{-\boldsymbol{l}\cdot\boldsymbol{m}/2} \omega_D^{-\boldsymbol{l}\cdot\boldsymbol{m}/2} \chi_\rho^{\rm DV}(\boldsymbol{l},\boldsymbol{m})^*,\end{aligned} \tag{E9}$$

which shows (60).

Using (60) and the fact that $|\chi_\phi^{\rm DV}(\boldsymbol{l},\boldsymbol{m})| = d^{-n}$ for $(4d)^n$ elements in $\boldsymbol{l},\boldsymbol{m} \in \mathbb{Z}_{2d}^n$ and zero otherwise, we can get for a pure qudit state ϕ that

$$\|\chi_{\phi_{\rm GKP}}^{\rm CV}\|_{p,\rm cell} = (4d)^{n/p}\left(\frac{2\pi}{d}\right)^{n/2}. \tag{E10}$$

We then get, again by using (60), that

$$\begin{aligned}\|\chi_{\rho_{\rm GKP}}^{\rm CV}\|_{p,\rm cell} &= \left[\sum_{\boldsymbol{l},\boldsymbol{m}\in\mathbb{Z}_{2d}^n}\left\{\left(\frac{2\pi}{d}\right)^{n/2} d^n |\chi_\rho^{\rm DV}(\boldsymbol{l},\boldsymbol{m})|\right\}^p\right]^{1/p} \\ &= \left[4^n \sum_{\boldsymbol{l},\boldsymbol{m}\in\mathbb{Z}_{d}^n}\left\{(2\pi d)^{n/2}\,|\chi_\rho^{\rm DV}(\boldsymbol{l},\boldsymbol{m})|\right\}^p\right]^{1/p} \\ &= 4^{n/p}(2\pi d)^{n/2}\|\chi_\rho^{\rm DV}\|_p \\ &= d^{n(1-1/p)}\|\chi_\rho^{\rm DV}\|_p,\end{aligned} \tag{E11}$$

completing the proof.

Appendix F: Simulation algorithm

For the convenience of the reader we will use the frame notation from the works of [37]

$$F(\lambda) = \frac{O_\lambda}{d^n} \tag{F1}$$

$$G(\lambda) = O_\lambda \tag{F2}$$

$$\rho = \sum_\lambda \operatorname{Tr}\left(\rho\frac{O_\lambda}{d^n}\right)O_\lambda = \sum_\lambda G(\lambda)\operatorname{Tr}\left(\rho F(\lambda)\right). \tag{F3}$$

Unitary evolution of a state can be rewritten in this notation as

$$\begin{aligned}U\rho U^\dagger &= \sum_\lambda UG(\lambda)U^\dagger \operatorname{Tr}\left(\rho F(\lambda)\right) &\text{(F4)}\\ &= \sum_{\lambda,\lambda'} G(\lambda')\operatorname{Tr}\left(F(\lambda')UG(\lambda)U^\dagger\right)\operatorname{Tr}\left(\rho F(\lambda)\right) &\text{(F5)}\end{aligned}$$

and the output of a measurement Π is

$$\operatorname{Tr}\left(\Pi U\rho U^\dagger\right) = \sum_{\lambda,\lambda'} x_\Pi(\lambda')x_U(\lambda',\lambda)x_\rho(\lambda) \tag{F6}$$

with

$$x_\rho(\lambda) = \operatorname{Tr}\left(\rho F(\lambda)\right) \tag{F7}$$

$$x_U(\lambda',\lambda) = \operatorname{Tr}\left(F(\lambda')UG(\lambda)U^\dagger\right) \tag{F8}$$

$$x_\Pi(\lambda) = \operatorname{Tr}\left(\Pi G(\lambda)\right). \tag{F9}$$

Out of these quantities we can define the following probability distributions

$$P(\lambda|\rho) = \frac{|x_\rho(\lambda)|}{\|x_\rho\|_1} \tag{F10}$$

$$P(\lambda'|U,\lambda) = \frac{|x_U(\lambda',\lambda)|}{\|x_U(\lambda)\|_1} \tag{F11}$$

$$\|x_U(\lambda)\|_1 = \sum_{\lambda'}|x_U(\lambda',\lambda)| \tag{F12}$$

$$\|x_\rho\|_1 = \sum_\lambda |x_\rho(\lambda)| \tag{F13}$$

Thus we can rewrite the Born rule probability as

$$\begin{aligned}P(\Pi|U\rho U^\dagger) &= \sum_{\lambda,\lambda'} x_\Pi(\lambda')x_U(\lambda',\lambda)x_\rho(\lambda) &\text{(F14)}\\ &= \sum_{\lambda,\lambda'} M_{\lambda,\lambda'}P(\lambda'|U,\lambda)P(\lambda|\rho) &\text{(F15)}\end{aligned}$$

with $M_{\lambda,\lambda'} = \operatorname{sign}(x_\Pi(\lambda')x_U(\lambda',\lambda))x_\Pi(\lambda')\|x_U(\lambda)\|_1\|x_\rho\|_1$.

The simulation strategy is to sample λ from $P(\lambda|\rho)$ and then consider a possible transition to λ' from $P(\lambda'|U,\lambda)$. This can easily be generalized to a sequence of unitaries of length T as well. We then define a random variable as

$$\begin{aligned}M_{\vec{\lambda}} &= x_\Pi(\lambda_T)\operatorname{sign}(x_\rho(\lambda_0))\|x_\rho\|_1 &\text{(F16)}\\ &\times \prod_{t=1}^T \operatorname{sign}(x_{U_t}(\lambda_t,\lambda_{t-1}))\|x_{U_t}(\lambda_{t-1})\|_1. &\text{(F17)}\end{aligned}$$

The expectation value of this random variable is

$$\begin{aligned}\mathbb{E}(M_{\vec{\lambda}}) &= \sum_{\vec{\lambda}} P(\lambda_0|\rho)\prod_{t=1}^T P(\lambda_t|U_t,\lambda_{t-1})M_{\vec{\lambda}} &\text{(F18)}\\ &= \sum_{\vec{\lambda}} x_\Pi(\lambda_T)\prod_{t=1}^T x_{U_t}(\lambda_t,\lambda_{t-1})x_\rho(\lambda_0) &\text{(F19)}\end{aligned}$$

which is exactly the Born probability we want to estimate. The random variable output from our sampling algorithm is an unbiased estimator for the Born probability. The number of samples needed to achieve a given precision can be computed using the Hoeffding inequality Given a sequence of K *iid* random variables X_j bounded by $|X_j| \leq b$ and expected mean $\mathbb{E}(X)$, the probability that $\sum_{j=1}^{K} X_j/K$ deviated from the mean by more than ϵ is upper bounded by

$$P\left(\left|\mathbb{E}(X)-\sum_{j=1}^{K}\frac{X_j}{K}\right| \geq \epsilon\right) \leq 3\exp\left(-\frac{K\epsilon^2}{2b^2}\right) \tag{F20}$$

or equivalently we can achieve precision $\left|\mathbb{E}(X)-\sum_{j=1}^{K}\frac{X_j}{K}\right| \leq \epsilon$ with probability at least $(1-p_f)$ by setting the number of samples as

$$K = \left\lceil 2b^2\frac{1}{\epsilon^2}\ln\left(\frac{2}{p_f}\right)\right\rceil . \tag{F21}$$

We then define the negativity of the entire circuit as

$$\mathcal{M}_{\rightarrow} = \|x_\rho\|_1 \prod_{t=1} \max_{\lambda_t} \|x_{U_t}(\lambda_t)\|_1 \max_{\lambda_T} |x_\Pi(\lambda_T)| \tag{F22}$$

so it is the maximum negativity over all trajectories. This bounds the random variable from above, so we need at least

$$K \geq 2\mathcal{M}_{\rightarrow}^2\frac{1}{\epsilon^2}\ln\left(\frac{2}{p_f}\right) \tag{F23}$$

samples.

Appendix G: Hyperpolyhedral states

In this section, we investigate the phenomena of hyperpolyhedral states. In [38] the authors encounter hyperoctahedral states for qubit systems. They define these states as the states which have the stabilizer norm smaller than 1 or in our formulation $\sum_{\boldsymbol{l},\boldsymbol{m}} |x_{\boldsymbol{l},\boldsymbol{m}}| < 1$. For odd dimensional states these states are equivalent to Wigner positive states $\sum_{\boldsymbol{l},\boldsymbol{m}} |x_{\boldsymbol{l},\boldsymbol{m}}| = 1$. This set is strictly bigger than the set of stabilizer states.

For even dimensions, the question of a Wigner function is more difficult, especially related to computability, even though one can define such a quantity [42, 48, 49]. We define the Hyperpolyhedral states similarly to the qubit case for all even dimensions with $\sum_{\boldsymbol{l},\boldsymbol{m}} |x_{\boldsymbol{l},\boldsymbol{m}}| \leq 1$. Here we show that hyperpolyhedral states exist for all even dimensions and that they are not equivalent to stabilizer states.

The computational basis states can be expanded in the operators $O_{l,m}$ as

$$|0\rangle\langle 0| = \frac{1}{d}\sum_{i=0}^{d-1} O_{0,i} \tag{G1}$$

$$|1\rangle\langle 1| = X_d\,|0\rangle\langle 0|\,X_d^\dagger = \frac{1}{d}\sum_{i=0}^{d-1} O_{2,i} \tag{G2}$$

$$\dots \tag{G3}$$

$$\left|\frac{d}{2}\right\rangle\left\langle\frac{d}{2}\right| = X_d^{\frac{d}{2}}\,|0\rangle\langle 0|\,X_d^{\frac{d}{2}\dagger} \tag{G4}$$

$$= \frac{1}{d}\sum_{i=0}^{d-1} O(d,i) = \frac{1}{d}\sum_{i=0}^{d-1}(-1)^i O_{0,i} \tag{G5}$$

$$\dots \tag{G6}$$

$$|d-1\rangle\langle d-1| = X_d^{d-1}\,|0\rangle\langle 0|\,X_d^{d-1\dagger} \tag{G7}$$

$$= \frac{1}{d}\sum_{i=0}^{d-1}(-1)^i O_{d-1,i} \tag{G8}$$

Thus, we can reorder them to pairs in the following way

$$|0\rangle\langle 0| + \left|\frac{d}{2}\right\rangle\left\langle\frac{d}{2}\right| = \frac{1}{d}\sum_{i=0}^{d-1}(1+(-1)^i)O_{0,i} \tag{G9}$$

$$\dots \tag{G10}$$

$$|k\rangle\langle k| + \left|k+\frac{d}{2}\right\rangle\left\langle k+\frac{d}{2}\right| = \frac{1}{d}\sum_{i=0}^{d-1}(1+(-1)^i)O_{k,i} \tag{G11}$$

The maximally mixed state is $\frac{\mathbb{1}}{d} = \frac{1}{d}\sum_{i=0}^{d-1}|i\rangle\langle i|$. Therefore, if we compute

$$\sum_{l,m=0}^{d-1}\left|\mathrm{Tr}\left[\frac{\mathbb{1}}{d}O_{l,m}\right]\right| = \frac{1}{d}, \tag{G12}$$

we get a value that is smaller than the one for a pure stabilizer state. Therefore, one can "hide" magic in a product state of a magic state and the maximally mixed state or similarly including Clifford equivalent states. Since this quantity goes directly into the simulator cost, we see that the hyperpolyhedral states are easier to simulate than pure stabilizer states.

Appendix H: Decompositions of stabilizer states

In this section, we show how to obtain the decompositions of stabilizer states in the basis of $O_{\boldsymbol{l},\boldsymbol{m}}$ given their stabilizers.

Every stabilizer state with a d^n dimensional stabilizer group S fulfills the following eigenvalue equations [16]

$$\omega_d^{\boldsymbol{v}\Omega\boldsymbol{m}^T} P_d(\boldsymbol{m})\,|M_S, v\rangle = |M_S, v\rangle \tag{H1}$$

where M_S is the space of coordinates associated with the stabilizer group and $\boldsymbol{v}$ is the coordinate of one Heisenberg-Weyl operator. Note that $\boldsymbol{m} \in \mathbb{Z}_d^{2n}$ and that the phases are taken care of by the phase factor $\omega_d^{\boldsymbol{v}\Omega\boldsymbol{m}^T}$. This $\boldsymbol{v}$ takes care of the phase in front of the Heisenberg-Weyl operator. The stabilizer group S and in turn the set of coordinates are generated by n Heisenberg-Weyl operators $S = \langle S_1, ..., S_n\rangle$ or n coordinates $M_S = \langle \boldsymbol{s_1}, ..., \boldsymbol{s_n}\rangle$ respectively. The set M_S includes a linear combinations involving the n generators $\boldsymbol{s_i}$ with coefficients $k_i \in \mathbb{Z}_d$. The characteristic function of a stabilizer state $|\phi\rangle\langle\phi|$ can be represented as [17]

$$\chi^{\mathrm{DV}}_{|\phi\rangle\langle\phi|}(\boldsymbol{a}) = \frac{1}{d^n}\omega_d^{\boldsymbol{v}\Omega\boldsymbol{a}^T}\delta_{M_S}(\boldsymbol{a}) \tag{H2}$$

where $\delta_{M_S}(\boldsymbol{a})$ is the indicator function that $\delta_{M_S}(\boldsymbol{a}) = 1$, iff $\boldsymbol{a} \in M_S$ and 0 otherwise.

For odd dimensions, the phase space point operators $A(a_1, a_2)$ had a one-to-one correspondence with the operators $O_{l,m}$. Something similar holds for even dimensions as well. In that case, the operators $O_{l,m}$ are directly connected with operators $\tilde{A}(a_1, a_2)$ that are identically defined as the phase space point operators but do not fulfill the same set of properties.

In the proof to show the connection between the phase space point operators in odd dimensions and the operators $O_{l,m}$, we used the resummation formula

$$\frac{1}{d}\sum_{k=0}^{d-1} e^{2\pi i \frac{kn}{d}} = \delta_{0,n}. \tag{H3}$$

For even dimensions, the sums appear with $2d$ instead of just d and then

$$\frac{1}{d}\sum_{k=0}^{d-1} e^{2\pi i \frac{kn}{2d}} \neq \delta_{0,n}, \tag{H4}$$

so one cannot easily use the discrete resummation formula. However, the equation can be modified to hold in all dimensions. In even dimensions, it holds that

$$\frac{1}{2d}\sum_{k=0}^{2d-1} e^{2\pi i \frac{kn}{2d}} = \frac{1}{\tilde{d}}\sum_{k=0}^{\tilde{d}-1} e^{2\pi i \frac{kn}{d}} = \delta_{0,n}. \tag{H5}$$

We see that by doubling the domain of the sum, we recover the discrete resummation formula. So we can use the discrete resummation formula in all dimensions by considering

$$\frac{1}{D}\sum_{k=0}^{D-1} e^{2\pi i \frac{kn}{D}} = \delta_{0,n} \tag{H6}$$

and in consequence

$$\frac{1}{D^n}\sum_{\boldsymbol{x}\in\mathbb{Z}_D^{2n}} \omega_D^{-(\boldsymbol{u}+\boldsymbol{v})\Omega\boldsymbol{x}^T} = \delta_{0,\boldsymbol{u}+\boldsymbol{v}}. \tag{H7}$$

We define the symplectic Fourier transform as

$$(\mathcal{F}f)(\boldsymbol{a}) = \frac{1}{D^n}\sum_{\boldsymbol{b}\in\mathbb{Z}_D^{2n}} \omega_D^{-\boldsymbol{a}\Omega\boldsymbol{b}^T} f(\boldsymbol{b}). \tag{H8}$$

We see here again that the parameters $\boldsymbol{a}$ are not over $\mathbb{Z}_d^{2n}$ but over $\mathbb{Z}_D^{2n}$ as mentioned before. In order to differentiate between the phase-space point operators in odd dimensions $A(\boldsymbol{a}) = \frac{1}{d^n}\sum_{\boldsymbol{b}\in\mathbb{Z}_d^{2n}} \omega_d^{-\boldsymbol{a}\Omega\boldsymbol{b}^T} P_d^\dagger(\boldsymbol{b})$ with their intimate relation with the discrete Wigner function, we define the equivalently defined operator $\tilde{A}(\boldsymbol{a}) = \frac{1}{D^n}\sum_{\boldsymbol{b}\in\mathbb{Z}_D^{2n}} \omega_D^{-\boldsymbol{a}\Omega\boldsymbol{b}^T} P^\dagger(\boldsymbol{b})$ for even dimensions.

Then consequently for even dimension, we can rewrite $\tilde{A}(\boldsymbol{a})$ as

$$\tilde{A}(\boldsymbol{a}) = \frac{1}{D}\sum_{\boldsymbol{b}\in\mathbb{Z}_D^{2n}} \omega_D^{-\boldsymbol{a}\Omega\boldsymbol{b}^T} P_d^\dagger(\boldsymbol{b}) \tag{H9}$$

$$= \frac{1}{D}\sum_{\boldsymbol{b}\in\mathbb{Z}_D^{2n},\boldsymbol{x}\in\mathbb{Z}_d^n} \omega_d^{\boldsymbol{b_1}(\frac{\boldsymbol{a_2}}{2}+\frac{\boldsymbol{b_2}}{2}-\boldsymbol{x})}\omega_D^{-\boldsymbol{a_1}\boldsymbol{b_2}} \left|\boldsymbol{x}-\boldsymbol{b_2}\right\rangle\left\langle\boldsymbol{x}\right| \tag{H10}$$

$$= \frac{1}{D}\sum_{\boldsymbol{b_2}\in\mathbb{Z}_D^{2n},\boldsymbol{x}\in\mathbb{Z}_d^n} \delta_{\boldsymbol{b_2},2\boldsymbol{x}-\boldsymbol{a_2}}\omega_D^{-\boldsymbol{a_1}\boldsymbol{b_2}} \left|\boldsymbol{x}-\boldsymbol{b_2}\right\rangle\left\langle\boldsymbol{x}\right| \tag{H11}$$

$$= \frac{1}{D}\sum_{\boldsymbol{x}\in\mathbb{Z}_d^n} \omega_d^{\boldsymbol{a_1}\boldsymbol{a_2}/2}\omega_d^{-\boldsymbol{a_1}\boldsymbol{x}} \left|\boldsymbol{a_2}-\boldsymbol{x}\right\rangle\left\langle\boldsymbol{x}\right| \tag{H12}$$

which is equivalent to $O_{\boldsymbol{l},\boldsymbol{m}}$ for $\boldsymbol{l} = \boldsymbol{a_2}, \boldsymbol{m} = -\boldsymbol{a_1}$.

We transform the characteristic function to get the coefficients $x_{|\phi\rangle\langle\phi|}$ corresponding to the operators $O_{l,m}$ for a stabilizer state ϕ as

$$\mathcal{F}(\chi^{\mathrm{DV}}_{|\phi\rangle\langle\phi|})(\boldsymbol{a}) = \frac{1}{(2d)^n}\frac{1}{d^n}\sum_{\boldsymbol{b}\in\mathbb{Z}_{2d}^{2n}} \omega_{2d}^{-\boldsymbol{a}\Omega\boldsymbol{b}^T}\delta_{M_s}(\boldsymbol{b})\omega_d^{\boldsymbol{v}\Omega\boldsymbol{b}^T} \tag{H13}$$

$$= \frac{1}{(2d)^n}\frac{1}{d^n}\sum_{\boldsymbol{b}\in M_S\cup M_S+d} \omega_{2d}^{-(\boldsymbol{a}-\boldsymbol{2v})\Omega\boldsymbol{b}^T}. \tag{H14}$$

We used that M_S was defined on $\mathbb{Z}_d^{2n}$, but the sum goes over $\mathbb{Z}_{2d}^{2n}$ so we need to take this into account when dealing with the phase factors. We write $M_S \cup M_S + d$ as the extension from $\mathbb{Z}_d^{2n}$ to $\mathbb{Z}_{2d}^{2n}$. This set is generated by the same generators $\boldsymbol{s_i}$ but includes now lienar combinations with coefficients $k_i \in \mathbb{Z}_{2d}$. We can simplify the sum by using the generators of the coordinate space $M_S = \langle \boldsymbol{s_1}, ..., \boldsymbol{s_n}\rangle$ to

$$\mathcal{F}(\chi^{\mathrm{DV}}_{|\phi\rangle\langle\phi|})(\boldsymbol{a}) = \frac{1}{(2d)^n}\frac{1}{d^n}\sum_{\boldsymbol{b}\in M_S\cup M_S+d} \omega_{2d}^{-(\boldsymbol{a}-\boldsymbol{2v})\Omega\boldsymbol{b}^T} \tag{H15}$$

$$= \prod_{i=1}^{n}\left(\sum_{k_i=0}^{2d-1}\omega_{2d}^{-(\boldsymbol{a}-\boldsymbol{2v})\Omega[k_i\boldsymbol{s_i}]^T}\right) \tag{H16}$$

$$= \prod_{i=1}^{n}\left(\sum_{k_i=0}^{2d-1}\omega_{2d}^{-k_i(\boldsymbol{a}-\boldsymbol{2v})\Omega\boldsymbol{s_i}^T}\right) \tag{H17}$$

$$= \frac{1}{d^n}\delta_{M_S+2\boldsymbol{v}}(\boldsymbol{a}). \tag{H18}$$

From the first to the second line we decomposed the elements $\boldsymbol{b} \in M_S \cup M_S + d$ using the generators $M_S \cup M_S + d$. Each element $\boldsymbol{b}$ can be decomposed into a linear combination of the generators $\boldsymbol{s_i}$ and coefficients $k_i \in \mathbb{Z}_{2d}$. In the last line, we used the resummation formula (H7) and saw that the sum is 0 by using except in the case where $(\boldsymbol{a} - 2\boldsymbol{v})\Omega\boldsymbol{b}^T = 0$ and thus the Pauli operators in the stabilizer group commute with Pauli operators with coordinates $\boldsymbol{a} - 2\boldsymbol{v}$. This implies that $\boldsymbol{a} - 2\boldsymbol{v} \in M_S$ since S is a stabilizer group with the maximal number of commuting Pauli operators. As shown in (H12), the expression in Eq. (H18) coincides with $x_{|\phi\rangle\langle\phi|}(l = \boldsymbol{a_2}, m = -\boldsymbol{a_1})$. A few comments are in order. We have shown that we can write every pure stabilizer state using d^n operators $O_{\boldsymbol{l},\boldsymbol{m}}$ that all have the phase $+1$

$$|\phi\rangle\langle\phi| = \sum_{(\boldsymbol{l},\boldsymbol{m})\in\mathbb{Z}_{2d}^{2n}} x_{|\phi\rangle\langle\phi|}(\boldsymbol{l},\boldsymbol{m}) O_{\boldsymbol{l},\boldsymbol{m}} \tag{H19}$$

$$= \frac{1}{d^n} \sum_{(-\boldsymbol{m},\boldsymbol{l})\in M_s+2\boldsymbol{v}} O_{\boldsymbol{l},\boldsymbol{m}}. \tag{H20}$$

Note that the sums go over D and not d, which makes a difference in even dimensions. As we know, the operators $O_{\boldsymbol{l},\boldsymbol{m}}$ repeat with period d with the opposite sign. Let us take the example of qubits $Z_2 = O_{0,1}$ while $-Z_2 = O_{2,1}$. So if we constrain $(\boldsymbol{l},\boldsymbol{m}) \in \mathbb{Z}_d^{2n}$ we can get phases ±1, while if we allow for all $(\boldsymbol{l},\boldsymbol{m}) \in \mathbb{Z}_D^{2n}$ we get decompositions with only $+1$ signs.

The search for a unique measure of entanglement: A story of entropy, reversibility, and hypothesis testing

Bartosz Regula[1] *

[1] *RIKEN Center for Quantum Computing, Japan*

Abstract. The methods to characterise quantum resources such as entanglement are often based on our understanding of thermodynamics. Such connections hinted at the possibility of a unique measure of entanglement emerging in a suitable regime, which would exactly mirror the role that entropy plays in the second law of thermodynamics. This conjecture turned out to be deeply related to an important problem in quantum hypothesis testing of entangled states, whose seminal solution in 2010 inspired a large body of work in the study of quantum resources. However, 12 years later, this claimed solution was found to be incorrect, casting doubt on the whole supposed parallel between entanglement and thermodynamics, and reopening the search for a unique measure of entanglement.

In this talk, I will overview the motivations for these fundamental conjectures, the recent developments surrounding the problems, and the remaining open questions. In particular, I will discuss how a 'second law of entanglement' — if at all possible — must be fundamentally different from the second law of thermodynamics, and how the conjectured unique measure of entanglement can indeed be proven to be true when certain relaxed assumptions are taken.

Abstract. While quantum state tomography is notoriously hard, most states hold little interest to practically-minded tomographers, as those appearing in Nature have bounded gate complexity. In this work, we prove that to learn a state/unitary with gate complexity G to a small trace/average-case distance, the optimal sample complexity scales linearly in G. In contrast, the computational complexity must scale exponentially in G under cryptographic conjectures. These results establish fundamental limitations on quantum machine learning models and provide new perspectives on no-free-lunch theorems. Together, our results relate the complexity of learning quantum states and unitaries to that of creating them.

Keywords: quantum learning theory, state tomography, unitary tomography, sample complexity, computational complexity

The tasks of general *state* and *process tomography* – that is, determining an unknown quantum state/unitary from copies of it/queries to it – are practically ubiquitous [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13] but exponentially costly [14, 15, 16]. Despite this theoretical obstacle, there is hope that efficient tomography remains within reach, since the vast majority of states and unitaries are not of immediate physical interest [17, 18, 19]. Indeed, practitioners may be able to leverage *prior knowledge* about the unknown state or process. Previous works have demonstrated efficient learning if the unknown state is known to be a stabilizer [20, 21, 22, 23], of limited T-gate count [24, 25, 26, 27], or the output of a shallow circuit [28]; or if the unknown process is a local Pauli noise channel [29].

Our work centers around a prior that is fundamental in physics and timely to the current state of quantum technology, albeit underexplored in tomography: gate complexity. While the vast majority of many-body states and unitaries have exponential gate complexity, those that can even be prepared "in Nature" [17, 18, 19] are likely to have at most polynomial gate complexity. This raises the following question:

What is the complexity of learning states/unitaries with bounded gate complexity?

We first study the *sample/query complexity* of learning an n-qubit state/unitary implemented by G two-qubit gates: the number of samples collected from the system or queries to the process required to output an ϵ-accurate classical description of the unknown object. Previously, [30] showed that the state learning task can be accomplished with sample complexity $\tilde{\mathcal{O}}(nG^2/\epsilon^4)$. However, it is not known if this is the optimal sample complexity for the state learning task. In this work, we fully resolve this problem by proving a matching upper and lower bound (up to log factors) of $\tilde{\Theta}(G/\epsilon^2)$ for learning n-qubit states generated by G gates to trace distance ϵ. For learning unitaries, we establish a query complexity scaling linear in the gate complexity G and independent of the system size n, which is optimal in the scaling of G (up to log factors). Turning to the question of *computational complexity*, we demonstrate that any quantum learning algorithm requires computational time scaling exponentially in G.

Our results pose fresh implications in other subfields of quantum information. Firstly, the Brown-Susskind conjecture [31, 32, 33, 34, 35, 36] states that the complexity of a generic local quantum circuit grows linearly with the number of gates for an exponentially long time, holographically dual to the steady growth of a wormhole's volume in the bulk theory. This conjecture has recently been confirmed [37, 38] with "complexity" understood as (exact) "circuit complexity" [35]. Our work suggests that this conjecture may also be true for an alternative notion of complexity – that of learning the quantum circuit. Secondly, our work completely characterizes the complexity of inferring a classical circuit description of a quantum circuit from limited copies of its output state: yet such a description holds the key to computing arbitrarily many more properties of this state (via classical simulation algorithms) than would have been possible by using the limited state copies directly. We thus expect our results to shed light on the link between classical simulability and learnability of quantum states [39, 40]. They also provide a *learning* perspective on the celebrated recent notion of state complexity classes [41, 42], which ask what

states can be synthesized by polynomial-space quantum circuits.

1 Learning quantum states and unitaries

Learning quantum states. First, we consider learning quantum states of bounded complexity. Let $|\psi\rangle = U|0\rangle^{\otimes n}$ be an n-qubit pure state generated by a unitary U consisting of G two-qubit gates. Given N copies of $\rho \triangleq |\psi\rangle\!\langle\psi|$, we aim to learn a classical circuit description $\hat{\rho}$ of ρ that is ϵ-close to ρ in trace distance: $\mathrm{d}_{\mathrm{tr}}(\hat{\rho}, \rho) = \|\hat{\rho} - \rho\|_1/2 < \epsilon$. We fully characterize the sample complexity in the following theorem.

Theorem 1 (State learning) $N = \tilde{\Theta}\left(G/\epsilon^2\right)$ *copies of an n-qubit pure state with circuit complexity G are necessary and sufficient to learn it to within ϵ trace distance with high probability.*

This result also resolves an open question from [43] and improves [30] to achieve the optimal scaling. In the regime where $G = \mathcal{O}(\mathsf{poly}(n))$, our algorithm improves substantially over the sample complexity $N = \mathcal{O}(2^n)$ of the sample-optimal result for arbitrary pure quantum states [14, 15]. Note that we do not need to have access to the unitary U which generates the unknown state $|\psi\rangle$.

While our algorithm to learn the unknown quantum state $|\psi\rangle$ is sample-efficient and sample-optimal, it is computationally inefficient. We prove that this cannot be avoided in general: any quantum algorithm that learns $|\psi\rangle$ given access to copies of this state must use time exponential-in-G, under the commonly-believed cryptographic assumption that $\mathsf{RingLWE}$ [44] cannot be solved by a quantum computer in sub-exponential time. This imposes strong computational complexity limitations on learning even comparatively simple states, in stark contrast with our sample complexity results. Meanwhile, we show that the learning task is computationally-efficiently solvable for $G = \mathcal{O}(\log n)$, implying a transition point of computational efficiency. Previous work [45, 46] arrives at related hardness results for $G = \mathrm{poly}(n)$, but our detailed analysis allows us to sharpen the computational lower bound and obtain this transition point.

Theorem 2 (Computational hardness; States) *Any quantum algorithm that learns an n-qubit state with circuit complexity G to within ϵ trace distance requires* $\exp(\Omega(\min(G, n)))$ *time, assuming the quantum sub-exponential hardness of* $\mathsf{RingLWE}$*. Meanwhile, for* $G = \mathcal{O}(\log n)$*, an efficient learning algorithm exists.*

Learning quantum unitaries. Next, we consider learning unitaries of bounded complexity. Let U be a unitary consisting of G two-qubit gates. Given query access to U, we aim to learn a classical circuit description $\hat{U}$ of U that is ϵ-close to U. A natural distance metric analogous to the trace distance for states is the diamond distance $\mathrm{d}_{\diamond}(U, V) = \max_{\rho} \|(U \otimes I)\rho(U \otimes I)^{\dagger} - (V \otimes I)\rho(V \otimes I)^{\dagger}\|_1$. We find that in this worst-case learning task, a number of queries exponential in G is necessary.

Theorem 3 (Worst-case unitary learning) *Any quantum algorithm learning an n-qubit unitary with circuit complexity G in diamond distance with high probability must use at least* $\Omega\left(2^{\min\{G/(2C), n/2\}}/\epsilon\right)$ *queries, where* $C > 0$ *is a universal constant. Meanwhile, there exists such an algorithm using* $\tilde{\mathcal{O}}(2^n G/\epsilon)$ *queries.*

Having established this no-go theorem for worst-case learning, we turn to a more realistic average-case learning alternative. Here, the accuracy is measured using the average-case metric, $\mathrm{d}_{\mathrm{avg}}(U, V) = \sqrt{\mathbb{E}_{|\psi\rangle}[\mathrm{d}_{\mathrm{tr}}(U|\psi\rangle, V|\psi\rangle)^2]}$. This metric characterizes the average error when testing the learned unitary on Haar-random inputs. We find that, similarly to the state learning task, linear-in-G many queries is optimal.

Theorem 4 (Average-case unitary learning) $N = \tilde{\mathcal{O}}\left(G \min\{1/\epsilon^2, \sqrt{2^n}/\epsilon\}\right)$ *queries are sufficient to learn an n-qubit unitary with circuit complexity G to ϵ root mean squared trace distance with high probability. Meanwhile, at least* $\Omega\left(G/\epsilon\right)$ *queries to the unitary, its inverse, or the controlled versions are necessary.*

The similar linear-in-G sample/query complexity in Theorems 1 and 4 hints at a common underlying source of complexity. However, in contrast to state learning, unitary learning comes with two natural such sources: (1) to readout input and output states, and (2) to learn the mapping from inputs to outputs. Our results suggest that the former may encapsulate the central difficulty whereas the latter may be easy. This seemingly contradicts recent quantum no free lunch theorems [47, 48], which state that $\Omega(2^n)$ samples are required to learn a generic unitary even from classically described input-output state pairs. To resolve this, we reformulate the quantum no free lunch theorem from an information-theoretic perspective.

Theorem 5 (Learning with classical descriptions) $\mathcal{O}(2^n/r)$ *classically described samples with mixed (entangled) input states of (Schmidt) rank r are sufficient to learn any n-qubit unitary to any accuracy with high probability. Moreover, any such algorithm that is robust to noise needs at least* $\Omega(2^n/r)$ *samples.*

Similarly to state learning, our average-case unitary learning algorithm is not computationally efficient. This is again inevitable, and the same is true for worst-case unitary learning. Moreover, the hard instances we construct are implementable with Clifford+T circuits with $\tilde{\omega}(\log n)$ T gates [24], so, together with Theorem 2, this gives a negative answer to an open question (the fifth question) in the survey [39].

Theorem 6 (Computational hardness; Unitaries) *Any quantum algorithm that learns an n-qubit unitary with circuit complexity G requires* $\exp(\Omega(\min(G, n)))$ *time, assuming the quantum sub-exponential hardness of* $\mathsf{RingLWE}$*. Meanwhile, for* $G = \mathcal{O}(\log n)$*, an efficient learning algorithm exists.*

Apart from learning quantum states and dynamics themselves, a more classically minded learner may care more about learning classical functions resulting from quantum processes. We define these *physical functions* $f(x) : [0, 1]^{\nu} \to \mathbb{R}$ in three steps: (1) a fixed state preparation procedure that can depend on x; (2) a unitary evolution consisting of G tunable two-qubit gates and arbitrary fixed unitaries that can depend on x, arranged in a circuit structure; (3) the measurement of a fixed observable, whose expectation is the function output. Despite the generality of this setup, we find that certain well-behaved functions are actually not physical: they cannot be efficiently approximated or learned via physical functions. This reveals a fundamental limitation on the functional expressivity of both nature and practical quantum machine learning models [49, 50, 51, 52].

Theorem 7 (Learning physical functions) *At least $G \geq \tilde{\Omega}(1/\epsilon^{\nu/2})$ gates and $N \geq \Omega(1/\epsilon^{\nu})$ samples are needed to approximate and learn arbitrary 1-bounded and 1-Lipschitz $\mathbb{R}$-valued functions on $[0,1]^{\nu}$ to accuracy ϵ in $\|\cdot\|_{\infty}$ with high probability using physical functions.*

2 Proof ideas

Sample complexity upper bounds. We prove the upper bounds in Theorems 1 and 4 by explicitly constructing learning algorithms using a hypothesis selection protocol [53] based on classical shadow tomography [54]. Specifically, we construct a covering net $\mathcal{N}$ over the set of states/unitaries with gate complexity G such that for any such state/unitary, there exists a candidate in $\mathcal{N}$ that is ϵ-close in trace/average case distance to it, respectively. To select the candidate closest to our unknown object, we utilize classical shadows with random Clifford measurements to estimate all distances simultaneously to ϵ error using $\mathcal{O}(\log|\mathcal{N}|/\epsilon^2) \leq \tilde{\mathcal{O}}(G/\epsilon^2)$ copies/queries. The last inequality follows because we are able to prove that $|\mathcal{N}| \leq e^{\tilde{\mathcal{O}}(G)}$. Finally, we output the closest candidate.

The above strategy leads to a sample complexity that depends logarithmically on n, which is undesirable when G is smaller than $n/2$ (i.e., when some qubits are untouched by the circuit). We improved upon this by first performing a junta learning step [55] to identify which qubits are acted upon non-trivially. After identifying the non-trivial qubits, we perform a measure-and-postselect step. This allows us to construct a covering net only over the qubits acted upon non-trivially, whose cardinality no longer depends on n. Proceeding as before, we can remove the n dependence in the sample complexity.

Furthermore, for unitary learning, we improve the ϵ dependence to the Heisenberg scaling $\tilde{\mathcal{O}}(1/\epsilon)$ via a bootstrap method [16], using the above learner as a subroutine. We iteratively refine our learning outcome $\hat{U}$ by performing hypothesis selection over a covering net of $(U\hat{U}^{\dagger})^p$, with p increasing exponentially as the iteration proceeds. Although the circuit complexity of $(U\hat{U}^{\dagger})^p$ grows with p, a covering net with p-independent cardinality can be constructed based on the one-to-one correspondence with U. However, unlike the diamond distance learner in [16], which has fine control over every eigenvalue of the unitaries, our average-case learner only has average control over eigenvalues. Thus for the bootstrap to work (i.e., for the learning error to decrease with increasing p), the average-case learner has to work in an exponentially small error regime, which results in a dimensional factor in the final sample complexity $\tilde{\mathcal{O}}(\sqrt{2^n}G/\epsilon)$.

Sample complexity lower bounds. We prove the lower bounds in Theorems 1 and 4 by reduction to a distinguishing task: if we can approximately learn states/unitaries, then we can use this learning algorithm to distinguish a set of states/unitaries that are far apart from each other. Hence a lower bound on the sample complexity of distinguishing states/unitaries in a packing net implies a lower bound for learning.

For state learning, we construct a packing net $\mathcal{M}$ of the set of $(\log_2 G)$-qubit states. These states have circuit complexity $\sim G$ because $\mathcal{O}(2^k)$ two-qubit gates can implement any pure k-qubit states [56]. We prove that $|\mathcal{M}| \geq e^{\Omega(G)}$, which means that to distinguish these states, one has to gather $\Omega(\log|\mathcal{M}|) \geq \Omega(G)$ bits of information. Meanwhile, Holevo's theorem [57] asserts that the amount of information carried by each sample is upper bounded by $\tilde{\mathcal{O}}(\epsilon^2)$ [58]. Hence, we need at least $\tilde{\Omega}(G/\epsilon^2)$ copies of the unknown state.

Similarly, for unitary learning, we construct a packing net by stacking all the gates into $\log_4 G$ qubits, using the fact that $\mathcal{O}(4^k)$ two-qubit gates can implement any k-qubit unitaries [59]. Lacking an analog of Holevo's theorem for unitary queries, we turn to a recently established bound on the success probability of unitary discrimination [60] and obtain an $\Omega(G)$ sample complexity lower bound for constant ϵ. To incorporate the ϵ dependence, we follow [16] and map the problem into a fractional query problem. We show that with N queries, we can use the learning algorithm to simulate [61, 62] an $\mathcal{O}(\epsilon N)$ query algorithm that solves the above constant-error distinguishing problem. This gives us the desired $\Omega(G/\epsilon)$ lower bound.

Computational hardness. We prove the computational complexity lower bounds in Theorems 2 and 6 by reduction to the task of distinguishing pseudorandom states/functions [63, 64] from truly random states/functions. The hardness of this task relies on the computational assumption that Ring Learning with Errors ($\mathsf{RingLWE}$) cannot be solved efficiently with a quantum computer [65]. In particular, if we consider learning a pseudorandom state or a unitary implementing a pseudorandom function, then an efficient learner implies an efficient distinguisher from Haar-random states or truly random functions, thus contradicting the pseudorandomness assumption. The circuit complexity at which this computational hardness kicks in is the complexity of the circuit required to implement pseudorandom states/functions. Indeed, we show that the pseudorandom functions constructed in [65] based on the hardness of $\mathsf{RingLWE}$ can be implemented with $G = \mathcal{O}(\mathsf{poly}(n))$ gates and depth $\mathcal{O}(\mathsf{polylog}(n))$, Then, we can also construct pseudorandom quantum states from these pseudorandom functions [66], which can be implemented with $G = \mathcal{O}(\mathsf{poly}(n))$ gates and depth $\mathcal{O}(\mathsf{polylog}(n))$. We can boost this to our exponential computational complexity lower bound by assuming the sub-exponential hardness of $\mathsf{RingLWE}$ rather than just polynomial hardness. The efficient learning algorithm at $G = \mathcal{O}(\log n)$ follows by junta learning [55] and standard tomography methods.

While quantum state tomography is notoriously hard, most states hold little interest to practically-minded tomographers. Given that states and unitaries appearing in Nature are of bounded gate complexity, it is natural to ask if efficient learning becomes possible. In this work, we prove that to learn a state generated by a quantum circuit with G two-qubit gates to a small trace distance, a sample complexity scaling linearly in G is necessary and sufficient. We also prove that the optimal query complexity to learn a unitary generated by G gates to a small average-case error scales linearly in G. While sample-efficient learning can be achieved, we show that under reasonable cryptographic conjectures, the computational complexity for learning states and unitaries of gate complexity G must scale exponentially in G. We illustrate how these results establish fundamental limitations on the expressivity of quantum machine learning models and provide new perspectives on no-free-lunch theorems in unitary learning. Together, our results answer how the complexity of learning quantum states and unitaries relate to the complexity of creating these states and unitaries.

I. INTRODUCTION

A central problem in quantum physics is to characterize a quantum system by constructing a full classical description of its state or its unitary evolution based on data from experiments. These two tasks, named *quantum state tomography* [1–4] and *quantum process tomography* [5–9], are (in)famous for being ubiquitous yet highly expensive. The applications of tomography include quantum metrology [10, 11], verification [12, 13], benchmarking [5–8, 14–17], and error mitigation [18]. Yet tomography provably requires exponentially many (in the system size n) copies of the unknown state [19, 20] or runs of the unknown process [21]. This intuitively arises from the exponential scaling of the number of parameters needed to describe an *arbitrary* quantum system.

But the situation is less dire than it theoretically appears. In practice, tools for analyzing many-body systems often exploit *known structures* cleverly to predict their phenomenology or classically simulate them. Notable examples include the BCS theory for superconductivity [22], tensor networks [23, 24], and neural network [25–27] Ansätze. Indeed, while *most* of the states or unitaries may have exponential gate complexity [28], such objects are also unphysical: an exponentially-complex state or unitary cannot be produced in Nature with a reasonable amount of time [29]. In particular, [29] shows that quantum states/unitaries with bounded gate complexity are precisely those that can be produced by bounded-time evolution of time-dependent local Hamiltonians.

In this work, we study if tomography, too, can benefit from the observation that Nature can only produce states and unitaries with bounded complexity. This gives rise to the following main question.

Can we efficiently learn states/unitaries of bounded gate complexity?

In particular, we consider the following two tasks:

1. Given copies (samples) of a pure quantum state $|\psi\rangle$ generated by G two-qubit gates, learn $|\psi\rangle$ to within ϵ trace distance; see Figure 1(a).
2. Given uses (queries) of a unitary U composed of G two-qubit gates, learn U to within ϵ root mean squared trace distance between output states (average-case learning); see Figure 1(b).

Note that the G quantum gates can act on arbitrary pairs of qubits without any geometric locality constraint. By allowing general gates beyond discrete gate sets, this setting encompasses continuous time-dependent Hamiltonian dynamics via Trotterization [29] and thus analog quantum simulation [30]. It also includes states heavily studied in condensed matter such as symmetry-protected topologically

ordered states [31–33] and tensor network states [34–36]. Previously, [37] showed that Task 1 can be accomplished with a sample complexity of $\tilde{\mathcal{O}}(nG^2/\epsilon^4)$. In our work, we present algorithms for both of these tasks that use a number of samples/queries linear in the circuit complexity G up to logarithmic factors. Moreover, the sample complexity is independent of system size. Thus, for G scaling polynomially with the number of qubits, our learning procedures improve upon previous work [37] and have significantly lower sample/query complexities than required for general tomography, answering our central question affirmatively. We also prove matching lower bounds (up to logarithmic factors), showing that our algorithms are effectively optimal. Moreover, we show that the focus on average-case learning is crucial in the case of unitaries: unitary tomography up to error ϵ in diamond distance (a worst-case metric over input states) requires a number of queries scaling exponentially in G, establishing an exponential separation between average and worst case.

While our learning algorithms for bounded-complexity states and unitaries are efficient in terms of sample/query complexity, they are not computationally efficient. We prove that this is unavoidable. Assuming the quantum subexponential hardness of Ring Learning with Errors (RingLWE) [38–43], any quantum algorithm that learns arbitrary states/unitaries with $\tilde{\mathcal{O}}(G)$ gates requires computational time scaling exponentially in G. This result highlights a significant computational complexity limitation on learning even comparatively simple states and unitaries. This result also answers an open question in [44]. Meanwhile, we show that poly(n)-time algorithms are possible for $G = \mathcal{O}(\log n)$. Together, this establishes a crossover in computational hardness at $G \sim \log n$, kicking in far before the sample complexity becomes exponential (at $G = \exp(n)$). This means that relatively few samples/queries already contain enough information for the learning task, but it is hard to retrieve the information.

Finally, we study two variations of unitary learning which deepen our insights about the problem. The first variation utilizes classical (not quantum) descriptions of input and output pairs, and explains why both learning states and unitaries display a linear-in-G sample complexity: The underlying source of complexity in learning unitaries is, in fact, the readout of input and output quantum states, rather than learning the mapping. We generalize recent quantum no-free lunch theorems [45, 46] to reach this conclusion. For the second variation we study quantum machine learning (QML) models. We focus on learning classical functions that map variables controlling the input states and the evolution to some experimentally observed property of the outputs (Figure 1(c)). Surprisingly, we find that certain well-behaved many-variable functions can in fact not (even approximately) be implemented by quantum experiments with bounded complexity. This highlights a fundamental limitation on the functional expressivity of both Nature and practical QML models.

Sample complexity	State	Unitary (average-case)	Unitary (worst-case)
Upper bound	$\tilde{\mathcal{O}}\left(G/\epsilon^2\right)$	$\tilde{\mathcal{O}}\left(G \min\left\{1/\epsilon^2, \sqrt{2^n}/\epsilon\right\}\right)$	$\tilde{\mathcal{O}}\left(2^n G/\epsilon\right)$
Lower bound	$\tilde{\Omega}\left(G/\epsilon^2\right)$	$\Omega\left(G/\epsilon\right)$	$\Omega\left(2^{\min\{G/(2C), n/2\}}/\epsilon\right)$

Table I. **Sample complexity of learning n-qubit states and unitaries with circuit complexity G.** The learning accuracy ϵ is measured in trace distance for states, root mean squared trace distance for average case unitary learning, and diamond distance for worst case. Here, $C > 0$ is some universal constant. Throughout the manuscript, $\tilde{\mathcal{O}}, \tilde{\Theta}$ and $\tilde{\Omega}$ denote that we are suppressing non-leading logarithmic factors.

II. RESULTS

In this section, we discuss our rigorous guarantees for learning quantum states and unitaries with circuit complexity G. Our sample complexity results are summarized in Table I and Figure 1(d).

We also present computational complexity results, where we establish the exponential-in-G growth of computational complexity, implying that $\log n$ gate complexity is a transition point at which learning becomes computationally inefficient. In particular, we prove that for circuit complexity $\tilde{\mathcal{O}}(G)$, any quantum algorithm for learning states in trace distance or unitaries in average-case distance must use time exponential in G, under the conjecture that RingLWE cannot be solved by a quantum computer in sub-exponential time. Hence, for a number G of gates that scales slightly higher than $\log n$, the learning tasks cannot be solved by any polynomial-time quantum algorithm under the same conjecture. Meanwhile, for $G = \mathcal{O}(\log n)$, both learning tasks can be solved efficiently in polynomial time.

A. Learning quantum states

We consider the task of learning quantum states of bounded circuit complexity. Let $|\psi\rangle = U|0\rangle^{\otimes n}$ be an n-qubit pure state generated by a unitary U consisting of G two-qubit gates acting on the zero state. Throughout this section, we denote $\rho \triangleq |\psi\rangle\!\langle\psi|$. Given N identically prepared copies of ρ, the goal is to output a classical circuit description of a quantum state $\hat{\rho}$ that is ϵ-close to ρ in trace distance: $\mathrm{d}_{\mathrm{tr}}(\hat{\rho}, \rho) = \|\hat{\rho} - \rho\|_1/2 < \epsilon$. We establish the following theorem, which states that linear-in-G many samples (up to logarithmic factors) are both necessary and sufficient to learn the unknown quantum state $|\psi\rangle$ within a small trace distance.

Theorem 1 (State learning)**.** *Suppose we are given N copies of an n-qubit pure state $\rho = |\psi\rangle\!\langle\psi|$, where $|\psi\rangle = U|0\rangle^{\otimes n}$ is generated by a unitary U consisting of G two-qubit gates. Then, $N = \tilde{\Theta}\left(G/\epsilon^2\right)$ copies are necessary and sufficient to learn the state within ϵ-trace distance d_{tr} with high probability.*

Previous work [37] obtained a sample complexity of $\tilde{\mathcal{O}}(nG^2/\epsilon^4)$ for this task, which we show to be sub-optimal. Notably, our result achieves the optimal scaling in both G and ϵ up to logarithmic factors and is independent of the system size n. Thus, we completely characterize the sample complexity, resolving an open question from [47]. We prove the upper bound in Appendix B 1, utilizing covering nets [48] and quantum hypothesis selection [49]. Our proposed algorithm first creates a covering net over the space of all unitaries consisting of G two-qubit gates. This can easily be transformed into a covering net over the space of all quantum states generated by G two-qubit gates by applying each element of the unitary covering net to the zero state. Thus, any quantum state generated by G two-qubit gates is close (in trace distance) to some element of the covering net. We can then apply quantum hypothesis selection [49] to the covering net, which allows us to identify the element in the covering net that is close to the unknown target state $|\psi\rangle$ and achieve the optimal ϵ dependence. We also note that our algorithm for learning quantum states does not require knowledge of or access to the unitary U which generates the unknown state $|\psi\rangle$. Only the condition that some unitary U consisting of G gates generates $|\psi\rangle$ is needed. The lower bound is proven in Appendix B 2 by using an information-theoretic argument via reduction to distinguishing a packing net over G-gate states [19].

Our algorithm to learn the unknown quantum state $|\psi\rangle$ is computationally inefficient, as it requires a search over a covering net whose cardinality is exponential in G. We show that for circuits of size $\tilde{\mathcal{O}}(G)$, any quantum algorithm that can learn $|\psi\rangle$ to within a small trace distance given access to copies of this state must use time exponential in G, under commonly-believed cryptographic assumptions [38–43]. Meanwhile, the learning task is computationally-efficiently solvable for $G = \mathcal{O}(\log n)$ via junta learning [50] and standard tomography methods. This implies a transition point of computational efficiency at $\log n$ circuit complexity. Previous work [51, 52] arrives at similar hardness results for polynomial circuit complexity, but our detailed analysis allows us to sharpen the computational lower bound and obtain this transition point. [53] also proves computational complexity lower bounds for distribution learning that are similar in spirit.

Theorem 2 (State learning computational complexity)**.** *Suppose we are given N copies of an unknown n-qubit pure state $|\psi\rangle = U|0\rangle^{\otimes n}$ generated by an arbitrary unknown unitary U consisting of $\tilde{\mathcal{O}}(G)$ two-qubit gates. Suppose that* RingLWE *cannot be solved by a quantum computer in sub-exponential time. Then, any quantum algorithm that learns the state to within ϵ trace distance d_{tr} must use $\exp(\Omega(\min\{G,n\}))$ time. Meanwhile, for $G = \mathcal{O}(\log n)$, the learning task can be solved in polynomial time.*

B. Learning quantum unitaries

For learning unitaries, a natural distance metric analogous to the trace distance for states is the diamond distance $\mathrm{d}_\diamond(U,V) = \max_\rho \|(U\otimes I)\rho(U\otimes I)^\dagger - (V\otimes I)\rho(V\otimes I)^\dagger\|_1$, where ρ is over any arbitrarily extended Hilbert space. It characterizes the optimal success probability for discriminating between two unitary channels. Moreover, it can be reinterpreted in terms of the largest distance between $U|\psi\rangle$ and $V|\psi\rangle$ over all input states $|\psi\rangle$, and thus represents the error we make in the worst case over input states. We find that in this worst-case learning task, a number of queries exponential in G is necessary to learn the unitary.

Theorem 3 (Worst-case unitary learning)**.** *To learn an n-qubit unitary composed of G two-qubit gates to accuracy ϵ in diamond distance $\mathrm{d}_\diamond$ with high probability, any quantum algorithm must use at least $\Omega\left(2^{\min\{G/(2C),n/2\}}/\epsilon\right)$ queries to the unknown unitary, where $C > 0$ is a universal constant. Meanwhile, there exists such an algorithm using $\tilde{\mathcal{O}}(2^n G/\epsilon)$ queries.*

The complete proof is given in Appendix C 1 and relies on the adversary method [54–57]. We construct a set of unitaries that a worst-case learning algorithm can successfully distinguish, but that only make minor differences when acting on states so that a minimal number of queries have to be made in order to distinguish them. The upper bound is achieved by the average-case learning algorithm in Theorem 4 below when applied in the regime of exponentially small error.

Having established this no-go theorem for worst-case learning, we turn to a more realistic average-case learning alternative. Here, the accuracy is measured using the root mean squared trace distance between output states over Haar-random inputs, $\mathrm{d}_{\mathrm{avg}}(U,V) = \sqrt{\mathbb{E}_{|\psi\rangle}[\mathrm{d}_{\mathrm{tr}}(U|\psi\rangle, V|\psi\rangle)^2]}$. This metric characterizes the average error when testing the learned unitary on randomly chosen input states.

We find that, similarly to the state learning task, linear-in-G many queries are both necessary and sufficient to learn a unitary in the average case.

Theorem 4 (Average-case unitary learning)**.** *There exists an algorithm that learns an n-qubit unitary composed of G two-qubit gates to accuracy ϵ in root mean squared trace distance $\mathrm{d}_{\mathrm{avg}}$ with high probability using $\tilde{\mathcal{O}}\left(G\min\{1/\epsilon^2, \sqrt{2^n}/\epsilon\}\right)$ queries to the unknown unitary. Meanwhile, $\Omega\left(G/\epsilon\right)$ queries to the unitary or its inverse or the controlled versions are necessary for any such algorithm.*

We show the upper bound in Appendix C 2 by combining a covering net with quantum hypothesis selection similarly to the upper bound in Theorem 1. Our algorithm achieving the query complexity $\tilde{\mathcal{O}}(G/\epsilon^2)$ uses maximally entangled states and the Choi–Jamiołkowski duality [58–60]. With a bootstrap method similar to quantum phase estimation [21], we improve the ϵ-dependence to the Heisenberg scaling $\tilde{\mathcal{O}}(1/\epsilon)$, albeit at the cost of a dimensional factor. Without auxiliary systems, we prove a query complexity bound of $\tilde{\mathcal{O}}(G\min\{1/\epsilon^4, (\sqrt{2^n})^3/\epsilon\})$. The lower bound is proven in Appendix C 3 by mapping to a fractional query problem [21, 61, 62] and making use of a recent upper bound on the success probability in unitary distinguishing tasks [63]. In the case of learning generic unitaries, our result yields a $\Omega(4^n/\epsilon)$ lower bound, improving upon the $\Omega(4^n/n^2)$ bound from the recent work [51], which studies the hardness of learning Haar-(pseudo)random unitaries.

As Haar-random states are hard to generate in practice, we also discuss other input state ensembles of physical interest. Relying on the equivalence of root mean squared trace distances over different locally scrambled ensembles [64, 65], recently established in [66], our algorithm achieves the same average-case guarantee over any such ensemble. Notable examples of locally scrambled ensembles include products of Haar-random single-qubit states or of random single-qubit stabilizer states, 2-designs on n-qubit states, and output states of random local quantum circuits with any fixed architecture.

The similar linear-in-G sample/query complexity scaling in Theorems 1 and 4 hints at a common underlying source of complexity. However, in contrast to state learning, unitary learning comes with two natural such sources: (1) to readout input and output states, and (2) to learn the mapping from inputs to outputs. The similarity between learning states and unitaries in terms of complexities suggests that the former may encapsulate the central difficulty in unitary learning whereas the latter may be easy. This seemingly contradicts recent quantum no-free-lunch theorems [45, 46, 67], which state $\Omega(2^n)$ samples are required to learn a generic unitary even from classical descriptions of input-output state pairs, highlighting the difficulty of (2).

To resolve this apparent contradiction, we reformulate the quantum no-free-lunch theorem (Theorem 17) from a unifying information-theoretic perspective in Appendix C 4. We highlight that enlarging the space for the classically described data allows to systematically reduce the sample complexity until a single sample suffices to learn a general unitary. Therefore, the difficulty of learning the mapping, as indicated by quantum no-free-lunch theorems, vanishes when we allow auxiliary systems and query access to the unitary. Inspired by this observation, we give two ways of enlarging the representation space with auxiliary systems. The first is fundamentally quantum, making use of entangled input states [46]. The other is purely classical, relying on mixed state inputs [68].

Theorem 5 (Learning with classical descriptions)**.** *There exists an algorithm that learns a generic n-qubit unitary with any non-trivial accuracy and with high success probability using $\mathcal{O}(2^n/r)$ classically described input-output pairs with mixed (entangled) input states of (Schmidt) rank r. Moreover, any such algorithm that is robust to noise needs at least $\Omega(2^n/r)$ samples.*

Similarly to the case for state learning, our average-case unitary learning algorithm is not computationally efficient. We show that this cannot be avoided. Under commonly-believed cryptographic assumptions [38–43], any quantum algorithm that can learn unknown unitaries with circuit size $\tilde{\mathcal{O}}(G)$ to a small error in average-case distance from queries must have a computational time exponential in G. This implies the same computational hardness for worst-case unitary learning, and a $\log n$ transition point of computational efficiency. Note that the hard instances we construct are implementable with a similar number of Clifford and T gates [69]. Therefore, together with Theorem 2, this implies that there is no polynomial time quantum algorithms for learning Clifford+T circuits with $\tilde{\omega}(\log n)$ T gates, answering an open question (the fifth question) in the survey [44] negatively.

Theorem 6 (Unitary learning computational complexity)**.** *Suppose we are given N queries to an arbitrary unknown n-qubit unitary U consisting of $\tilde{\mathcal{O}}(G)$ two-qubit gates. Assume that $\mathsf{RingLWE}$ cannot be solved by a quantum computer in sub-exponential time. Then, any quantum algorithm that learns the unitary to within ϵ average-case distance $\mathrm{d}_{\mathrm{avg}}$ must use $\exp(\Omega(\min\{G,n\}))$ time. Meanwhile, for $G = \mathcal{O}(\log n)$, the learning task can be solved in polynomial time.*

C. Learning physical functions

Apart from learning quantum states and dynamics themselves, a more classically minded learner may care more about learning classical functions resulting from quantum processes. We define these *physical functions* in Appendix D as functions $f(x, \{U_i\}_{i=1}^G, a)$ mapping $x \in [0,1]^\nu$ to $\mathbb{R}$ resulting from a physical experiment consisting of three steps: (1) a fixed state preparation procedure that can depend on x; (2) a unitary evolution consisting of G tunable two-qubit gates $\{U_i\}_{i=1}^G$ and arbitrary fixed unitaries that can depend on x, arranged in a circuit architecture a; (3) the measurement of a fixed observable, whose expectation is the function output. By tuning the local gates $\{U_i\}_{i=1}^G$ and potentially changing architecture a, we obtain a resulting class of functions that can be implemented in this general experimental setting. Despite the generality of this setup, we find that certain well-behaved functions are actually not physical in this sense: they cannot be efficiently approximated or learned via physical functions.

Theorem 7 (Approximating and learning with physical functions)**.** *To approximate and learn arbitrary 1-bounded and 1-Lipschitz $\mathbb{R}$-valued functions on $[0,1]^\nu$ to accuracy ϵ in $\|\cdot\|_\infty$ with high probability, using physical functions with G gates and variable circuit structures, we must use $G \geq \tilde{\Omega}(1/\epsilon^{\nu/2})$ gates and collect at least $\Omega(1/\epsilon^\nu)$ samples.*

We prove this in Appendix D by noting that to approximate arbitrary 1-bounded and 1-Lipschitz functions well, the complexity of experimentally implementable functions cannot be too small, as measured by pseudo-dimension [70] or fat-shattering dimension [71]. Then the gate complexity lower bound follows because the function class complexity is limited by the circuit complexity [72], and we can appeal to results in classical learning theory [73] to obtain our sample complexity lower bound.

It has been established that a classical neural network can learn to approximate any 1-bounded and 1-Lipschitz functions to accuracy ϵ in $\|\cdot\|_\infty$ with $\tilde{\Theta}(1/\epsilon^\nu)$ parameters, exponential in the number of variables ν, known as the curse of dimensionality [74]. Our results show that quantum neural networks can do no better. This result not only is relevant to the practical implementation of quantum machine learning, complementing existing results on the universal approximation of quantum neural networks [75–78], but also has deep implications to the physicality of the function class at consideration. It means that there are some many-variable 1-bounded and 1-Lipschitz functions that cannot be implemented in Nature efficiently. On the other hand, certain more restricted function classes can be approximated using only $\mathcal{O}(1/\epsilon^2)$ parameters with both classical [74] and quantum neural networks [75], independent of the number of variables. This reveals a fundamental limitation on the functional expressivity of Nature, practical QML models, and quantum signal processing algorithms [79, 80].

III. DISCUSSION

Our work provides a new, more fine-grained perspective on the fundamental problems of state and process tomography by analyzing them for the broad and physically relevant class of bounded-complexity states and unitaries. It complements existing literature on learning restricted classes of states/unitaries or their properties. Examples include stabilizer circuits and states [81–84], Clifford circuits with few non-Clifford T gates and their output states [69, 85–88], matrix product operators [24] and states [89–91], phase states [82, 92–94], permutationally invariant states [95–97], outputs of shallow quantum circuits [98], PAC learning quantum states [99], shadow tomography [37], classical shadow formalism [14, 100–102], and property prediction of the outputs of quantum processes [103–105]. It also raises many interesting questions for future research.

Firstly, to account for decoherence and imperfections in realistic experiments, it is natural to generalize our results to mixed states and channels. As our learning algorithms based on hypothesis selection and classical shadows rely on the purity/unitarity of the unknown state/process, it seems that different algorithmic approaches would be needed to go beyond states of constant rank. Moreover, while our results show that learners using only single-copy measurements and no coherent quantum processing can achieve optimal sample/query complexity (in G) for pure state/unitary learning (in line with the state tomography protocol in [20], which uses at most $\mathrm{rank}(\rho)$ copies at a time for the tomography of general state ρ), quantum-enhanced learners, using multi-copy measurements and coherent processing, may have an advantage in the case of mixed states and channels. Such a quantum advantage is known for general mixed state tomography [106, 107] and in certain channel learning scenarios [103, 105, 108–112], however, to our knowledge not yet under assumptions of bounded complexity.

Secondly, there are several regimes of interest in which our results may be further extended. For instance, while we establish computational efficiency transition for state and unitary learning at logarithmic circuit complexity, we leave open the question of computationally efficient learning with constraints beyond circuit complexity (e.g., constant-depth circuits where the gates are spread out). Another potential improvement related to the computational complexity is in regards to average-case computational hardness. While our computational lower bounds hold in the worst-case, this does not tell us if most states/unitaries of bounded gate complexity are computationally hard to learn. Are there a worst-case to average-case reduction for this problem? Or perhaps is there an average-case notion of pseudorandomness that one could leverage here? An additional regime where our work can be extended is as follows. Our adaptation of the bootstrap strategy from [21] to average-case unitary learning achieves Heisenberg scaling only at the cost of a dimension-dependent factor. Given recent work in state shadow tomography [113–115], it may not be possible to find a learner free from this dimensional factor while achieving the ϵ^{-1} scaling. Finding such a learner or disproving its existence could serve as an important contribution to recent progress on Heisenberg-limited learning in different scenarios [116–118].

Thirdly, can we make learning even more efficient if the circuit structure is fixed and known in advance? Our upper bound already implies an algorithm with $\tilde{\mathcal{O}}(G)$ sample complexity for fixed circuit structure, but the lower bound proof crucially relies on the ability to place gates freely in the construction of the packing net. A particular fixed circuit structure of physical relevance is the brickwork circuit [119]. In Appendix E, we give preliminary results showing that if an n-qubit G-gate brickwork circuit suffices to implement an approximate unitary t-design [120], then the metric entropy of this unitary class with respect to $\mathrm{d}_{\mathrm{avg}}$ is lower bounded by $\Omega(tn)$. Considering the known lower bound of $G \geq \tilde{\Omega}(tn)$ on the size of brickwork circuits implementing t-designs [120], whose tightness is still an open problem [121], this may hint at a similar $\tilde{\Theta}(G)$ sample complexity of learning brickwork circuits.

Lastly, we outline a potential connection to the Brown-Susskind conjecture [122, 123] originating from the wormhole-growth paradox in holographic duality [124–127]. Informally, the conjecture states that the complexity of a generic local quantum circuit grows linearly with the number of 2-qubit gates for an exponentially long time, dual to the steady growth of a wormhole's volume in the bulk theory. With "complexity" understood as "circuit complexity" [126], this conjecture has recently been confirmed for exact circuit complexity [128, 129] while the case of approximate circuit complexity is only partially resolved [130, 131]. Our work suggests an alternative approach to the Brown-Susskind conjecture. Namely, we have demonstrated that the complexity of learning quantum circuits grows linearly with the number of local gates in the worst case. If our bounds were extended to hold with high probability over random circuits with G gates, this would yield a sample complexity version of the Brown-Susskind conjecture, suggesting the complexity of learning as a dual of the wormhole volume.

Via these open questions, tomography problems dating back to the early days of quantum computation and information connect closely to different avenues of current research in the field. Consequently, answering these questions will shed new light on fundamental quantum physics as well as on the frontiers of quantum complexity and quantum learning.

IV. METHODS

In this section, we discuss the main ideas behind the proof of our results on the sample complexity of learning states (Theorem 1) and unitaries (Theorem 4), along with the computational complexity (Theorems 2 and 6).

A. Sample complexity upper bounds

We prove the upper bounds in Theorems 1 and 4 using a hypothesis selection protocol similar to [49], but now based on classical shadow tomography [100] that enables a linear-in-G scaling.

a. State learning For state learning, we first take a minimal covering net $\mathcal{N}$ over the set of states with bounded circuit complexity G such that for any such state $|\psi\rangle$, there exists a state in the covering net that is ϵ-close to $|\psi\rangle$ in trace distance. This net then serves as a set of candidate states from which the learning algorithm will select one. Importantly, we prove that the cardinality of $\mathcal{N}$ can be upper bounded by $|\mathcal{N}| \leq e^{\tilde{\mathcal{O}}(G)}$. Here, note that the tilde hides a logarithmic factor in terms of system size, which we remove using a more detailed analysis with ideas from junta learning [50].

Next, we use classical shadows created via random Clifford measurements [100] to estimate the trace distance between the unknown state and each of the candidates in $\mathcal{N}$. This is achieved by estimating the expectation value of the Helstrom measurement [132], which is closely related to the trace distance between two states. As the rank of Helstrom measurements between pure states is at most 2, Clifford classical shadows can efficiently estimate all $\binom{|\mathcal{N}|}{2}$ of them simultaneously to ϵ error using $\mathcal{O}(\log|\mathcal{N}|/\epsilon^2) \leq \tilde{\mathcal{O}}(G/\epsilon^2)$ copies of $|\psi\rangle$. Then we select the candidate that has the smallest trace distance from $|\psi\rangle$ as the output.

The above strategy leads to a sample complexity upper bound that depends logarithmically on the number of qubits n. This is undesirable when the circuit complexity G is smaller than $n/2$ (i.e., when some of the qubits are in fact never influenced by the circuit). We improve our algorithm in this small-size regime by first performing a junta learning step [50] to identify which of the qubits are acted on non-trivially. After that, we enhance our protocol with a measure-and-postselect step. This allows us to construct a covering net only over the qubits acted upon non-trivially whose cardinality no longer depends on n. We then perform the hypothesis selection as before. In this way, we are able to achieve a sample complexity independent of system size.

b. Unitary learning The algorithm for unitary learning is similar to the state learning protocol. When allowing the use of an auxiliary system, we utilize the fact that the average-case distance between unitaries is equivalent to the trace distance between their Choi states. This way, we can reduce the problem to state learning of the Choi states and achieve the $\tilde{\mathcal{O}}(G/\epsilon^2)$ sample complexity. Without auxiliary systems, we can sample random input states and perform one-shot Clifford shadows on the outputs to estimate the squared average-case distance, resulting in an $\tilde{\mathcal{O}}(G/\epsilon^4)$ sample complexity with a sub-optimal ϵ-dependence.

Furthermore, we improve the ϵ dependence in unitary learning to the Heisenberg scaling $\tilde{\mathcal{O}}(1/\epsilon)$ via a bootstrap method similar to [21], using the above learning algorithm as a sub-routine. Specifically, we iteratively refine our learning outcome $\hat{U}$ by performing hypothesis selection over a covering net of $(U\hat{U}^\dagger)^p$, with p increasing exponentially as the iteration proceeds. Although the circuit complexity of $(U\hat{U}^\dagger)^p$ grows with p, a covering net with p-independent cardinality can be constructed based on the one-to-one correspondence to U. However, unlike the diamond distance learner considered in [21], which has fine control over every eigenvalue of the unitaries, our average-case learner only has control over the average of the eigenvalues. Thus for the bootstrap to work (i.e., for the learning error to decrease with increasing p), the average-case learner has to work in an exponentially small error regime, which results in a dimensional factor in the final sample complexity $\tilde{\mathcal{O}}(\sqrt{2^n}G/\epsilon)$.

B. Sample complexity lower bounds

We prove the sample complexity lower bounds in Theorems 1 and 4 by reduction to distinguishing tasks. Specifically, if we can learn the state/unitary to within ϵ error, then we can use this learning algorithm to distinguish a set of states/unitaries that are 3ϵ far apart from each other. Hence a lower bound on the sample complexity of distinguishing states/unitaries from a packing net implies a lower bound for the learning task.

a. State learning For state learning, we construct a packing net $\mathcal{M}$ of the set of $(\log_2 G)$-qubit states, which we later tensor product with zero states on the remaining qubits. These states have circuit complexity $\sim G$ because $\mathcal{O}(2^k)$ two-qubit gates can implement any pure k-qubit states [133]. We prove that the cardinality of $\mathcal{M}$ can be lower bounded by $e^{\Omega(G)}$. This means that to distinguish the states in $\mathcal{M}$, one has to gather $\Omega(\log|\mathcal{M}|) \geq \Omega(G)$ bits of information. Meanwhile, Holevo's theorem [134] asserts that the amount of information carried by each sample is upper bounded by $\tilde{\mathcal{O}}(\epsilon^2)$ [135]. Hence, we need at least $\tilde{\Omega}(G/\epsilon^2)$ copies of the unknown state.

b. Unitary learning Similarly, for unitary learning, we construct a packing net by stacking all the gates into $\log_4 G$ qubits, using the fact that $\mathcal{O}(4^k)$ two-qubit gates suffice to implement any k-qubit unitaries [136]. Lacking an analogue of Holevo's theorem for unitary queries, we turn to a recently established bound on the success probability of unitary discrimination [63] and obtain an $\Omega(G)$ sample complexity lower bound for constant ϵ. To incorporate the ϵ dependence, we follow [21] and map the problem into a fractional query problem. We show that with N queries, we can use the learning algorithm to simulate [61, 62] an $\mathcal{O}(\epsilon N)$ query algorithm that solves the above constant-accuracy distinguishing problem. This gives us the desired $N \geq \Omega(G/\epsilon)$ lower bound.

C. Computational hardness

We prove the computational complexity lower bounds in Theorems 2 and 6 again by reduction to distinguishing tasks, whose hardness relies on cryptographic primitives in this case. In particular, we show that if we can learn the state/unitary in polynomial time, then we can use this learning algorithm to efficiently distinguish between pseudorandom states/functions [137, 138] and truly random states/functions. We note that similar ideas have been used to establish a cryptographic no-cloning theorem [137] for PRS, but without gate complexity dependence and the unitary counterpart. The RingLWE hardness assumption here may also be relaxed to the existence of appropriate quantum-secure PRS/PRF constructions that have the same gate complexity discussed below.

Our proofs rely on the construction of quantum-secure pseudorandom functions (PRFs) that can be implemented using TC^0 circuits, subject to the assumption that Ring Learning with Errors (RingLWE) cannot be solved by a quantum computer in sub-exponential time [40]. We show that the circuit construction of [40] can be implemented quantumly using $G = \mathcal{O}(n\mathsf{polylog}(n))$ gates by converting this TC^0 circuit into a quantum circuit that computes the same function. With this construction, we can prove the computational hardness of learning when $G = \mathcal{O}(n\mathsf{polylog}(n))$ as follows.

a. State learning For state learning, we utilize these quantum-secure PRFs to construct pseudorandom quantum states (PRS), in particular binary phase states from [137, 139], with $G = \mathcal{O}(n\mathsf{polylog}(n))$ gates. Given copies of some unknown quantum state that is promised to either be a PRS or a Haar-random state, we design a procedure that can distinguish these two cases. The distinguisher uses our algorithm for learning states along with the SWAP test applied to the learned state and the given state [140, 141]. Thus, we show that if our learning algorithm was able to computationally efficiently learn PRS, then we would have an efficient distinguisher between PRS and Haar-random states, contradicting the definition of a PRS [137].

b. Unitary learning The proof idea in the unitary setting is similar. In this case, we consider PRFs directly rather than the PRS construction. Given query access to some unknown unitary that is promised to be the unitary oracle of either a PRF or a uniformly random Boolean function, we design a procedure that can distinguish these two cases. The distinguisher uses our algorithm for learning unitaries along with the SWAP test [140, 141]. Here, we query the given/learned unitaries on a random tensor product of single-qubit stabilizer states and conduct the SWAP test between the output states. This way, we show that if our learning algorithm was able to computationally efficiently learn a unitary implementing a PRF, then we would have an efficient distinguisher between PRFs and uniformly random functions, which contradicts the definition of a PRF [138].

We then go one step further and show computational hardness for circuit size $\tilde{\mathcal{O}}(G)$. To do this we rely critically on the assumption that RingLWE is hard not just to polynomial-time quantum algorithms, but even to quantum algorithms that run for longer (sub-exponential) time. This allows us to take a much smaller input size to the PRS/PRF in our previous constructions (i.e., over $\mathcal{O}(G)$ qubits which can be implemented with $\tilde{\mathcal{O}}(G)$ gates). The sub-exponential computational hardness of $\mathsf{RingLWE}$ then implies that solving the learning tasks requires time exponential in G.

Meanwhile, for $G = \mathcal{O}(\log n)$, the learning tasks can be solved efficiently by junta learning and standard tomography methods. This establishes $\log n$ circuit complexity as a transition point of computational efficiency. This also implies that the circuit complexity of the PRS/PRF constructions in [40, 139] is optimal up to logarithmic factors, otherwise it would contradict efficient tomography of $\mathcal{O}(\log n)$-complexity states/unitaries. Finally, we note that the PRS/PRF we consider can be implemented with a similar number of Clifford and T gates, extending our results to Clifford+T circuits.

ACKNOWLEDGMENTS

The authors thank John Preskill for valuable feedback and continuous support throughout this project. The authors also thank Ryan Babbush, Yiyi Cai, Charles Cao, Alexandru Gheorghiu, András Gilyén, Alex B. Grilo, Jerry Huang, Nadine Meister, Chris Pattison, Alexander Poremba, Xiao-Liang Qi, Ruohan Shen, Mehdi Soleimanifar, Yu Tong, Tzu-Chieh Wei, Tai-Hsuan Yang, Nengkun Yu for fruitful discussions. Finally, the authors thank Antonio Anna Mele and the anonymous reviewers at QIP 2024 for feedback on an earlier version of this paper. Appendices

CONTENTS

Appendix A: Preliminaries

Throughout the appendices, we use $d = 2^n$ to denote the dimension of the n-qubit Hilbert space unless otherwise stated.

1. Distance metrics

Here we review some distance metrics and their properties used throughout our proofs. In the main text we have already introduced the trace distance

$$\mathrm{d_{tr}}(|\psi\rangle, |\phi\rangle) = \frac{1}{2}\| \, |\psi\rangle\!\langle\psi| - |\phi\rangle\!\langle\phi| \, \|_1 \, , \tag{A.1}$$

which is analogously defined for density matrices as $\mathrm{d_{tr}}(\rho, \sigma) = \|\rho - \sigma\|_1/2$, the diamond distance

$$\mathrm{d}_\diamond(U, V) = \max_\rho \|(U \otimes I)\rho(U \otimes I)^\dagger - (V \otimes I)\rho(V \otimes I)^\dagger\|_1 \, , \tag{A.2}$$

and the root mean squared trace distance

$$\mathrm{d_{avg}}(U, V) = \sqrt{\mathop{\mathbb{E}}_{|\psi\rangle}[\mathrm{d_{tr}}(U|\psi\rangle, V|\psi\rangle)^2]} \tag{A.3}$$

where the expectation is taken over Haar measure[2].

Apart from these, we also use the following auxiliary distance metrics. We define the quotient spectral distance

$$d_2'(U,V) = \min_{e^{i\phi}\in U(1)} \|U - e^{i\phi}V\| \tag{A.4}$$

to be the spectral distance $d_2(U,V) = \|U - V\|$ up to a global phase. Similarly, we define the quotient normalized Frobenius distance

$$d_F'(U,V) = \min_{e^{i\phi}\in U(1)} \frac{1}{\sqrt{d}}\|U - e^{i\phi}V\|_F \tag{A.5}$$

as the normalized Frobenius norm distance $d_F(U,V) = \frac{1}{\sqrt{d}}\|U - V\|_F$ up to a global phase.

The following lemma shows that (quotient) spectral distance and diamond distance are equivalent.

Lemma 1 (Spectral and diamond distance of unitaries, variant of [142, Lemma B.5])**.** *For any two d-dimensional unitaries U and V, we have*

$$\frac{1}{\sqrt{2}} d_2'(U,V) \le \frac{1}{2}\,\mathrm{d}_\diamond(U,V) \le d_2'(U,V) \le \|U - V\|. \tag{A.6}$$

Proof. Since stabilization is not necessary for computing the diamond distance of two unitary channels [143], we have

$$\begin{aligned}
\frac{1}{2}\,\mathrm{d}_\diamond(U,V) &= \max_{|\psi\rangle} \frac{1}{2}\|U|\psi\rangle\langle\psi|U^\dagger - V|\psi\rangle\langle\psi|V^\dagger\|_1 = \max_{|\psi\rangle}\sqrt{1 - |\langle\psi|U^\dagger V|\psi\rangle|^2}\\
&= \max_{|\psi\rangle}\sqrt{(1 + |\langle\psi|U^\dagger V|\psi\rangle|)(1 - |\langle\psi|U^\dagger V|\psi\rangle|)} \ge \max_{|\psi\rangle}\frac{1}{\sqrt{2}}\sqrt{2(1 - |\langle\psi|U^\dagger V|\psi\rangle|)}\\
&= \frac{1}{\sqrt{2}}\min_{e^{i\phi}\in U(1)}\max_{|\psi\rangle}\|U|\psi\rangle - e^{i\phi}V|\psi\rangle\|_2 = \frac{1}{\sqrt{2}}\min_{e^{i\phi}\in U(1)}\|U - e^{i\phi}V\| = \frac{1}{\sqrt{2}}d_2'(U,V),
\end{aligned} \tag{A.7}$$

where we have used $\left|\langle\psi|U^\dagger V|\psi\rangle\right| \ge 0$ and the standard conversion between trace distance and fidelity. This proves the first inequality. Similarly, we have

$$\begin{aligned}
\frac{1}{2}\,\mathrm{d}_\diamond(U,V) &= \max_{|\psi\rangle} \frac{1}{2}\|U|\psi\rangle\langle\psi|U^\dagger - V|\psi\rangle\langle\psi|V^\dagger\|_1 = \max_{|\psi\rangle}\sqrt{1 - |\langle\psi|U^\dagger V|\psi\rangle|^2}\\
&= \max_{|\psi\rangle}\sqrt{(1 + |\langle\psi|U^\dagger V|\psi\rangle|)(1 - |\langle\psi|U^\dagger V|\psi\rangle|)} \le \max_{|\psi\rangle}\sqrt{2(1 - |\langle\psi|U^\dagger V|\psi\rangle|)}\\
&= \min_{e^{i\phi}\in U(1)}\max_{|\psi\rangle}\|U|\psi\rangle - e^{i\phi}V|\psi\rangle\|_2 = \min_{e^{i\phi}\in U(1)}\|U - e^{i\phi}V\| = d_2'(U,V),
\end{aligned} \tag{A.8}$$

where we have used $\left|\langle\psi|U^\dagger V|\psi\rangle\right| \le 1$, proving the second inequality. The third inequality follows immediately from $d_2'(U,V) = \min_{e^{i\phi}\in U(1)}\|U - e^{i\phi}V\| \le \|U - V\|$. □

We will also utilize the subadditivity of the diamond distance.

Lemma 2 (Subadditivity of diamond distance [144, Prop. 3.48])**.** *For any d-dimensional unitaries U_1, U_2, V_1, V_2, we have the following inequality:*

$$\mathrm{d}_\diamond(U_2U_1, V_2V_1) \le \mathrm{d}_\diamond(U_2, V_2) + \mathrm{d}_\diamond(U_1, V_1). \tag{A.9}$$

From the standard relationship between different p-norms, we have the following relation between d_2' and d_F'.

Lemma 3 (Norm conversion between quotient spectral and normalized Frobenius distance)**.** *For any two d-dimensional unitaries U and V, we have*

$$\frac{1}{\sqrt{d}} d_2'(U,V) \le d_F'(U,V) \le d_2'(U,V). \tag{A.10}$$

[2] Due to the concentration of Lipschitz functions on inputs drawn from the Haar measure, controlling this root mean squared distance also leads to error bounds that hold with high probability over random input states.

Proof. For any $e^{i\phi} \in U(1)$, the standard relation between matrix norms gives us

$$\|U - Ve^{i\phi}\| \leq \|U - Ve^{i\phi}\|_F \leq \sqrt{d}\|U - Ve^{i\phi}\|. \tag{A.11}$$

Taking the minimum of $\|U - Ve^{i\phi}\|_F$ over $e^{i\phi}$ in the first inequality and dividing by $\sqrt{d}$, we obtain

$$\frac{1}{\sqrt{d}} d_2'(U,V) \leq \frac{1}{\sqrt{d}}\|U - Ve^{i\phi}\| \leq d_F'(U,V). \tag{A.12}$$

Similarly, taking the minimum of $\|U - Ve^{i\phi}\|$ over $e^{i\phi}$ in the second inequality and dividing by $\sqrt{d}$ yields

$$d_F'(U,V) \leq \frac{1}{\sqrt{d}}\|U - Ve^{i\phi}\|_F \leq d_2'(U,V). \tag{A.13}$$

Thus we have the desired results. □

The following lemma collects some useful properties of d_F' and in particular shows that d_F' and $\mathrm{d_{avg}}$ are equivalent.

Lemma 4 (Properties of quotient normalized Frobenius distance)**.** *For any two d-dimensional unitaries U and V, we have:*

1. $\frac{1}{2}d_F'(U,V) \leq \mathrm{d_{avg}}(U,V) \leq d_F'(U,V)$.
2. *For any integer $p \geq 1$, $d_F'(U^p, V^p) \leq p d_F'(U,V)$.*
3. *For any integer $p \geq 1$, if $d_F'(U,I), d_F'(V,I) \leq \frac{4/(25\pi)}{\sqrt{d}}$, then $d_F'(U^{1/p}, V^{1/p}) \leq \frac{2}{p} d_F'(U,V)$.*

Item 3 can be viewed as a version of [21, Lemma 3.1].

Proof. Item 1: From properties of the Haar integral (see e.g., [145, Example 50]), we have

$$\mathrm{d_{avg}}(U,V)^2 = 1 - \frac{d + |\operatorname{tr}(U^\dagger V)|^2}{d(d+1)}. \tag{A.14}$$

On the other hand, we have

$$d_F'^2(U,V) = \min_{e^{i\phi}\in U(1)} \frac{1}{d}\|U - Ve^{i\phi}\|_F^2 = \min_{e^{i\phi}\in U(1)} 2 - \frac{2}{d}\mathrm{Re}[\operatorname{tr}(U^\dagger V e^{i\phi})] = 2 - \frac{2}{d}|\operatorname{tr}(U^\dagger V)|. \tag{A.15}$$

Combining them, we get

$$\mathrm{d_{avg}}(U,V)^2 = \frac{d}{d+1} d_F'^2(U,V)\left(1 - \frac{d_F'^2(U,V)}{4}\right) \in \left[\frac{1}{4}d_F'^2(U,V), d_F'^2(U,V)\right], \tag{A.16}$$

because $d_F'^2(U,V) \in [0,2]$. Thus we have established Item 1.

Item 2: From triangle inequality, we have

$$d_F'(U^p, V^p) \leq \sum_{k=1}^p d_F'(U^{p+1-k}V^{k-1}, U^{p-k}V^k) = \sum_{k=1}^p d_F'(U,V) = p d_F'(U,V), \tag{A.17}$$

where we have used the unitary invariance of d_F'. This proves Item 2.

Item 3: We first prove the following modified version without the global phase: "If $d_F(U,I), d_F(V,I) \leq \frac{4/(5\pi)}{\sqrt{d}}$, then $d_F(U^{1/p}, V^{1/p}) \leq \frac{2}{p} d_F(U,V)$." Let $U = e^X, V = e^Y$ with $\|X\|, \|Y\| \leq \pi$. We can refine the bound on $\|X\|, \|Y\|$ by noting the following

$$\|X\| \leq \frac{\pi}{2}\|e^X - I\| \leq \frac{\pi}{2}\|U - I\|_F = \frac{\pi\sqrt{d}}{2} d_F(U,I) \leq \frac{2}{5}, \tag{A.18}$$

where the first inequality can be seen from eigenvalue analysis as follows: Let $i\theta_k$ be the eigenvalues of X with $|\theta_k| \leq \pi$. Then we have

$$\|X\| = \max_k |\theta_k| \leq \pi \max_k \left|\sin\frac{\theta_k}{2}\right| = \frac{\pi}{2}\max_k \left|e^{i\theta_k} - 1\right| = \frac{\pi}{2}\|e^X - I\|. \tag{A.19}$$

Similarly, we have $\|Y\| \le 2/5$.

Next, we prove the following inequality when $\|X\|, \|Y\| \le 2/5$ (similar to [146, Appendix D]):

$$\frac{1}{2}\|X-Y\|_F \le \|e^X - e^Y\|_F \le \|X-Y\|_F. \tag{A.20}$$

For the upper bound, we use the triangle inequality and a telescoping sum representation: For any $m \in \mathbb{N}$,

$$\|e^X - e^Y\|_F \le \sum_{k=1}^{m} \|e^{(k-1)X/m}(e^{X/m} - e^{Y/m})e^{(m-k)Y/m}\|_F = m\|e^{X/m} - e^{Y/m}\|_F\,, \tag{A.21}$$

and by taking $m \to \infty$ we arrive at the upper bound. For the lower bound, note that by triangle inequality, we have

$$\|e^X - e^Y\|_F = \left\|\sum_{k=1}^{\infty}\frac{1}{k!}(X^k - Y^k)\right\|_F \ge \|X-Y\|_F - \left\|\sum_{k=2}^{\infty}\frac{1}{k!}(X^k - Y^k)\right\|_F. \tag{A.22}$$

The second term can be upper bounded by

$$\begin{aligned}\left\|\sum_{k=2}^{\infty}\frac{1}{k!}(X^k - Y^k)\right\|_F &= \left\|\sum_{k=2}^{\infty}\sum_{l=1}^{k}\frac{1}{k!}X^{l-1}(X-Y)Y^{k-l}\right\|_F\\ &\le \sum_{k=2}^{\infty}\frac{k}{k!}\left(\frac{2}{5}\right)^k \|X-Y\|_F\\ &= (e^{2/5}-1)\|X-Y\|_F\,,\end{aligned} \tag{A.23}$$

where we have used $\|AB\|_F \le \|A\| \cdot \|B\|_F$ and $\|X\|, \|Y\| \le 2/5$. Plugging this bound back in, we arrive at the lower bound

$$\|e^X - e^Y\|_F \ge (2 - e^{2/5})\|X-Y\|_F \ge \frac{1}{2}\|X-Y\|_F. \tag{A.24}$$

Equation (A.20) in particular implies

$$d_F(U^{1/p}, V^{1/p}) \le \frac{1}{p\sqrt{d}}\|X-Y\|_F \le \frac{2}{p}d_F(U,V)\,, \tag{A.25}$$

and thus the modified version of our claim.

Finally, we deal with the global phase and prove the d'_F version, where we assume $d'_F(U,I), d'_F(V,I) \le \frac{4/(25\pi)}{\sqrt{d}}$. Let $e^{i\phi_U}, e^{i\phi_V}, e^{i\phi} \in U(1)$ denote the global phases that minimize $d_F(U, Ie^{i\phi_U}), d_F(V, Ie^{i\phi_V})$ and $d_F(Ue^{-i\phi_U}, Ve^{-i\phi_V}e^{i\phi})$, respectively. Then $d_F(U, Ie^{i\phi_U}), d_F(V, Ie^{i\phi_V}) \le \frac{4/(25\pi)}{\sqrt{d}}$ by assumption, and $d_F(Ue^{-i\phi_U}, Ve^{-i\phi_V}) \le d_F(U, Ie^{i\phi_U}) + d_F(V, Ie^{i\phi_V}) \le \frac{8/(25\pi)}{\sqrt{d}}$. Therefore,

$$\begin{aligned}d_F(e^{i\phi}, I) &\le d_F(e^{i\phi}, (Ve^{-i\phi_V})^\dagger(Ue^{-i\phi_U})) + d_F((Ve^{-i\phi_V})^\dagger(Ue^{-i\phi_U}), I)\\ &= d_F(Ue^{-i\phi_U}, Ve^{-i\phi_V}e^{i\phi}) + d_F(Ue^{-i\phi_U}, Ve^{-i\phi_V})\\ &\le 2d_F(Ue^{-i\phi_U}, Ve^{-i\phi_V})\\ &\le \frac{16/(25\pi)}{\sqrt{d}}.\end{aligned} \tag{A.26}$$

This means that $d_F(Ue^{-i\phi_U}e^{-i\phi}, I) \le d_F(U, Ie^{i\phi_U}) + d_F(e^{i\phi}, I) \le \frac{(4+16)/(25\pi)}{\sqrt{d}} = \frac{4/(5\pi)}{\sqrt{d}}$. We also know that $d_F(Ve^{-i\phi_V}, I) \le \frac{4/(25\pi)}{\sqrt{d}} \le \frac{4/(5\pi)}{\sqrt{d}}$. Thus the two matrices $Ue^{-i\phi_U}e^{-i\phi}$ and $Ve^{-i\phi_V}$ satisfy the condition of the modified version without global phase, and we thus have

$$\begin{aligned}d'_F(U^{1/p}, V^{1/p}) &\le d'_F(U^{1/p}, V^{1/p}(e^{-i\phi_V})^{1/p}(e^{i\phi_U})^{1/p}(e^{i\phi})^{1/p})\\ &= d_F((Ue^{-i\phi_U}e^{-i\phi})^{1/p}, (Ve^{-i\phi_V})^{1/p})\\ &\le \frac{2}{p}d_F(Ue^{-i\phi_U}e^{-i\phi}, Ve^{-i\phi_V}) = d'_F(U,V).\end{aligned} \tag{A.27}$$

This concludes the proof of Item 3. □

Haar-random states are in general hard to generate. One may want to use other ensembles of input states and the associated distance metric for average-case learning. A class of ensembles of physical interest is that of locally scrambled ensembles [64, 65] defined as follows:

Definition 1 (Locally scrambled ensembles up to the second moment)**.** *An ensemble $\mathcal{S}$ of (i.e., a distribution over) n-qubit states is called a locally scrambled ensemble up to the second moment if it is of the form $\mathcal{S} = \mathcal{U}\left|0\right\rangle^{\otimes n}$, where $\mathcal{U}$ is an ensemble of unitaries that is locally scrambled up to the second moment. That is, there exists another unitary ensemble $\mathcal{U}'$, such that: (1) for any U' randomly sampled from $\mathcal{U}'$ and for any tensor product of single-qubit unitaries $\otimes_{i=1}^{n} U_i$, $U' \otimes_{i=1}^{n} U_i$ follows the same distribution of $\mathcal{U}'$; and (2) for any $2n$-qubit density matrices ρ, we have $\mathbb{E}_{U\sim\mathcal{U}}[U^{\otimes 2}\rho(U^\dagger)^{\otimes 2}] = \mathbb{E}_{U'\sim\mathcal{U}'}[U'^{\otimes 2}\rho(U'^\dagger)^{\otimes 2}]$. We use $\mathbb{S}_{\mathrm{LS}}^{(2)}$ to denote the set of all such state ensembles.*

Notable examples of these ensembles include n-qubit Haar-random states, products of Haar-random single-qubit states, products of random single-qubit stabilizer states, 2-designs on n-qubit states, and output states of random local quantum circuits with any fixed architecture. The following lemma from the study of out-of-distribution generalization [66] shows that these ensembles lead to mutually equivalent average-case distance metrics.

Lemma 5 (Equivalence of locally scrambled average-case distances [66, Theorem 1])**.** *We denote by $d_P(U,V) = \sqrt{\mathbb{E}_{\left|\psi\right\rangle\sim P}[\mathrm{d_{tr}}(U\left|\psi\right\rangle, V\left|\psi\right\rangle)^2]}$ the root mean squared trace distance with respect to an ensemble P. For any $P, Q \in \mathbb{S}_{\mathrm{LS}}^{(2)}$ and for any unitaries U, V, we have*

$$\frac{1}{\sqrt{2}} d_Q(U,V) \leq d_P(U,V) \leq \sqrt{2} d_Q(U,V). \tag{A.28}$$

The following lemma shows that the triangle inequality holds for d_P (and in particular, $\mathrm{d_{avg}}$).

Lemma 6 (Triangle inequality for average-case distance)**.** *Let $d_P(U,V) = \sqrt{\mathbb{E}_{\left|\psi\right\rangle\sim P}[\mathrm{d_{tr}}(U\left|\psi\right\rangle, V\left|\psi\right\rangle)^2]}$ be the root mean squared trace distance with respect to an ensemble P. For any three unitaries U, V and W, we have the triangle inequality*

$$d_P(U,V) \leq d_P(U,W) + d_P(W,V). \tag{A.29}$$

Proof. Note that

$$\begin{aligned}
d_P^2(U,V) &= \mathbb{E}_{\left|\psi\right\rangle\sim P}[\mathrm{d_{tr}}(U\left|\psi\right\rangle, V\left|\psi\right\rangle)^2] \leq \mathbb{E}_{\left|\psi\right\rangle\sim P}[(\mathrm{d_{tr}}(U\left|\psi\right\rangle, W\left|\psi\right\rangle) + \mathrm{d_{tr}}(W\left|\psi\right\rangle, V\left|\psi\right\rangle))^2] \\
&= d_P^2(U,W) + d_P^2(W,V) + 2\mathbb{E}_{\left|\psi\right\rangle\sim P}[\mathrm{d_{tr}}(U\left|\psi\right\rangle, W\left|\psi\right\rangle)\,\mathrm{d_{tr}}(W\left|\psi\right\rangle, V\left|\psi\right\rangle)] \\
&\leq d_P^2(U,W) + d_P^2(W,V) + 2\sqrt{\mathbb{E}_{\left|\psi\right\rangle\sim P}[\mathrm{d_{tr}}(U\left|\psi\right\rangle, W\left|\psi\right\rangle)^2]} \cdot \sqrt{\mathbb{E}_{\left|\psi\right\rangle\sim P}[\mathrm{d_{tr}}(W\left|\psi\right\rangle, V\left|\psi\right\rangle)^2]} \\
&= \left(d_P(U,W) + d_P(W,V)\right)^2,
\end{aligned} \tag{A.30}$$

where we have used the triangle inequality for $\mathrm{d_{tr}}$ and the Cauchy-Schwartz inequality. Taking the square root gives us the desired result. □

2. Covering and packing nets

Our results in state and unitary learning utilize a tool from high-dimensional probability theory, namely covering and packing nets. We employ covering nets in our proofs of the sample complexity upper bounds and packing nets in our proofs of sample complexity lower bounds. Intuitively, covering and packing nets characterize the complexity of a space by discretizing it with small balls of a given resolution. We formally define these concepts below.

Definition 2 (Covering net/number and metric entropy)**.** *Let (X, d) be a metric space. Let $K \subseteq X$ be a subset and $\epsilon > 0$. Then, define the following.*

- *$N \subseteq K$ is an* ϵ-covering net *of K if for any $x \in K$, there exists a $y \in N$ such that $d(x,y) \leq \epsilon$.*
- *The* covering number *$\mathcal{N}(K, d, \epsilon)$ of K is the smallest possible cardinality of an ϵ-covering net of K.*
- *The* metric entropy *is $\log \mathcal{N}(K, d, \epsilon)$.*

We can similarly define a packing net.

Definition 3 (Packing net/number). *Let (X, d) be a metric space. Let $K \subseteq X$ be a subset and $\epsilon > 0$. Then, define the following.*

- *$N \subseteq K$ is an ϵ-*packing net *of K if for any $x, y \in N$, $d(x, y) > \epsilon$.*
- *The* packing number *$\mathcal{M}(K, d, \epsilon)$ of K is the largest possible cardinality of an ϵ-packing net of K.*

The following equivalence between covering and packing numbers is often useful.

Lemma 7 (Covering and packing are equivalent, [48, Section 4.2]). *Let (X, d) be a metric space. Let $K \subseteq X$ and $\epsilon > 0$. We have*

$$\mathcal{N}(K, d, \epsilon/2) \geq \mathcal{M}(K, d, \epsilon) \geq \mathcal{N}(K, d, \epsilon). \tag{A.31}$$

Covering numbers also have the following monotonicity property.

Lemma 8 (Monotonicity of covering number, [48, Section 4.2]). *Let (K, d) be a metric space. If $L \subseteq K$, then $\mathcal{N}(L, d, \epsilon) \leq \mathcal{N}(K, d, \epsilon/2)$.*

For our purposes, we need the following upper and lower bounds on the covering number of the unitary group. Since the states that we consider can be generated by unitaries applied to a fixed input state, a covering number upper bound for unitaries with respect to the diamond distance implies a corresponding covering number upper bound for states with respect to the trace distance.

Lemma 9 (Covering number of the unitary group, [147, Proposition 7], [146, Lemma 1] and [142, Lemma C.1]). *Let $\|\cdot\|'$ be any unitarily invariant norm. there exist universal constants $c_1, c_2 > 0$ such that for any $\epsilon \in (0, 2]$, the covering number of the d-dimensional unitary group $U(d)$ with respect to the norm $\|\cdot\|'$ satisfies:*

$$\left(\frac{c_1}{\epsilon}\right)^{d^2} \leq \mathcal{N}(U(d), \|\cdot\|', \|I\|'\epsilon) \leq \left(\frac{c_2}{\epsilon}\right)^{d^2}. \tag{A.32}$$

In particular, for the spectral norm $\|\cdot\|$, we have the upper bound $\mathcal{N}(U(d), \|\cdot\|, \epsilon) \leq (6/\epsilon)^{2d^2}$. For the Frobenius norm $\|\cdot\|_F$, we have $(c_1/\epsilon)^{d^2} \leq \mathcal{N}(U(d), \|\cdot\|_F, \sqrt{d}\epsilon) \leq (c_2/\epsilon)^{d^2}$.

We can use this result to bound the covering number for n-qubit unitaries consisting of G two-qubit gates.

Theorem 8 (Covering number of G-gate unitaries). *Let $U^G \subseteq U(2^n)$ be the set of n-qubit unitaries that can be implemented by G two-qubit gates. Then for any $\epsilon \in (0, 1]$, there exist universal constants $c_1, c_2, C > 0$ such that for $1 \leq G/C \leq 4^{n+1}$, the metric entropy of U^G with respect to the normalized Frobenius distance d_F can be bounded as*

$$\frac{G}{4C}\log\left(\frac{c_1}{\epsilon}\right) \leq \log\mathcal{N}(U^G, d_F, \epsilon) \leq 16G\log\left(\frac{c_2 G}{\epsilon}\right) + 2G\log n. \tag{A.33}$$

Moreover, the metric entropy with respect to diamond distance $\mathrm{d}_\diamond$ can be explicitly upper bounded by

$$\log\mathcal{N}(U^G, \mathrm{d}_\diamond, \epsilon) \leq 32G\log\left(\frac{12G}{\epsilon}\right) + 2G\log n. \tag{A.34}$$

Proof. The proof of the upper bounds is similar to the proof of Theorem C.1 in [142]. We first prove the upper bound for diamond distance.

Let $\epsilon \in (0, 1]$, and define $\epsilon' = \epsilon/2G$. Then by Lemma 9, there exists an ϵ'-covering net $\tilde{\mathcal{N}}_{\epsilon'}$ of the set of two-qubit unitaries $U(2^2)$ with respect to the spectral norm $\|\cdot\|$ of size

$$|\tilde{\mathcal{N}}_{\epsilon'}| \leq \left(\frac{6}{\epsilon'}\right)^{32} = \left(\frac{12G}{\epsilon}\right)^{32}. \tag{A.35}$$

This bound applies when the two-qubit unitary acts on a fixed set of two qubits. We can consider two-qubit unitaries that act on any of the n qubits. Let $U^{2q} \subset U(2^n)$ denote this set of two-qubit unitaries that can act on any pair of the n qubits of the system. Because there are $\binom{n}{2}$ pairs of qubits that the unitary could act on, the size of the covering net $\tilde{\mathcal{N}}_{\epsilon',n}$ of U^{2q} is bounded by

$$|\tilde{\mathcal{N}}_{\epsilon',n}| \leq \binom{n}{2}\left(\frac{12G}{\epsilon}\right)^{32}. \tag{A.36}$$

Recall that we want to find a covering net for the set U^G of n-qubit unitaries consisting of G two-qubit gates. Any unitary $U \in U^G$ can be written as $U_G U_{G-1}...U_1$ for $U_i \in U^{2q}$, where we suppress the tensor product with identity for readability. We consider the set of unitaries obtained by multiplying elements of the covering net $\tilde{\mathcal{N}}_{\epsilon',n}$ of U^{2q}. Namely, we define

$$\mathcal{N}_\epsilon \triangleq \{U_G U_{G-1}...U_1 | U_i \in \tilde{\mathcal{N}}_{\epsilon',n}, 1 \leq i \leq G\}. \tag{A.37}$$

Let $U \in U^G$ be any arbitrary unitary that can be implemented by G two-qubit gates, i.e., it can be written as $U = U_G U_{G-1}...U_1$ for $U_i \in U^{2q}$. As $\tilde{\mathcal{N}}_{\epsilon',n}$ is an ϵ'-covering net of the set U^{2q} of two-qubit unitaries, for each U_i comprising the circuit U, we can find a $\tilde{U}_i \in \tilde{\mathcal{N}}_{\epsilon',n}$ such that $\|U_i - \tilde{U}_i\| \leq \epsilon'$ for all $1 \leq i \leq G$, where $\|\cdot\|$ denotes the spectral norm. Then, the unitary $\tilde{U} \triangleq \tilde{U}_G \tilde{U}_{G-1}...\tilde{U}_1 \in \mathcal{N}_{\epsilon_1}$ satisfies

$$\mathrm{d}_\diamondsuit(U, \tilde{U}) \leq \sum_{i=1}^{G} \mathrm{d}_\diamondsuit(U_i, \tilde{U}_i) \leq 2\sum_{i=1}^{G} \left\| U_i - \tilde{U}_i \right\| \leq 2G\epsilon' = \epsilon, \tag{A.38}$$

where we have employed the subadditivity of the diamond distance (Lemma 2) in the first inequality and then used the relationship between the diamond norm and spectral norm in the second inequality (Lemma 1). In the last inequality, we used that $\left\|U_i - \tilde{U}_i\right\| \leq \epsilon'$ and $\epsilon' = \epsilon/2G$.

Thus, $\mathcal{N}_\epsilon$ is an ϵ-covering net of the set U^G of n-qubit unitaries that can be implemented by G two-qubit gates with respect to the diamond distance. By definition of $\mathcal{N}_\epsilon$, we have $|\mathcal{N}_\epsilon| = |\tilde{\mathcal{N}}_{\epsilon',n}|^G$, since each unitary in the length G strings of unitaries comprising elements of $\mathcal{N}_\epsilon$ are chosen from $\tilde{\mathcal{N}}_{\epsilon',n}$. Then

$$|\mathcal{N}_\epsilon| \leq \binom{n}{2}^G \left(\frac{12G}{\epsilon}\right)^{32G} \leq n^{2G}\left(\frac{12G}{\epsilon}\right)^{32G}. \tag{A.39}$$

Taking the logarithm gives the desired result for diamond distance.

We can argue similarly for the normalized Frobenius distance d_F. Specifically, we make use of the subadditivity of $\|\cdot\|_F$: $\forall U_1, V_1, U_2, V_2 \in U(2^n)$, we have

$$\|U_2U_1 - V_2V_1\|_F \leq \|U_2U_1 - U_2V_1\|_F + \|U_2V_1 - V_2V_1\|_F = \|U_1 - V_1\|_F + \|U_2 - V_2\|_F, \tag{A.40}$$

where we have used triangle inequality and $\|\cdot\|_F$ being unitary invariant.

Consider any $U \in U^G, U = U_G \cdots U_1$, where $U_i, 1 \leq i \leq T$ are 2-qubit unitaries acting on some pair of qubits. Take $\epsilon' = \epsilon/G$ and let $\mathcal{N}_{\epsilon'}$ be an ϵ'-covering net of $U(2^2)$ with respect to $\|\cdot\|_F$. Then there exist $V_i \in \mathcal{N}, 1 \leq i \leq G$, such that $\|U_i - V_i\| \leq \epsilon/G$ when the V_i are placed on the corresponding qubits. Let $V = V_G \cdots V_1$. By sub-additivity, we have

$$\|U - V\|_F \leq \sum_{i=1}^{G} \sqrt{2^{n-2}}\|U_i - V_i\|_F \leq \sqrt{2^{n-2}}G\epsilon' = \sqrt{2^{n-2}}\epsilon, \tag{A.41}$$

where we have used the facts that the Frobenius norm is multiplicative w.r.t. tensor products and that an $(n-2)$-qubit identity has Frobenius norm equal to $\sqrt{2^{n-2}}$. Therefore, the set of $V = V_G \cdots V_1$, where $V_i \in U(2^2)$ and acting on all possible pair of qubits is a $(2^{n-2}\epsilon)$-covering net of U^G. Since the number of choices for qubits to act on is $\binom{n}{2}$ for each V_i, we have

$$\mathcal{N}(U^G, \|\cdot\|_F, \sqrt{2^{n-2}}\epsilon) \leq \left[\binom{n}{2}\mathcal{N}(U(2^2), \|\cdot\|_F, \epsilon/G)\right]^G \leq n^{2G}\left(\frac{c_2 G\sqrt{2^2}}{\epsilon}\right)^{16G}, \tag{A.42}$$

where we have used Lemma 9. Redefining ϵ to be $\epsilon/\sqrt{2^2}$ and switching to the normalized d_F, we obtain

$$\log \mathcal{N}(U^G, d_F, \epsilon) \leq 16G \log\left(\frac{c_2 G}{\epsilon}\right) + 2G\log n. \tag{A.43}$$

Finally, we prove the lower bound. For this, we consider a particular set of circuit structures where all the G gates are placed on the first $k \leq n$ qubits. The set of unitaries that can be implemented by such circuits is denoted by $U_G^{\leq k} \subseteq U^G$. From the theory of universal quantum gates (see [136]), we know that to implement an arbitrary k-qubit unitary, we only need $G_k = \mathcal{O}(4^k)$ two-qubit gates that can implement single-qubit gates and CNOT. That is, there exists a universal constant $C > 0$, such that $C4^k \geq G_k$. Therefore, for any integer $k \leq n$ satisfying $C4^k \leq G$, we have $G \geq G_k$. Then all possible k-qubit unitaries can be implemented with these G gates: $U^n(2^k) = \{U \otimes I_{2^{n-k}} : U \in U(2^k)\} \subseteq U_G^{\leq k} \subseteq U^G$, where $U^n(2^k)$ denotes the set obtained by embedding the k-qubit unitaries into the n-qubit unitaries via tensor-multiplication with the identity. Thus $\mathcal{N}(U^G, \|\cdot\|_F, \epsilon) \geq \mathcal{N}(U^n(2^k), \|\cdot\|_F, 2\epsilon)$ by monotonicity.

Next, we prove that $\mathcal{N}(U^n(2^k), \|\cdot\|_F, 2\epsilon) \geq \mathcal{N}(U(2^k), \|\cdot\|_F, 2\epsilon/\sqrt{2^{n-k}})$. To do this, we take a minimal 2ϵ-covering net $\mathcal{N}$ of $U^n(2^k)$ with $|\mathcal{N}| = \mathcal{N}(U^n(2^k), \|\cdot\|_F, 2\epsilon)$. Hence $\forall U \in U(2^k)$, $U \otimes I_{2^{n-k}} \in U^n(2^k)$, $\exists V \otimes I_{2^{n-k}} \in \mathcal{N}$, such that $\|U - V\|_F = \|U \otimes I_{2^{n-k}} - V \otimes I_{2^{n-k}}\|_F/\sqrt{2^{n-k}} \leq 2\epsilon/\sqrt{2^{n-k}}$. Therefore, $\{V : V \otimes I_{2^{n-k}} \in \mathcal{N}\}$ forms a $2\epsilon/\sqrt{2^{n-k}}$-covering net of $U(2^k)$, and we have $\mathcal{N}(U^n(2^k), \|\cdot\|_F, 2\epsilon) \geq \mathcal{N}(U(2^k), \|\cdot\|_F, 2\epsilon/\sqrt{2^{n-k}})$.

Combining the above inequalities, we have

$$\log \mathcal{N}(U^G, \|\cdot\|_F, \epsilon) \geq \log \mathcal{N}(U^n(2^k), \|\cdot\|_F, 2\epsilon) \geq \log \mathcal{N}(U(2^k), \|\cdot\|_F, 2\epsilon/\sqrt{2^{n-k}}) \geq 2^{2k} \log \frac{c_1\sqrt{2^n}}{2\epsilon}, \quad \text{(A.44)}$$

where the last inequalities follow from Lemma 9. The largest possible k is given by $k = \lfloor \log_4(G/C) \rfloor \geq \log_4 G/(4C)$. Thus, by redefining ϵ to be $\epsilon/\sqrt{2^n}$ and switching to d_F, we arrive at

$$\log \mathcal{N}(U^G, d_F, \epsilon) \geq \frac{G}{4C} \log \frac{c_1}{2\epsilon}. \quad \text{(A.45)}$$

This completes the proof of Theorem 8. □

The d_F covering number bounds in Theorem 8 do not yet properly take into account the global $U(1)$ phase. To obtain covering number for the average-case distance d_{avg}, which is equivalent to the quotient normalized Frobenius distance d'_F (Lemma 4 Item 1), we need to quotient out the global phase. This is formalized in the following lemma.

Lemma 10 (Packing number of quotient distance metric, variant of [146, Lemma 4])**.** *For any d-dimensional unitaries U and V, let $d_F(U,V) = \|U - V\|_F/\sqrt{d}$ be the normalized Frobenius distance, and $d'_F(U,V) = \min_{W \in U(1)} d_F(U, VW)$ be the corresponding quotient distance. Then there exists a universal constant $c_2 > 0$ such that the packing number of any set $\mathcal{U} \subseteq U(d)$ with respect to d_F and d'_F satisfies*

$$\log \mathcal{M}(\mathcal{U}, d_F, 4\epsilon) - \log(c_2/\epsilon) \leq \log \mathcal{M}(\mathcal{U}, d'_F, \epsilon) \leq \log \mathcal{M}(\mathcal{U}, d_F, \epsilon). \quad \text{(A.46)}$$

Proof. We focus on the lower bound first. Take a minimal ϵ-covering $\mathcal{N}_1$ of $\mathcal{U}$ with respect to d'_F and a minimal ϵ-covering $\mathcal{N}_2$ of $U(1)$ with respect to the absolute value distance $d_A(e^{i\phi}, e^{-i\phi'}) = |e^{i\phi} - e^{-i\phi'}|$. Then, for any $U \in \mathcal{U}$, there exists $V \in \mathcal{N}_1$ such that $d'_F(U,V) \leq \epsilon$. Let $e^{i\phi^\star} = \arg\min_{e^{i\phi}} d_F(U, Ve^{i\phi})$. Then $d_F(U, Ve^{i\phi^\star}) \leq \epsilon$, and there exists $e^{i\phi'} \in \mathcal{N}_2$ such that $d_A(e^{i\phi^\star}, e^{i\phi'}) \leq \epsilon$. Therefore,

$$d_F(U, Ve^{i\phi'}) \leq d_F(U, Ve^{i\phi^\star}) + d_F(Ve^{i\phi^\star}, Ve^{i\phi'}) = d_F(U, Ve^{i\phi^\star}) + d_F(Ie^{i\phi^\star}, Ie^{i\phi'}) \leq 2\epsilon, \quad \text{(A.47)}$$

where we have used the triangle inequality, d_F being unitary invariant, and $d_F(Ie^{i\phi^\star}, Ie^{i\phi'}) = \frac{1}{\sqrt{d}}\|Ie^{i\phi^\star} - Ie^{i\phi'}\|_F = \frac{\|I\|_F}{\sqrt{d}}|e^{i\phi^\star} - e^{i\phi'}| = d_A(e^{i\phi^\star}, e^{i\phi'}) \leq \epsilon$. Hence, the set $\{Ve^{i\phi'} : V \in \mathcal{N}_1, e^{i\phi'} \in \mathcal{N}_2\}$ is a (2ϵ)-covering of $\mathcal{U}$ with respect to d_F. Then

$$\mathcal{N}(\mathcal{U}, d_F, 2\epsilon) \leq \mathcal{N}(\mathcal{U}, d'_F, \epsilon)\mathcal{N}(U(1), d_A, \epsilon). \quad \text{(A.48)}$$

Therefore, using the equivalence of covering and packing (Lemma 7) and the covering number bound for $U(1)$ (Lemma 9), we arrive at

$$\log \mathcal{M}(\mathcal{U}, d'_F, \epsilon) \geq \log \mathcal{M}(\mathcal{U}, d'_F, 4\epsilon) - \log(c_2/\epsilon). \quad \text{(A.49)}$$

For the upper bound, note that $\forall U, V \in \mathcal{U}$, we have

$$d'_F(U,V) = \min_{e^{i\phi} \in U(1)} d_F(U, Ve^{i\phi}) \leq d_F(U,V). \quad \text{(A.50)}$$

Therefore, a maximal ϵ-packing net with respect to d'_F is an ϵ-packing net with respect to d_F. Therefore,

$$\mathcal{M}(\mathcal{U}, d'_F, \epsilon) \leq \mathcal{M}(\mathcal{U}, d_F, \epsilon). \quad \text{(A.51)}$$

This concludes the proof of Lemma 10. □

With Lemma 10, we can obtain the covering number of G-gate unitaries with respect to the average-case distance.

Corollary 1 (Covering number with average-case distance)**.** *Let $U^G \subseteq U(2^n)$ be the set of n-qubit unitaries that can be implemented by G two-qubit gates. Then for any $\epsilon \in (0,1]$, there exist universal constants $c_1, c_2, C > 0$ such that for $1 \leq G/C \leq 4^{n+1}$, the metric entropy of U^G with respect to the average-case distance $\mathrm{d}_{\mathrm{avg}}(U,V) = \sqrt{\mathbb{E}_{|\psi\rangle}[\mathrm{d}_{\mathrm{tr}}(U|\psi\rangle, V|\psi\rangle)^2]}$, where the expectation value is over Haar measure, can be bounded as*

$$\frac{G}{4C}\log\left(\frac{c_1}{8\epsilon}\right) - \log\left(\frac{c_2}{2\epsilon}\right) \leq \log \mathcal{N}(U^G, \mathrm{d}_{\mathrm{avg}}, \epsilon) \leq 16G\log\left(\frac{c_2 G}{\epsilon}\right) + 2G\log n. \tag{A.52}$$

Proof. The corollary follows directly from Theorem 8, Lemma 10, and the equivalence of d'_F and $\mathrm{d}_{\mathrm{avg}}$ (Lemma 4 Item 1). □

3. Classical shadows and hypothesis selection

Our proofs of the sample complexity upper bounds crucially rely on a known algorithm for quantum hypothesis selection [148]. The high-level idea is to find a covering net over all unitaries consisting of only G two-qubit gates and to then use quantum hypothesis selection to identify a candidate in the covering net close to the unknown target state/unitary. A similar idea has previously appeared in [103]. In this section, we discuss the quantum hypothesis selection algorithm from [148] and prove a performance guarantee when basing it on classical shadow tomography [100].

The quantum hypothesis selection algorithm takes as input (classical descriptions of) a set of hypothesis states $\sigma_1, \ldots, \sigma_m$ and quantum copies of an unknown state ρ. Using these copies, the algorithm identifies a hypothesis state σ_k that is close to the unknown state ρ in trace distance. Importantly, quantum hypothesis selection black-box reduces to shadow tomography [37], i.e., one can use the shadow tomography protocol as a black-box to solve quantum hypothesis selection. To obtain a better sample complexity scaling, we instead utilize classical shadow tomography [100].

Recall that a classical shadow is a succinct classical description of a quantum state that allows us to predict many expectation values accurately. One can construct this classical shadow description by applying a random unitary to the quantum state and measuring in the computational basis. The most prevalent examples are random Clifford measurements, where the random unitary is chosen to be a random Clifford circuit, or random Pauli measurements, where the random unitary is chosen to be a tensor product of random Pauli gates. Moreover, we have the following rigorous guarantee for using classical shadows to predict expectation values.

Theorem 9 (Theorem 1 in [100])**.** *Let $O_1, \ldots, O_M$ be Hermitian $2^n \times 2^n$ matrices, and let $\epsilon, \delta \in [0,1]$. Then,*

$$N = \mathcal{O}\left(\frac{\log(M/\delta)}{\epsilon^2} \max_{1\leq i \leq M} \left\| O_i - \frac{\mathrm{tr}(O_i)}{2^n}\mathbb{I} \right\|_{\mathrm{shadow}}^2\right) \tag{A.53}$$

copies of an unknown quantum state ρ suffice to predict $\hat{o}_i$ such that

$$|\hat{o}_i - \mathrm{tr}(O_i\rho)| \leq \epsilon \tag{A.54}$$

for all $1 \leq i \leq M$, with probability at least $1-\delta$.

Here, $\|\cdot\|_{\mathrm{shadow}}$ denotes the shadow norm, which depends on the ensemble of unitary transformations used to create the classical shadow. For instance, in the case of random Cliffords, the shadow norm can be controlled via the (unnormalized) Frobenius norm, compare [100, Proposition S1].

Now, we can prove a new guarantee for the quantum hypothesis selection by replacing shadow tomography with classical shadow in the proof in [148].

Proposition 1 (Proposition 5.3 in [148]; Classical Shadow Version)**.** *Let $0 < \epsilon, \delta < 1/2$. Given access to unentangled copies of a pure quantum state ρ and classical descriptions of m fixed pure hypothesis states $\sigma_1, \ldots, \sigma_m$, there exists a quantum algorithm that selects σ_k such that $\mathrm{d}_{\mathrm{tr}}(\rho, \sigma_k) \leq 3\eta + \epsilon$ with probability at least $1-\delta$, where $\eta = \min_i \mathrm{d}_{\mathrm{tr}}(\rho, \sigma_i)$. Moreover, this algorithm uses*

$$N = \mathcal{O}\left(\frac{\log(m/\delta)}{\epsilon^2}\right) \tag{A.55}$$

copies of the quantum state ρ.

In [148], they prove the guarantee on the quantum hypothesis selection algorithm using Helstrom's Theorem. We follow a similar proof. Thus, we first state Helstrom's Theorem and recall a corollary of it, which will be useful in the proof of Prop. 1.

Theorem 10 (Helstrom's Theorem [132])**.** *Consider two d-dimensional quantum states ρ and σ. Then, the trace distance between ρ and σ can be written as*

$$\frac{1}{2}\|\rho-\sigma\|_1 = \max_{\|O\|_\infty \leq 1} |\operatorname{tr}(O\rho) - \operatorname{tr}(O\sigma)|, \tag{A.56}$$

where the maximum is taken over all observables $O \in \mathbb{C}^{d\times d}$.

Corollary 2. *Consider two d-dimensional quantum states ρ and σ. Then, there exists an observable A achieving the maximum such that*

$$\operatorname{tr}(A\rho) - \operatorname{tr}(A\sigma) = \frac{1}{2}\|\rho-\sigma\|_1. \tag{A.57}$$

Proof of Corollary 2. We will construct an observable A that maximizes $\operatorname{tr}(O(\rho-\sigma))$ over all observables O with $\|O\|_\infty \leq 1$. Choose a representation of $\rho-\sigma$ in terms of eigenstates $|v\rangle$. Suppose the eigenvalues are discrete:

$$(\rho-\sigma)\,|v\rangle = \lambda_v\,|v\rangle\,. \tag{A.58}$$

Then, we can write the quantity we wish to maximize as

$$\operatorname{tr}(O(\rho-\sigma)) = \sum_v \lambda_v \,\langle v|O|v\rangle\,. \tag{A.59}$$

We can maximize this by choosing A such that

$$\langle v|A|v\rangle = \begin{cases} 1 & \text{if } \lambda_v > 0 \\ 0 & \text{if } \lambda_v \leq 0. \end{cases} \tag{A.60}$$

In this way, we can write A as a sum of projectors

$$A = \sum_{v:\lambda_v>0} |v\rangle\!\langle v|\,. \tag{A.61}$$

This maximizes $\operatorname{tr}(O(\rho-\sigma))$, so the corollary has been proven. □

With this, we can now prove Prop. 1.

Proof of Prop. 1. The proof of Proposition 5.3 in [148] uses shadow tomography as a black box. We follow the same strategy but use classical shadow tomography [100] instead of shadow tomography. Recall that in [148], they run the shadow tomography algorithm from [37] with observables given by Helstrom's Theorem [132]. This is the key step that uses samples of the unknown quantum state ρ, so we need to analyze it when using classical shadow instead of shadow tomography. In our setting, Corollary 2 states that for any $i \neq j$, there exists an observable A_{ij} such that

$$\operatorname{tr}(A_{ij}\sigma_i) - \operatorname{tr}(A_{ij}\sigma_j) = \frac{1}{2}\|\sigma_i - \sigma_j\|_1. \tag{A.62}$$

Thus, the algorithm in [148] uses $M = \binom{m}{2} = \mathcal{O}(m^2)$ observables $\{A_{ij}\}$ to select the hypothesis state, where m is the size of the hypothesis set. Using classical shadow instead of shadow tomography requires

$$N = \tilde{\mathcal{O}}\left(\frac{\log(M/\delta)}{\epsilon^2}\max_{i,j}\left\|A_{ij} - \frac{\operatorname{tr}(A_{ij})}{2^n}\mathbb{I}\right\|^2_{\text{shadow}}\right) \tag{A.63}$$

copies of ρ by Theorem 9, where M is the number of observables A_{ij} that we want to predict. Here, $M = \mathcal{O}(m^2)$ so that we require

$$N = \tilde{\mathcal{O}}\left(\frac{\log(m/\delta)}{\epsilon^2}\max_{i,j}\left\|A_{ij} - \frac{\operatorname{tr}(A_{ij})}{2^n}\mathbb{I}\right\|^2_{\text{shadow}}\right) \tag{A.64}$$

copies of ρ. We claim that

$$\max_{i,j} \left\| A_{ij} - \frac{\operatorname{tr}(A_{ij})}{2^n}\mathbb{I} \right\|_{\text{shadow}}^2 = \mathcal{O}(1). \tag{A.65}$$

The lemma then follows from this claim. We can prove this bound on the shadow norm using the construction of the observables A_{ij} from Helstrom's Theorem, as seen in Corollary 2. In our case, the states σ_i are pure, and hence of rank 1. Thus, the rank of $\sigma_i - \sigma_j$ is at most 2 so that A_{ij} is a projector of rank at most 2. Thus, the Frobenius norm of every A_{ij} is $\mathcal{O}(1)$ and, by [100, Proposition S1], the same holds for the shadow norm of the centered version of A_{ij}. □

4. Characterizing the complexity of function classes

In the proof of Theorem 7 (in Appendix D), we will need to characterize the complexity of certain function classes. The following definitions will be useful. Throughout the work, we use $\mathcal{Y}^{\mathcal{X}}$ to denote the set of functions from $\mathcal{X}$ to $\mathcal{Y}$.

Definition 4 (Growth function, [149]). *Let $\mathcal{F} \subseteq \mathcal{Y}^{\mathcal{X}}$ be a class of functions with finite target space $\mathcal{Y}$. For every subset $\Xi \subseteq X$, define the restriction of $\mathcal{F}$ to Ξ as $\mathcal{F}|_{\Xi} = \{f \in \mathcal{Y}^{\Xi} : \exists F \in \mathcal{F}, \forall x \in \Xi, f(x) = F(x)\}$. We define the growth function Γ of $\mathcal{F}$ as*

$$\Gamma(\mu) = \max_{\Xi \subseteq \mathcal{X} : |\Xi| \leq \mu} |\mathcal{F}|_{\Xi}| \tag{A.66}$$

for any $\mu \in \mathbb{N}$.

The growth function characterizes the size of $\mathcal{F}$ when restricted to a domain of μ points. With growth function, we can define the VC dimension that characterizes the complexity of binary functions.

Definition 5 (VC dimension, [149]). *The Vapnik-Chervonenkis (VC) dimension of a function class $\mathcal{F} \subseteq \{0,1\}^{\mathcal{X}}$ is defined as*

$$\operatorname{VCdim}(\mathcal{F}) = \max\{\mu \in \mathbb{N} : \Gamma(\mu) = 2^\mu\}, \tag{A.67}$$

or ∞ if the maximum does not exist. Here $\Gamma(\mu)$ is the growth function of $\mathcal{F}$. Or equivalently, $\operatorname{VCdim}(\mathcal{F})$ *is the largest $D \in \mathbb{N} \cup \{\infty\}$ such that there exists a set of points $\{x_i\}_{i=1}^D \subseteq \mathcal{X}$ that for all $C \subseteq [D]$, there is a function $f \in \mathcal{F}$ satisfying*

$$f(x_i) = 1 \iff i \in C. \tag{A.68}$$

These points are said to be shattered by $\mathcal{F}$.

To go beyond binary functions, we can use pseudo dimension defined below.

Definition 6 (Pseudo dimension, [70]). *The pseudo dimension of a real-valued function class $\mathcal{F} \subseteq \mathbb{R}^{\mathcal{X}}$ is defined as*

$$\operatorname{Pdim}(\mathcal{F}) = \operatorname{VCdim}(\{\mathcal{X} \times \mathbb{R} \ni (x,y) \to \operatorname{sgn}[f(x) - y] : f \in \mathcal{F}\}). \tag{A.69}$$

Or equivalently, $\operatorname{Pdim}(\mathcal{F})$ *is the largest $D \in \mathbb{N} \cup \{\infty\}$ such that there exists a set of points $\{(x_i, y_i)\}_{i=1}^D \subseteq \mathcal{X} \times \mathbb{R}$ that for all $C \subseteq [D]$, there is a function $f \in \mathcal{F}$ satisfying*

$$f(x_i) \geq y_i \iff i \in C. \tag{A.70}$$

These points are said to be pseudo-shattered by $\mathcal{F}$.

We will also use the fat-shattering dimension, a scale-sensitive variant of the pseudo-dimension.

Definition 7 (Fat-shattering dimension, [71]). *Let $\alpha > 0$. The α-fat-shattering dimension* $\operatorname{fat}(\mathcal{F}, \alpha)$ *of a real-valued function class $\mathcal{F} \subseteq \mathbb{R}^{\mathcal{X}}$ is defined as the largest $D \in \mathbb{N} \cup \{\infty\}$ such that there exists a set of points $\{(x_i, y_i)\}_{i=1}^D \subseteq \mathcal{X} \times \mathbb{R}$ that for all $C \subseteq [D]$, there is a function $f \in \mathcal{F}$ satisfying*

$$\begin{aligned} f(x_i) &\geq y_i + \alpha \quad \text{if} \quad i \in C, \\ f(x_i) &\leq y_i - \alpha \quad \text{if} \quad i \notin C. \end{aligned} \tag{A.71}$$

Such a set of points is said to be α-fat-shattered by $\mathcal{F}$.

5. Cryptography

Our computational complexity lower bounds rely on cryptographic primitives such as pseudorandom functions [138] and pseudorandom quantum states [137, 139]. A family of pseudorandom functions is a set of functions such that sampling from this family is indistinguishable from a uniformly random function. We present the formal definition below, following the presentation in [40].

Definition 8 (Pseudorandom functions (PRFs) [138])**.** *Let λ denote the security parameter. Let $\mathcal{K} = \{\mathcal{K}_\lambda\}_{\lambda\in\mathbb{N}}$ be an efficiently sampleable key space. Let $\mathcal{X} = \{\mathcal{X}_\lambda\}_{\lambda\in\mathbb{N}}, \{\mathcal{Y}_\lambda\}_{\lambda\in\mathbb{N}}$ be collections of finite sets. Let $\mathcal{F} = \{f_\lambda\}_{\lambda\in\mathbb{N}}$ be a family of efficiently-computable keyed functions $f_\lambda : \mathcal{K}_\lambda \times \mathcal{X}_\lambda \to \mathcal{Y}_\lambda$. $\mathcal{F}$ is a* pseudorandom function *if for every polynomial-time probabilistic algorithm* Adv*, there exists a negligible function* $\mathsf{negl}(\cdot)$ *such that for every security parameter $\lambda \in \mathbb{N}$*

$$\left| \Pr_{\mathbf{k}\leftarrow\mathcal{K}_\lambda}[\mathsf{Adv}^{f(\mathbf{k},\cdot)}(\cdot) = 1] - \Pr_{g\in\mathcal{U}_\lambda}[\mathsf{Adv}^{g}(\cdot) = 1] \right| \le \mathsf{negl}(\lambda), \tag{A.72}$$

where the key $\mathbf{k}$ is picked uniformly at random from the key space $\mathcal{K}_\lambda$ and g is picked uniformly at random from $\mathcal{U}_\lambda$, the set of all functions from $\mathcal{X}_\lambda$ to $\mathcal{Y}_\lambda$. Here, $\mathsf{negl}(\lambda)$ *denotes a negligible function, i.e., a function that grows more slowly than any inverse polynomial in λ.*

Concretely, it is common to take the input and output spaces to be $\mathcal{X}_\lambda = \{0,1\}^m$ and $\mathcal{Y}_\lambda = \{0,1\}$ for some input length $m = m(\lambda)$ that depends on the security parameter λ. We consider this setting throughout the work.

Definition 9 (Quantum secure PRFs [40])**.** *Let λ denote the security parameter. A pseudorandom function is* quantum secure against $t(\lambda)$ adversaries *if it satisfies Definition 8 where* Adv *is a $t(\lambda)$-time quantum algorithm with quantum query access to $f_{\mathbf{k}}$ and g. When $t(\lambda) = \mathsf{poly}(\lambda)$, we say that the PRF is* quantum secure*.*

There are several constructions for implementing PRFs with low-depth circuits [40, 150, 151]. We will focus on the construction of [40], which relies on the assumption that the Ring Learning with Errors ($\mathsf{RingLWE}$) problem [38] is hard even for quantum computers. Specifically, we assume that $\mathsf{RingLWE}$ cannot be solved by a quantum computer in sub-exponential time, which is a commonly believed cryptographic assumption [39–43]. Here, $\mathsf{RingLWE}$ is a variant of the more well-known Learning with Errors problem [39] over polynomial rings. The $\mathsf{RingLWE}$ problem is to find a secret ring element $s \in R_q \triangleq \mathbb{Z}_q[x]/\langle x^\lambda - 1\rangle$ given pairs $(a, a\cdot s + e \bmod R_q)$, where λ denotes the security parameter, e is some error, q is a parameter of the problem. We only state this informally here and refer the reader to [38] for a formal definition and discussion. In [40], assuming that $\mathsf{RingLWE}$ cannot be solved by quantum computers in $t(\lambda)$ time, their construction produces a PRF secure against $\mathcal{O}(t(\lambda))$ quantum adversaries that is implementable by constant-depth, polynomial-size circuits. We state the precise result below.

Theorem 11 (Lemmas 3.15 and 3.16 in [40])**.** *Let λ denote the security parameter. Let the input size be $m = m(\lambda) = \omega(\log\lambda)$ and set the parameter $q = \lambda^{\omega(1)}$ to be a power of two such that $\log(q) \le \mathcal{O}(\mathsf{poly}(\lambda))$. Let $\mathcal{K} = \{\mathcal{K}_\lambda\}_{\lambda\in\mathbb{N}}$, where $\mathcal{K}_\lambda = R_q^{m+1}$. There exists a PRF $\mathcal{RF} = \{f_\lambda\}_{\lambda\in\mathbb{N}}$, where $f_\lambda : R_q^{m+1} \times \{0,1\}^m \to \{0,1\}$, satisfying the following two properties.*

1. *Every $f_\lambda(\mathbf{k},\cdot) \in \mathcal{RF}$ with $\mathbf{k} \in \mathcal{K}_\lambda$ can be computed by a TC^0 circuit.*
2. *Suppose there exists a distinguisher $\mathcal{D}$ for $\mathcal{RF}$, i.e., there exists an $\mathcal{O}(t(\lambda))$-time quantum algorithm $\mathcal{D}$ that satisfies*

$$\left| \Pr_{\mathbf{k}\leftarrow\mathcal{K}_\lambda}[\mathcal{D}^{|f_\lambda(\mathbf{k},\cdot)\rangle}(\cdot) = 1] - \Pr_{g\in\mathcal{U}}[\mathcal{D}^{|g\rangle}(\cdot) = 1] \right| > \mathsf{negl}(\lambda), \tag{A.73}$$

where the key $\mathbf{k}$ is picked uniformly at random from the key space $\mathcal{K}_\lambda$, g is picked uniformly at random from $\mathcal{U}$, the set of all functions from $\mathcal{X}_\lambda$ to $\mathcal{Y}_\lambda$, and $\mathcal{D}^{|f_\lambda(\mathbf{k},\cdot)\rangle}$ indicates that $\mathcal{D}$ has quantum oracle access to the function $f_\lambda(\mathbf{k},\cdot)$. Then, there exists a $t(\lambda)$-time quantum algorithm that solves $\mathsf{RingLWE}$.

In Property 2, this is equivalent to saying that the PRF is quantum secure against $\mathcal{O}(t(\lambda))$ adversaries, assuming that $\mathsf{RingLWE}$ cannot be solved by a $t(\lambda)$-time quantum algorithm. Also, note that in Property 1, TC^0 circuits refer to constant-depth, polynomial-size circuits with unbounded fan-in AND, OR, NOT, and $\mathsf{MAJORITY}$ gates. We claim that every TC^0 circuit has a quantum circuit computing the same function with poly-logarithmic overhead in depth.

Proposition 2 (Quantum circuits for TC^0)**.** *Let C be a TC^0 circuit on m inputs computing some Boolean function $f : \{0,1\}^m \to \{0,1\}$. Then, there exists a quantum circuit C' on $n = \mathcal{O}(\mathsf{poly}(m))$ qubits of size $\mathcal{O}(n\mathsf{polylog}(n))$ and depth $\mathcal{O}(\mathsf{polylog}(n))$ that implements f.*

Here, when we say that C' implements the function f, we mean that $C' |x\rangle |z\rangle = C' |x\rangle |z \oplus f(x)\rangle$.

Proof. Note that the number of qubits is $n = \mathcal{O}(\mathsf{poly}(m))$ because after each gate in the classical circuit C, we must store the result in an ancilla qubit to maintain unitarity. Recall that TC^0 circuits are constant-depth, polynomial-size circuits with unbounded fan-in AND, OR, NOT, and MAJORITY gates. Thus, it suffices to find the depth of implementing each of these gates quantumly. The size then follows because a circuit of depth d on n qubits can have at most nd gates. NOT gates can clearly be implemented in constant depth since this is just an X gate. An AND gate with m inputs can be completed in logarithmic depth by computing AND pairwise with CNOT. Similarly, we can compute an OR gate with the same logarithmic depth. It remains to analyze the depth needed for computing a MAJORITY gate. Recall that the MAJORITY gate is defined as

$$\mathsf{MAJ}(x_1, \ldots, x_m) = \left\lfloor \frac{1}{2} + \frac{(\sum_{i=1}^m x_i) - 1/2}{m} \right\rfloor = \left\lfloor \frac{1}{2} + \frac{\sum_{i=1}^m x_i}{m} - \frac{1}{2m} \right\rfloor. \tag{A.74}$$

Here, addition is done over the integers and $x_i \in \{0,1\}$. We first analyze the depth/size required for the addition $\sum_{i=1}^m x_i$. Note that the maximum value of this sum is m, which can be stored in $\mathcal{O}(\log m)$ bits. Thus, we can write each of the x_i in binary using $\log m$ bits by padding with zeros and perform addition in this way. We can perform the addition of the m inputs pairwise, parallelized to $\mathcal{O}(\log m)$ depth and requiring $\mathcal{O}(m)$ addition operations. Moreover, one can perform these addition operations using quantum circuits of size and depth $\mathcal{O}(\log m)$ [152]. The construction in [152] uses Toffoli gates, but these can be decomposed into two-qubit gates with constant overhead [153]. In total, we have that $\sum_{i=1}^m x_i$ can be implemented by a quantum circuit of depth $\mathcal{O}(\log^2 m)$.

To divide this sum by m, note that there exist classical Boolean circuits for integer division of depth $\mathcal{O}(\log\log m)$ since our inputs can be represented in binary using $\log m$ bits [154]. These Boolean circuits use only standard AND, OR, and NOT gates. As explained previously, these can be implemented quantumly, and for fan-in-2 AND and OR gates, this can be done with constant overhead. Thus, this division step requires depth $\mathcal{O}(\log\log m)$ in total.

Finally, we need to compute the remaining addition/subtraction and floor operations. The addition/-subtraction can be ignored since they only occur once so that the depth is dominated by the other additions. For the floor, because the quantity inside can only be less than or equal to 1, then this is the same as deciding whether the quantity inside is less than 1 or not. This can be done in a constant number of operations.

Putting everything together, we see that the circuit depth for implementing a MAJORITY gate is dominated by $\mathcal{O}(\log^2 m)$.

Recall again that TC^0 describes constant-depth, polynomial-size circuits with unbounded fan-in AND, OR, NOT, and MAJORITY gates. We just analyzed the depth for each of these gates individually. In summary, we computed that $\mathcal{O}(\log m)$ quantum depth is sufficient for AND and OR. Constant $\mathcal{O}(1)$ depth is sufficient for NOT. Finally, $\mathcal{O}(\log^2 m)$ depth is sufficient for MAJORITY. In the overall circuit, this totals to $\mathcal{O}(\mathsf{polylog}(m))$ depth. Because a circuit of depth d on n qubits can have at most nd gates, then the size of this circuit is $\mathcal{O}(n\mathsf{polylog}(m))$ gates. Then, because $n = \mathcal{O}(\mathsf{poly}(m))$, we obtain the claim. □

Alternatively, we note that one can obtain a similar result using [155]. As a simple corollary of this along with Theorem 11, we can bound the depth/size of a quantum circuit for computing a PRF.

Corollary 3. *Let $\lambda = n$ denote the security parameter. Assuming that $\mathsf{RingLWE}$ cannot be solved in $t(n)$ time by a quantum computer, there exists a PRF $\mathcal{F} = \{f_\lambda\}_{\lambda\in\mathbb{N}}$ that is secure against $\mathcal{O}(t(n))$ quantum adversaries such that for keys $\mathbf{k} \in \mathcal{K}_\lambda$ (for the same key space as in Theorem 11), $f_\lambda(\mathbf{k}, \cdot) : \{0,1\}^m \to \{0,1\}$ is computable by an n-qubit quantum circuit of size $\mathcal{O}(n\mathsf{polylog}(n))$ and depth $\mathcal{O}(\mathsf{polylog}(n))$.*

Note here that by the above analysis, we have $m = \omega(\log(\lambda))$. Since $\mathcal{O}(\mathsf{poly}(m))$ qubits suffice to implement these PRFs, we can take $n = \lambda$, similar to [139].

Our proofs also require the notion of pseudorandom quantum states. Informally, pseudorandom quantum states are ensembles of quantum states that are indistinguishable from Haar-random states to any efficient (quantum) algorithm. Moreover, it is known how to construct these states using efficient quantum circuits. Recently, pseudorandom quantum states have been of great interest in quantum cryptography [156–158] and complexity theory [159]. We define them formally below, following the presentation in [137, 139].

Definition 10 (Pseudorandom quantum states (PRS) [137])**.** *Let $\lambda = n$ denote the security parameter. Let $\mathcal{K} = \{\mathcal{K}_\lambda\}_{\lambda \in \mathbb{N}}$ be the key space. A keyed family of pure quantum states $\{|\phi_k\rangle\}_{k \in \mathcal{K}_\lambda}$ is* pseudorandom against $t(n)$ adversaries *if the following two conditions hold:*

1. *(Efficient generation). There is a polynomial-time quantum algorithm* Gen *that generates state $|\phi_k\rangle$ on input k. That is, for all $\lambda \in \mathbb{N}$ and for all $k \in \mathcal{K}_\lambda$, $\mathsf{Gen}(1^\lambda, k) = |\phi_k\rangle$.*
2. *(Pseudorandomness). Any polynomially many copies of $|\phi_k\rangle$ with the same random $k \in \mathcal{K}_\lambda$ are computationally indistinguishable from the same number of copies of a Haar-random state. More precisely, for any $t(n)$-time quantum algorithm $\mathcal{D}$ and any $N = \mathsf{poly}(\lambda)$, there exists a negligible function* $\mathsf{negl}(\cdot)$ *such that for all $\lambda \in \mathbb{N}$,*

$$\left| \Pr_{k \leftarrow \mathcal{K}_\lambda} \left[\mathcal{D}\left(|\phi_k\rangle^{\otimes N} \right) = 1 \right] - \Pr_{|\psi\rangle \leftarrow \mu} \left[\mathcal{D}\left(|\psi\rangle^{\otimes N} \right) = 1 \right] \right| \leq \mathrm{negl}(\lambda), \tag{A.75}$$

where μ is the Haar measure over pure states on n qubits.

When $t(n) = \mathsf{poly}(n)$, we simply say that the states are pseudorandom*.*

There exist efficient procedures to generate pseudorandom quantum states under standard cryptographic assumptions. In particular, we consider the construction by [139], which assumes the existence of quantum-secure pseudorandom functions.

Proposition 3 (Corollary of Claims 3 and 4 in [139])**.** *Let $\lambda = n$ denote the security parameter and $t(n) \geq \mathsf{poly}(n)$. Assuming that* $\mathsf{RingLWE}$ *cannot be solved by a quantum computer in $t(n)$ time, pseudorandom quantum states secure against $\mathcal{O}(t(n))$ adversaries with key space $\mathcal{K}$ (for the same key space as in Theorem 11) can be prepared using n-qubit quantum circuits of depth $\mathcal{O}(\mathsf{polylog}(n))$ and size $\mathcal{O}(n\mathsf{polylog}(n))$.*

Proof. Note that using the PRF from [40] and tracing through the proof of Claim 3 in [139], one can clearly see that security holds for $\mathcal{O}(t(n))$ adversaries rather than only efficient adversaries. We need to prove that the size and depth are as stated for the construction of pseudorandom quantum states in [139] using the PRF from [40]. To obtain the depth and size bounds, we analyze the construction in [139]. In Claim 3 of [139], they show that their constructed states can be prepared by applying a single layer of Hadamard gates followed by applying a quantum-secure PRF. First, the layer of Hadamards has depth 1 and size n. Using the construction from Corollary 3, applying the PRF can then be implemented in $\mathcal{O}(\mathsf{polylog}(n))$ depth and $\mathcal{O}(n\mathsf{polylog}(n))$ size. Thus, overall, the depth and size are dominated by the cost of evaluating the PRF. Moreover, in Claim 4 of [139], they prove that this is indeed constructs a pseudorandom quantum state. □

Note again that the number of qubits n in the quantum circuit depends on the security parameter λ. In fact, due to the construction used, the n depends on λ in the same way as for the PRF construction. Also note that the above constructions of PRF/PRS can be implemented using a number of Clifford and T gates of the same order. This is because the TC^0 circuits in the PRF constructions are classical circuits which can be implemented exactly by Toffoli gates, and Toffoli gates can be constructed using a constant number of Clifford and T gates. Also in the PRS construction, the remaining gates are Hadamard gates which are Clifford gates. Therefore, the computational hardness results in Appendices B 3 and C 5 also apply to Clifford+T circuits of the same gate complexity.

Appendix B: Learning quantum states

Recall that, given copies of a pure state of bounded circuit complexity, we wish to find a classical description for a quantum circuit that approximately implements this state. It is natural to require the learner to output a circuit description since this ensures that the output of the learner can indeed be used to prepare (approximate) copies of the unknown state. This model is similar-in-spirit to learning an (approximate) generator for an unknown classical probability distribution [160]. Nevertheless, our sample complexity results hold for learning classical descriptions beyond circuit descriptions, and our computational complexity results immediately extend to learners that output classical descriptions from which a circuit description can be derived efficiently (e.g., matrix product states/operators with constant bond dimension [34, 35], stabilizer descriptions, etc.).

Specifically, let $|\psi\rangle = U|0\rangle^{\otimes n}$, where U is a unitary consisting of G two-qubit gates. Throughout this section, we denote $\rho \triangleq |\psi\rangle\langle\psi|$. Suppose we are given N identically prepared copies of ρ. The goal is to learn a classical circuit description of a quantum state $\hat{\rho}$ that is ϵ-close to ρ in trace distance, i.e., $\mathrm{d}_{\mathrm{tr}}(\hat{\rho}, \rho) = \|\hat{\rho} - \rho\|_1/2 \leq \epsilon$.

In this appendix, we provide a proof of Theorem 1, which characterizes the sample complexity for this task. We restate the theorem below.

Theorem 12 (State learning, detailed restatement of Theorem 1)**.** *Let $\epsilon, \delta > 0$. Suppose we are given N copies of a pure n-qubit state density matrix $\rho = |\psi\rangle\!\langle\psi|$, where $|\psi\rangle = U|0\rangle^{\otimes n}$ is generated by a unitary U consisting of G two-qubit gates. Then, any algorithm that can output $\hat{\rho}$ such that $\mathrm{d}_{\mathrm{tr}}(\hat{\rho}, \rho) \leq \epsilon$ with probability at least $1-\delta$ requires at least*

$$N = \Omega\left(\min\left(\frac{2^n}{\epsilon^2}, \frac{G(1-\delta)}{\epsilon^2 \log(G/\epsilon)}\right) + \frac{\log(1/\delta)}{\epsilon^2}\right). \tag{B.1}$$

Meanwhile, there exists such an algorithm using

$$N = \mathcal{O}\left(\min\left(\frac{2^n \log(1/\delta)}{\epsilon^2}, \frac{G\log(G/\epsilon) + \log(1/\delta)}{\epsilon^2}\right)\right). \tag{B.2}$$

Here, the minimum with $2^n/\epsilon^2$ corresponds to the sample-optimal approaches for full quantum state tomography [19, 20]. The theorem in the main text corresponds to $\delta = \mathcal{O}(1)$ so that the upper and lower bounds are equal up to logarithmic factors.

In Appendix B 1 we prove the sample complexity upper bound, and in Appendix B 2, we show the sample complexity lower bound. Moreover, in Appendix B 3, we prove Theorem 2, which gives a lower bound on the computational complexity required for this task.

1. Sample complexity upper bound

In this section, we prove the sample complexity upper bound for Theorem 12. We provide an algorithm for learning the unknown quantum state within trace distance ϵ by constructing a covering net over the space of all unitaries consisting of G two-qubit gates. We can then obtain a covering net over all pure quantum states generated by G two-qubit gates by applying each element of the unitary covering net to the zero state. With this covering net, we can use quantum hypothesis selection [148] based on classical shadows [100] (discussed in Appendix A 3) to identify a state in the covering net that is close to the unknown target state. We note that this strategy may be adapted to other restricted state/unitary classes as long as we can construct a covering net with bounded cardinality.

Proposition 4 (State learning upper bound)**.** *Let $\epsilon, \delta > 0$. Suppose we are given N copies of a pure n-qubit state density matrix $\rho = |\psi\rangle\!\langle\psi|$, where $|\psi\rangle = U|0\rangle^{\otimes n}$ is generated by a unitary U consisting of G two-qubit gates. Then, there exists an algorithm that can output $\hat{\rho}$ such that $\mathrm{d}_{\mathrm{tr}}(\hat{\rho}, \rho) \leq \epsilon$ with probability at least $1-\delta$ using*

$$N = \mathcal{O}\left(\min\left(\frac{2^n \log(1/\delta)}{\epsilon^2}, \frac{G\log(G/\epsilon) + \log(1/\delta)}{\epsilon^2}\right)\right) \tag{B.3}$$

samples of $|\psi\rangle$.

Here, we take the minimum with $2^n/\epsilon^2$, as this is the upper bound achieved for full quantum state tomography on an arbitrary n-qubit pure state [19, 20]. Thus, we focus on proving the second term in the minimum. We prove this upper bound by considering two cases: (1) $G \geq n/2$ and (2) $G < n/2$. The upper bounds for each case agree and are given by Equation (B.3). We first prove the proposition for Case (1) and indicate what changes for Case (2).

Proof of Case (1). As previously described, this follows by first creating a covering net over all unitaries consisting of G two-qubit gates and then using quantum hypothesis selection [148].

By Theorem 8, we know that there exists an $(\epsilon/6)$-covering net $\mathcal{N}_{\epsilon/6}$ of the space of unitaries implemeted by G two-qubits gates with respect to the diamond distance $\mathrm{d}_\diamond$ with metric entropy bounded by

$$\log(|\mathcal{N}_{\epsilon/6}|) \leq 32G\log\left(\frac{72G}{\epsilon}\right) + 2G\log(n). \tag{B.4}$$

Applying each unitary $V' \in \mathcal{N}_{\epsilon/6}$ to the zero state, we obtain a new covering net

$$\mathcal{N}'_{\epsilon/6} = \{V' \, |0\rangle\langle 0|^{\otimes n} \, V'^{\dagger} : V' \in \mathcal{N}_{\epsilon/6}\} \tag{B.5}$$

for the set of pure quantum states generated by G two-qubit gates with respect to trace distance. We argue that this is true as follows. Any pure quantum state generated by G two-qubit gates can be written as $|\phi\rangle = V\,|0\rangle^{\otimes n}$ for some unitary V implemented by G two-qubit gates and let $\sigma = |\phi\rangle\langle\phi|$. Using the definition of the covering net $\mathcal{N}_{\epsilon/6}$, there exists a unitary $V' \in \mathcal{N}_{\epsilon/6}$ such that $\mathrm{d}_{\diamondsuit}(V, V') < \epsilon/6$. Consider $|\phi'\rangle = V'\,|0\rangle^{\otimes n}$ and let $\sigma' = |\phi'\rangle\langle\phi'| \in \mathcal{N}'_{\epsilon/6}$. By the definition of the diamond distance in terms of a worst case over input states, we also have $\mathrm{d}_{\mathrm{tr}}(\sigma, \sigma') \leq \mathrm{d}_{\diamondsuit}(V, V') \leq \epsilon/12 < \epsilon/6$. Thus, $\mathcal{N}'_{\epsilon/6}$ satisfies the definition of a covering net over the pure quantum states generated by G two-qubit gates with respect to trace distance d_{tr}. Moreover, we clearly see that $|\mathcal{N}'_{\epsilon/6}| \leq |\mathcal{N}_{\epsilon/6}|$.

We can consider this covering net $\mathcal{N}'_{\epsilon/6}$ as the set of hypothesis states in Proposition 1. Let $\rho = |\psi\rangle\langle\psi|$ be the unknown quantum state that we have copies of. By Proposition 1, there exists an algorithm to learn $\tilde{\rho}$ such that

$$\mathrm{d}_{\mathrm{tr}}(\rho, \tilde{\rho}) \leq 3 \cdot \frac{\epsilon}{6} + \frac{\epsilon}{2} = \epsilon \tag{B.6}$$

with probability at least $1 - \delta$. Here, note that we used $\eta = \epsilon/6$ in Proposition 1 by definition of an $(\epsilon/6)$-covering net. Furthermore, we may choose $\epsilon_2 = \epsilon/2$ and $\delta_1 = \delta/2$. In this way, we obtain $\tilde{\rho}$ such that $\mathrm{d}_{\mathrm{tr}}(\rho, \tilde{\rho}) \leq \epsilon$ with probability at least $1 - \delta$. Moreover, by Proposition 1, this algorithm to find $\tilde{\rho}$ requires at most

$$N = \mathcal{O}\left(\frac{\log\left(|\mathcal{N}'_{\epsilon/6}|/\delta\right)}{\epsilon^2}\right) = \mathcal{O}\left(\frac{G\log(G/\epsilon) + G\log(n) + \log(1/\delta)}{\epsilon^2}\right) \tag{B.7}$$

copies of ρ, where the second equality follows from Eq. (B.4). Because we are considering $G \geq n/2$ in this case, then we have

$$N = \mathcal{O}\left(\frac{G\log(G/\epsilon) + \log(1/\delta)}{\epsilon^2}\right), \tag{B.8}$$

as claimed. □

Notice in the above proof that we used $G \geq n/2$ in the last step to remove the extra $\log(n)$ factor. However, in Case (2), we can no longer execute this step and must consider a more careful strategy to remove the dependence on system size n. The key observation is that if $G < n/2$, some qubits in the system will be left in the zero state because no gate has acted upon them (for G two-qubit gates, at most $2G < n$ qubits are acted upon nontrivially). Notice that we only need to learn the quantum state on these $2G$ qubits rather than the whole system, since we can simply tensor product with the zero state for the remaining qubits. Thus, we require the ability to discern which qubits have been acted upon by the G two-qubit gates. Once we find this set of qubits, the idea is to consider a covering net for the set of pure quantum states generated by G two-qubit gates *on this restricted system*. Then, we can follow a similar argument to the above proof of Case (1).

We prove Case (2) of Proposition 4 in the following sections. For the rest of this section, let $\rho = |\psi\rangle\langle\psi|$. In Appendix B 1 a, we discuss an algorithm that identifies the qubits acted on nontrivially by the G two-qubit gates with high probability and show that restricting to these identified qubits does not cause much error. In Appendix B 1 b, we resolve a technical issue for defining the covering net on the restricted system, which stems from the algorithm possibly not identifying all qubits. Finally, in Appendix B 1 c, we combine these pieces to provide the full proof of Case (2).

a. *Postselection*

First, we present an algorithm to determine which qubits of the unknown quantum state $\rho = |\psi\rangle\langle\psi|$ have been acted upon nontrivially by the G two-qubit gates. We then prove a guarantee about the number of samples of ρ needed to determine these qubits with high probability. We also show that considering ρ to be the zero state on the rest of the qubits does not incur much error.

Suppose that the true set of qubits acted upon by the G two-qubit gates is denoted as A. To determine which qubits are in the set A, consider the procedure given in Algorithm 1. The idea behind this algorithm

Algorithm 1: Identify qubits acted upon nontrivially (state version)

```
Input: Copies of unknown $n$-qubit quantum state $\rho$.
Output: List $\hat{A} \subseteq [n]$ of qubits.
1 Initialize $\hat{A} = \emptyset$.
2 Repeat the following $N = \mathcal{O}\left(\frac{G+\log(1/\delta_1)}{\epsilon_1}\right)$ times:
    (a) Measure all qubits of the unknown state $\rho$ in the computational basis.
    (b) Given the measurement outcome $|x\rangle$, set $\hat{A} \leftarrow \hat{A} \cup \mathrm{supp}(x)$, where $\mathrm{supp}(x) = \{i \in [n] : x_i \neq 0\}$.
```

is simple. If we measure a qubit in the computational basis and receive a nonzero measurement outcome, then it must have been acted upon by one of the G two-qubit gates because the quantum state is assumed to have been initialized in the zero state. We prove that $\mathcal{O}\left(\frac{G+\log(1/\delta_1)}{\epsilon_1}\right)$ copies of ρ suffice to obtain, with high probability $1-\delta_1$, the desired property that measuring the qubits in $\hat{B} \triangleq [n] \setminus \hat{A}$ of ρ yields the all zero bit string with high probability $1-\epsilon_1$.

Lemma 11. *Let $\epsilon_1, \delta_1 > 0$. Suppose we are given copies of a pure n-qubit quantum state $\rho = |\psi\rangle\langle\psi|$ generated by G two-qubit gates acting on a subset of the qubits $A \subseteq [n]$. Then, Algorithm 1 uses $N = \mathcal{O}\left(\frac{G+\log(1/\delta_1)}{\epsilon_1}\right)$ copies of ρ and outputs with probability at least $1-\delta_1$ a list $\hat{A} \subset [n]$ such that*

$$\left\langle 0_{\hat{B}} \middle| \rho_{\hat{B}} \middle| 0_{\hat{B}} \right\rangle \geq 1 - \epsilon_1, \tag{B.9}$$

where $\rho_{\hat{B}}$ denotes the reduced density matrix of ρ when tracing out all qubits other than those in the set $\hat{B} = [n] \setminus \hat{A}$ and $\left|0_{\hat{B}}\right\rangle$ denotes the zero state on all qubits in $\hat{B}$.

Proof. Let A' be any possible set that could be output by Algorithm 1. Let $B' \triangleq [n] \setminus A'$. We first define some random variables to state our claim more precisely. Let $E_{i,A'}$ be the event that round i of measurement of the qubits in $B' = [n] \setminus A'$ in Algorithm 1 yields the all zero bitstring. Let $X_{i,A'}$ be the indicator random variable corresponding to the event $E_{i,A'}$. Then, we have that $\bar{X}_{A'} \triangleq \frac{1}{N}\sum_{i=1}^{N} X_{i,A'}$ is the number of times the qubits in B' are all measured to be zero divided by the total number of measurements. In other words, $\bar{X}_{A'}$ is an empirical estimate for the overlap that the state $\rho_{B'}$ on qubits in B' has with the all zero state. Moreover, we have

$$\mathbb{E}[X_{A'}] \triangleq \mathbb{E}[X_{i,A'}] = \langle 0_{B'}|\rho_{B'}|0_{B'}\rangle \tag{B.10}$$

for all A'. Note that the first definition makes sense because for any i, the $X_{i,A'}$ are identically distributed. This says that the true expectation of our random variables is the true overlap of the state $\rho_{B'}$ with the all zero state.

We claim that for any A', if the true overlap is less than $1-\epsilon_1$, then the estimated overlap is less than $1-\epsilon_1/2$ with high probability. Formally, in terms of our random variables, this is the following statement:

Claim 1. *For any set A' that could be output by Algorithm 1, if $\mathbb{E}[X_{A'}] < 1-\epsilon_1$, then $\bar{X}_{A'} < 1-\epsilon_1/2$ with probability at least $1-\delta_1$.*

Thus, we have reduced our task to a concentration problem. Note that it suffices to prove this because the set $\hat{A}$ actually identified by Algorithm 1 has $\bar{X}_{\hat{A}} = 1$. This is true because a qubit is only added to the set $\hat{A}$ in the algorithm if it measured and observed a nonzero outcome. Thus, all qubits in $\hat{B} = [n] \setminus \hat{A}$ must have given zero when measured throughout all rounds of measurement. By definition, this gives us that $\bar{X}_{\hat{A}} = 1$. Then, by the contrapositive of Claim 1, we see that $\mathbb{E}[X_{\hat{A}}] = \left\langle 0_{\hat{B}} \middle| \rho_{\hat{B}} \middle| 0_{\hat{B}} \right\rangle \geq 1-\epsilon_1$, with probability at least $1-\delta_1$. We now prove this claim using classical concentration inequalities.

Proof of Claim 1. First, fix some set A' that could be output by Algorithm 1. Suppose

$$\mathbb{E}[X_{A'}] \triangleq 1 - a < 1 - \epsilon_1, \tag{B.11}$$

where $a > \epsilon_1$. Recall the Bhatia-Davis Inequality, which states that for $X \in [b,d]$ that

$$\mathrm{Var}(X) \leq (d - \mathbb{E}[X])(\mathbb{E}[X] - b). \tag{B.12}$$

In our case, we have $X_{A'} \in [0,1]$ since they are indicator random variables so that the inequality gives us

$$\mathrm{Var}(X_{A'}) \leq (1 - \mathbb{E}[X])\mathbb{E}[X] \leq 1 - \mathbb{E}[X] = a. \tag{B.13}$$

Now, recall Bernstein's Inequality, which states that for independent random variables X_i with $|X_i| \leq c$ and $\sigma^2 = \frac{1}{N}\sum_{i=1}^N \mathrm{Var}(X_i)$, we have for any $t > 0$,

$$\Pr\left(\frac{1}{N}\sum_{i=1}^N X_i - \mathbb{E}[X] > t\right) \leq \exp\left(-\frac{Nt^2}{2\sigma^2 + 2ct/3}\right). \tag{B.14}$$

In our case, $c = 1, \sigma^2 \leq a$, and $t = a/2$. Then, Bernstein's Inequality results in

$$\Pr\left(\bar{X}_{A'} - \mathbb{E}[X] > \frac{a}{2}\right) \leq \exp\left(-\frac{Na^2/4}{2a + a/3}\right). \tag{B.15}$$

Plugging in $\mathbb{E}[X] = 1 - a$ and simplifying, we have

$$\Pr\left(\bar{X}_{A'} > 1 - \frac{a}{2}\right) \leq \exp\left(-\frac{3Na}{28}\right) \leq \exp\left(-\frac{3N\epsilon_1}{28}\right). \tag{B.16}$$

Since $a > \epsilon_1$, then $1 - a/2 < 1 - \epsilon_1/2$ so that we have

$$\Pr\left(\bar{X}_{A'} > 1 - \frac{\epsilon_1}{2}\right) \leq \exp\left(-\frac{3N\epsilon_1}{28}\right). \tag{B.17}$$

Plugging in $N = \frac{28\log\left(2^{2G}/\delta_1\right)}{3\epsilon_1}$, we have

$$\Pr\left(\bar{X}_{A'} > 1 - \frac{\epsilon_1}{2}\right) \leq \frac{\delta_1}{2^{2G}}. \tag{B.18}$$

Recall that this inequality was for a single fixed set A', but we want our claim to hold for any set A'. Thus, we need to union bound overall possible sets A' output by Algorithm 1.

We claim that the number of such sets is at most 2^{2G}. This is clear because if A' is output by the algorithm, then $A' \subseteq A$, where A is the true set of qubits that the G gates act nontrivially on. This is true by construction because in order for a qubit to be added to the set output by Algorithm 1, its result upon measurement must have yielded a nonzero outcome so that a gate must have acted upon this qubit. Hence $A' \subseteq A$, and because $|A| \leq 2G$, the number of possible subsets A' of A is at most 2^{2G}.

Thus, applying a union bound to Eq. (B.18), we see that the probability that, for any A', $\bar{X}_{A'}$ is greater than $1 - \epsilon_1/2$ is at most δ_1. In other words, $\bar{X}_{A'}$ is less than $1 - \epsilon_1/2$ with probability at least $1 - \delta_1$. Moreover, here we used

$$N = \frac{28\log\left(2^{2G}/\delta_1\right)}{3\epsilon_1} = \mathcal{O}\left(\frac{G + \log(1/\delta_1)}{\epsilon_1}\right). \tag{B.19}$$

This concludes the proof of the claim, which gives the result in Lemma 11 as explained previously. □

□

With this, we know that measuring qubits in $\hat{B} = [n] \setminus \hat{A}$ of ρ yields the all zero bistring with high probability. We want to show that, in fact, we can consider $\rho_{\hat{B}}$ as being the zero state without incurring much error. In particular, we want to show the following lemma.

Lemma 12. *Let $\epsilon, \delta_1 > 0$. Suppose we are given $N = \mathcal{O}\left(\frac{G+\log(1/\delta_1)}{\epsilon^2}\right)$ copies of an n-qubit quantum state ρ generated by G gates. Let $\hat{A} \subset [n]$ be as in Algorithm 1 and $\hat{B} = [n] \setminus \hat{A}$. Then, for $\Lambda = |0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I_{\hat{A}}$ (where $|0_{\hat{B}}\rangle$ denotes the zero state on all qubits in $\hat{B}$) and for the post-measurement state*

$$\rho' \triangleq \frac{\sqrt{\Lambda}\rho\sqrt{\Lambda}}{\mathrm{Tr}(\Lambda\rho)}, \tag{B.20}$$

we have

$$\mathrm{d_{tr}}(\rho, \rho') \leq \frac{\epsilon}{24} \tag{B.21}$$

with probability at least $1 - \delta_1$.

In other words, we want to show that our original state ρ is not far in trace distance from the new state ρ', where ρ' is the state ρ with the qubits in $\hat{B}$ projected to the zero state. In this way, we can effectively only consider the system on qubits in $\hat{A}$ when defining the covering net and using hypothesis selection. This turns out to be a bit more nuanced, but this is the general idea. To show this, we will use the Gentle Measurement Lemma, following the presentation in [143].

Lemma 13 (Lemma 9.4.1 in [143])**.** *Consider a density operator ρ and a measurement operator Λ, where $0 \leq \Lambda \leq I$. The measurement operator could be an element of a POVM. Suppose that the measurement operator Λ has a high probability of detecting the state ρ:*

$$\mathrm{Tr}(\Lambda\rho) \geq 1 - \epsilon, \tag{B.22}$$

where $\epsilon \in [0, 1]$ (the probability of detection is high if ϵ is close to zero). Then the post-measurement state

$$\rho' \triangleq \frac{\sqrt{\Lambda}\rho\sqrt{\Lambda}}{\mathrm{Tr}(\Lambda\rho)} \tag{B.23}$$

is $\sqrt{\epsilon}$-close to the original state ρ in trace distance:

$$\mathrm{d}_{\mathrm{tr}}(\rho, \rho') \leq \sqrt{\epsilon}. \tag{B.24}$$

Thus, the measurement does not disturb the state ρ by much if ϵ is small.

With this, we can now prove Lemma 12.

Proof of Lemma 12. As stated above, let $\hat{A} \subset [n]$ be as in Algorithm 1, and let $A \subset [n]$ be true the set of qubits acted non-trivially on by the G gates. Let $\hat{B} \triangleq [n] \setminus \hat{A}$ and let $B \triangleq [n] \setminus A$.

In order to apply the Gentle Measurement Lemma, we need to show that

$$\mathrm{Tr}(\Lambda\rho) \geq 1 - \left(\frac{\epsilon}{24}\right)^2. \tag{B.25}$$

Since $\Lambda = |0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I_{\hat{A}}$, where $|0_{\hat{B}}\rangle$ denotes the zero state on all qubits in $\hat{B}$, we have

$$\mathrm{Tr}(\Lambda\rho) = \mathrm{Tr}\big((|0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I_{\hat{A}})\rho\big) = \mathrm{Tr}\big(|0_{\hat{B}}\rangle\langle 0_{\hat{B}}|\, \rho_{\hat{B}}\big) = \langle 0_{\hat{B}}|\rho_{\hat{B}}|0_{\hat{B}}\rangle, \tag{B.26}$$

where $\rho_{\hat{B}}$ denotes the reduced density matrix obtained by tracing out all qubits in $[n] \setminus \hat{B}$. Thus, it suffices to show that

$$\langle 0_{\hat{B}}|\rho_{\hat{B}}|0_{\hat{B}}\rangle \geq 1 - \left(\frac{\epsilon}{24}\right)^2. \tag{B.27}$$

Intuitively, this makes sense because in Algorithm 1, we identified the qubits in $\hat{B}$ as those being close to the zero state. Indeed, this holds by Lemma 11 when choosing $\epsilon_1 = (\epsilon/24)^2$. Thus, the result follows. □

b. *Permutation*

Before we can prove Proposition 4, we must resolve a technical issue. Namely, ideally, we would like to consider a covering net on the subsystem of qubits in the set A (the true set of qubits that the G gates generating the unknown state ρ act nontrivially on). In this way, because $\hat{A} \subseteq A$, where $\hat{A}$ is the set of qubits identified by Algorithm 1, then our postselected state ρ' from Lemma 12 should be close to some state in this covering net on the subsystem. This nearby state in the covering net can then be identified via quantum hypothesis selection [49]. By Lemma 12, this state from hypothesis selection is also close to the original unknown state ρ.

However, the problem with the above is that we do not know the true set of qubits A; we only know the identified set of qubits $\hat{A}$. Moreover, it is possible that $\hat{A} \subsetneq A$, i.e., Algorithm 1 may not have been able to detect certain qubits as having been acted upon nontrivially by the G gates. For example, suppose that when preparing the unknown state ρ, certain qubits are used as workspace ancillas and are reset to the zero state at the end of the computation.

In order to define a covering net on a system on which the G gates act (the setting of Lemma 9), we need to somehow identify the qubits in $A \setminus \hat{A}$ that are undetected by the algorithm. To do so, we argue that we can permute the qubits outside of the set $\hat{A}$ and not deviate much from the original state ρ. In this way, without loss of generality, we can permute the qubits such that those in $A \setminus \hat{A}$ are grouped together in some fixed set of qubits. Then, we can define a covering net on the system of qubits defined by this fixed set containing the qubits in $A \setminus \hat{A}$ and our identified set $\hat{A}$. By construction, we know that the G gates act on this subset of qubits, so this is the correct setting of Lemma 9. We note that the permutations used in the proof are a mathematical tool for the analysis, but the learner has to neither know nor perform these permutations.

To formalize this, we first define a permutation and claim that permuting the qubits outside of the set $\hat{A}$ does not change the post selected state ρ'.

Definition 11 (Permutation). *A unitary $W \in \mathrm{U}(2^n)$ is a* permutation unitary *if it satisfies the following property: W corresponds to a permutation $\sigma_W \in S_n$ of order 2, where S_n is the symmetric group of size n, and W acts as*

$$W |x_1 \dots x_n\rangle = |x_{\sigma_W(1)} \cdots x_{\sigma_W(n)}\rangle , \tag{B.28}$$

where $x = x_1 \cdots x_n \in \{0,1\}^n$. Moreover, we use W_S for a set $S \subseteq \{1, \dots, n\}$ to denote a permutation unitary where the corresponding permutation σ_{W_S} is such that $\sigma_{W_S}|_{\overline{S}} = \mathrm{id}$, where $\overline{S} = [n] \setminus S$. In other words, σ_{W_S} only permutes the elements in S.

It is easy to see here that because the corresponding permutation is of order 2, W is Hermitian. Our next lemma shows that such permutations when acting only on $\hat{B}$ do not change our post selected state.

Lemma 14. *Let ρ' be as in Lemma 12. Explicitly, let $\hat{A} \subset [n]$ be as in Algorithm 1 and $\hat{B} = [n] \setminus \hat{A}$. Then, for $\Lambda = |0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I_{\hat{A}}$ (where $|0_{\hat{B}}\rangle$ denotes the zero state on all qubits in $\hat{B}$), define*

$$\rho' = \frac{\sqrt{\Lambda}\rho\sqrt{\Lambda}}{\mathrm{Tr}(\Lambda\rho)}. \tag{B.29}$$

Then, we have

$$\rho'' \triangleq W_{\hat{B}}\rho' W_{\hat{B}} = \rho', \tag{B.30}$$

where $W_{\hat{B}}$ is any permutation unitary which only permutes qubits in $\hat{B}$.

Proof. To see the claim, we can simply expand the expression for ρ'':

$$\begin{aligned}
\rho'' &= W_{\hat{B}}\rho' W_{\hat{B}} && \text{(B.31)}\\
&= W_{\hat{B}} \frac{\sqrt{\Lambda}\rho\sqrt{\Lambda}}{\mathrm{Tr}(\Lambda\rho)} W_{\hat{B}} && \text{(B.32)}\\
&= W_{\hat{B}} \frac{\Lambda\rho\Lambda}{\mathrm{Tr}(\Lambda\rho)} W_{\hat{B}} && \text{(B.33)}\\
&= \frac{W_{\hat{B}}(|0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I)\rho(|0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I)W_{\hat{B}}}{\mathrm{Tr}(\Lambda\rho)} && \text{(B.34)}\\
&= \frac{(|0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I)\rho(|0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I)}{\mathrm{Tr}(\Lambda\rho)} && \text{(B.35)}\\
&= \rho', && \text{(B.36)}
\end{aligned}$$

where in the third line we used that Λ is a projector so that $\sqrt{\Lambda} = \Lambda$, and in the fifth line, we used the $W_{\hat{B}}$ only permutes the qubits in $\hat{B}$, which does not have any effect because here all qubits in $\hat{B}$ are in the zero state. □

Lemma 15. *Let $\epsilon, \delta_2 > 0$. The trace distance between ρ and the permuted state $\tilde{\rho} = W_{\hat{B}}\rho W_{\hat{B}}$, where $W_{\hat{B}}$ is any permutation unitary which only permutes qubits in $\hat{B}$, is less than $\epsilon/24$:*

$$\mathrm{d}_{\mathrm{tr}}(\rho, \tilde{\rho}) \leq \frac{\epsilon}{12} \tag{B.37}$$

with probability at least $1 - \delta_2$.

Proof. This proof combines Lemmas 12 and 14. The idea is the following. We know from Lemma 12 that ρ and the post selected state ρ' are close in trace distance. Moreover, by Lemma 14, we know that the post selected state ρ' and the permuted post selected state ρ'' are the equal (without error). We can also show similarly to Lemma 12 that the permuted state $\tilde{\rho}$ is close to the post selected state $\tilde{\rho}'$, where this postselection is done in the same way as Lemma 12 by replacing ρ with $\tilde{\rho}$. Moreover, we can see that $\rho'' = \tilde{\rho}'$, so the claim then follows by triangle inequality.

Now, let us formalize this. By Lemma 12, we have

$$\mathrm{d_{tr}}(\rho, \rho') \leq \frac{\epsilon}{24}, \tag{B.38}$$

with probability at least $1 - \delta_2/2$ (choosing $\delta_1 = \delta_2/2$) where

$$\rho' = \frac{\sqrt{\Lambda}\rho\sqrt{\Lambda}}{\mathrm{Tr}(\Lambda\rho)} \tag{B.39}$$

for $\Lambda = |0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I_{\hat{A}}$. By Lemma 14, we know that

$$\rho'' \triangleq W_{\hat{B}}\rho' W_{\hat{B}} = \rho', \tag{B.40}$$

where $W_{\hat{B}}$ is a permutation that only affects qubits in $\hat{B}$. Now, consider the permuted state $\tilde{\rho} = W_{\hat{B}}\rho W_{\hat{B}}$. Recall that in the proof of Lemma 12, to obtain Eq. (B.38), it sufficed to show that $\mathrm{Tr}(\Lambda\rho) \geq 1-(\epsilon/24)^2$, and the result followed by the Gentle Measurement Lemma (Lemma 13). Thus, by the same proof, as long as $\mathrm{Tr}(\Lambda\tilde{\rho}) \geq 1 - (\epsilon/24)^2$, then we also have

$$\mathrm{d_{tr}}(\tilde{\rho}, \tilde{\rho}') \leq \frac{\epsilon}{24}, \tag{B.41}$$

with probability at least $1 - \delta_2/2$, where

$$\tilde{\rho}' \triangleq \frac{\sqrt{\Lambda}\tilde{\rho}\sqrt{\Lambda}}{\mathrm{Tr}(\Lambda\tilde{\rho})}. \tag{B.42}$$

We can clearly see that this condition holds:

$$\mathrm{Tr}(\Lambda\tilde{\rho}) = \mathrm{Tr}\big((|0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I_{\hat{A}})W_{\hat{B}}\rho W_{\hat{B}}\big) = \mathrm{Tr}\big((|0_{\hat{B}}\rangle\langle 0_{\hat{B}}| \otimes I_{\hat{A}})\rho\big) = \mathrm{Tr}(\Lambda\rho) \geq 1 - (\epsilon/24)^2, \tag{B.43}$$

where the second equality follows because $W_{\hat{B}}$ only permutes qubits in $\hat{B}$, which (rearranging with the trace) does not have any effect on $|0_{\hat{B}}\rangle\langle 0_{\hat{B}}|$ because all qubits in $\hat{B}$ are in the zero state. Thus, Eq. (B.41) holds.

We also claim that $\rho'' = \tilde{\rho}'$. This follows by effectively the same proof as Lemma 14.

Putting everything together, we have that $\rho' = \rho'' = \tilde{\rho}'$. Thus, by Eq. (B.38),

$$\mathrm{d_{tr}}(\rho, \tilde{\rho}') \leq \frac{\epsilon}{24} \tag{B.44}$$

with probability at least $1 - \delta_2/2$. By triangle equality with Eq. (B.41), we then obtain the claim:

$$\mathrm{d_{tr}}(\rho, \tilde{\rho}) \leq \frac{\epsilon}{12} \tag{B.45}$$

with probability at least $1 - \delta_2$. □

c. Proof of Case (2) of Proposition 4

With this, we can prove Case (2) of Proposition 4. Recall that in Case (2), we require that $G < n/2$. We provided a sketch of the argument throughout the previous sections, so we put everything together here.

Proof of Case (2) of Proposition 4. Let $\epsilon, \delta > 0$. Consider $G < n/2$. Because G is small compared to n, there exist some qubits that have not been acted upon by the G gates used to generate the state $\rho = |\psi\rangle\langle\psi|$. Thus, since we assume that the unknown quantum state ρ is constructed by applying a unitary to the all zero state, then these qubits not acted upon by the G gates remain in the zero state.

Using the techniques in Appendix B 1 a, we can find the qubits that are acted on nontrivially by the G gates. Then, we want to consider the covering net on only this set of qubits. However, because our algorithm does not necessarily find *all* qubits acted on nontrivially by the G gates, we argue in Appendix B 1 b that we can permute the qubits in the system without significantly affecting the original state ρ. In this way, we can consider a permutation which gathers those qubits acted upon nontrivially that our algorithm did not find into some fixed set. We can then define the covering net on the subsystem consisting of this fixed set along with the identified set of qubits.

Let us now formalize these ideas. Let $\hat{A}$ be the set of qubits identified by Algorithm 1, and let A be the true set of qubits acted on nontrivially by the G gates. Let $W_{\hat{B}}$ be a permutation only affecting the qubits in $\hat{B} \triangleq [n] \setminus A$ (Definition 11) which gathers the qubits in $A \setminus \hat{A}$ into some fixed set of qubits C. Since $|C| + |\hat{A}| = |A \setminus \hat{A}| + |\hat{A}| = |A| \leq 2G$, then $C \cup \hat{A}$ has at most $2G$ qubits and these qubits are acted upon by G gates.

By Theorem 8 we know that there exists an $(\epsilon/12)$-covering net $\mathcal{N}_{\epsilon/12}$ of the space of unitaries implemented by G two-qubit gates on the permuted system consisting of only qubits in $C \cup \hat{A}$ with respect to the diamond distance $\mathrm{d}_{\diamondsuit} = \max_\rho \left\| (U \otimes I)\rho(U \otimes I)^\dagger - (V \otimes I)\rho(V \otimes I)^\dagger \right\|_1$. Moreover, this covering net has metric entropy bounded by

$$\log\left(|\mathcal{N}_{\epsilon/12}|\right) \leq 32G \log\left(\frac{144G}{\epsilon}\right) + 2G\log(2G) = \mathcal{O}\left(G\log(G/\epsilon)\right). \tag{B.46}$$

We can instead consider

$$\mathcal{N}'_{\epsilon/12} = \{V' \left|0_{C\cup\hat{A}}\middle\rangle\!\middle\langle 0_{C\cup\hat{A}}\right| V'^\dagger : V' \in \mathcal{N}_{\epsilon/12}\}, \tag{B.47}$$

where $\left|0_{C\cup\hat{A}}\right\rangle$ denotes the zero state on all qubits in our subsystem $C \cup \hat{A}$. By the same argument as in Case (1), $\mathcal{N}'_{\epsilon/12}$ defines a covering net over the set of pure quantum states on the subsystem $C \cup \hat{A}$ generated by G two-qubit gates with respect to trace distance. Moreover, $|\mathcal{N}'_{\epsilon/12}| \leq |\mathcal{N}_{\epsilon/12}|$.

Since this covering net $\mathcal{N}'_{\epsilon/12}$ is only for states on at most $2G$ qubits, let $\mathcal{N}''_{\epsilon/12}$ be the set of states where each state in $\mathcal{N}'_{\epsilon/12}$ is tensored with the zero state for qubits in $[n] \setminus (C \cup \hat{A})$. Let $\tilde{\rho} = W_{\hat{B}}\rho W_{\hat{B}}$ be the original state on this permuted system. By definition of a covering net, we know that there exists some $\sigma_i \in \mathcal{N}''_{\epsilon/12}$ such that

$$\mathrm{d}_{\mathrm{tr}}(\tilde{\rho}, \sigma_i) \leq \frac{\epsilon}{12}. \tag{B.48}$$

We justify this further in the following. By definition, the only qubits in the state $\tilde{\rho}$ that are acted on nontrivially by the G gates are those in $C \cup \hat{A}$. Since no gates act on qubits outside of $C \cup \hat{A}$, then the other qubits in $\tilde{\rho}$ must be in the zero state. Hence, we can write $\tilde{\rho} = \tilde{\rho}_{C\cup\hat{A}} \otimes |0\rangle\!\langle 0|^{\otimes(n-|C\cup\hat{A}|)}$, where $\tilde{\rho}_{C\cup\hat{A}}$ denotes the state of the qubits in $C \cup \hat{A}$ which are acted upon by the G gates. Moreover, by definition of a covering net, then there exists some $\sigma_{i,C\cup\hat{A}} \in \mathcal{N}'_{\epsilon/12}$ such that

$$\mathrm{d}_{\mathrm{tr}}(\tilde{\rho}_{C\cup\hat{A}}, \sigma_{i,C\cup\hat{A}}) \leq \frac{\epsilon}{12}, \tag{B.49}$$

where similarly $\sigma_{i,C\cup\hat{A}}$ is a state on the qubits in $C \cup \hat{A}$ which are acted upon by G gates. Taking the tensor product with the zero state on the remaining qubits does not affect the trace distance. Thus, we can write $\sigma_i = \sigma_{i,C\cup\hat{A}} \otimes |0\rangle\!\langle 0|^{\otimes(n-|C\cup\hat{A}|)} \in \mathcal{N}''_{\epsilon/12}$, where this satisfies

$$\mathrm{d}_{\mathrm{tr}}(\tilde{\rho}, \sigma_i) = \mathrm{d}_{\mathrm{tr}}(\tilde{\rho}_{C\cup\hat{A}}, \sigma_{i,C\cup\hat{A}}) \leq \frac{\epsilon}{12}, \tag{B.50}$$

as claimed. Moreover, by Lemma 15, choosing $\delta_2 = \delta/2$, we know that

$$\mathrm{d}_{\mathrm{tr}}(\rho, \tilde{\rho}) \leq \frac{\epsilon}{12} \tag{B.51}$$

with probability at least $1 - \delta/2$. Recall that this approximation requires only

$$N_1 = \mathcal{O}\left(\frac{G + \log(1/\delta)}{\epsilon^2}\right) \tag{B.52}$$

copies of ρ (from Lemma 12) for identifying the set $\hat{A}$. By triangle inequality, we have that there exists some $\sigma_i \in \mathcal{N}''_{\epsilon/12}$ such that

$$\mathrm{d_{tr}}(\rho, \sigma_i) \leq \frac{\epsilon}{6} \tag{B.53}$$

with probability at least $1 - \delta/2$.

Using hypothesis selection on the covering net $\mathcal{N}''_{\epsilon/12}$ and the unknown state ρ, by Proposition 1, there exists an algorithm to learn σ such that

$$\mathrm{d_{tr}}(\rho, \sigma) \leq \epsilon \tag{B.54}$$

with probability at least $1 - \delta$, where we chose $\eta = \epsilon/6$ and $\epsilon/2, \delta/2$ for the parameters in Proposition 1. Moreover, by Proposition 1 and Equation (B.46), this algorithm requires only

$$N_2 = \mathcal{O}\left(\frac{G\log(G/\epsilon) + \log(1/\delta)}{\epsilon^2}\right) \tag{B.55}$$

copies of ρ. Putting everything together, we have that

$$\mathrm{d_{tr}}(\rho, \sigma) \leq \epsilon \tag{B.56}$$

with probability at least $1 - \delta$, where our algorithm to find σ requires only

$$N = N_1 + N_2 = \mathcal{O}\left(\frac{G\log(G/\epsilon) + \log(1/\delta)}{\epsilon^2}\right). \tag{B.57}$$

This matches our upper bound for Case (1) and thus concludes the proof of Proposition 4. □

2. Sample complexity lower bound

In this section, we prove the sample complexity lower bound for Theorem 12.

Proposition 5 (State learning lower bound)**.** *Let $\epsilon, \delta > 0$. Suppose we are given N copies of an n-qubit pure state density matrix $\rho = |\psi\rangle\langle\psi|$, where $|\psi\rangle = U|0\rangle^{\otimes n}$ is generated by a unitary U consisting of G two-qubit gates. Then, any algorithm that can output $\hat{\rho}$ such that $\mathrm{d_{tr}}(\hat{\rho}, \rho) \leq \epsilon$ with probability at least $1 - \delta$ requires at least*

$$N = \Omega\left(\min\left(\frac{2^n}{\epsilon^2}, \frac{G(1-\delta)}{\epsilon^2\log(G/\epsilon)}\right) + \frac{\log(1/\delta)}{\epsilon^2}\right) \tag{B.58}$$

samples of $|\psi\rangle$.

Here, similarly to the upper bound, we take the minimum with $\Omega(2^n/\epsilon^2)$, as this is the lower bound achieved for full quantum state tomography [19, 20]. We thus focus on the second term in the minimum. We first consider the number of samples required to learn n-qubit pure quantum states generated by G gates *applied only to the first $\lfloor\log_2(G/C)\rfloor$ qubits* (for some constant C specified later) of the $n \geq \lfloor\log_2(G/C)\rfloor$ qubits in total. Denote this set of states as S_1. Note that if $n \leq \lfloor\log_2(G/C)\rfloor$, then we can simply import the lower bound for full quantum state tomography [19, 20]. We later reduce the general case, where the G gates can be applied on any of the qubits, to this case. Namely, we prove the following proposition.

Proposition 6. *Let $\epsilon, \delta > 0$. Suppose we are given N copies of an n-qubit pure state density matrix $\rho = |\psi\rangle\langle\psi|$, where $|\psi\rangle = (U \otimes I)|0\rangle^{\otimes n} \in S_1$ is generated by a unitary U consisting of G two-qubit gates applied only to the first $\lfloor\log_2(G/C)\rfloor$ qubits for some constant C. Then, any algorithm that can output $\hat{\rho}$ such that $\mathrm{d_{tr}}(\hat{\rho}, \rho) \leq \epsilon$ with probability at least $1 - \delta$ requires at least*

$$N = \Omega\left(\min\left(\frac{2^n}{\epsilon^2}, \frac{G(1-\delta)}{\epsilon^2\log(G/\epsilon)}\right) + \frac{\log(1/\delta)}{\epsilon^2}\right) \tag{B.59}$$

samples of $|\psi\rangle$.

We note that for constant error ϵ, the $\Omega(G/\log G)$ lower bound can be improved to $\Omega(G)$ using [161, 162]. We prove Proposition 6 by combining results from [19, 133]. Namely, the lower bound in [19] works by lower bounding the sample complexity of learning any rank r, d-dimensional quantum state in terms of the packing number of this space of states. We apply their results to our setting, where the space of states that the packing net is defined over is S_1 instead. We first recall important results from [19, 133] that we use throughout the proof. [19] lower bounded the sample complexity of learning a d-dimensional pure state as follows.

Theorem 13 (In Proof of Theorem 3 in [19]). *Let $\epsilon \in (0,1)$ and $\delta \in (0,1)$. Suppose there exists a POVM $\{M_\sigma d\sigma\}$ on $(\mathbb{C}^d)^{\otimes N}$ such that for a pure quantum state $\rho \in \mathbb{C}^{d\times d}$,*

$$\int_{\mathrm{d_{tr}}(\sigma,\rho)\leq\epsilon} d\sigma \, \mathrm{Tr}\big[M_\sigma \rho^{\otimes N}\big] \geq 1-\delta. \tag{B.60}$$

Then

$$N \geq \frac{(1-\delta)\ln m - \ln 2}{\chi_0}, \tag{B.61}$$

where m is the size of an (2ϵ)-packing net of the space of d-dimensional pure state density matrices, and

$$\chi_0 \triangleq S(\mathbb{E}_U[U\rho_x U]) - S(\rho_x) \tag{B.62}$$

is the Holevo information, where ρ_x is any element of the (2ϵ)-packing net, S is the von Neumann entropy, and the expectation is taken over the Haar measure.

This states that any measurement procedure which can identify a state ρ up to ϵ-trace distance requires at least N copies of ρ, where N is given by Equation (B.61) and depends on the size of an (2ϵ)-packing net of the space of d-dimensional pure state density matrices. Moreover, [19] bounded the size of such a packing net.

Lemma 16 (Lemma 5 in [19]). *There exists an ϵ-packing net $\{\rho_1,\dots,\rho_m\}$ of the space of d-dimensional pure state density matrices satisfying*

$$c\ln m \geq d, \tag{B.63}$$

for c a sufficiently large constant and $d > 3$. This packing net also satisfies

$$\frac{\chi_0}{c} \leq \epsilon^2 \ln\left(\frac{d}{\epsilon}\right) \tag{B.64}$$

for a sufficiently large constant $c > 0$, where χ_0 is given by Equation (B.62).

Finally, the last result we will need gives a bound on the number of gates needed to generate an arbitrary n-qubit pure state.

Lemma 17 (Section 4 of [133]). *Any n-qubit pure quantum state can be recursively defined as the result of a quantum circuit implemented by $\mathcal{O}(2^n)$ two-qubit gates applied to the $|0\rangle^{\otimes n}$ state. Explicitly, this quantum circuit has at most $C\cdot 2^n$ two-qubit gates for some constant C.*

With these results, we can prove Proposition 6. The idea is that using Lemma 17, any pure state on the first $k \sim \log_2 G$ qubits can be generated by G gates. Then, we can use the same packing net construction as [19] from Lemma 16. Plugging into Theorem 13 then gives our lower bound. We also add an additional term to account for expected asymptotic δ behavior.

Proof of Proposition 6. We wish to construct a (2ϵ)-packing net over the space S_1 of n-qubit pure quantum states generated by applying G gates to the first $k = \lfloor \log_2(G/C)\rfloor$ qubits, where C is taken to be the same constant as in Lemma 17. First, consider only the subsystem consisting of the first k qubits. Notice that by Lemma 17, any k-qubit pure state can be generated by at most G gates. Thus, the space of k-qubit pure states is the same as the space of k-qubit pure states generated by at most G gates. In this way, we can construct a packing net for our subsystem of only the first k qubits by constructing a packing net for all k-qubit pure states. By Theorem 13, there exists an (2ϵ)-packing net $\mathcal{M}_{2\epsilon} = \{\sigma_1,\dots,\sigma_m\}$ of the space of k-qubit pure state density matrices satisfying

$$\ln m \geq \frac{2^k}{c}, \quad \chi_0 \leq 4c\epsilon^2 \ln\left(\frac{2^{k-1}}{\epsilon}\right). \tag{B.65}$$

From this, we can construct a packing net for our entire n-qubit system as follows.

$$\mathcal{M}'_{2\epsilon} \triangleq \{\sigma_i \otimes |0\rangle\langle 0|^{\otimes(n-k)} : \sigma_i \in \mathcal{M}_{2\epsilon}\}; \tag{B.66}$$

We claim that this is indeed a (2ϵ)-packing net of S_1. Let $|\psi\rangle = (U \otimes I)\,|0\rangle^{\otimes n} \in S_1$ and let $\rho = |\psi\rangle\langle\psi|$. Because U only acts on the first k qubits, then we can write $\rho = \rho_k \otimes |0\rangle\langle 0|^{\otimes(n-k)}$, where $\rho_k = U\,|0\rangle\langle 0|^{\otimes k}\,U$. Thus, we can see that $\mathcal{M}'_{2\epsilon} \subseteq S_1$. Importantly, all elements of $\mathcal{M}'_{2\epsilon}$ are n-qubit pure states generated by G gates on the first k qubits. Moreover, for any $\sigma'_i, \sigma'_j \in \mathcal{M}'_{2\epsilon}$, we have

$$\mathrm{d}_{\mathrm{tr}}(\sigma'_i, \sigma'_j) = \mathrm{d}_{\mathrm{tr}}(\sigma_i \otimes |0\rangle\langle 0|^{\otimes(n-k)}, \sigma_j \otimes |0\rangle\langle 0|^{\otimes(n-k)}) = \mathrm{d}_{\mathrm{tr}}(\sigma_i, \sigma_j) > 2\epsilon, \tag{B.67}$$

where the first equality follows by definition of $\mathcal{M}'_{2\epsilon}$ and the last inequality follows because $\sigma_i, \sigma_j \in \mathcal{M}_{2\epsilon}$.

Hence, $\mathcal{M}'_{2\epsilon}$ is indeed a (2ϵ)-packing net of S_1, which is the set of states we wish to learn. Moreover, it is of the same size as $\mathcal{M}_{2\epsilon}$, which had cardinality m satisfying Equation (B.65). Plugging Equation (B.65) into Theorem 13, we have that in order to learn ρ up to ϵ-trace distance, we require

$$N_1 \geq \frac{(1-\delta)\frac{2^k}{c} - \ln 2}{4c\epsilon^2 \ln(2^{k-1}/\epsilon)} \geq C_1 \frac{(1-\delta)G - C_2}{\epsilon^2 \ln(G/(2\epsilon))} = \Omega\left(\frac{G(1-\delta)}{\epsilon^2 \log(G/\epsilon)}\right), \tag{B.68}$$

where in the second inequality, C_1 and C_2 are constants, where C_1 depends on c.

This concludes the proof for the second term in the minimum in Proposition 6. Again, for $n < \lfloor \log_2(G/C) \rfloor$, we can appeal to the full quantum state tomography lower bound of [19, 20]. Thus, we obtain the lower bound

$$N_1 = \Omega\left(\min\left(\frac{2^n}{\epsilon^2}, \frac{G(1-\delta)}{\epsilon^2 \log(G/\epsilon)}\right)\right). \tag{B.69}$$

Notice, however, that in the limit as $\delta \to 0$ one should find $N \to \infty$. This behavior is not captured in Theorem 13 due to the use of the classical Fano's inequality, which treats the measurement procedure as a classical random variable. This behavior is also not present in lower bounds from [19, 20], where they assume that $\delta = \Theta(1)$. In order to recover the dependence on δ, we prove the following lemma.

Lemma 18. *Let $|\psi_0\rangle, |\psi_1\rangle$ be any two n-qubit pure quantum states. Suppose that $|\psi_0\rangle$ and $|\psi_1\rangle$ satisfy $\mathrm{d}_{\mathrm{tr}}(|\psi_0\rangle, |\psi_1\rangle) \geq \epsilon$. Then, for $\delta \in (0,1]$,*

$$N_2 = \Omega\left(\frac{\log(1/\delta)}{\epsilon^2}\right) \tag{B.70}$$

copies of $|\psi\rangle \in \{|\psi_0\rangle, |\psi_1\rangle\}$ are needed to distinguish whether $|\psi\rangle = |\psi_0\rangle$ or $|\psi\rangle = |\psi_1\rangle$ with probability at least $1-\delta$.

Proof. For pure states, we know that the relationship between fidelity and trace distance is given by

$$\mathrm{d}_{\mathrm{tr}}(|\alpha\rangle, |\beta\rangle) = \sqrt{1 - |\langle\alpha|\beta\rangle|^2}. \tag{B.71}$$

In our case, because $\mathrm{d}_{\mathrm{tr}}(|\psi_0\rangle, |\psi_1\rangle) \geq \epsilon$, then we have

$$|\langle\psi_0|\psi_1\rangle|^2 \leq 1 - \epsilon^2. \tag{B.72}$$

Using the Holevo-Helstrom Theorem [132, 163], in order to distinguish $|\psi_0\rangle$ from $|\psi_1\rangle$ with probability at least $1-\delta$, one requires at least N_2 copies of $|\psi\rangle \in \{|\psi_0\rangle, |\psi_1\rangle\}$ satisfying

$$1 - \delta \leq \frac{1}{2} + \frac{1}{2}\sqrt{1 - |\langle\psi_0|\psi_1\rangle|^{2N_2}} \tag{B.73}$$

Rearranging this inequality, we have

$$N_2 \geq \frac{\log(4\delta(1-\delta))}{\log(|\langle\psi_0|\psi_1\rangle|^2)} = \frac{\log\left(\frac{1}{4\delta(1-\delta)}\right)}{\log\left(\frac{1}{|\langle\psi_0|\psi_1\rangle|^2}\right)} \tag{B.74}$$

By Equation (B.72), this in particular requires

$$N_2 \geq \frac{\log\left(\frac{1}{4\delta(1-\delta)}\right)}{\log\left(\frac{1}{1-\epsilon^2}\right)} = \Omega\left(\frac{\log(1/\delta)}{\epsilon^2}\right). \tag{B.75}$$

□

In our case, note that the conditions of Lemma 18 hold by the existence of the packing net in Equation (B.66), where $|\psi_0\rangle, |\psi_1\rangle$ can be any two states in the packing net. Moreover, because approximating the unknown $|\psi\rangle$ to $(\epsilon/3)$-trace distance suffices to solve the distinguishing task in Lemma 18, then this lower bound also applies for the task of learning a state $|\psi\rangle$. Thus, combining Lemma 18 with Equation (B.69), we have

$$N = \Omega\left(\max\left(N_1, \frac{\log(1/\delta)}{\epsilon^2}\right)\right) = \Omega\left(\min\left(\frac{2^n}{\epsilon^2}, \frac{G(1-\delta)}{\epsilon^2\log(G/\epsilon)}\right) + \frac{\log(1/\delta)}{\epsilon^2}\right), \tag{B.76}$$

as claimed. □

This concludes the proof of Proposition 6. Recall that we are seeking a sample complexity lower bound for states for which we allow our G gates to act on any pair of the n qubits rather than only the first $\lfloor\log_2(G/C)\rfloor$ qubits. We complete the proof of Proposition 5 by reducing to the case of Proposition 6.

Proof of Proposition 5. As before, denote the set of n-qubit quantum states generated by G gates applied to only the first $\lfloor\log_2(G/C)\rfloor$ qubits as S_1. Similarly, denote the set of n-qubit quantum states generated by G gates (applied to any of the qubits) as S_2. Our claim is that the sample complexity of learning states in S_2 is at least the sample complexity of learning states in S_1.

By Proposition 6, we know that the sample complexity of learning states in S_1 is

$$N = \Omega\left(\min\left(\frac{2^n}{\epsilon^2}, \frac{G(1-\delta)}{\epsilon^2\log(G/\epsilon)}\right) + \frac{\log(1/\delta)}{\epsilon^2}\right) \tag{B.77}$$

By the definition of sample complexity, this means that there exists some state $\rho \in S_1$ requiring N copies to learn within ϵ trace distance. Then, because $S_1 \subseteq S_2$, then $\rho \in S_2$ as well. Thus, there exists a state $\rho \in S_2$ that requires N copies to learn, so the sample complexity of learning states within S_2 is at least N as well. □

3. Computational complexity

Theorem 12 states that the sample complexity for learning a description of an unknown n-qubit pure quantum state is linear (up to logarithmic factors) in the number of gates G used to generate the state. Nevertheless, the algorithm described in Appendix B 1 is not computationally efficient, as it constructs and searches over an exponentially large (in G) covering net for all pure states generated by G two-qubit gates. This raises the question: Does there exist a computationally efficient algorithm?

In this section, we first show that there is no polynomial-time algorithm for learning states generated by $G = \mathcal{O}(n\mathsf{polylog}(n))$ gates, assuming $\mathsf{RingLWE}$ cannot be solved efficiently on a quantum computer. This result also holds for states generated by a depth $d = \mathcal{O}(\mathsf{polylog}(n))$ circuit. Then we invoke a stronger assumption that $\mathsf{RingLWE}$ cannot be solved by any sub-exponential-time quantum algorithm, and show that any quantum algorithm for learning states generated by $\tilde{\mathcal{O}}(G)$ gates must use $\exp(\Omega(G))$ time. This means that the computational hardness already kicks in at $G = \tilde{\omega}(\log n)$. Finally, we explicitly construct an efficient learning algorithm for $G = \mathcal{O}(\log n)$, thus establishing $\log n$ gate complexity as a transition point of computational efficiency. Previous work [51, 52] arrives at similar hardness results for polynomial circuit complexity, but our detailed analysis allows us to sharpen the computational lower bound and obtain this transition point.

Theorem 14 (State learning computational complexity lower bound assuming polynomial hardness of $\mathsf{RingLWE}$)**.** *Let $\lambda = n$ be the security parameter and $\mathcal{K}$ be the key space parametrized by λ. Let U be a unitary consisting of $G = \mathcal{O}(n\mathsf{polylog}(n))$ gates (or a depth $d = \mathcal{O}(\mathsf{polylog}(n))$ circuit) that prepares a pseudorandom quantum state $|\phi_k\rangle$ for some randomly chosen key $k \in \mathcal{K}$. Such a unitary U exists by Proposition 3 assuming that $\mathsf{RingLWE}$ cannot be solved by polynomial-time quantum algorithms. Suppose we are given $N = \mathsf{poly}(\lambda)$ copies of $|\phi_k\rangle = U|0\rangle^{\otimes n}$. There does not exist a polynomial-time algorithm for learning a circuit description of $|\phi_k\rangle$ to within $\epsilon \leq 1/8$ trace distance with success probability at least $2/3$.*

Proof. Suppose for the sake of contradiction that there is an efficient algorithm $\mathcal{A}_0$ that can learn a description of $|\phi_k\rangle$ to within ϵ trace distance. Then by standard boosting of success probability (see e.g, [21, Proposition 2.4]), there is an efficient algorithm $\mathcal{A}$ that can learn $|\phi_k\rangle$ to the same accuracy with probability at least $p = 1 - 1/128$ with only a constant factor overhead in time complexity. Note that this boosting requires the distance metric to be efficiently computable, which is guaranteed by the SWAP

Algorithm 2: Distinguisher $\mathcal{D}$ for PRS

```
  Input: $\rho^{\otimes N} = |\psi\rangle\langle\psi|^{\otimes N}$
  Output: $b \in \{0,1\}$
1 Store one copy of $\rho$ in quantum memory.
2 Run $\mathcal{A}$ on inputs $\rho^{\otimes (N-1)}$, receiving $\hat{\rho}$.
3 Run the SWAP test on the remaining copy $\rho$ and $\hat{\rho}$, receiving a bit $b \in \{0,1\}$.
4 Output $b$.
```

test elaborated below. We will construct a polynomial-time quantum distinguisher $\mathcal{D}$ that invokes $\mathcal{A}$ to distinguish between $|\phi_k\rangle$ and a Haar-random state $|\phi\rangle$. This contradicts Definition 10.

The distinguisher $\mathcal{D}$ operates according to Algorithm 2.

Recall that the SWAP test [140, 141] takes two quantum states σ_1, σ_2 as input and outputs 1 with probability $(1+\mathrm{tr}(\sigma_1\sigma_2))/2$. We denote this algorithm as $\mathsf{SWAP}(\sigma_1, \sigma_2)$. Note that here we have switched the labels of 0 and 1 compared to the canonical SWAP test presented in [140, 141].

Notice that the hypothetical efficient learner $\mathcal{A}$ always produces the circuit description of the output state $\hat{\rho}$ in polynomial time. This means that the circuit description and thus the state $\hat{\rho}$ must also be efficiently implementable. As the SWAP test is also efficient, Step 3 of Algorithm 2 can thus indeed be performed efficiently on a quantum computer. Hence, the distinguisher is indeed an efficient quantum algorithm.

Throughout this section, we denote $\rho = |\psi\rangle\langle\psi|$. We analyze the probability that the distinguisher $\mathcal{D}$ outputs 1 when given the pseudorandom state $|\phi_k\rangle$ versus the Haar-random state $|\phi\rangle$.

Case 1: $|\psi\rangle = |\phi_k\rangle$, for a randomly chosen $k \in \mathcal{K}$. We have $\rho = |\psi\rangle\langle\psi| = |\phi_k\rangle\langle\phi_k|$. By the guarantees of $\mathcal{A}$, with probability at least p, we have $\mathrm{d}_{\mathrm{tr}}(\hat{\rho}, \rho) \leq \epsilon$, where $\hat{\rho}$ is the (potentially mixed) quantum state learned by algorithm $\mathcal{A}$. We can rewrite this as

$$\langle\psi|\hat{\rho}|\psi\rangle \geq 1 - \epsilon \tag{B.78}$$

where we used the relationship between fidelity and trace distance (when one state is pure)

$$\mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \geq 1 - \langle\psi|\hat{\rho}|\psi\rangle\,. \tag{B.79}$$

Then it immediately follows from Equation (B.78) that

$$\begin{aligned}
\Pr_{\substack{k \leftarrow \mathcal{K} \\ \mathcal{A}, \mathsf{SWAP}}}\left[\mathcal{D}\left(|\phi_k\rangle^{\otimes N}\right) = 1\right] &= \Pr_{\substack{k \leftarrow \mathcal{K} \\ \mathcal{A}, \mathsf{SWAP}}}\left[\mathsf{SWAP}\left(|\phi_k\rangle\langle\phi_k|\,, \hat{\rho}\right) = 1\right] \\
&= \mathop{\mathbb{E}}_{k \leftarrow \mathcal{K}}\left[\Pr_{\mathcal{A}, \mathsf{SWAP}}\left[\mathsf{SWAP}(|\phi_k\rangle\langle\phi_k|\,, \hat{\rho}) = 1 |\, |\phi_k\rangle\right]\right] \\
&\geq p \mathop{\mathbb{E}}_{k \leftarrow \mathcal{K}}\left[\frac{1}{2} + \frac{1}{2}(1-\epsilon)\right] = p\left(1 - \frac{\epsilon}{2}\right),
\end{aligned} \tag{B.80}$$

where the probability is taken over the random choice of the key $k \in \mathcal{K}$, the randomness in the learning algorithm $\mathcal{A}$ when run on samples $|\phi_k\rangle^{\otimes N}$, and the randomness in the SWAP test. In the inequality, we split the probability into two terms conditioned on the success and failure of $\mathcal{A}$, and we lower bound the term conditioned on the failure of $\mathcal{A}$ by zero.

Case 2: $|\psi\rangle = |\phi\rangle \sim \mu$, where μ is the Haar measure over pure quantum states. We have $\rho = |\psi\rangle\langle\psi| = |\phi\rangle\langle\phi|$. We want to upper bound the probability that the distinguisher $\mathcal{D}$ outputs 1 when given copies of $|\phi\rangle$. The intuition is that a Haar-random state is likely to be far from any state generated by a circuits with a polynomial-sized description, the space in which output of $\mathcal{A}$ lie. Let $S_{\mathcal{A}}(|\phi\rangle)$ be the set of quantum states corresponding to all possible outputs of the algorithm $\mathcal{A}$ when run on N copies of $|\phi\rangle$. We follow a similar reasoning as in Equation (B.80) and obtain

$$\Pr_{\substack{|\phi\rangle \sim \mu \\ \mathcal{A}, \mathsf{SWAP}}}\left[\mathcal{D}\left(|\phi\rangle^{\otimes N}\right) = 1\right] \leq \mathop{\mathbb{E}}_{|\phi\rangle \sim \mu}\left[\max_{\hat{\rho} \in S_{\mathcal{A}}(|\phi\rangle)}\left(\frac{1}{2} + \frac{1}{2}\langle\phi|\hat{\rho}|\phi\rangle\right)\right] + (1-p) \tag{B.81}$$

$$= \frac{1}{2} + \frac{1}{2}\mathop{\mathbb{E}}_{|\phi\rangle \sim \mu}\left[\max_{\hat{\rho} \in S_{\mathcal{A}}(|\phi\rangle)}\langle\phi|\hat{\rho}|\phi\rangle\right] + (1-p) \tag{B.82}$$

$$\triangleq \frac{1}{2} + \frac{1}{2}\mathop{\mathbb{E}}_{|\phi\rangle \sim \mu}[O_\phi] + (1-p), \tag{B.83}$$

where in the first line we split the probability according to whether $\mathcal{A}$ succeeds or fails, and we upper bound the failing term by $(1-p)$, and in the last line we define the random variable

$$O_\phi \triangleq \max_{\hat{\rho} \in S_{\mathcal{A}}(|\phi\rangle)} \langle\phi|\hat{\rho}|\phi\rangle \,. \tag{B.84}$$

Furthermore, we can split $\mathbb{E}_{|\phi\rangle\sim\mu}[O_\phi]$ into two parts by introducing a cut-off θ:

$$\mathop{\mathbb{E}}_{|\phi\rangle\sim\mu}[O_\phi] \leq \Pr\left[O_\phi \leq 1-\frac{\theta}{2}\right] \cdot \left(1-\frac{\theta}{2}\right) + \Pr\left[O_\phi > 1-\frac{\theta}{2}\right] \cdot 1 \leq 1-\frac{\theta}{2} + \Pr\left[O_\phi > 1-\frac{\theta}{2}\right], \tag{B.85}$$

where in the first inequality, we used that $O_\phi \leq 1$. Plugging this into our previous expression, we have

$$\Pr_{\substack{|\phi\rangle\sim\mu \\ \mathcal{A},\mathsf{SWAP}}}\left[\mathcal{D}\left(|\phi\rangle^{\otimes N}\right)=1\right] \leq 1-\frac{\theta}{4}+\frac{1}{2}\Pr\left[O_\phi > 1-\frac{\theta}{2}\right] + (1-p) \tag{B.86}$$

We aim to upper bound the probability $\Pr[O_\phi > 1-\theta/2]$. Notice that we have

$$\Pr\left[O_\phi > 1-\frac{\theta}{2}\right] \leq \sum_{\hat{\rho}\in\mathcal{N}_{\sqrt{\theta/2}}} \Pr_{|\phi\rangle\sim\mu}\left[\langle\phi|\hat{\rho}|\phi\rangle > 1-\frac{\theta}{2}\right], \tag{B.87}$$

where $N_{\sqrt{\theta/2}}$ be a minimal $(\sqrt{\theta/2})$-covering net with respect to trace distance of the set $S_{\mathcal{A}}(|\phi\rangle)$ of quantum states corresponding to all possible outputs of the algorithm $\mathcal{A}$ when run on N copies of $|\phi\rangle$. We can bound this probability using concentration results. Let $d = 2^n$.

$$\begin{aligned}
\Pr_{|\phi\rangle\sim\mu}\left[\langle\phi|\hat{\rho}|\phi\rangle > 1-\frac{\theta}{2}\right] &\leq \Pr_{|\phi\rangle\sim\mu}\left[\exp\left(\frac{d}{2}\langle\phi|\hat{\rho}|\phi\rangle\right) \geq \exp\left(\frac{d}{2}\left(1-\frac{\theta}{2}\right)\right)\right] && \text{(B.88)}\\
&\leq \exp\left(-\frac{d}{2}\left(1-\frac{\theta}{2}\right)\right) \mathop{\mathbb{E}}_{|\phi\rangle\sim\mu}\left[\exp\left(\frac{d}{2}\langle\phi|\hat{\rho}|\phi\rangle\right)\right] && \text{(B.89)}\\
&= \exp\left(-\frac{d}{2}\left(1-\frac{\theta}{2}\right)\right) \sum_{k=0}^{\infty} \frac{1}{k!}\frac{d^k}{2^k} \mathop{\mathbb{E}}_{|\phi\rangle\sim\mu}[\langle\phi|\hat{\rho}|\phi\rangle^k] && \text{(B.90)}\\
&= \exp\left(-\frac{d}{2}\left(1-\frac{\theta}{2}\right)\right) \sum_{k=0}^{\infty} \frac{1}{k!}\frac{d^k}{2^k} \frac{1}{\binom{k+d-1}{k}} \operatorname{tr}\left(\hat{\rho}^{\otimes k} P_{\mathrm{sym}}^{(d,k)}\right) && \text{(B.91)}\\
&\leq \exp\left(-\frac{d}{2}\left(1-\frac{\theta}{2}\right)\right) \sum_{k=0}^{\infty} \frac{1}{2^k} \operatorname{tr}\left(\hat{\rho}^{\otimes k} P_{\mathrm{sym}}^{(d,k)}\right) && \text{(B.92)}\\
&\leq 2\exp\left(-\frac{d}{2}\left(1-\frac{\theta}{2}\right)\right). && \text{(B.93)}
\end{aligned}$$

Here, the first two lines follow from the following inequality, which holds for $\alpha > 0$ and a random variable X:

$$\Pr[X \geq \epsilon] \leq \Pr[\exp(\alpha X) \geq \exp(\alpha\epsilon)] \leq \exp(-\alpha X)\,\mathbb{E}[\exp(\alpha X)]. \tag{B.94}$$

The third line follows from the Taylor expansion of $\exp(x)$. The fourth line follow from the identity

$$\mathop{\mathbb{E}}_{|\phi\rangle\sim\mu} \langle\phi|O|\phi\rangle^k = \frac{1}{\binom{k+d-1}{k}} \operatorname{tr}\left(O^{\otimes k} P_{\mathrm{sym}}^{(d,k)}\right), \tag{B.95}$$

where we chose $O = \hat{\rho}$ and $P_{\mathrm{sym}}^{(d,k)}$ is the orthogonal projector onto the symmetric subspace of $(\mathbb{C}^d)^{\otimes k}$. See, e.g., Example 50 in [145] for a proof of this identity. The fifth line follows from the inequality $1/\binom{k+d-1}{k} \leq k!/d^k$. Finally, the last line is true by the following inequalities:

$$\begin{aligned}
\operatorname{tr}\left(\hat{\rho}^{\otimes k} P_{\mathrm{sym}}^{(d,k)}\right) &\leq \left|\operatorname{tr}\left(\hat{\rho}^{\otimes k} P_{\mathrm{sym}}^{(d,k)}\right)\right| && \text{(B.96)}\\
&\leq \left\|\hat{\rho}^{\otimes k} P_{\mathrm{sym}}^{(d,k)}\right\|_1 && \text{(B.97)}\\
&\leq \left\|P_{\mathrm{sym}}^{(d,k)}\right\|_\infty \|\hat{\rho}\|_1^k && \text{(B.98)}
\end{aligned}$$

$$\leq 1, \tag{B.99}$$

which follows via properties of the trace norm and because $P_{\text{sym}}^{(d,k)}$ is a projector. Plugging this back into Equation (B.87), we have

$$\Pr\left[O_\phi > 1 - \frac{\theta}{2}\right] \leq \sum_{\hat{\rho} \in \mathcal{N}_{\sqrt{\theta/2}}} \Pr_{|\phi\rangle \sim \mu}\left[\langle\phi|\hat{\rho}|\phi\rangle > 1 - \frac{\theta}{2}\right] \tag{B.100}$$

$$\leq 2\mathcal{N}(S_{\mathcal{A}}(|\phi\rangle), \mathrm{d}_{\mathrm{tr}}, \sqrt{\theta/2}) \exp\left(-\frac{2^n}{2}\left(1 - \frac{\theta}{2}\right)\right) \tag{B.101}$$

Moreover, since $S_{\mathcal{A}}(|\phi\rangle)$ is the set of quantum states corresponding to all possible outputs of the algorithm $\mathcal{A}$ when run on $|\phi\rangle^{\otimes N}$, then all states in $S_{\mathcal{A}}(|\phi\rangle)$ must have a $\mathsf{poly}(n)$-size circuit description (because $\mathcal{A}$ is assumed to be efficient). Thus our covering number upper bound (setting $G = \mathsf{poly}(n)$ in Appendix B 1) implies

$$\mathcal{N}(S_{\mathcal{A}}(|\phi\rangle), \mathrm{d}_{\mathrm{tr}}, \sqrt{\theta/2}) = \mathcal{O}\left((1/\theta)^{\mathsf{poly}(n)}\right). \tag{B.102}$$

Thus, the above bounds along with Equation (B.101) gives us,

$$\Pr\left[O_\phi > 1 - \frac{\theta}{2}\right] = \mathrm{negl}(n), \tag{B.103}$$

where $\mathrm{negl}(n)$ denotes a negligible function in n. Putting everything together with Equation (B.86), we have

$$\Pr_{\substack{|\phi\rangle \sim \mu \\ \mathcal{A}, \mathsf{SWAP}}}\left[\mathcal{D}\left(|\phi\rangle^{\otimes N}\right) = 1\right] \leq 1 - \frac{\theta}{4} + \mathrm{negl}(n) + (1 - p). \tag{B.104}$$

Combining with Equation (B.80), we conclude that

$$\left|\Pr_{\substack{k \leftarrow \mathcal{K} \\ \mathcal{A}, \mathsf{SWAP}}}\left[\mathcal{D}\left(|\phi_k\rangle^{\otimes N}\right) = 1\right] - \Pr_{\substack{|\phi\rangle \sim \mu \\ \mathcal{A}, \mathsf{SWAP}}}\left[\mathcal{D}\left(|\phi\rangle^{\otimes N}\right) = 1\right]\right| \geq p\left(1 - \frac{\epsilon}{2}\right) - 2 + \frac{\theta}{4} + p - \mathrm{negl}(n) \tag{B.105}$$

$$\geq \frac{1}{16} - \mathrm{negl}(n) \tag{B.106}$$

$$\geq \frac{1}{32}, \tag{B.107}$$

where we have taken $\theta = 1/2, \epsilon \leq 1/8, p = 1 - 1/128$, and the last inequality follows by taking n large enough. This contradicts the assumption that $\{|\phi_k\rangle\}_{k \leftarrow \mathcal{K}}$ are pseudorandom quantum states under the assumption that RingLWE cannot be solved by polynomial-time quantum algorithms. □

Next, we invoke the stronger assumption that RingLWE cannot be solved by any sub-exponential-time quantum algorithm and show that learning states generated by $\tilde{\mathcal{O}}(G)$ gates requires exponential-in-G time.

Theorem 15 (State learning computational complexity lower bound assuming sub-exponential hardness of RingLWE, restatement of lower bound in Theorem 2)**.** *Let $\lambda = l = \Theta(G)$ with $l \leq n$ be the security parameter and $\mathcal{K}$ be the key space parametrized by λ. Let U be an l-qubit unitary consisting of $\mathcal{O}(l\mathsf{polylog}(l)) = \mathcal{O}(G\mathsf{polylog}(G))$ gates (or a depth $d = \mathcal{O}(\mathsf{polylog}(G))$ circuit) that prepares an l-qubit pseudorandom quantum state $|\phi_k\rangle$ against sub-exponential adversaries for some randomly chosen key $k \in \mathcal{K}$. Such a unitary U exists by Proposition 3 assuming that RingLWE cannot be solved by sub-exponential quantum algorithms. Suppose we are given $N = \mathsf{poly}(\lambda)$ copies of $|\psi_k\rangle = |\phi_k\rangle \otimes |0\rangle^{\otimes(n-l)} = U|0\rangle^{\otimes n}$. Any quantum algorithm for learning a circuit description of $|\psi_k\rangle$ to within $\epsilon \leq 1/8$ trace distance with success probability at least $2/3$ must use $\exp(\Omega(\min\{G, n\}))$ time.*

Proof. With polynomial hardness of RingLWE replaced by sub-exponential hardness, Theorem 14 asserts that there are no sub-exponential (in l) quantum algorithms that can learn the l-qubit pseudorandom state $|\phi_k\rangle$ to within trace distance $\epsilon < 1/8$ with success probability at least $2/3$. That is, any such learning algorithms must use time at least $\exp(\Omega(l)) = \exp(\Omega(\min\{G, n\}))$ time, since $l \leq n$. Meanwhile, a learning algorithm for the n-qubit state $|\psi_k\rangle$ can be used to learn the l-qubit state $|\phi_k\rangle$ in the same runtime by post-selecting on the last $(n - l)$ qubits being $|0\rangle$, because trace distance does not increase under such an operation. This implies the $\exp(\Omega(\min\{G, n\}))$ time lower bound for the n-qubit learning algorithm. □

Finally, we briefly show that learning becomes efficient when $G = \mathcal{O}(\log n)$. The idea is that with $\mathcal{O}(\log n)$ gates, there can only be at most $\mathcal{O}(\log n)$ qubits affected. Thus we can focus on these qubits and learning the states amounts to manipulating vectors of size at most $2^{\mathcal{O}(\log n)} = \mathsf{poly}(n)$, which is efficient. Specifically, we have the following statement.

Proposition 7 (Learning states with logarithmic circuit complexity efficiently, restatement of upper bound in Theorem 2)**.** *Let $\epsilon > 0$. Suppose we are given N copies of a pure n-qubit state $\rho = |\psi\rangle\langle\psi|$, where $|\psi\rangle = U\,|0\rangle^{\otimes n}$ is generated by a unitary U consisting of $G = \mathcal{O}(\log n)$ two-qubit gates. There exists a learning algorithm that outputs a $\hat{\rho}$ such that $\mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \leq \epsilon$ with probability at least $2/3$ using $\mathsf{poly}(n, 1/\epsilon)$ copies and time.*

Proof. We prove this by explicitly constructing a learning algorithm based on junta learning (Appendix B 1) and standard tomography methods as follows.

Firstly, we execute Algorithm 1 on copies of ρ and post-select on the trivial qubits being zero as in Appendix B 1. This step uses $\mathsf{poly}(n, 1/\epsilon)$ copies and time, and gives us post-selected states $\rho' = \rho'' \otimes (|0\rangle\langle 0|)^{\otimes(n-2G)}$ that satisfies $\mathrm{d}_{\mathrm{tr}}(\rho, \rho') \leq \epsilon/4$ by appropriate choice of accuracy. Here ρ'' is a state on $2G = \mathcal{O}(\log n)$ qubits.

Next, we carry out the most straightforward tomography method of measuring all the Pauli coefficients. Concretely, we can represent $\rho'' = \sum_P \alpha_P P$ as a linear combination of all Pauli strings over the $2G$ qubits. Using this representation, we estimate all the coefficients α_P by measuring $\mathrm{tr}(\rho' P)$ and obtain a $\hat{\rho} = \hat{\rho}'' \otimes (|0\rangle\langle 0|)^{\otimes(n-2G)}$. By measuring all Pauli string expectation values $\mathrm{tr}(\rho' P)$ to accuracy $\mathcal{O}(\epsilon/4^{2G})$, we have $\mathrm{d}_{\mathrm{tr}}(\rho', \hat{\rho}) \leq \epsilon/4$ and thus $\mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \leq \epsilon/2$. From standard Chernoff-Hoeffding concentration inequalities, this can be achieved with $\mathcal{O}(4^{2G}/(\epsilon/4^{2G})^2) = \mathsf{poly}(n, 1/\epsilon)$ copies. Finally, we diagonalize $\hat{\rho}''$ and calculate its eigenvector $|\hat{\psi''}\rangle$ with the largest eigenvalue, such that $|\hat{\psi''}\rangle$ is the pure state closest to $\hat{\rho}''$ in trace distance. Let $|\hat{\psi}\rangle = |\hat{\psi''}\rangle \otimes |0\rangle^{\otimes(n-2G)}$. Recall that $\mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \leq \epsilon/2$ and ρ is a pure state. Therefore, $\mathrm{d}_{\mathrm{tr}}(|\hat{\psi}\rangle\langle\hat{\psi}|, \hat{\rho}) \leq \mathrm{d}_{\mathrm{tr}}(\rho, \hat{\rho}) \leq \epsilon/2$ and thus $\mathrm{d}_{\mathrm{tr}}(|\hat{\psi}\rangle\langle\hat{\psi}|, \rho) \leq \epsilon$. We output $|\hat{\psi}\rangle$ as the learning outcome whose circuit description can be found by finding a unitary with $|\hat{\psi''}\rangle$ as its first column using orthogonalization. Since we are manipulating matrices of size $\mathcal{O}(2^{2G}) = \mathsf{poly}(n)$, the computational complexity is also $\mathcal{O}(n, 1/\epsilon)$. □

Appendix C: Learning quantum unitaries

In this appendix, we give detailed proofs of Theorem 3 for worst-case unitary learning, Theorem 4 for average-case unitary learning, and Theorem 5 for learning with classically described data.

1. Worst-case learning

We begin with the worst-case unitary learning problem, which measures reconstruction error in terms of the diamond distance $\mathrm{d}_\diamondsuit(U, V) = \max_\rho \|(U \otimes I)\rho(U \otimes I)^\dagger - (V \otimes I)\rho(V \otimes I)^\dagger\|_1$. In particular, we consider the task of using queries to an unknown unitary U with bounded circuit complexity G to output a classical circuit description $\hat{U}$ such that $\mathrm{d}_\diamondsuit(\hat{U}, U) \leq \epsilon$ with probability at least $2/3$. The diamond distance has a similar operational meaning as the trace distance in state learning. It characterizes the ability to distinguish two processes with arbitrary input states and measurements. If we can learn the unitary with small error in the diamond distance, then we will only make small error even if we test $\hat{U}$ against U on the worst choice of input states. However, we find the following result stating that this task necessarily requires a number of queries exponential in G, indicating the hardness of worst-case unitary learning.

Theorem 16 (Worst-case unitary learning, restatement of Theorem 3)**.** *Given query access to an n-qubit unitary U composed of G two-qubit gates, any algorithm that can output a unitary $\hat{U}$ such that $\mathrm{d}_\diamondsuit(\hat{U}, U) \leq \epsilon \in (0, 1/4]$ with probability at least $2/3$ must query U at least $\Omega\left(2^{\min\{G/(2C), n/2\}}/\epsilon\right)$ times, where $C > 0$ is a universal constant. Meanwhile, there exists such an algorithm using $\mathcal{O}(2^n G \log\left(\sqrt{2^n} G/\epsilon\right)/\epsilon)$ queries.*

Proof. The upper bound follows from the average-case learning algorithm (Theorem 4, proved below) when working in the exponentially small error regime. Specifically, Theorem 4 gives us an algorithm that uses $\mathcal{O}(G\sqrt{d}\log(G/\epsilon')/\epsilon')$ queries to output a $\hat{U}$ that satisfies $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \epsilon'$. Meanwhile, from Lemma 1, Lemma 3 and Lemma 4, we know that $\mathrm{d}_\diamondsuit(\hat{U}, U) \leq 2d_2'(\hat{U}, U) \leq 2\sqrt{d}d_F'(\hat{U}, U) \leq 4\sqrt{d}\,\mathrm{d}_{\mathrm{avg}} \leq 4\sqrt{d}\epsilon'$. Setting $\epsilon = 4\sqrt{d}\epsilon'$, we arrive at the desired worst-case learning query complexity.

The proof of the lower bound is inspired by the adversary method [54, Chapter 6] and the optimality of Grover's algorithm [164]. The idea is to construct a set of unitaries that can be distinguished by the worst-case learning algorithm, but only make minor difference when acting on states so that a minimal number of queries have to be made in order to distinguish them.

Specifically, we consider all the length-2^k bit-strings x that have Hamming weight 1, i.e., $x_i = 1$ for some $i \in [2^k]$ and all the other bits are 0. We focus on the task of distinguishing this set of strings, denoted by X, from the all zero string $Y = \{0\dots 0\}$. We access any such bit-strings x through a phase oracle, which is defined as a k-qubit unitary U_x that obeys $U_x |j\rangle = e^{i\epsilon' x_j} |j\rangle$ for all $j \in [2^k]$. In other words, U_x is diagonal and each diagonal element is $e^{i\epsilon'}$ if the corresponding bit is 1 and is 1 if the bit is 0. The unitary for the all zero string is the identity.

To implement such unitaries with 2-qubit gates, we note that since the strings have Hamming weight at most one, each of the unitaries is equivalent to a $(k-1)$-controlled phase gate with proper control rule. The control rule can be realized by $\mathcal{O}(k)$ pairs of 1-qubit gates acting on each qubit, and the $(k-1)$-controlled phase gate can be decomposed into $\mathcal{O}(k)$ 2-qubit gates [165]. Therefore, with $\mathcal{O}(k)$ gates, one can implement U_x for any 2^k-bit string x with Hamming weight at most one.

Suppose Ck gates suffice to implement these U_x. Set $k = \min\{\lfloor G/C \rfloor, n\}$. Then for any $x \in X \cup Y$, $U_x \otimes I_{n-k}$ is an n-qubit gate composed of at most G gates. Meanwhile, the unitaries for X are far apart from that for Y, because for any $x \in X$, suppose $x_j = 1$, we can take another $x' \neq x$ from X with $x'_{j'} = 1$, and let $|\psi_{jj'}\rangle = (|j\rangle + |j'\rangle)/\sqrt{2}$. Then we have

$$\begin{aligned} \mathrm{d}_\Diamond(U_x, U_{0\dots0}) &\geq \|U_x |\psi_{jj'}\rangle\langle\psi_{jj'}| U_x^\dagger - U_{0\dots0} |\psi_{jj'}\rangle\langle\psi_{jj'}| U_{0\dots0}^\dagger\|_1 \\ &= \left\| \frac{e^{i\epsilon'}-1}{2} |j\rangle\langle j'| + \frac{e^{-i\epsilon'}-1}{2} |j'\rangle\langle j| \right\|_1 = 2\sin\frac{\epsilon'}{2} \geq \frac{\epsilon'}{2}, \end{aligned} \tag{C.1}$$

for $\epsilon' \in (0,1]$. Therefore, if we have a learning algorithm that can learn U_T^n using m queries with accuracy $\epsilon = \epsilon'/4 \in (0, 1/4]$ in diamond norm with probability 2/3, it can also distinguish X from Y with the same probability. Note that this also works if the learning algorithm is for (quotient) spectral distance, but not for $\mathrm{d}_{\mathrm{avg}}$ because $\mathrm{d}_{\mathrm{avg}}(U_x, U_{0\dots0})$ is exponentially small for every x with Hamming weight one.

In addition, we have the following query complexity lower bound from the adversary method.

Lemma 19. *(Phase adversary method, [54, Lemma 6.4]). Let D be a finite set of functions from a finite set Q to $\mathbb{R}$. To each function $x \in D$, assign an oracle U_x of the form $U_x|q\rangle = e^{ix(q)}|q\rangle$. Let X and Y be two disjoint subsets of D. Let $R \subseteq X \times Y$ be a binary relation on $X \times Y$. For $x \in X$, we write $R(x) = \{y \in Y : (x,y) \in R\}$, and similarly $R(y)$ for $y \in Y$. Define*

$$m = \min_{x\in X} |R(x)|, \quad m' = \min_{y \in Y} |R(y)|, \quad l_{q,x} = \sum_{y\in R(x)} |x(q) - y(q)|, \quad l_{q,y} = \sum_{x \in R(y)} |x(q)-y(q)|,$$

and let $l_{\max} = \max_{q\in Q, x\in X, y\in Y} l_{q,x} l_{q,y}$. Then to distinguish X and Y with success probability at least 2/3, any algorithm needs at least

$$\Omega\left(\sqrt{\frac{mm'}{l_{\max}}}\right) \tag{C.2}$$

queries to the oracle.

For our problem, let $R = X \times Y$. For all bit-strings x, define $x(q) = \epsilon x_q$. Then we have $m = |Y| = 1, m' = |X| = 2^k, l_{q,x} = \epsilon x_q, l_{q,y} = \epsilon$ because for a specific q, only one $x \in R(y) = X$ has $x_q = 1$. Thus $l_{\max} = \epsilon^2$. Plugging these into the above lemma, we obtain a query complexity lower bound of $\Omega(\sqrt{2^k}/\epsilon)$. Since $k = \min\{\lfloor G/C \rfloor, n\}$, we arrive at the final query complexity lower bound $\Omega\left(2^{\min\{G/(2C), n/2\}}/\epsilon\right)$. □

2. Average-case query complexity upper bounds

Having seen that worst-case unitary learning is hard, we move on to the setting of average-case learning. In particular, we consider the task of using queries to an unknown unitary U with bounded circuit complexity G to output the classical circuit description of a unitary $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) = \sqrt{\mathbb{E}_{|\psi\rangle}[\mathrm{d}_{\mathrm{tr}}(\hat{U}|\psi\rangle, U|\psi\rangle)^2]} \leq \epsilon$ with probability at least 2/3. In the following, we give explicit algorithms that solve this learning task with linear-in-G queries, using similar hypothesis selection techniques as in the state learning task (Appendix B 1).

Proposition 8 (Average case unitary learning upper bounds, upper bounds in Theorem 4)**.** *There exists an algorithm that, given query access to an n-qubit unitary U composed of G two-qubit gates, can output a unitary $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \epsilon$ with probability at least $2/3$ using*

$$\mathcal{O}\left(\min\left\{\frac{4^n}{\epsilon}, \frac{G\log(G/\epsilon)}{\epsilon^2}, \frac{\sqrt{2^n}G\log(G/\epsilon)}{\epsilon}\right\}\right) \tag{C.3}$$

queries to the unknown unitary U. Moreover, there is another such algorithm that uses $\mathcal{O}(G\log(G/\epsilon)/\epsilon^4)$ queries without employing auxiliary quantum systems.

The $\mathcal{O}(4^n/\epsilon)$ scaling comes from the diamond norm learning algorithm in [21, Theorem 1.1], which directly implies an average-case learning algorithm because $\mathrm{d}_{\mathrm{avg}}(U,V) \leq d'_F(U,V) \leq d'_2(U,V) \leq \frac{1}{\sqrt{2}}\,\mathrm{d}_{\diamond}(U,V)$ from Lemmas 1, 3 and 4. Note that this part of the bound does not make use of the promise that the unknown unitary can be implemented with G two-qubit gates. In the following, we prove the G-dependent parts of the upper bound.

a. Unitary learning without ancillary systems

We begin by describing the learning algorithm without ancillary systems. The algorithm works similarly to the state learning procedure. It constructs a covering net over G-gate unitaries with respect to $\mathrm{d}_{\mathrm{avg}}$, and regards them as candidates for the unknown unitary. In contrast to our state learning procedure, where the algorithm estimates the trace distance between states, here the algorithm estimates the overlap between unitaries by inputting random states and apply single-shot Clifford classical shadow, which translates into $\mathrm{d}_{\mathrm{avg}}$. Then, we select the candidate closest to the unknown unitary as the learning outcome.

Specifically, we consider a $\sqrt{\epsilon'}$-covering net $\mathcal{N}$ of the set of n-qubit unitaries implemented by G two-qubit gates with respect to $\mathrm{d}_{\mathrm{avg}}$ as in Corollary 1, and regard the elements $U_i \in \mathcal{N}$ as potential candidates for the unknown unitary U. Our strategy is to use classical shadow to estimate the distances $\mathrm{d}_{\mathrm{avg}}(U_i, U)$ for every U_i in the covering net. Then we can find the one with minimal distance as the output of our learning algorithm.

To achieve this, consider a randomly sampled tensor product of 1-qubit stabilizer states

$$|x\rangle = U_x\,|0\rangle^{\otimes n} \sim Q = \mathrm{Uniform}[\{|0\rangle, |1\rangle, |x+\rangle, |x-\rangle, |y+\rangle, |y-\rangle\}^{\otimes n}], \tag{C.4}$$

where $U_x = \otimes_{i=1}^n U_{x_i}$ is the state preparation unitary, and $x \in \mathbb{Z}_6^n$ labels the state. We apply the unknown unitary U to it and obtain $U|x\rangle$. Then we invoke a single use of the Clifford classical shadow protocol [100]: We randomly sample an n-qubit Clifford gate C and apply it to $U|x\rangle$, and then measure in the computational basis to get an outcome $|b\rangle, b \in \{0,1\}^n$, with probability $|\langle b|CU|x\rangle|^2$. Let $\hat{\rho} = (2^n+1)C^\dagger|b\rangle\langle b|C - I$. From [100], we know that $\mathbb{E}_{C,b}[\hat{\rho}] = U|x\rangle\langle x|U^\dagger$. Now we consider the observable $O_i = U_i|x\rangle\langle x|U_i^\dagger$ and the estimator $\hat{o}_i = \mathrm{tr}(O_i\hat{\rho})$. Then we have the expectation value

$$\mathop{\mathbb{E}}_{|x\rangle,C,b}[\hat{o}_i] = \mathop{\mathbb{E}}_{|x\rangle}\left[\mathrm{tr}\left(O_i \mathop{\mathbb{E}}_{C,b}[\hat{\rho}]\right)\right] = \mathop{\mathbb{E}}_{|x\rangle}\left[|\langle x|U_i^\dagger U|x\rangle|^2\right] = 1 - d_Q^2(U_i, U)\,, \tag{C.5}$$

where $d_Q(U_i,U) = \sqrt{\mathbb{E}_{|\psi\rangle\sim Q}[\mathrm{d}_{\mathrm{tr}}(U_i|\psi\rangle, U|\psi\rangle)^2]}$ is the root mean squared trace distance with respect to Q as defined in Lemma 5. Next, we show that $\hat{o}_i$ has bounded variance. Note that

$$\mathrm{Var}[\hat{o}_i] = \mathop{\mathbb{E}}_{|x\rangle,C,b}[\hat{o}_i^2] - \left(\mathop{\mathbb{E}}_{|x\rangle,C,b}[\hat{o}_i]\right)^2 \leq \mathop{\mathbb{E}}_{|x\rangle}\left[\mathop{\mathbb{E}}_{C,b}[\hat{o}_i^2]\right] \leq \mathop{\mathbb{E}}_{|x\rangle}[3\,\mathrm{tr}(O_i^2)] = 3, \tag{C.6}$$

where we have used the variance bound for Clifford shadows [100, Lemma S1 and Proposition S1] and the fact that $\mathrm{tr}(O_i^2) = \mathrm{tr}(O_i) = 1$.

To estimate the expectation values of $\hat{o}_i$, we can draw m i.i.d. samples of such input states $\{|x_j\rangle\}_{j=1}^m$ from Q, construct the observables $O_{ij} = U_i|x_j\rangle\langle x_j|U_i^\dagger$ and carry out the above protocol to get the estimators $\hat{o}_{ij}$ for $1 \leq i \leq |\mathcal{N}|, 1 \leq j \leq m$. Suppose we take $m = NK$ and construct a median-of-mean estimator

$$\hat{o}_i(N,K) = \mathrm{median}\{\hat{o}_i^{(1)}, \ldots, \hat{o}_i^{(K)}\}, \quad \text{where} \quad \hat{o}_i^{(k)} = \frac{1}{N}\sum_{j=N(k-1)+1}^{Nk} \hat{o}_{ij}, \quad 1 \leq k \leq K. \tag{C.7}$$

Then, with the same reasoning as in [100, Theorem S1], we have the following concentration guarantee: For any $0 < \epsilon', \delta < 1$, if $K = 2\log(2|\mathcal{N}|/\delta)$ and $N = 102/\epsilon'^2$, then

$$|\hat{o}_i(N,K) - (1 - d_Q^2(U_i, U))| \le \epsilon' \quad \text{for all} \quad 1 \le i \le |\mathcal{N}| \tag{C.8}$$

with probability at least $1 - \delta$.

With $\hat{o}_i$ in hand, we can select $i^\star \in \operatorname{argmax}_i \hat{o}_i$, and output $U_{i^\star}$. Then we have

$$\begin{aligned} \mathrm{d}_{\mathrm{avg}}(U_{i^\star}, U) &\le \sqrt{2} d_Q(U_{i^\star}, U) \le \sqrt{2(1 - \hat{o}_{i^\star} + \epsilon')} \\ &= \sqrt{2(\epsilon' + \min_i(1 - \hat{o}_i))} \le \sqrt{2(\epsilon' + \min_i(d_Q^2(U_i, U) + \epsilon'))} \le \sqrt{8\epsilon'} \end{aligned} \tag{C.9}$$

with probability at least $1 - \delta$, where we have used the concentration guarantee, Lemma 5, and $\min_i d_Q^2(U_i, U) \le \min_i 2\, \mathrm{d}_{\mathrm{avg}}(U_i, U)^2 \le 2\epsilon'$ because $\mathcal{N}$ is a $\sqrt{\epsilon'}$-covering net with respect to $\mathrm{d}_{\mathrm{avg}}$. Setting $\epsilon' = \epsilon^2/8$, we arrive at a learning algorithm that uses

$$m = NK = \mathcal{O}(\log(|\mathcal{N}|/\delta)/\epsilon^4) \tag{C.10}$$

samples to learn the unknown unitary with accuracy ϵ and success probability at least $1 - \delta$.

If we plug in the covering number upper bound $\log \mathcal{N} \le \mathcal{O}(G \log(G/\epsilon) + T \log n)$ from Corollary 1, we have sample complexity

$$\mathcal{O}\left(\frac{G\log(G/\epsilon) + \log(1/\delta)}{\epsilon^4}\right) \tag{C.11}$$

for large G, say $G \ge n/10$, as desired.

For $G < n/10$, a direct application of the above strategy will give us a suboptimal sample complexity of $\mathcal{O}(G \log(n/\epsilon)/\epsilon^4)$. To overcome this issue, we can carry out a junta learning step similar to Algorithm 1 and [50] to identify the subset of qubits $A \subset [n]$ that U acts non-trivially on. Since U only has G 2-qubit gates, we must have $|A| \le 2G$. The specific procedure is listed in Algorithm 3.

Algorithm 3: Identify qubits acted upon nontrivially (unitary version)

```
Input: Query access to the unknown unitary $U$ with $G$ two-qubit gates.
Output: List $\hat{A} \subseteq [n]$ of qubits.
Initialize $\hat{A} = \emptyset$.
Repeat the following $N = \mathcal{O}\left(\frac{G+\log(1/\delta)}{\epsilon^2}\right)$ times:
    (a) Sample a random tensor product of 1-qubit stabilizer states $|x\rangle = U_x |0\rangle^{\otimes n}$, apply $U$ and $U_x^\dagger$, and obtain $U_x^\dagger U U_x |0\rangle^{\otimes n}$
    (b) Measure in the computational basis and obtain a bit string $|b\rangle, b \in \{0,1\}^n$
    (b) Given the measurement outcome $|b\rangle$, set $\hat{A} \leftarrow \hat{A} \cup \mathrm{supp}(b)$, where $\mathrm{supp}(b) = \{i \in [n] : b_i \neq 0\}$.
```

Similar to Appendix B 1 a, we use Algorithm 3 to identify the non-trivial qubits with high probability. Importantly, from Lemma 11, we have the following guarantee that shows the expected state on the estimated trivial qubits is close to zero.

Lemma 20. *Let $\epsilon, \delta > 0$. Suppose we are given query access to an n-qubit unitary U composed of G two-qubit gates acting on a subset of the qubits $A \subseteq [n]$. Let $|x\rangle = U_x |0\rangle^{\otimes n}$ be a random tensor product of 1-qubit stabilizer states. Let $\rho^x = U_x^\dagger U U_x |0\rangle\langle 0| U_x^\dagger U^\dagger U_x$. Then, Algorithm 3 uses $N = \mathcal{O}\left(\frac{G+\log(1/\delta)}{\epsilon^2}\right)$ queries to U and outputs, with probability at least $1 - \delta$, a list $\hat{A} \subset [n]$ such that*

$$\left\langle 0_{\hat{B}} \middle| \mathbb{E}_x[\rho^x_{\hat{B}}] \middle| 0_{\hat{B}} \right\rangle \ge 1 - \epsilon^2, \tag{C.12}$$

where $\rho_{\hat{B}}$ denotes the reduced density matrix of ρ when tracing out all qubits other than those in the set $\hat{B} = [n] \setminus \hat{A}$ and $\left|0_{\hat{B}}\right\rangle$ denotes the zero state on all qubits in $\hat{B}$.

Proof. This follows directly from the proof of Lemma 11 because Algorithm 3 is the same as executing Algorithm 1 on the mixed state $\mathbb{E}_x[\rho^x]$, and for the trivial qubits, the $U_x^\dagger$ following U_x and U restores the state to $|0\rangle$. So the proof goes verbatim as in Lemma 11. □

With this, we can show that ignoring the rest of the qubits $\hat{B} = [n] \setminus \hat{A}$ does not make much of a difference. Let $B = [n] \setminus A$. We again consider a randomly sampled 1-qubit stabilizer state and apply U to get $|\psi_x\rangle = UU_x |0\rangle^{\otimes n}$. Let $\rho_x = |\psi_x\rangle \langle\psi_x|$ be the associated density matrix, and let $U_x^{\hat{B}} = \otimes_{j\in\hat{B}} U_{x_j}$ be the part of U_x that acts on $\hat{B}$. Now we measure the qubits in $\hat{B}$ in the basis $U_x^{\hat{B}} |b\rangle_{\hat{B}}$, where $b \in \{0,1\}^{|\hat{B}|}$. Note that for qubits in $\hat{B}$, the reduced density matrix in the basis $U_x^{\hat{B}} |b\rangle_{\hat{B}}$ is the same as the $\rho^x_{\hat{B}}$ from Lemma 20 in the junta learning step. So we have $\langle 0_{\hat{B}} | \mathbb{E}_x[\rho^x_{\hat{B}}] | 0_{\hat{B}} \rangle \geq 1 - \epsilon^2$. After the measurement of the qubits in $\hat{B}$, we do a post-selection on the observed measurement outcomes being $U_x^{\hat{B}} |0\rangle_{\hat{B}}$. This post-selection is represented by $\Lambda = I_A \otimes (U_x^{\hat{B}} |0\rangle_{\hat{B}} \langle 0| U_x^{\hat{B}\dagger})$, with $\Lambda^2 = \Lambda$. Let $\rho'_x = \frac{\sqrt{\Lambda}\rho_x\sqrt{\Lambda}}{\mathrm{tr}(\Lambda\rho_x)}$ be the post-selected state. Now we want to show ρ'_x is close to ρ_x on average. We invoke the following gentle measurement lemma for normalized ensembles.

Lemma 21 (Gentle measurement lemma for normalized ensembles, variant of [166, Lemma 9.4.3])**.** *Let $\{x, \rho_x\}$ be an ensemble of states. If Λ is a positive semi-definite operator with $\Lambda \leq I$ and $\mathrm{tr}(\Lambda\mathbb{E}_x[\rho_x]) \geq 1 - \epsilon$ where $\epsilon \in [0,1]$, then*

$$\mathbb{E}_x \left\| \rho_x - \frac{\sqrt{\Lambda}\rho_x\sqrt{\Lambda}}{\mathrm{tr}(\Lambda\rho_x)} \right\|_1 \leq 3\sqrt{\epsilon}. \tag{C.13}$$

Proof. Let $\rho'_x = \frac{\sqrt{\Lambda}\rho_x\sqrt{\Lambda}}{\mathrm{tr}(\Lambda\rho_x)}$. From [166, Lemma 9.4.3], we know that $\mathbb{E}_x \left\| \rho_x - \sqrt{\Lambda}\rho_x\sqrt{\Lambda} \right\|_1 \leq 2\sqrt{\epsilon}$. Note that the left hand side can be lower bounded by

$$\begin{aligned}
\mathbb{E}_x \left\| \rho_x - \sqrt{\Lambda}\rho_x\sqrt{\Lambda} \right\|_1 &= \mathbb{E}_x \left\| \rho_x - \rho'_x + \rho'_x - \sqrt{\Lambda}\rho_x\sqrt{\Lambda} \right\|_1 \\
&\geq \mathbb{E}_x\|\rho_x - \rho'_x\|_1 - \mathbb{E}_x\|\rho'_x - \sqrt{\Lambda}\rho_x\sqrt{\Lambda}\|_1 \\
&= \mathbb{E}_x\|\rho_x - \rho'_x\|_1 - \mathbb{E}_x(1 - \mathrm{tr}(\Lambda\rho_x))\|\rho'_x\|_1 \geq \mathbb{E}_x\|\rho_x - \rho'_x\|_1 - \epsilon,
\end{aligned} \tag{C.14}$$

where we have used triangle inequality, $\|\rho'_x\|_1 = 1$, and $\mathrm{tr}(\Lambda\mathbb{E}_x[\rho_x]) \geq 1 - \epsilon$. Therefore, we arrive at

$$\mathbb{E}_x\|\rho_x - \rho'_x\|_1 \leq 2\sqrt{\epsilon} + \epsilon \leq 3\sqrt{\epsilon}, \tag{C.15}$$

because $\epsilon \in [0,1]$, concluding the proof of Lemma 21. □

Using Lemma 21 for our scenario, we have $\mathbb{E}_x\|\rho_x - \rho'_x\|_1 \leq 3\epsilon$ with probability at least $1-\delta$. After the post-selection, we apply the same Clifford shadow strategy as in the $T \geq n/10$ case, with two differences. Firstly, note that after post-selection, the action on every qubit in $\hat{B}$ is identity. So we can without loss of generality pick an arbitrary subset A' of those qubits in $\hat{B}$ as $A \setminus \hat{A}$, and consider an $\sqrt{\epsilon}$-covering net $\mathcal{N}$ of G gate unitaries on qubits $\hat{A} \cup A'$ with respect to $\mathrm{d}_{\mathrm{avg}}$, with $|\hat{A} \cup A'| = |A| \leq 2G$. Then we have $\min_{U_i\in\mathcal{N}} \mathrm{d}_{\mathrm{avg}}(U_i, U) \leq \epsilon$, and $\log|\mathcal{N}| \leq \mathcal{O}(G\log(G/\epsilon) + G\log(|A \cup A'|)) \leq \mathcal{O}(G\log(G/\epsilon))$. Secondly, for each element U_i in the covering net, we can construct an observable $O_i = U_i |x\rangle \langle x| U_i^\dagger$ similar to before, but now the estimator will concentrate around a slightly different expectation value. Specifically, if we use a median-of-mean estimator $\hat{o}_i(N,K)$ with $K = 2\log(2|\mathcal{N}|/\delta)$ and $N = 102/\epsilon^2$, then we have

$$|\hat{o}_i(N,K) - \mathbb{E}_x[\mathrm{tr}(\rho'_x O_i)]| \leq \epsilon \quad \text{for all} \quad 1 \leq i \leq |\mathcal{N}|, \tag{C.16}$$

with probability at least $1 - \delta$. Nevertheless, since ρ'_x and ρ_x are close on average, we have

$$\begin{aligned}
|\hat{o}_i(N,K) - (1 - d_Q^2(U_i \otimes I, U))| &= |\hat{o}_i(N,K) - \mathbb{E}_x[\mathrm{tr}(\rho'_x O_i)] + \mathbb{E}_x[\mathrm{tr}(\rho'_x O_i)] - \mathbb{E}_x[\mathrm{tr}(\rho_x O_i)]| \\
&\leq |\hat{o}_i(N,K) - \mathbb{E}_x[\mathrm{tr}(\rho'_x O_i)]| + \mathbb{E}_x[|\,\mathrm{tr}(\rho'_x O_i) - \mathrm{tr}(\rho_x O_i)|] \\
&\leq \epsilon + \mathbb{E}_x[\|\rho'_x - \rho_x\|_1\|O_i\|] \leq \epsilon + 3\epsilon = 4\epsilon, \quad \text{for all} \quad 1 \leq i \leq |\mathcal{N}|,
\end{aligned} \tag{C.17}$$

with probability at least $1-2\delta$, where we have used triangle inequality, $\|O_i\| = 1$, and $\mathbb{E}_x\|\rho_x - \rho'_x\|_1 \leq 3\epsilon$. With this concentration guarantee, we can select the candidate with the largest $\hat{o}_i$: $i^\star \in \mathrm{argmax}_i \hat{o}_i$ and output $U_{i^\star} \otimes I$. As before, we have with probability at least $1 - 2\delta$,

$$\mathrm{d}_{\mathrm{avg}}(U_{i^\star} \otimes I, U) \leq \sqrt{2} d_Q(U_{i^\star} \otimes I, U) \leq \sqrt{2(4\epsilon + 2\epsilon + 4\epsilon)} = \sqrt{20\epsilon}. \tag{C.18}$$

Redefining 20ϵ to be ϵ^2 and 2δ to be δ, we arrive at a learning algorithm that uses

$$m = \mathcal{O}\left(\frac{G + \log(1/\delta)}{\epsilon^4}\right) + NK = \mathcal{O}\left(\frac{G\log(G/\epsilon) + \log(1/\delta)}{\epsilon^4}\right) \tag{C.19}$$

queries to the unitary to learn it with accuracy ϵ in $\mathrm{d}_{\mathrm{avg}}$ and success probability at least $1-\delta$ when $G < n/10$. Combined with the case of $G \geq n/10$, this concludes the learning algorithm without ancillary system in Proposition 8.

b. Unitary learning with ancillary systems

The above $\mathcal{O}(1/\epsilon^4)$ scaling is suboptimal. It arises from the fact that in the classical shadow estimation, the estimated quantity is the square of $\mathrm{d}_{\mathrm{avg}}$ rather than $\mathrm{d}_{\mathrm{avg}}$ itself. To improve the ϵ-dependence, we make use ancillary systems via the Choi–Jamiołkowski duality [58–60]. Specifically, we consider the maximally entangled state over a pair of n-qubit systems $|\Phi\rangle = \frac{1}{\sqrt{d}}\sum_{i=1}^{2^n}|i\rangle \otimes |i\rangle$ and define the Choi state $|U\rangle\!\rangle$ corresponding to a unitary U as $|U\rangle\!\rangle = (U \otimes I)\,|\Phi\rangle$. That is, the Choi state $|U\rangle\!\rangle$ of an n-qubit unitary U is a pure $(2n)$-qubit state constructed by applying U on half of the qubits in n EPR pairs. For any subset $A \subseteq [n]$ of the qubits that are acted upon by U, we refer to the corresponding $|A|$ qubits in the EPR pairs as the entangled qubits corresponding to A. We note the following fact, which relates the trace distance between Choi states to the average-case distance between the unitaries.

Lemma 22 (Equivalence of trace distance between Choi states and average-case distance)**.** *Let $U, V \in U(2^n)$ be two n-qubit unitaries, $|\Phi\rangle = \frac{1}{\sqrt{d}}\sum_{i=1}^{2^n}|i\rangle \otimes |i\rangle$ be a maximally entangled state, and $|U\rangle\!\rangle = (U \otimes I)\,|\Phi\rangle\,, |V\rangle\!\rangle = (V \otimes I)\,|\Phi\rangle$ be the corresponding Choi states. Then we have*

$$\frac{1}{\sqrt{2}}\,\mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |V\rangle\!\rangle) \leq \mathrm{d}_{\mathrm{avg}}(U,V) \leq \mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |V\rangle\!\rangle). \tag{C.20}$$

Proof. By the standard conversion between fidelity and the trace distance between pure states, we have

$$\mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |V\rangle\!\rangle) = \sqrt{1 - |\langle\!\langle U|V\rangle\!\rangle|^2} = \sqrt{1 - \frac{1}{d^2}|\operatorname{tr}(U^\dagger V)|^2.}, \tag{C.21}$$

where the last step used that $\langle\Phi|\,A \otimes B\,|\Phi\rangle = \frac{1}{d}\operatorname{tr}\bigl[A^T B\bigr]$, compare for instance [167, Example 1.2]. On the other hand, from Equation (A.14), we have

$$\mathrm{d}_{\mathrm{avg}}(U,V) = \sqrt{1 - \frac{d + |\operatorname{tr}(U^\dagger V)|^2}{d^2 + d}}. \tag{C.22}$$

Combining these two equations, we get

$$\mathrm{d}_{\mathrm{avg}}(U,V) = \sqrt{\frac{d}{d+1}}\,\mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |V\rangle\!\rangle) \in \left[\frac{1}{\sqrt{2}}\,\mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |V\rangle\!\rangle), \mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |V\rangle\!\rangle)\right]. \tag{C.23}$$

□

With Lemma 22, we construct a covering net over Choi states corresponding to G-gate unitaries as follows. From Corollary 1, we take an ϵ'-covering net $\mathcal{N}$ of G-gate unitaries with respect to $\mathrm{d}_{\mathrm{avg}}$ that has cardinality $|\mathcal{N}| \leq \mathcal{O}(G\log(G/\epsilon) + G\log n)$. Then for any G-gate unitary U, there exists a $U_i \in \mathcal{N}$ such that $\mathrm{d}_{\mathrm{avg}}(U, U_i) \leq \epsilon'$. Hence $\mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |U_i\rangle\!\rangle) \leq \sqrt{2}\,\mathrm{d}_{\mathrm{avg}}(U, U_i) \leq \sqrt{2}\epsilon'$ by Lemma 22. Therefore, the Choi states of the unitaries in $\mathcal{N}$ form a $(\sqrt{2}\epsilon)$-covering net of the Choi states of G-gate unitaries.

Now, we can use these pure Choi states as candidates for hypothesis selection. By Proposition 1, the hypothesis selection algorithm based on classical shadow uses $\mathcal{O}(\log(|\mathcal{N}|/\delta)/\epsilon'^2)$ samples of the Choi state $|U\rangle\!\rangle$ to output a candidate $|\hat{U}\rangle\!\rangle, \hat{U} \in \mathcal{N}$, such that $\mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |\hat{U}\rangle\!\rangle) \leq 3\sqrt{2}\epsilon' + \epsilon'$ with probability at least $1-\delta$. Setting $(3\sqrt{2}+1)\epsilon' = \epsilon$, we find a $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \mathrm{d}_{\mathrm{tr}}(|U\rangle\!\rangle, |\hat{U}\rangle\!\rangle) \leq \epsilon$ with probability at least $1-\delta$ using

$$\mathcal{O}\left(\frac{G\log(G/\epsilon) + G\log n + \log(1/\delta)}{\epsilon^2}\right) \tag{C.24}$$

queries to the unknown unitary U. When $G \geq n/10$, this gives the desired $\mathcal{O}((G\log(G/\epsilon) + \log(1/\delta))/\epsilon^2)$ query complexity.

Algorithm 4: Identify qubits acted upon nontrivially (Choi version)

```
Input: Query access to the unknown unitary $U$ with $G$ two-qubit gates.
Output: List $\hat{A} \subseteq [n]$ of qubits.
1 Initialize $\hat{A} = \emptyset$.
2 Repeat the following $N = \mathcal{O}\left(\frac{G+\log(1/\delta)}{\epsilon^2}\right)$ times:
    (a) Prepare the Choi state $|U\rangle\rangle$ by applying $U \otimes I$ to the maximally entangled state $|\Phi\rangle$
    (b) Measure in the basis of Pauli Choi states $|\sigma_x\rangle\rangle = \otimes_{i=1}^n (\sigma_{x_i} \otimes I)\,|\Phi\rangle, x \in \mathbb{Z}_4^n$, and obtain a string $|b\rangle, b \in \{0,1,2,3\}^n$
    (b) Given the measurement outcome $|b\rangle$, set $\hat{A} \leftarrow \hat{A} \cup \mathrm{supp}(b)$, where $\mathrm{supp}(b) = \{i \in [n] : b_i \neq 0\}$.
```

For $G < n/10$, we again need a junta learning step to identify the set of qubits $A \subseteq [n]$ that are acted on non-trivially. To do this, we follow the idea of Algorithm 1, Algorithm 3 and [50, Algorithm 8] and consider the following procedure that makes use of Choi states of Pauli matrices $\sigma_0 = I, \sigma_1 = X, \sigma_2 = Y, \sigma_3 = Z$.

Similarly to Lemma 11 and Lemma 20, we have the following guarantee that the Choi state on the estimated trivial qubits is close to the Choi state of the identity.

Lemma 23. *Let $\epsilon, \delta > 0$. Suppose we are given query access to an n-qubit unitary U composed of G two-qubit gates acting on a subset of the qubits $A \subseteq [n]$. Let $\rho = |U\rangle\rangle\langle\langle U|$ be the Choi state of U. Then, Algorithm 4 uses $N = \mathcal{O}\left(\frac{G+\log(1/\delta)}{\epsilon^2}\right)$ queries to U and outputs, with probability at least $1-\delta$, a list $\hat{A} \subset [n]$ such that*

$$\langle\langle I_{\hat{B}}|\rho_{\hat{B}}|I_{\hat{B}}\rangle\rangle \geq 1 - \epsilon^2, \tag{C.25}$$

where $\rho_{\hat{B}}$ denotes the reduced density matrix for ρ by tracing out all qubits other than those in the set $\hat{B} = [n] \setminus \hat{A}$ and the corresponding entangled qubits, and $|I_{\hat{B}}\rangle\rangle$ denotes the Choi state of the identity on qubits in $\hat{B}$.

Proof. The proof goes similarly to that of Lemma 11 except that $|0\rangle$ is replaced by $|I\rangle\rangle$. The measurement over Pauli Choi states in Algorithm 4 can be understood as measuring each entangled pair of qubits in the basis $\{|I\rangle\rangle, |X\rangle\rangle, |Y\rangle\rangle, |Z\rangle\rangle\}$ and gives an element from $\{0,1,2,3\} = \mathbb{Z}_4$. Specifically, let A' be any set that could be output by Algorithm 4. We want to identify A' with the actual identified set $\hat{A}$. Let $B' \triangleq [n] \setminus A'$. Let $E_{i,A'}$ be the event that round i of measurement of the qubits in $B' = [n] \setminus A'$ in Algorithm 4 yields the all zero $\mathbb{Z}_4$ string. Let $X_{i,A'}$ be the indicator random variable corresponding to the event $E_{i,A'}$. Then, we have that $\bar{X}_{A'} \triangleq \frac{1}{N}\sum_{i=1}^N X_{i,A'}$ is the number of times the entangled pair in B' are all measured to be zero divided by the total number of measurements. In other words, $\bar{X}_{A'}$ is the estimated overlap that the state $\rho_{B'}$ on qubits in B' has with the identity Choi state on B'. Moreover, we have

$$\mathbb{E}[X_{A'}] \triangleq \mathbb{E}[X_{i,A'}] = \langle\langle I_{B'}|\rho_{B'}|I_{B'}\rangle\rangle \tag{C.26}$$

for all A'. This says that the true expectation of our random variables is the true overlap of the state $\rho_{B'}$ with the identity Choi state on B'. Then we have the same Claim 1 as in Lemma 11 and Lemma 23 follows. □

With this, we can again show that ignoring the rest of the qubits $\hat{B} = [n] \setminus \hat{A}$ does not make much difference. Let $B = [n] \setminus A$. We prepare the Choi state $\rho = |U\rangle\rangle\langle\langle U|, |U\rangle\rangle = (U \otimes I)\,|\Phi\rangle$, and measure in the basis of Pauli Choi states over the qubits in $\hat{B}$: $\{|\sigma_x\rangle\rangle_{\hat{B}} : x \in \mathbb{Z}_4^{|\hat{B}|}\}$. After the measurement, we do a post-selection on the observed measurement outcomes being $|I_{\hat{B}}\rangle\rangle$. This post-selection is represented by $\Lambda = I \otimes |I_{\hat{B}}\rangle\rangle\langle\langle I_{\hat{B}}|$, with $\Lambda^2 = \Lambda$, and the first identity over the entangled pairs outside $\hat{B}$. Let $\rho' = \frac{\sqrt{\Lambda}\rho\sqrt{\Lambda}}{\mathrm{tr}(\Lambda\rho)}$ be the post-selected state. Now we want to show ρ' is close to ρ. From Lemma 23, we know that $\mathrm{tr}(\Lambda\rho) \geq 1-\epsilon^2$ with probability at least $1-\delta$. Then by the gentle measurement lemma (Lemma 13), we have $\mathrm{d}_{\mathrm{tr}}(\rho', \rho) \leq \epsilon$ with the same probability.

Now we can apply the hypothesis selection protocol to ρ' as in the $G > n/10$ case, but with a different covering net. Specifically, note that after post-selection, the action on every entangled pair in $\hat{B}$ is identity. So we can with loss of generality pick an arbitrary subset A' of those qubits in $\hat{B}$ as $A \setminus \hat{A}$, and consider an ϵ-covering net $\mathcal{N}$ of G gate unitaries on qubits $\hat{A} \cup A'$ with respect to $\mathrm{d}_{\mathrm{avg}}$, with $|\hat{A} \cup A'| = |A| \leq 2G$, with each element tensor product with identity over the rest qubits. Then we have $\min_{U_i\in\mathcal{N}} \mathrm{d}_{\mathrm{tr}}(|U_i\rangle\!\rangle, |U\rangle\!\rangle) \leq \sqrt{2}\,\mathrm{d}_{\mathrm{avg}}(U_i, U) \leq \sqrt{2}\epsilon$, and $\log|\mathcal{N}| \leq \mathcal{O}(G\log(G/\epsilon) + G\log(|A\cup A'|)) \leq \mathcal{O}(G\log(G/\epsilon))$. Since $\mathrm{d}_{\mathrm{tr}}(\rho', \rho) \leq \epsilon$, we also have $\min_{U_i\in\mathcal{N}} \mathrm{d}_{\mathrm{tr}}(|U_i\rangle\!\rangle\langle\!\langle U_i|, \rho') \leq \epsilon + \sqrt{2}\epsilon = (\sqrt{2}+1)\epsilon$.

With this covering net, we apply the hypothesis selection based on classical shadow (Proposition 1) to ρ'. This procedure uses $\mathcal{O}(\log(|\mathcal{N}|/\delta)/\epsilon^2)$ copies of ρ' (each prepared using one query to U) and output a $|U_{i^\star}\rangle\!\rangle$ such that $\mathrm{d}_{\mathrm{tr}}(|U_{i^\star}\rangle\!\rangle\langle\!\langle U_{i^\star}|, \rho') \leq 3(\sqrt{2}+1)\epsilon + \epsilon = (3\sqrt{2}+4)\epsilon$ with probability at least $1-\delta$. This means that

$$\mathrm{d}_{\mathrm{avg}}(U_{i^\star}, U) \leq \mathrm{d}_{\mathrm{tr}}(|U_{i^\star}\rangle\!\rangle, |U\rangle\!\rangle) \leq \mathrm{d}_{\mathrm{tr}}(|U_{i^\star}\rangle\!\rangle\langle\!\langle U_{i^\star}|, \rho') + \mathrm{d}_{\mathrm{tr}}(\rho', \rho) \leq (3\sqrt{2}+4)\epsilon + \epsilon = 4(\sqrt{2}+1)\epsilon \quad \text{(C.27)}$$

with a total probability at least $1-2\delta$ (considering both the junta learning and hypothesis selection).

Therefore, by redefining $4(\sqrt{2}+1)\epsilon$ to be ϵ and 2δ to be δ, we arrive at a desired algorithm for $G \leq n/10$ that uses in total

$$\mathcal{O}\left(\frac{G+\log(1/\delta)}{\epsilon^2}\right) + \mathcal{O}\left(\frac{G\log(G/\epsilon)+\log(1/\delta)}{\epsilon^2}\right) = \mathcal{O}\left(\frac{G\log(G/\epsilon)+\log(1/\delta)}{\epsilon^2}\right) \quad \text{(C.28)}$$

queries to the unknown unitary U. Combined with the $G \geq n/10$ case, we conclude the learning algorithm with ancillary system that achieves the $\mathcal{O}((G\log(G/\epsilon)+\log(1/\delta)/\epsilon^2)$ query complexity in Proposition 8.

c. *Bootstrap to improve ϵ-dependence*

To further improve the ϵ-dependence, we modify the bootstrap method in [21] and achieve a Heisenberg scaling $\tilde{\mathcal{O}}(1/\epsilon)$. However, with our average case distance, which can only control the average behavior of the eigenvalues of the unitaries, we are not able to perform the bootstrap for general ϵ. Instead, the bootstrap works only when the error is exponentially small, $\epsilon = O(1/\sqrt{d})$, and achieves the Heisenberg scaling at the cost of a dimensional factor, leading to a query complexity of

$$\mathcal{O}\left(\frac{\sqrt{2^n}(G\log(G/\epsilon)+\log(1/\delta))}{\epsilon}\right). \quad \text{(C.29)}$$

Whether a general Heisenberg scaling without dimension-dependent scaling is achievable remains open.

Now we state the bootstrap method in Algorithm 5, which uses the unitary learning algorithm with ancillary systems (Appendix C 2 b) as a sub-routine. We need to prove two things about Algorithm 5: (1) it outputs a $\hat{U}$ that satisfies $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \epsilon$ with probability at least $1-\delta$; (2) the query complexity is $\mathcal{O}\left(\sqrt{d}(G\log(G/\epsilon)+\log(1/\delta))/\epsilon\right)$.

Algorithm 5: Bootstrapping to Heisenberg scaling

```
Input:  Query access to the unknown $n$-qubit $G$-gate unitary $U$.
        An error parameter $\epsilon \in (0, 1/\sqrt{d})$.
Output: A unitary $\hat{U}$.
Let $t \leftarrow \left\lceil \log_2(1/(\epsilon\sqrt{d})) \right\rceil$.
Let $V_0 \leftarrow I$.
Let $\mathcal{N} \leftarrow$ an $(\epsilon/10^5)$-covering net of $G$-gate unitaries with respect to $\mathrm{d}_{\mathrm{avg}}$.
for $j \leftarrow 0$ to $t$ do
    Let $p_j \leftarrow 2^j$.
    Let $\eta_j \leftarrow 8^{j-t-1}\delta$.
    Use the algorithm $\mathcal{A}$ in Appendix C 2 b with success probability $1-\eta_j$ and accuracy $1/(25000\sqrt{d})$ to
      find a candidate $R_j$ in $\{(U_iV_j^\dagger)^{p_j} \mid U_i \in \mathcal{N}\}$ that is closest to $(UV_j^\dagger)^{p_j}$ in $\mathrm{d}_{\mathrm{avg}}$.
    Let $V_{j+1} \leftarrow R_j^{1/p_j}V_j$.
return $\hat{U} \leftarrow V_{t+1}$
```

We first prove (1) by induction. Before doing so, we need to show that the learning algorithm $\mathcal{A}$ can indeed learn $(UV_j^\dagger)^{p_j}$ well for all j. Let $c = 10^{-5}$. Note that with the definition of $\mathcal{N}$, we know that for any G-gate unitary U, $\exists U_i \in \mathcal{N}$ such that $\mathrm{d}_{\mathrm{avg}}(U, U_i) \leq c\epsilon$, and therefore

$$\mathrm{d}_{\mathrm{avg}}((U_iV_j^\dagger)^{p_j}, (UV_j^\dagger)^{p_j}) \leq d'_F((U_iV_j^\dagger)^{p_j}, (UV_j^\dagger)^{p_j}) \leq p_j d'_F(U_i, U) \leq 2p_j\,\mathrm{d}_{\mathrm{avg}}(U_i, U) \leq 4c/\sqrt{d}, \quad \text{(C.30)}$$

where we have used Item 1 and 2 in Lemma 4, unitary invariance of d'_F, and $p_j = 2^j \leq 2^t \leq 2/(\epsilon\sqrt{d})$. Thus $\{(U_i V_j^\dagger)^{p_j}, U_i \in \mathcal{N}\}$ forms an $4c/\sqrt{d}$-covering net of $\{(UV_j^\dagger)^{p_j} \mid U \text{ is a } G\text{-gate unitary}\}$, which can be used by the hypothesis selection algorithm $\mathcal{A}$ as set of candidates. The output R_j of $\mathcal{A}$ satisfies $d'_F(R_j, (UV_j^\dagger)^{p_j}) \leq 2\,\mathrm{d}_{\mathrm{avg}}(R_j, (UV_j^\dagger)^{p_j}) \leq 4(\sqrt{2}+1)\cdot 4c/\sqrt{d} < 40c/\sqrt{d}$ (see Equation (C.27)). The number of queries to U that this procedure uses is $\mathcal{O}\left(p_j \frac{G\log(G/c\epsilon)+\log(1/\eta_j)}{(4c/\sqrt{d})^2}\right) = \mathcal{O}\left(p_j d(G\log(G/\epsilon)+\log(1/\eta_j))\right)$.

Now we proceed to prove (1) by induction. Let's assume that the learning algorithm succeeds for all $j = 1, \ldots, t$. Let $\delta_j = d'_F(U, V_j) = d'_F(UV_j^\dagger, I)$ be the error after iteration $j-1$. We will prove that $\delta_k \leq 2^{-k-5}/\sqrt{d}$. For iteration 0, we have $p_0 = 1$, and by the accuracy of $\mathcal{A}$, we know $\delta_1 = d'_F(U, V_1) < 40c/\sqrt{d} < 2^{-6}/\sqrt{d}$. Now we assume $\delta_k \leq 2^{-k-5}/\sqrt{d}$ and prove $\delta_{k+1} \leq 2^{-k-6}/\sqrt{d}$. Note that $(UV_k^\dagger)^{p_k}$ and R_k are sufficiently close to identity in the sense that

$$d'_F((UV_k^\dagger)^{p_k}, I) \leq p_k d'_F(UV_k^\dagger, I) = p_k\delta_k \leq \frac{2^{-5}}{\sqrt{d}} < \frac{4/(25\pi)}{\sqrt{d}}, \tag{C.31}$$

and

$$d'_F(R_k, I) \leq d'_F(R_k, (UV_k^\dagger)^{p_k}) + d'_F((UV_k^\dagger)^{p_k}, I) \leq \frac{40c}{\sqrt{d}} + \frac{2^{-5}}{\sqrt{d}} < \frac{4/(25\pi)}{\sqrt{d}}. \tag{C.32}$$

Thus, we can invoke Item 3 of Lemma 4 and obtain

$$\delta_{k+1} = d'_F(U, V_{k+1}) = d'_F(UV_k^\dagger, R_k^{1/p_k}) \leq \frac{2}{p_k} d'_F((UV_k^\dagger)^{p_k}, R_k) \leq \frac{80c}{p_k\sqrt{d}} < \frac{2^{-k-6}}{\sqrt{d}}. \tag{C.33}$$

Therefore, by induction, we have shown that $\delta_k \leq 2^{-k-5}/\sqrt{d}$. At the end of the iteration, when $k = t = \left\lceil \log_2(1/(\sqrt{d}\epsilon)) \right\rceil$, we have

$$\delta_{t+1} = d'_F(U, V_{t+1}) \leq \frac{2^{-t-6}}{\sqrt{d}} < \epsilon. \tag{C.34}$$

The above accuracy is conditioned on the success of all executions of the learning algorithm. By the union bound, the failure probability is upper bounded by

$$\sum_{j=0}^{t} \eta_j = \delta \sum_{j=0}^{t} 8^{-(t-j)-1} = \delta \sum_{j=0}^{t} 8^{-j-1} < \delta. \tag{C.35}$$

This concludes the proof of (1).

Next we move on to (2) and count the overall number of queries to the unknown unitary. Summing over all iterations, the number of queries is

$$\begin{aligned}
&\mathcal{O}\left(\sum_{j=0}^{t} p_j d(G\log(G/\epsilon) + \log(1/\eta_j))\right) \\
&= \mathcal{O}\left(dG\log(G/\epsilon)\sum_{j=0}^{t} 2^j + d\log(1/\delta)\sum_{j=0}^{t} 2^j(t-j+1)\right) \\
&= \mathcal{O}\left(d(G\log(G/\epsilon)+\log(1/\delta))2^t\right) = \mathcal{O}\left(\frac{\sqrt{d}(G\log(G/\epsilon)+\log(1/\delta))}{\epsilon}\right).
\end{aligned} \tag{C.36}$$

This concludes the proof of the $\mathcal{O}(1/\epsilon)$ scaling algorithm in Proposition 8.

Finally, we note that an analogous bootstrap method can also be applied to improve the ϵ-dependence for our unitary learning procedure without auxiliary systems, albeit again incurring a dimension factor. Namely, a variant of Algorithm 5 relying on the algorithm of Appendix C 2 a as a subroutine succeeds at outputting a $\hat{U}$ that satisfies $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \epsilon$ with probability at least $1-\delta$ using $\mathcal{O}\left(d^{3/2}(G\log(G/\epsilon)+\log(1/\delta))/\epsilon\right)$ queries to the unknown unitary U, assuming $\epsilon < {}^{1}/_{d^{3/2}}$.

3. Average-case query complexity lower bounds

For the lower bound, we construct a packing net consisting of G-gate unitaries that are pairwise sufficiently far apart, so that an average-case learning algorithm can discriminate them. Meanwhile, the success probability of distinguishing a set of unitaries is upper bounded by the number of queries made [63]. This gives us an $\Omega(G)$ query complexity lower bound. To incorporate ϵ-dependence, we follow [21] and map the problem to a fractional query problem [61, 62]. This way, we arrive at the following result.

Proposition 9 (Average case unitary learning lower bound, lower bound in Theorem 4)**.** *Let U be an n-qubit unitary composed of G two-qubit gates. Any algorithm that, given query access to U, $U^\dagger$, $cU = |0\rangle\langle 0| \otimes I + |1\rangle\langle 1| \otimes U$ and $cU^\dagger = |0\rangle\langle 0| \otimes I + |1\rangle\langle 1| \otimes U^\dagger$, can output a unitary $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \epsilon \in (0, 1/32)$ with probability at least $2/3$, must use at least $\Omega(G/\epsilon)$ queries.*

Note that the lower bound holds even for learning algorithms that have a stronger form of access to U than considered for our upper bounds. There, we only assumed query access to U. In contrast, the lower bound holds even assuming query access to U and $U^\dagger$ as well as controlled versions thereof.

Proof of Proposition 9. The proof builds on the following lemma that maps the problem to a fractional query one [21].

Lemma 24 (Reduction to fractional query algorithms, [21, Lemma 4.5 and proof of Theorem 1.2])**.** *Let $R \in U(d)$ be a Hermitian unitary (i.e., $R^2 = I$). Define $R^\alpha = (I + R)/2 + e^{-i\pi\alpha}(I - R)/2$ for some $\alpha \in (0, 1]$. Suppose there exists an algorithm $\mathcal{A}$ that uses Q queries to R^α or $R^{\alpha\dagger}$ and produces some output with probability at least $2/3$. Then there exists another algorithm $\mathcal{A}'$ that uses $50 + 100\alpha Q$ queries to controlled-R and produces the same output with probability at least $\exp(-\alpha\pi Q)/2$.*

To use this lemma, we need to construct a packing net of Hermitian unitaries, and give an upper bound on the maximum probability of successfully distinguishing them. Thus we need the following two lemmas.

Lemma 25 (Packing net of Hermitian unitaries, variant of [21, Proposition 4.1])**.** *There exists a set of Hermitian unitaries $\mathcal{P} = \{R_i\}_i \subset U(d)$ with $\log |P| \geq \Omega(d^2)$ and $R_i^2 = I$ for $R_i \in \mathcal{P}$, such that for any $R_i \neq R_j \in \mathcal{P}$, $d'_F(R_i, R_j) \geq 1/8$.*

Proof. Let $d = 2r + 1$ if d is odd, or $d = 2r + 2$ if d is even. [135, Lemma 7] (or Lemma 8 in [19]) asserts that there exists a set of rank r density matrices in dimension $2r$ with cardinality at least $\exp(r^2/8)$, such that all the non-zero eigenvalues are equal to $1/r$, and any two different density matrices have trace distance at least $1/4$. We can write this set as $\{(I_{2r} + V_i)/(2r), i = 1, \ldots, N\}$, where $V_i \in U(2r)$ is a Hermitian unitary of trace zero. Then $N \geq \exp(r^2/8)$, and $\forall i \neq j$,

$$\frac{1}{4} \leq \frac{1}{2}\left\| \frac{I_{2r} + V_i}{2r} - \frac{I_{2r} + V_j}{2r} \right\|_1 = \frac{1}{4r}\|V_i - V_j\|_1 \leq \frac{1}{\sqrt{2r}}\|V_i - V_j\|_F. \tag{C.37}$$

where we have used $\|V_i\|_1 \leq \sqrt{2r}\|V_i\|_F$. Then we embed $V_i \to R_i = V_i \oplus I_b \in U(d)$, where $b = 1$ or 2, depending on whether d is odd or even. We have

$$d_F(R_i, R_j) = \frac{1}{\sqrt{d}}\|R_i - R_j\|_F \geq \frac{1}{4}\sqrt{\frac{2r}{2r + b}} \geq \frac{1}{8}. \tag{C.38}$$

Now we would like to translate d_F into d'_F. From Lemma 10, we know that changing to the quotient metric for any set of unitaries only decreases $\log N$ by an additive constant (since here we consider constant ϵ). Therefore, we still have $\log |P| \geq \Omega(d^2)$ for $d'_F(R_i, R_j) \geq \frac{1}{8}$. □

Lemma 26 (Upper bound on success probability of distinguishing unitaries, [63, Theorem 5])**.** *Let $\mathcal{P} \subseteq U(d)$ be a set of unitaries. Let $\mathcal{A}$ be any algorithm that uses Q queries to an input unitary U_x and output a guess $\hat{x}$. Suppose the input unitary is randomly picked from $\mathcal{P}$ with uniform probability. Then the maximal probability that the output satisfies $\hat{x} = x$ is upper bounded by $\frac{1}{|\mathcal{P}|}\binom{Q+d^2-1}{Q}$.*

Now we can proceed to prove the lower bound in Proposition 9. Suppose we have a learning algorithm $\mathcal{A}$ that uses Q queries and outputs a $\hat{U}$ that has accuracy ϵ in $\mathrm{d}_{\mathrm{avg}}$ with success probability at least $2/3$. From the theory of universal gates [136], we know that $G = \mathcal{O}(4^k)$ gates suffice to implement an arbitrary k-qubit unitary, i.e., there exists constant C such that G gates can implement arbitrary unitary on $k = \lfloor \log_4(G/C) \rfloor$ qubits. Let $d = \min\{2^n, 2^k\}$, and focus on the first $\min\{n, k\}$ qubits. The algorithm $\mathcal{A}$ thus is able to learn any unitary on these qubits.

Consider the packing net $\mathcal{P} = \{R_i\}$ from Lemma 25 for this choice of d. We want to identify $R \in \mathcal{P}$, but using only access to R^α for $1/\alpha = \lfloor 1/32\epsilon \rfloor > 1$. If we apply $\mathcal{A}$ to R^α, then with probability at least $2/3$, the output U satisfies $\mathrm{d}_{\mathrm{avg}}(U, R^\alpha) \le \epsilon$. From the equivalence of $\mathrm{d}_{\mathrm{avg}}$ and d'_F (Lemma 4), and the triangle inequality and unitary invariance of d'_F, we have

$$d'_F(U^{1/\alpha}, R) \le \sum_{p=1}^{1/\alpha} d'_F(U^p R^{1-\alpha p}, U^{p-1} R^{1-\alpha p+\alpha}) = \frac{2}{\alpha}\, \mathrm{d}_{\mathrm{avg}}(U, R^\alpha) \le \frac{2\epsilon}{\alpha} \le \frac{1}{16}. \tag{C.39}$$

Since $R \in \mathcal{P}$ have pairwise distance at least $1/8$, the algorithm can identify R with success probability at least $2/3$ by finding the closest element of $\mathcal{P}$ to $U^{1/\alpha}$.

Now, via Lemma 24, we know that there is a learning algorithm $\mathcal{A}'$ that can use $50 + 100\alpha Q$ queries to controlled-R to identify R with success probability at least $\exp(-\alpha\pi Q)/2$. On the other hand, we know the success probability cannot exceed the upper bound $\binom{Q+d^2-1}{Q}/|\mathcal{P}|$ set by Lemma 26 with $\log|P| \ge \Omega(d^2)$. Combined with a technical lemma [21, Lemma 4.3], this means that the number of queries must be at least $\Omega(d^2)$. That is,

$$50 + 100\alpha Q \ge \Omega(d^2) \implies Q \ge \Omega\left(\frac{d^2}{\alpha}\right) = \Omega\left(\frac{d^2}{\epsilon}\right) = \Omega\left(\frac{\min\{4^n, G\}}{\epsilon}\right). \tag{C.40}$$

This concludes the proof of Proposition 9. □

We comment on the connection of our results to the recent work [51] on the hardness of learning Haar-random unitaries, where the authors proved a sample complexity lower bound $\Omega\left(\frac{d^2}{\log^2 d}\right)$ for learning d-dimensional Haar-random unitaries to constant accuracy w.r.t. d'_F. The direct consequence of our lower bound when applied to learning the whole unitary group $U(d)$, without assumptions of limited complexity, is a lower bound of $\Omega\left(d^2\right)$, which is stronger than that of [51, Theorem 1] by a factor of $\log^2 d$. We note that this difference is a consequence of proof techniques that comes about in two ways. One $\log d$ factor comes from their analysis of the differential entropy, which only calculated the contribution of $\Theta\left(\frac{d}{\log d}\right)$ columns of the matrix elements, instead of all d columns. This issue does not arise for us because we focus on the discrete entropy with the use of a packing net. The other $\log d$ comes from the mutual information upper bound, where they use the straightforward Holevo bound: Each d-dimensional quantum state can carry at most $\mathcal{O}(\log d)$ bits of information. We manage to get rid of this factor by making use of a more refined bound on success probability as in Lemma 26.

Lastly, we remark on the proof technique used here compared to the Holevo information bound in the state learning case (Appendix B 2). The Holevo bound is particularly useful in proving these lower bounds because, combined with the data processing inequality, it gives an upper bound on the amount of information that can be extracted from quantum states. In particular, it asserts that, given an ensemble of d-dimensional states $\{\rho_X\}$ with random classical labels $X \in [M]$, the maximal mutual information with the underlying random label when using k copies of the state is upper bounded by $\chi(X; \rho_X^{\otimes k}) \triangleq S(\mathbb{E}_X[\rho_X^{\otimes k}]) - \mathbb{E}_X[S(\rho_X^{\otimes k})]$. Meanwhile, the information needed to distinguishing a packing net of d-dimensional states is lower bounded by $\Omega(d)$. Thus, upper bounding the Holevo χ via the number of samples k can give us sample complexity lower bounds. A naive upper bound is $\chi \le S(\mathbb{E}_X[\rho_X^{\otimes k}]) \le k \log d$ because $\mathbb{E}_X[\rho_X^{\otimes k}]$ is a d^k-dimensional mixed state and thus has entropy at most $k \log d$. This gives us a $\Omega(d/\log d)$ sample complexity lower bound with a sub-optimal logarithmic factor. To get rid of the $\log d$ factor, [168] noted that k copies of a d-dimensional pure state live in the symmetric subspace of the k-fold tensor power of d-dimensional Hilbert space. Therefore, the first term $S(\mathbb{E}_X[\rho_X])$, along with the Holevo χ, can be more tightly upper bounded by $\log\binom{k+d-1}{k}$, where the binomial coefficient is the dimension of the symmetric subspace. This can then be used to prove a $\Omega(d)$ lower bound, which is optimal in d.

However, an analogous result for unitaries (or more generally channels) queries is still lacking. Consider an ensemble of channels $\{C_X\}$ labeled by a classical random variable $X \in [M]$. In general, one can sequentially query the channel k times interleaved with processing operations to prepare a state carrying the information extracted from the queries. This then has the form $\rho_X^k = \mathcal{C}_k C_X \mathcal{C}_{k-1} C_X \cdots \mathcal{C}_1 C_X(\rho^0)$, where $\mathcal{C}_i$ are fixed channels independent of X, and ρ_0 is some fixed state. Then the amount of information that one can extract is given by the Holevo information $\chi(X; \rho_X^k) = S(\mathbb{E}_X[\rho_X^k]) - \mathbb{E}_X\, S([\rho_X^k])$. Upper bounding this quantity is in general difficult. [169] used induction and obtained $\chi \le k \log(d^2)$ which corresponds to the naive upper bound in the state case. Using this, however, can only give us a suboptimal $\Omega(d^2/\log d)$ query complexity lower bound. We suspect that an improved method, similar in spirit to [168], making use of the fact that all k queries are to the same channel C_X should be possible and give a

$$\chi(X;\rho_X^k) \leq \log \binom{k+d^2-1}{k} \tag{C.41}$$

upper bound. This would then also give an information-theoretic perspective on the binomial coefficient appearing in the unitary discrimination result Lemma 26 originally proved by positive-semi-definite programming. We leave the proof of this Holevo information bound as an open problem for future work.

4. Learning from classically described data

As we have seen in Theorems 1 and 4, the sample complexity of learning G-gate states and unitaries are both $\tilde{\Theta}(G)$. This suggests that they have similar source of complexity. However, differently from state learning, we can identify two sources of difficulty in unitary learning: (1) reading out the input and output quantum states, and (2) learning the mapping from inputs to outputs. The similar complexity $\tilde{\Theta}(G)$ of both state and unitary learning suggests that learning the mapping is actually easy and may only need a constant number of queries to the unknown unitary.

To formalize this idea, we consider a different access model for the unitary learning task: We focus on learning the mapping by assuming training data that contains classical descriptions of input and output states. Specifically, we consider a learning algorithm H that selects N input n-qubit states $\{|x_i\rangle\}_{i=1}^N$, and queries the unknown unitary to get $\{U|x_i\rangle\}_{i=1}^N$, where we have (repeated) access to the classical descriptions of all these input and output states. Based on these classically described data, we want to use the learning algorithm H to output a $\hat{U}$ that satisfies $\mathrm{d}_{\mathrm{avg}}(\hat{U},U) \leq \epsilon$.

A recent line of research on the quantum no-free-lunch theorem [45, 46] implies that the above task of learning the mapping from classically described data in the average-case distance requires at least $\Omega(2^n)$ samples. This seems to contradict our idea that learning the mapping should be easy. However, [46] also demonstrated how to circumvent the quantum no-free-lunch theorem. In particular, they showed that by entangling our input states with an ancillary system, applying the unitary on the original system, and collecting the output entangled states, we can reduce the sample requirement by a factor equal to the Schimidt rank r of the entangled states. In the limit of maximally entangled state where $r = 2^n$, the output state is in fact the Choi–Jamiołkowski state of the unitary, which already contains all the matrix elements of the unitary. Therefore, [46] concluded that using entangled data can reduce the data requirements and eventually make the unitary learning task easy, requiring only one sample with a maximally entangled input state.

Here, we aim to go beyond this result and provide a unified information-theoretic reformulation of the quantum no-free-lunch theorem (Theorem 17), which is not limited to entangled data. We find that the key ingredient to reduce the sample complexity of learning with classical description is to enlarge the representation space (i.e., the space that the output states live in). While entanglement is one way to achieve such an enlargement, it is not the only one. In fact, we find an alternative method that only uses classically mixed states and achieve the same reduction in sample complexity. Specifically, we establish the following theorem.

Proposition 10 (Upper bounds in learning with classical descriptions, restatement of upper bounds in Theorem 5)**.** *There exists a learning algorithm H_{entangle} that, for any n-qubit unitary $U \in U(2^n)$, uses $N = \lceil 2^n/r \rceil$ classically described data $\{(|x_i\rangle, (U\otimes I)|x_i\rangle)\}_{i=1}^N$, where $|x_i\rangle$ are bipartite entangled states over two n-qubit systems with Schmidt rank at most r, to output a $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U},U) \leq \epsilon$ for any $\epsilon > 0$.*

Similarly, there exists a learning algorithm H_{mixed} that, for any n-qubit unitary $U \in U(2^n)$, uses $N = \lceil 2^n/r \rceil$ classically described data $\{(\rho_i, (U\otimes I)\rho_i(U\otimes I)^\dagger)\}_{i=1}^N$, where ρ_i are classically mixed states over two n-qubit systems with rank at most r of the form

$$\rho_i = \sum_{j=1}^{r} p_{ij} |\phi_{ij}\rangle\!\langle\phi_{ij}| \otimes |\psi_{ij}\rangle\!\langle\psi_{ij}| \,, \tag{C.42}$$

to output a $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U},U) \leq \epsilon$ for any $\epsilon > 0$.

Note that, since the number N of training data points in Proposition 10 is independent of the desired accuracy $\epsilon > 0$, we can also learn w.r.t. $\mathrm{d}_\diamond$. In fact, we can even learn the unknown unitary exactly.

We prove Proposition 10 by explicitly constructing the learning algorithms. We remark that the $r = 2^n$ case for entangled data has previously appeared in [46], and a different strategy using mixed states was proposed in [68].

Proof. Let $d = 2^n$. We begin by describing the algorithm for entangled data. We consider the following set of input states

$$|x_j\rangle = \frac{1}{\sqrt{\mathcal{Z}_j}} \sum_{i=(j-1)r+1}^{\min\{jr,d\}} |i\rangle \otimes |i\rangle \,, \quad j = 1, \ldots, \lceil d/r \rceil \,. \tag{C.43}$$

where the normalization $\mathcal{Z}_j = r$ for $1 \leq j \leq \lceil d/r \rceil - 1$ and $\mathcal{Z}_j = d - (\lceil d/r \rceil - 1)r$ for $j = \lceil d/r \rceil$. They all have Schmidt rank at most r. If we apply $U \otimes I$ on $|x_j\rangle$, the output state reads

$$(U \otimes I)\,|x_j\rangle = \frac{1}{\sqrt{\mathcal{Z}_j}} \sum_{i=(j-1)r+1}^{\min\{jr,d\}} \sum_{k=1}^{d} \langle k|U|i\rangle \,|k\rangle \otimes |i\rangle \,. \tag{C.44}$$

Since we have the classical description, we can directly read off the matrix elements $\langle k|U|i\rangle$ with $1 \leq k \leq d$ and $(j-1)r + 1 \leq i \leq \min\{jr, d\}$. Combining different j, we can gather all the matrix elements we need to learn U.

Next, we describe the algorithm for mixed state data. We consider the input states to be

$$\rho_j = \sum_{i=(j-1)r+1}^{\min\{jr,d\}} p_j \,|ii\rangle \langle ii| \,, \quad j = 1, \ldots, \lceil d/r \rceil \,. \tag{C.45}$$

where the uniform mixing probability $p_j = 1/r$ for $1 \leq j \leq \lceil d/r \rceil - 1$ and $p_j = 1/(d - (\lceil d/r \rceil - 1)r)$ for $j = \lceil d/r \rceil$. Then all ρ_j have rank at most r. If we apply $U \otimes I$ on $|x_j\rangle$, the output state becomes

$$\rho_j = \sum_{i=(j-1)r+1}^{\min\{jr,d\}} p_j (U \otimes I)\,|ii\rangle \langle ii|\,(U \otimes I)^\dagger, \quad j = 1, \ldots, \lceil d/r \rceil \,. \tag{C.46}$$

We can interpret this output mixed state as randomly choosing a basis state in the ancillary system and applying the unitary to the same state in the original system. Since we have the classical description, we can use the ancillary system as a label for which state we inputted (e.g, $|i\rangle$), and read off all the amplitudes of $U|i\rangle$ on the original system, i.e., a column of the U matrix. Then by combing all the different basis elements $|i\rangle$, $1 \leq i \leq d$, we obtain all the matrix elements of U. □

Now we move on to the lower bound, which states that any noise-robust unitary learning algorithm needs at least $\Omega(2^n/r)$ samples to learn an arbitrary unknown unitary from classically described data. The noise-robust requirement here is in accordance with realistic learning scenarios where the tomography of input and output states necessarily involves reconstruction imperfection and noise. Specifically, we have the following proposition.

Proposition 11 (Lower bounds in learning with classical descriptions, restatement of lower bounds in Theorem 5)**.** *Let $\epsilon \in (0,1), \eta = \Theta(\epsilon)$. Let H_{entangle} be any learning algorithm that, for any n-qubit unitary $U \in U(2^n)$, uses classically described data $\{(|x_i\rangle, |y_i\rangle)\}_{i=1}^N$, where $|x_i\rangle$ are bipartite entangled states over two n-qubit systems with Schmidt rank at most r and $|y_i\rangle$ are η-noisy versions of $(U \otimes I)\,|x_i\rangle$ satisfying $\mathrm{d}_{\mathrm{tr}}(|y_i\rangle, (U \otimes I)\,|x_i\rangle) \leq \eta$, to output a $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \epsilon$. Then H_{entangle} needs at least $N \geq \Omega(2^n/r)$ samples.*

Similarly, let H_{mixed} be any learning algorithm that, for any n-qubit unitary $U \in U(2^n)$, uses classically described data $\{(\rho_i, \sigma_i)\}_{i=1}^N$, where ρ_i are classically mixed states over two n-qubit systems with rank at most r of the form

$$\rho_i = \sum_{j=1}^{r} p_{ij} \,|\phi_{ij}\rangle\!\langle\phi_{ij}| \otimes |\psi_{ij}\rangle\!\langle\psi_{ij}| \tag{C.47}$$

and σ_i are η-noisy versions of $(U \otimes I)\rho_i(U \otimes I)^\dagger$ satisfying $\mathrm{d}_{\mathrm{tr}}(\sigma_i, (U \otimes I)\rho_i(U \otimes I)^\dagger)) \leq \eta$, to output a $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(\hat{U}, U) \leq \epsilon$. Then H_{mixed} needs at least $N \geq \Omega(2^n/r)$ samples.

Proposition 11 is a consequence of the following information-theoretic reformulation of the quantum no-free-lunch theorem. The intuition behind this theorem is simple. On the one hand, to learn a unitary, we have to gather enough information to specify it. This required amount of information is quantified by the metric entropy of the unitary class. On the other hand, the information provided by each sample is limited and can be characterized by the metric entropy of the output state space. Therefore, the number of samples needed to learn the unitary is given by the former divided by the latter. In particular, we can see that the data requirement can be reduced if we increase the amount of information carried by each sample, represented by the metric entropy in the denominator.

Theorem 17 (Information-theoretic reformulation of quantum no-free-lunch theorem)**.** *Let $\eta, \epsilon \in (0,1)$. Let S be a set of input states (possibly with ancillas) and P be a distribution over S. Let $\{\rho_i\}_{i=1}^N \subset S^N$ be N classically described input states. Suppose that after applying the unknown n-qubit unitary U from a class $\mathcal{U} \subseteq U(2^n)$ of unitaries, they are transformed into the output states $\{\sigma_i\}_{i=1}^N$ through the map $f_U : \rho_i \mapsto \sigma_i = f_U(\rho_i)$. Let $\tilde{\sigma}_i$ be an η-noisy version of σ_i satisfying $\mathrm{d_{tr}}(\tilde{\sigma}_i, \sigma_i) \leq \eta$. Let $\mathcal{N}_\eta = \sup_{\rho \in S} \mathcal{N}(\{f_V(\rho) : V \in \mathcal{U}\}, \mathrm{d_{tr}}, \eta)$ be the maximal covering number of the set of all possible output states with different unitary acting on the input states. Let $\mathcal{F}_\mathcal{U} = \{f_V : V \in \mathcal{U}\}$ be the set of maps and $d_P(f_V, f_W) = \sqrt{\mathbb{E}_{\rho\sim P}[\mathrm{d_{tr}}(f_V(\rho), f_W(\rho))^2]}$ be the root mean squared trace distance. Then any learning algorithm H that uses the η-noisy classically described data $\{\rho_i, \tilde{\sigma}_i\}_{i=1}^N$ and outputs a $\hat{U}$ such that $d_P(f_{\hat{U}}, f_U) \leq \epsilon$ with probability at least $2/3$ needs at least*

$$N \geq \Omega\left(\frac{\log \mathcal{M}(\mathcal{F}_\mathcal{U}, d_P, 2\epsilon + 6\eta)}{\log \mathcal{N}_\eta}\right) \tag{C.48}$$

samples.

In particular, if $\eta = \Theta(\epsilon)$, $\mathcal{U} = U(2^n)$, P is a locally scrambled ensemble up to the second moment over n-qubit pure states (e.g., n-qubit Haar measure), S is the support of P, and $f_U(\rho) = U\rho U^\dagger$, then at least $\Omega(2^n)$ samples are needed.

We remark that $\eta = \Theta(\epsilon)$ is a convenient choice of noise level for stating the results, but in fact a weaker assumption $\log(1/\eta) = \Theta(\log(1/\epsilon))$ suffices.

In the following, we will first show that Theorem 17 implies Proposition 11 (the lower bounds in Theorem 5). Then we will turn to the proof of Theorem 17.

Proof of Proposition 11. In both cases (entangled or mixed), we prove the $\Omega(2^n/r)$ lower bound in two steps via Theorem 17: (1) show that the numerator $\log \mathcal{M}(\mathcal{F}_\mathcal{U}, d_P, 2\epsilon + 6\eta)$ in Theorem 17 is at least $\Omega(4^n \log(1/\epsilon))$; and (2) show that the denominator $\mathcal{N}_\epsilon$ is at most $\mathcal{O}(2^n r \log(1/\epsilon))$ when the input states are either entangled pure states of Schmidt rank at most r or mixed states of rank at most r. Then the desired results follow.

For step (1), we begin by defining the distribution P with respect to which the performance in Theorem 17 is measured. For both entangled and mixed cases, we define P to be the distribution of $|\psi\rangle \otimes |0\rangle^{\otimes n}$ where $|\psi\rangle$ is a Haar-random state on the original system, and $|0\rangle^{\otimes n}$ is a fixed state on the ancillary system. Note that this state is indeed both a bipartite entangled state with Schmidt rank at most r and of the form Equation (C.47) with rank at most r. Moreover, since in both cases, the map f_U is given by acting the unitary U on the original system and the identity on the ancillary system, the distance metric $d_P(f_V, f_W)$ is the same as $\mathrm{d_{avg}}$. Therefore, the packing number satisfies

$$\mathcal{M}(\mathcal{F}_{U(2^n)}, d_P, 2\epsilon + 6\eta) = \mathcal{M}(U(2^n), \mathrm{d_{avg}}, 2\epsilon + 6\eta). \tag{C.49}$$

To find the packing number $\mathcal{M}(U(2^n), \mathrm{d_{avg}}, 2\epsilon + 6\eta)$, we invoke the covering number bound for $U(2^n)$ with respect to the normalized Frobenius norm d_F (Lemma 9), the fact that quotient out global phase only change the metric entropy by a constant (Lemma 10), and the equivalence of d'_F and $\mathrm{d_{avg}}$ (Lemma 4, Item 1). We have

$$\log \mathcal{M}(\mathcal{F}_{U(2^n)}, d_P, 2\epsilon + 6\eta) = \log \mathcal{M}(U(2^n), \mathrm{d_{avg}}, 2\epsilon + 6\eta) \geq \Omega\left(4^n \log \frac{1}{\epsilon}\right), \tag{C.50}$$

where we used $\eta = \Theta(\epsilon)$.

Next, for step (2), we compute $\mathcal{N}_\eta$. For entangled data, note that applying unitaries on only the first n qubits does not change the bipartite Schmidt rank r, so the output states are pure states of the form $|\chi\rangle = \sum_{i,j=1}^{2^n} A_{ij} |i\rangle \otimes |j\rangle$, where $\|A\|_F = 1$ because of normalization, and the rank of A corresponds to the Schmidt rank which is at most r. Furthermore, the Euclidean distance between the output states is equal to the Frobenius distance between the corresponding A-matrices. With this correspondence, we can explicitly construct a covering net over the output states as follows. We take a minimal η-covering net $\mathcal{N}'$ over the set of complex matrices A with bounded rank r and $\|A\|_F = 1$ with respect to the Frobenius distance. Since they are contained in the unit ball ($\|A\|_F \leq 1$) in a real linear space of dimension $2 \cdot 2^n \cdot r$ [170, Theorem 1], by the monotinicity of covering number and the standard covering number bound for Euclidean balls via a volume argument [48, Corollary 4.2.13], we have $\log|\mathcal{N}'| \leq \mathcal{O}(2^n r \log(1/\eta))$. Meanwhile, similar to the proof in Lemma 1, the trace distance between any two pure states $|\psi\rangle, |\phi\rangle$ are bounded by the Euclidean distance, and thus the Frobenius distance between the corresponding A matrices:

$$\mathrm{d}_{\mathrm{tr}}(|\psi\rangle, |\phi\rangle) = \sqrt{1 - |\langle\psi|\phi\rangle|^2} \leq \sqrt{2(1 - |\langle\psi|\phi\rangle|)} \leq \sqrt{2(1 - \mathrm{Re}[\langle\psi|\phi\rangle])} = \||\psi\rangle - |\phi\rangle\|_2. \tag{C.51}$$

Therefore $\mathcal{N}'$ gives an η-covering net over the output states with respect to the trace distance d_{tr}. Hence, $\log \mathcal{N}_\eta \leq \log|\mathcal{N}'| \leq \mathcal{O}(2^n r \log(1/\eta)) = \mathcal{O}(2^n r \log(1/\epsilon))$ since $\eta = \Theta(\epsilon)$, and from Theorem 17 we have the desired lower bound

$$N \geq \Omega\left(\frac{4^n \log(1/\epsilon)}{2^n r \log(1/\epsilon)}\right) = \Omega\left(\frac{2^n}{r}\right). \tag{C.52}$$

The case of mixed states is similar. For a given input state $\rho = \sum_{i=1}^r p_i |\phi_i\rangle\langle\phi_i| \otimes |\psi_i\rangle\langle\psi_i|$, the output state reads

$$\sigma = \sum_{i=1}^r p_i U |\phi_i\rangle\langle\phi_i| U^\dagger \otimes |\psi_i\rangle\langle\psi_i|. \tag{C.53}$$

Now we take a minimal η-covering net $\mathcal{N}''$ over all pure n-qubit states with respect to Euclidean distance, which is a unit ball in a $2 \cdot 2^n$ dimensional real linear space. By standard covering number bound for Euclidean balls, we know $\log|\mathcal{N}''| \leq \mathcal{O}(2^n \log(1/\eta)) = \mathcal{O}(2^n \log(1/\epsilon))$. Then for any $U|\phi_i\rangle$, there exists a $|\eta_i\rangle \in \mathcal{N}''$ such that $\|U|\phi_1\rangle - |\eta_1\rangle\|_2 \leq \eta$. Let $\sigma' = \sum_{i=1}^r p_i |\eta_i\rangle\langle\eta_i| \otimes |\psi_i\rangle\langle\psi_i|$. Then the trace distance is bounded by

$$\begin{aligned}
\frac{1}{2}\|\sigma - \sigma'\|_1 &\leq \frac{1}{2}\sum_{i=1}^r p_i \big\|U|\phi_i\rangle\langle\phi_i| U^\dagger \otimes |\psi_i\rangle\langle\psi_i| - |\eta_i\rangle\langle\eta_i| \otimes |\psi_i\rangle\langle\psi_i|\big\|_1 \\
&\leq \frac{1}{2}\sum_{i=1}^r p_i \|U|\phi_i\rangle \otimes |\psi_i\rangle - |\eta_i\rangle \otimes |\psi_i\rangle\|_2 \\
&= \frac{1}{2}\sum_{i=1}^r p_i \|U|\phi_i\rangle - |\eta_i\rangle\|_2 \leq \frac{\eta}{2}\sum_{i=1}^r p_i = \frac{\eta}{2},
\end{aligned} \tag{C.54}$$

where we have used the subadditivity of trace norm, the fact that trace distance is upper bounded by Euclidean norm for pure states, and $\sum_{i=1}^r p_i = 1$. Hence the set

$$\left\{\sum_{i=1}^r p_i |\eta_i\rangle\langle\eta_i| \otimes |\psi_i\rangle\langle\psi_i| : |\eta_i\rangle \in \mathcal{N}'', 1 \leq i \leq r\right\} \tag{C.55}$$

forms an $\eta/2$-covering net of set of the output states and has cardinality $|\mathcal{N}''|^r$. Therefore, we have $\log \mathcal{N}_\eta = r \log|\mathcal{N}''| = \mathcal{O}(2^n r \log(1/\epsilon))$. From Theorem 17, we again arrive at the desired result

$$N \geq \Omega\left(\frac{4^n \log(1/\epsilon)}{2^n r \log(1/\epsilon)}\right) = \Omega\left(\frac{2^n}{r}\right). \tag{C.56}$$

This concludes the proof of Proposition 11, and together with Proposition 10, we have proved Theorem 5. □

Now we move on to prove our quantum no-free-lunch theorem (Theorem 17). We first establish the following information-theoretic lower bound on the sample complexity of learning discrete functions. We remark that a version for binary-valued functions was proved in a different fashion in [171, Proposition 8] and [172, Lemma 4.8].

Proposition 12 (Information-theoretic lower bound for learning discrete functions)**.** *Let $\epsilon > 0$, $k \in \mathbb{N}$ and $\mathcal{F}$ be a class of functions mapping $\mathcal{X}$ to $\mathcal{Y} = \{1, \ldots, k\}$ with a distance metric d. Any learning* *algorithm H that uses N samples $\{x_i \in \mathcal{X}, y_i = f(x_i)\}_{i=1}^N$ and outputs an $\hat{f}$ such that $d(\hat{f}, f) \leq \epsilon$ with probability at least 2/3 for any $f \in \mathcal{F}$ must use at least*

$$N \geq \Omega\left(\frac{\log \mathcal{M}(\mathcal{F}, d, 2\epsilon)}{\log k}\right) \tag{C.57}$$

samples.

Proof of Proposition 12. We begin by taking a maximal 2ϵ-packing $\mathcal{P}$ of $\mathcal{F}$, i.e., $|\mathcal{P}| = \mathcal{M}(\mathcal{F}, d, 2\epsilon)$ and for any $f_i \neq f_j \in \mathcal{P}$, $d(f_i, f_j) > 2\epsilon$. Now we design a communication protocol between two parties, Alice and Bob, as follows. The packing $\mathcal{P}$ is shared by both parties. Alice takes a random variable W uniformly sampled from $\{1, \ldots, \mathcal{M}(\mathcal{F}, d, 2\epsilon)\}$ and picks the corresponding function f_W from the packing $\mathcal{P}$. She then feeds the inputs $x = (x_1, \ldots, x_N)$ into f_W, generating a dataset $Z = ((x_1, f_W(x_1)), \ldots, (x_N, f_W(x_N)))$, and sends the dataset to Bob. Bob's task is to use this dataset to determine which function Alice used. Suppose Bob is given a learning algorithm described as in the proposition. The algorithm will learn from the dataset and output a hypothesis function $\hat{f}$ that satisfies

$$\mathbb{P}[d(\hat{f}, f_W) \leq \epsilon] \geq 2/3\,, \tag{C.58}$$

no matter which W was chosen by Alice. With $\hat{f}$ in hand, Bob can make the guess

$$\hat{W} = \mathrm{argmin}_{f_w \in \mathcal{P}} d(\hat{f}, f_w). \tag{C.59}$$

Note that as long as $d(\hat{f}, f_W) \leq \epsilon$, then for any $f_i \neq f_W \in \mathcal{P}$,

$$d(\hat{f}, f_i) \geq d(f_W, f_i) - d(\hat{f}, f_W) > 2\epsilon - \epsilon = \epsilon \geq d(\hat{f}, f_W). \tag{C.60}$$

Therefore, the error probability of Bob's guess is bounded by

$$\mathbb{P}[\hat{W} \neq W] = \mathbb{P}[\exists i \neq W : d(\hat{f}, f_i) \leq d(\hat{f}, f_W)] \leq \mathbb{P}[d(\hat{f}, f_W) > \epsilon] \leq 1/3. \tag{C.61}$$

By Fano's inequality [173, Theorem 2.10.1], the conditional entropy $S(W|\hat{W}) \leq s_2(1/3) + \frac{1}{3}\log \mathcal{M}(\mathcal{F}, d, 2\epsilon)$, where $s_2(\delta) = -\delta \log \delta - (1-\delta)\log(1-\delta)$ is the binary entropy function. Then the mutual information is at least

$$I(W; \hat{W}) = S(W) - S(W|\hat{W}) \geq (2/3) \log \mathcal{M}(\mathcal{F}, d, 2\epsilon) - s_2(1/3). \tag{C.62}$$

On the other hand, the sample size N controls the amount of information that Bob has access to. Since Bob's guess is produced by the dataset Z, by the data processing inequality [173, Theorem 2.8.1], we have

$$I(W; \hat{W}) \leq I(W; Z) = S(Z) - S(Z|W) = S(f_W(x_1), \ldots, f_W(x_N)) \leq N \log k, \tag{C.63}$$

where we used $S(Z|W) = 0$, since Z is determined by W, and the fact that $(f_W(x_1), \ldots, f_W(x_N))$ can take no more than k^N different values. Combining the above two inequalities, we arrive at

$$N \geq \Omega\left(\frac{\mathcal{M}(\mathcal{F}, d, 2\epsilon)}{\log k}\right). \tag{C.64}$$

□

With Proposition 12, we can prove Theorem 17 by quantizing the output states to the nearest elements in covering nets, similar to an idea employed in [174].

Proof of Theorem 17. Let $k = \mathcal{N}_\eta$. Since $\mathcal{N}_\eta \geq \mathcal{N}(\{f_V(\rho), V \in \mathcal{U}\}, \mathrm{d_{tr}}, \eta)$ for every $\rho \in S$, we can find an η-covering net $\mathcal{N}_\rho$ of size k for each $\rho \in S$. We label the elements of $\mathcal{N}_\rho$ using $\{1, \ldots, k\}$ and define $L_\rho(\sigma) \in [k]$ as the label of a covering net element $\sigma \in \mathcal{N}_\rho$.

Now we define the quantized function Qf_U that maps an input state ρ to an element of the covering net $\mathcal{N}_\rho$. Specifically, for any $\rho \in S$ and any $\sigma \in \{f_V(\rho), V \in \mathcal{U}\}$, there exists a $\sigma' \in \mathcal{N}_\rho$, such that $\mathrm{d_{tr}}(\sigma, \sigma') \leq \eta$. For any unitary $U \in \mathcal{U}$, we define

$$Qf_U(\rho) = \mathrm{argmin}_{\sigma \in \mathcal{N}_\rho} \mathrm{d_{tr}}(f_U(\rho), \sigma) \tag{C.65}$$

and $LQf_U(\rho) = L_\rho[Qf_U(\rho)]$ be the corresponding label. (Ties are broken arbitrarily.) Then LQf_U is a discrete-output function mapping input states S to labels $[k]$ and it is in one-to-one correspondence with Qf_U. We use $\mathcal{F}^Q$ to denote all these labeled quantized functions, $\mathcal{F}^Q = \{LQf_U, U \in \mathcal{U}\}$, and define the distance metric on labeled functions as $d_L(LQf_V, LQf_W) = d_P(Qf_V, Qf_W)$. A useful property is that for any unitary $U \in \mathcal{U}$, we have

$$d_P(f_U, Qf_U) = \sqrt{\mathbb{E}_{\rho\sim P}[\mathrm{d}_{\mathrm{tr}}(f_U(\rho), Qf_U(\rho))^2]} \leq \sqrt{\mathbb{E}_{\rho\sim P}[\eta^2]} = \eta. \tag{C.66}$$

Now we claim that if there exists a noise-robust learning algorithm H for $\mathcal{U}$ to accuracy ϵ in d_P with probability at least $2/3$, then we can use it to construct a learning algorithm H^Q for $\mathcal{F}^Q$ to accuracy $\epsilon + 2\eta$ in d_L with success probability at least $2/3$. Hence, the sample complexity for $\mathcal{U}$ must satisfy

$$N \geq \Omega\left(\frac{\log \mathcal{M}(\mathcal{F}^Q, d_L, 2\epsilon + 4\eta)}{\log k}\right), \tag{C.67}$$

by Proposition 12.

To show this claim, we construct H^Q as follows. For any $LQf_U \in \mathcal{F}^Q$, let the dataset be

$$Z = (\rho_1, Qf_U(\rho_1)), \ldots, (\rho_N, Qf_U(\rho_N)). \tag{C.68}$$

From the definition of quantized functions, we know that the $Qf_U(\rho_i)$ are η-noisy version of $f_U(\rho_i)$ because $\mathrm{d}_{\mathrm{tr}}(Qf_U(\rho_i), f_U(\rho_i)) \leq \eta$. Now we define H^Q as

$$H^Q[Z] = LQf_{H[Z]}. \tag{C.69}$$

Since the learning algorithm H is η-noise-robust, we have $d_P(f_{H[Z]}, f_U) \leq \epsilon$ and thus $d_P(f_{H[Z]}, Qf_U) \leq d_P(f_{H[Z]}, f_U) + d_P(f_U, Qf_U) \leq \epsilon + \eta$ with probability at least $2/3$. Then by the triangle inequality (proved similarly as in Lemma 6), we have

$$d_L(H^Q[Z], LQf_U) = d_P(Qf_{H[Z]}, Qf_U) \leq d_P(Qf_{H[Z]}, f_{H[Z]}) + d_P(f_{H[Z]}, Qf_U) \leq \epsilon + 2\eta \tag{C.70}$$

with probability at least $2/3$. Thus the claim is proved.

At this point, it remains to prove that

$$\mathcal{M}(\mathcal{F}^Q, d_L, 2\epsilon + 4\eta) \geq \mathcal{M}(\mathcal{F}_{\mathcal{U}}, d_P, 2\epsilon + 6\eta). \tag{C.71}$$

To prove this, we can take a maximal $(2\epsilon + 6\eta)$-packing $\mathcal{P}$ of $\mathcal{F}_{\mathcal{U}}$ with respect to d_P, with $|\mathcal{P}| = \mathcal{M}(\mathcal{F}_{\mathcal{U}}, d_P, 2\epsilon + 6\eta)$. Then $\forall f_{U_1} \neq f_{U_2} \in \mathcal{P}$, we have

$$2\epsilon + 6\eta < d_P(f_{U_1}, f_{U_2}) \leq d_P(f_{U_1}, Qf_{U_1}) + d_P(Qf_{U_1}, Qf_{U_2}) + d_P(Qf_{U_2}, U_2) \leq 2\eta + d_P(Qf_{U_1}, Qf_{U_2}). \tag{C.72}$$

Therefore, $d_L(LQf_{U_1}, LQf_{U_2}) = d_P(Qf_{U_1}, Qf_{U_2}) > 2\epsilon + 4\eta$. Hence,

$$\mathcal{M}(\mathcal{F}^Q, d_L, 2\epsilon + 4\eta) \geq |\{LQf_U, U \in \mathcal{P}\}| = |\mathcal{P}| = \mathcal{M}(\mathcal{F}_{\mathcal{U}}, d_P, 2\epsilon + 6\eta). \tag{C.73}$$

This concludes the proof of the main part in Theorem 17.

Finally, we illustrate the special case where $\eta = \Theta(\epsilon)$, $\mathcal{U} = U(2^n)$ is the whole unitary group, P is a locally scrambled ensemble up to the second moment over n-qubit pure states (e.g., n-qubit Haar measure, see Definition 1), S is the support of P, and $f_U(\rho) = U\rho U^\dagger$. We show that at least $\Omega(2^n)$ samples are needed, thus reproducing the quantum no-free-lunch theorem in the usual sense and generalizing it to locally scrambled ensembles.

To see this, we first compute $\log \mathcal{M}(\mathcal{F}_{U(2^n)}, d_P, 2\epsilon + 6\eta)$. From the covering number bound for $U(2^n)$ with respect to the normalized Frobenius norm d_F (Lemma 9), the fact that quotienting out the global phase only changes the metric entropy by an additive $\mathcal{O}(\log(1/(2\epsilon + 6\eta)))$ term (Lemma 10), and by the equivalence of d_F', $\mathrm{d}_{\mathrm{avg}}$, and d_P (Lemma 4 Item 1 and Lemma 5), we know that $\log \mathcal{M}(\mathcal{F}_{U(2^n)}, d_P, 2\epsilon + 6\eta) \geq \Omega\left(4^n \log(1/\epsilon)\right)$, where we used $\eta = \Theta(\epsilon)$.

Next, we move on to $\mathcal{N}_\eta$. Since the output states are still n-qubit pure states, $\mathcal{N}_\eta$ is the covering number of the set of pure states with respect to d_{tr}. Considering that $\frac{1}{2}\left\|\left|\psi\middle\rangle\!\middle\langle\psi\right|\right\|_1$ is less than one for any pure state $|\psi\rangle$, the covering number is upper bounded by the covering number of a unit Euclidean ball in a $\Theta(2^n)$ dimensional linear space. Therefore, we have $\log \mathcal{N}_\eta \leq \mathcal{O}(2^n \log(1/\eta)) = \mathcal{O}(2^n \log(1/\epsilon))$ since $\eta = \Theta(\epsilon)$. Hence we arrive at

$$N \geq \Omega\left(\frac{4^n \log(1/\epsilon)}{2^n \log(1/\epsilon)}\right) = \Omega(2^n). \tag{C.74}$$

This concludes the proof of Theorem 17. □

The information theoretic version of quantum no-free-lunch theorem (Theorem 17) also gives us a way to generalize quantum no-free-lunch to a restricted unitary class. For example, for unitaries with bounded circuit complexity G, the packing number in the enumerator is lower bounded by $\Omega(G)$, while the covering number in the denominator is upper bounded by $\mathcal{O}(\min\{G\log G + G\log n, 2^n\})$. This gives us a quantum no-free-lunch theorem for G-gate unitaries, where the sample complexity is lower bounded by $\Omega(1)$ for $G \leq \mathcal{O}(2^n)$, by $\Omega(G/2^n)$ for $\Omega(2^n) < G \leq \mathcal{O}(4^n)$ and $\Omega(2^n)$ for $G \geq \Omega(4^n)$.

5. Computational complexity

Similar to the state learning case, our algorithm for average-case unitary learning described in Appendix C 2 is not computationally efficient. In this section, we follow Appendix B 3 and first show that there is no polynomial-time algorithm for learning unitaries composed of $G = \mathcal{O}(n\mathsf{polylog}(n))$ two-qubit gates, assuming $\mathsf{RingLWE}$ cannot be solved efficiently on a quantum computer. This result also holds for unitaries with circuit depth $\mathcal{O}(\mathsf{polylog}(n))$. Then we invoke a stronger assumption that $\mathsf{RingLWE}$ cannot be solved by any sub-exponential-time quantum algorithm, and show that any quantum algorithm for learning unitaries composed of $\tilde{\mathcal{O}}(G)$ gates must use $\exp(\Omega(G))$ time. Finally, we explicitly construct an efficient learning algorithm for $G = \mathcal{O}(\log n)$, thus establishing $\log n$ gate complexity as a transition point of computational efficiency.

Theorem 18 (Unitary learning computational complexity lower bound assuming polynomial hardness of $\mathsf{RingLWE}$)**.** *Let $\lambda = n$ be the security parameter. Let U be a unitary consisting of $G = \mathcal{O}(n\mathsf{polylog}(n))$ gates (or a depth $d = \mathcal{O}(\mathsf{polylog}(n))$ circuit) that implements a pseudorandom function in $\mathcal{RF}$. Such a unitary U exists by Corollary 3. There exists no polynomial-time quantum algorithm for learning a circuit description of U to within $\epsilon \leq 1/64$ average-case distance $\mathrm{d}_{\mathrm{avg}}$ with probability at least $2/3$ from $N = \mathsf{poly}(\lambda)$ queries, if quantum computers cannot solve* $\mathsf{RingLWE}$ *in polynomial time.*

Proof. Suppose for the sake of contradiction that there is an efficient algorithm $\mathcal{A}_0$ that can learn a description of U to within ϵ average-case distance with probability at least 2/3. Then by standard boosting of success probability (see e.g, [21, Proposition 2.4]), there is an efficient algorithm $\mathcal{A}$ that can learn U to the same accuracy with probability at least $p = 1-1/8192$ with only a constant factor overhead in time complexity. Note that this boosting requires the distance metric to be efficiently computable, which is guaranteed by the SWAP test elaborated below. We will construct a polynomial-time quantum distinguisher $\mathcal{D}$ that invokes $\mathcal{A}$ to distinguish between U and the unitary $V \in \mathcal{U}$ corresponding to a random classical function. This contradicts Theorem 11 Item 2.

The distinguisher $\mathcal{D}$ operates according to Algorithm 6.

```
Algorithm 6: Distinguisher $\mathcal{D}$ for PRF
Input: $N$ query access to $U$
Output: $b \in \{0,1\}$
1 Run $\mathcal{A}$ using $(N-1)$ queries to $U$, receiving $\hat{U}$.
2 Prepare a random tensor product of 1-qubit stabilizer states $|x\rangle, x \in \mathbb{Z}_6^n$.
3 Query $U$ one more time to prepare $U|x\rangle$.
4 Run the SWAP test on $U|x\rangle$ and $\hat{U}|x\rangle$, receiving a bit $b \in \{0,1\}$.
5 Output $b$.
```

Recall that the SWAP test [140, 141] takes two quantum states $|\alpha\rangle, |\beta\rangle$ as input and outputs 1 with probability $(1 + |\langle\alpha|\beta\rangle|^2)/2$. We denote this algorithm as $\mathsf{SWAP}(|\alpha\rangle, |\beta\rangle)$.

Note that Step 2 in Algorithm 6, the preparation of tensor product of 1-qubit stabilizer states $|x\rangle, x \in \mathbb{Z}_6^n$, is computationally efficient, because it can be achieved by random one-qubit gates acting on each of the n qubits. Moreover, Step 4 can be implemented efficiently on a quantum computer because $\hat{U}$ is given in terms of efficient circuit description and because the SWAP test is efficiently implementable. Thus, assuming the hypothetical learner $\mathcal{A}$ to be efficient, the distinguisher $\mathcal{D}$ is efficient as well.

We analyze the probability that the distinguisher $\mathcal{D}$ outputs 1 when given the pseudorandom function U versus the random classical Boolean function V. We denote the distribution of $|x\rangle$ by Q. From Lemma 5, we have

$$d_Q(U,\hat{U}) = \sqrt{\mathbb{E}_{|x\rangle\sim Q}[\mathrm{d}_{\mathrm{tr}}(U|x\rangle, \hat{U}|x\rangle)^2]} \leq \sqrt{2}\,\mathrm{d}_{\mathrm{avg}}(U,\hat{U}). \tag{C.75}$$

Case 1: $U \in \mathcal{RF}$**.** By the guarantees of $\mathcal{A}$, with probability at least p, we have $\mathrm{d}_{\mathrm{avg}}(\hat{U},U) \leq \epsilon \leq 1/64$, where $\hat{U}$ is the unitary learned by algorithm $\mathcal{A}$. This implies

$$\mathop{\mathbb{E}}_{|x\rangle\sim Q} |\langle x|\hat{U}^\dagger U|x\rangle|^2 = 1 - d_Q^2(U,\hat{U}) \geq 1 - 2\epsilon^2, \tag{C.76}$$

where we used the relationship between fidelity and trace distance. Then it immediately follows from

Equation (C.76) that

$$\begin{aligned}
\Pr_{U\in\mathcal{RF},\mathcal{D}}\left[\mathcal{D}^{|U\rangle}(\cdot)=1\right] &= \Pr_{\substack{U\in\mathcal{RF},|x\rangle\sim Q\\ \mathcal{A},\mathsf{SWAP}}}\left[\mathsf{SWAP}\left(U|x\rangle,\hat{U}|x\rangle\right)=1\right]\\
&= \mathop{\mathbb{E}}_{U\in\mathcal{RF},|x\rangle\sim Q}\left[\Pr_{\mathcal{A},\mathsf{SWAP}}\left[\mathsf{SWAP}\left(U|x\rangle,\hat{U}|x\rangle\right)=1\middle| U,|x\rangle\right]\right]\\
&\geq p\mathop{\mathbb{E}}_{U\in\mathcal{RF}}\left[\frac{1}{2}+\frac{1}{2}\mathop{\mathbb{E}}_{\hat{U},|x\rangle\sim Q}\left[|\langle x|\hat{U}^\dagger U|x\rangle|^2\right]\right]\\
&\geq p\mathop{\mathbb{E}}_{U\in\mathcal{RF}}\left[\frac{1}{2}+\frac{1}{2}(1-2\epsilon^2)\right]=p(1-\epsilon^2)>\frac{8189}{8192},
\end{aligned}\tag{C.77}$$

where in the first inequality we split the probability into two terms conditioned on the success and failure of $\mathcal{A}$, and we lower bound the failure term by zero, and in the last inequality we have used the fact that $p(1-\epsilon^2)\geq(1-1/8192)(1-1/4096)>8189/8192$.

Case 2: $U=V\in\mathcal{U}$, where V is the n-qubit unitary implementing a randomly chosen classical function. We want to upper bound the probability that the distinguisher $\mathcal{D}$ outputs 1 when given queries to V. Let $\mathcal{C}$ be the set of all possible output unitaries of $\mathcal{A}$. We follow the same reasoning as in Equation (C.77) and note that

$$\begin{aligned}
\Pr_{V\in\mathcal{U},\mathcal{D}}\left[\mathcal{D}^{|V\rangle}(\cdot)=1\right] &\leq \mathop{\mathbb{E}}_{V\in\mathcal{U}}\left[\max_{W\in\mathcal{C}}\mathop{\mathbb{E}}_{|x\rangle\sim Q}\left[\frac{1}{2}+\frac{1}{2}|\langle x|V^\dagger W|x\rangle|^2\right]\right]+(1-p)\\
&\leq \mathop{\mathbb{E}}_{V\in\mathcal{U}}\left[\max_{W\in\mathcal{C}}\left[1-\frac{1}{4}\mathrm{d_{avg}}(V,W)^2\right]\right]+(1-p)\\
&\triangleq \mathop{\mathbb{E}}_{V\in\mathcal{U}}[O_V]+(1-p),
\end{aligned}\tag{C.78}$$

where we define $O_V=\max_{W\in\mathcal{C}}\left[1-\frac{1}{4}\mathrm{d_{avg}}(V,W)^2\right]$. Furthermore, we can split the right hand side into two parts by introducing a constant θ:

$$\mathop{\mathbb{E}}_{V\in\mathcal{U}}[O_V]\leq\Pr\left[O_V\leq 1-\frac{\theta^2}{4}\right]\cdot\left(1-\frac{\theta^2}{4}\right)+\Pr\left[O_V>1-\frac{\theta^2}{4}\right]\cdot 1\leq 1-\frac{\theta^2}{4}+\Pr\left[O_V>1-\frac{\theta^2}{4}\right],\tag{C.79}$$

where we have used the fact that $O_V\leq 1$. Note that

$$\begin{aligned}
\Pr\left[O_V>1-\frac{\theta^2}{4}\right] &\leq \Pr_{V\in\mathcal{U}}\left[\exists W\in\mathcal{C}:\mathrm{d_{avg}}(V,W)<\theta\right]\\
&\leq \sum_{W\in\mathcal{N}}\Pr_{V\in\mathcal{U}}\left[\mathrm{d_{avg}}(V,W)<\theta\right]\\
&= \sum_{W\in\mathcal{N}}\frac{1}{|\mathcal{U}|}\sum_{V\in\mathcal{U}}1\left\{\mathrm{d_{avg}}(V,W)<\theta\right\}\\
&\leq \frac{|\mathcal{N}|\max_{W\in\mathcal{N}}N_{W,\theta}}{|\mathcal{U}|}.
\end{aligned}\tag{C.80}$$

In the second line, we define $\mathcal{N}$ be a minimal θ-covering net over $\mathcal{C}$ with respect to $\mathrm{d_{avg}}$. Also, in the last line, we define $N_{W,\theta}\triangleq\sum_{V\in\mathcal{U}}1\{\mathrm{d_{avg}}(V,W)<\theta\}$ to be the number of $V\in\mathcal{U}$ that are θ-close to W in $\mathrm{d_{avg}}$.

Now we aim to upper bound $N_{W,\theta}$ by counting. We first note that $N_{W,\theta}\leq\max_{V\in\mathcal{U}}N_{V,4\theta}+1$. This is because, by definition of $N_{W,\theta}$, there exist $V_1,\ldots,V_{N_{W,\theta}}\in\mathcal{U}$ such that $\mathrm{d_{avg}}(V_i,W)<\theta, 1\leq i\leq N_{W,\theta}$. Then for V_1 and any $V_i, 2\leq i\leq N_{W,\theta}$, we have

$$\mathrm{d_{avg}}(V_1,V_i)\leq d'_F(V_1,V_i)\leq d'_F(V_1,W)+d'_F(V_i,W)\leq 2\,\mathrm{d_{avg}}(V_1,W)+2\,\mathrm{d_{avg}}(V_i,W)<4\theta.\tag{C.81}$$

This means that there are at least $N_{W,\theta}-1$ elements of $\mathcal{U}$ that are (4θ)-close to V_1. Therefore, $N_{V_1,4\theta}\geq N_{W,\theta}-1$ and hence $N_{W,\theta}\leq\max_{V\in\mathcal{U}}N_{V,4\theta}+1$.

Next, we upper bound $N_{V,4\theta}$ for any $V\in\mathcal{U}$. Recall that each $V\in\mathcal{U}$ is an oracle unitary of a Boolean function on $\{0,1\}^n$. We can represent it by $f_V(i)\in\{0,1\}, 1\leq i\leq 2^n$. Consider a different $V'\in\mathcal{U}$ corresponding to the Boolean function $f_{V'}$. If f_V and $f_{V'}$ differ on at least $\lceil 64\theta^2\cdot 2^n\rceil$ of the 2^n possible inputs $i\in[2^n]$, then the corresponding columns of the unitaries V and V' must also differ. In particular, in each of these columns, there will be a matrix element that is 1 for V but 0 for V'. This means that V and V' are 4θ apart from each other w.r.t. d_{avg}:

$$\mathrm{d}_{\text{avg}}(V, V') \geq \frac{1}{2} \min_{e^{i\phi} \in U(1)} \left\| V - V' e^{i\phi} \right\|_F \geq \frac{1}{2\sqrt{d}} \min_{e^{i\phi} \in U(1)} \sqrt{64\theta^2 \cdot 2^n |1 - 0 \cdot e^{i\phi}|^2} = 4\theta. \tag{C.82}$$

Therefore, all functions $f_{V'}$ corresponding to the $V' \in \mathcal{U}$ counted in $N_{V,4\theta}$ must differ from f_V on strictly less than $\lceil 64\theta^2 \cdot 2^n \rceil$ of the 2^n inputs. This gives us

$$N_{V,4\theta} \leq \sum_{k=0}^{\lceil 64\theta^2 \cdot 2^n \rceil} \binom{2^n}{k}, \tag{C.83}$$

where each term represents choosing k inputs where the output is different from f_V. The right hand side can be further bounded as

$$\sum_{k=0}^{\lceil 64\theta^2 \cdot 2^n \rceil} \binom{2^n}{k} \leq \left(\frac{e 2^n}{\lceil 64\theta^2 \cdot 2^n \rceil} \right)^{\lceil 64\theta^2 \cdot 2^n \rceil} \leq 2^{(64\theta^2 \cdot 2^n + 1) \log_2(e/64\theta^2)}. \tag{C.84}$$

Note that when $\theta = 1/16$, we have $64\theta^2 = 1/4$ and $64\theta^2 \log_2(e/64\theta^2) = \log_2(4e)/4 < 0.87$. Therefore, recalling that the set of all n-bit classical Boolean functions has size $|\mathcal{U}| = 2^{2^n}$, we obtain

$$\Pr\left[O_V > 1 - \frac{\theta^2}{4} \right] \leq |\mathcal{N}| 2^{-0.13 \cdot 2^n + \log_2(4e) + 1}, \tag{C.85}$$

where the extra one in the exponent takes the one in $N_{W,\theta} \leq \max_{V \in \mathcal{U}} N_{V,4\theta} + 1$ into account.

Finally, we move on to bound $|\mathcal{N}|$. Similar to Equation (B.102) in the state learning case, since our learning algorithm is a polynomial time algorithm that can only output circuit descriptions with size $\mathsf{poly}(n)$, we must have

$$|\mathcal{N}| \leq \mathcal{O}\left((1/\theta)^{\mathsf{poly}(n)} \right) = \mathcal{O}\left(2^{\mathsf{poly}(n)} \right). \tag{C.86}$$

Thus we arrive at

$$\Pr\left[O_V > 1 - \frac{\theta^2}{4} \right] \leq \mathcal{O}\left(2^{\mathsf{poly}(n) - 0.13 \cdot 2^n} \right) = \mathrm{negl}(n) \tag{C.87}$$

and therefore

$$\Pr\left[\mathcal{D}^{|V\rangle}(\cdot) = 1 \right] \leq 1 - \frac{\theta^2}{4} + \mathrm{negl}(n) + (1 - p) = \frac{8185}{8192} + \mathrm{negl}(n), \tag{C.88}$$

where we have used $\theta = 1/16$ and $p = 1 - 1/8192$.

Combining Equation (C.77) and Equation (C.87), we have

$$\left| \Pr_{U \in \mathcal{RF}} [\mathcal{D}^{|U\rangle}(\cdot) = 1] - \Pr_{V \in \mathcal{U}} [\mathcal{D}^{|V\rangle}(\cdot) = 1] \right| \geq \frac{4}{8192} - \mathrm{negl}(n) \geq \frac{1}{4096} \tag{C.89}$$

for large n. This contradicts the defining property of pseudorandom functions $\mathcal{RF}$ (Theorem 11 Item 2) under the assumption that $\mathsf{RingLWE}$ is hard. □

Next, we invoke the stronger assumption that $\mathsf{RingLWE}$ cannot be solved by any sub-exponential-time quantum algorithms and show that learning unitaries composed of $G = \mathcal{O}(\log n \cdot \mathsf{polyloglog} n)$ gates is computationally hard.

Theorem 19 (Unitary learning computational complexity lower bound assuming sub-exponential hardness of $\mathsf{RingLWE}$, restatement of lower bound in Theorem 6)**.** *Let $\lambda = l = \Theta(G)$ with $l \leq n$ be the security parameter. Let V be an l-qubit unitary consisting of $\mathcal{O}(l\mathsf{polylog}(l)) = \mathcal{O}(G\mathsf{polylog}(G))$ gates (or a depth $d = \mathcal{O}(\mathsf{polylog}(G))$ circuit) that implements a pseudorandom function in $\mathcal{RF}$. Such a unitary V exists by Corollary 3. Let $U = V \otimes I$, where the identity I is over the last $(n - l)$ qubits. Any quantum algorithm for learning a circuit description of the n-qubit unitary U to within $\epsilon \leq 1/64$ average-case distance d_{avg} with probability at least $2/3$ from $N = \mathsf{poly}(\lambda)$ queries to U must use $\exp(\Omega(\min\{G, n\}))$ time, if quantum computers cannot solve $\mathsf{RingLWE}$ in sub-exponential time.*

Proof. With polynomial hardness of $\mathsf{RingLWE}$ replaced by sub-exponential hardness, Theorem 18 asserts that there are no sub-exponential (in l) quantum algorithms that can learn the l-qubit unitary V to within average case distance $\epsilon < 1/64$ with success probability at least $2/3$. That is, any such learning algorithms must use time at least $\exp(\Omega(l)) = \exp(\Omega(\min\{G, n\}))$, since $l \leq n$. Meanwhile, a polynomial learning algorithm for the n-qubit unitary $U = V \otimes I$ can be used to learn the l-qubit unitary V in the same runtime by discarding the last $(n - l)$ qubits, because trace distance does not increase under such operation and thus neither does $\mathrm{d}_{\mathrm{avg}}$. This implies the $\exp(\Omega(\min\{G, n\}))$ time lower bound for the n-qubit learning algorithm. □

Finally, we briefly show that learning becomes efficient when $G = \mathcal{O}(\log n)$. The idea is that with $\mathcal{O}(\log n)$ gates, there can only be at most $\mathcal{O}(\log n)$ qubits affected. Thus we can focus on these qubits and learning the unitary amounts to manipulating at most $2^{\mathcal{O}(\log n)} = \mathsf{poly}(n)$ size matrices, which is efficient. Specifically, we have the following statement.

Proposition 13 (Learning unitaries with logarithmic circuit complexity efficiently, restatement of upper bound in Theorem 6)**.** *Let $\epsilon > 0$. Suppose we are given N queries to an n-qubit unitary U consisting of $G = \mathcal{O}(\log n)$ two-qubit gates. There exists a learning algorithm that outputs a $\hat{U}$ such that $\mathrm{d}_{\mathrm{avg}}(U, \hat{U}) \leq \epsilon$ with probability at least $2/3$ using $\mathsf{poly}(n, 1/\epsilon)$ queries and time.*

Proof. We prove this by a learning algorithm similar to Proposition 7 via junta learning based on Choi states (Appendix C 2 b) as follows.

Firstly, we prepare the Choi state of U by applying it to a maximally entangled state over $2n$ qubits, execute Algorithm 4, and post-select on the trivial qubits being in the state $|I\rangle\!\rangle$ as in Appendix C 2 b. This step uses $\mathsf{poly}(n, 1/\epsilon)$ queries and time, and gives us the post-selected Choi state which is non-trivial on only $4G = \mathcal{O}(\log n)$ qubits. Then we use the Pauli tomography method as in Proposition 7 to learn a trace-distance approximation to the $4G$-qubit Choi state $|\hat{V}\rangle\!\rangle$ using $\mathsf{poly}(n, 1/\epsilon)$ queries and time. We can enforce this approximation to be a valid Choi state by projecting it to the subspace spanned by $(A \otimes I)\,|\Phi\rangle$ and normalize the projected state, where A is an arbitrary matrix and $|\Phi\rangle$ is the maximally entangled state. This can be done via a projector which is a $2^{4G} = \mathsf{poly}(n)$ dimensional matrix. Finally, we calculate the corresponding unitary $\hat{V}$ and set $\hat{U} = \hat{V} \otimes I$. Note that this step is efficient as it only involves manipulating matrices of size $2^{4G} = \mathsf{poly}(n)$. Since the trace distance between Choi states is equivalent to the average-case distance between the corresponding unitaries, this gives us a $\mathsf{poly}(n, 1/\epsilon)$ learning algorithm for average-case unitary learning. □

Appendix D: Learning physical functions

As stated in the main text, learning classical functions that map variables controlling the input states and evolution to some property of the outputs is an alternative way of learning about Nature. Learning such functions has long been a central task of statistics and, more recently, classical and quantum machine learning. However, the physical mechanism that gives rise to these functions has largely been overlooked for the convenience of mathematical abstraction.

In fact, we can formulate the physical mechanism underlying a classical function as an experiment procedure involving a unitary with bounded circuit complexity. Specifically, we consider the following general experimental setting.

1. Given a set of ν variables $x \in [0, 1]^\nu$, we prepare a pure state that can depend on x in a fixed way.

2. We evolve the state using a unitary $U(x; \{U_i\}_{i=1}^G, a)$ that contains at most G two-qubit gates $\{U_i\}_{i=1}^G$, which can be tuned arbitrarily, and any number of fixed unitaries, which can depend on x, according to a circuit architecture a in an architecture class A.

3. We measure the output state with a fixed observable O and read out the expectation value as the function output.

We can w.l.o.g. absorb the state preparation into the unitary. Then the experiment gives rise to the function

$$f(\cdot; \{U_i\}, a) : [0, 1]^\nu \ni x \mapsto f(x; \{U_i\}, a) = \left\langle 0^n \middle| U(x; \{U_i\}, a)^\dagger O U(x; \{U_i\}, a) \middle| 0^n \right\rangle. \tag{D.1}$$

We define

$$\mathcal{F}_{G,A}^\nu = \{f(\cdot, \{U_i\}, a) : a \in A, U_i \in U(2^2), i = 1, \ldots, G\} \subseteq \mathbb{R}^{[0,1]^\nu} \tag{D.2}$$

to be the function class given by a class of architectures A for G-gate unitaries. We call such functions *physical functions*, and $\mathcal{F}^{\nu}_{G,A}$ the class of ν-variable physical functions with G gates and architectures A.

This experiment can also be understood as a quantum machine learning problem, where we want to collect training data $\{x, f(x)\}$ to learn to approximate certain functions in a function class using the ansatz described above. Then, the tunable gates $\{U_i\}$ can be understood as variational/trainable parameters of our quantum neural network. We note that the data encoding unitaries may simply use x as the angles for rotation, or it can also be arbitrarily complex (e.g., complex enough to implement a quantum random access memory [175] that prepares the amplitude encoding of the data) as long as it is not trainable. This encompass the case where the input data are classical descriptions of the input pure state. Also the order of the data encoding unitaries and the trainable unitaries can be arbitrary, thus accommodating data re-uploading strategies [176, 177].

We will show that to approximate a certain class of functions well, we need a minimal number of samples to learn and a minimal number of gates G (Theorem 7). In particular, we consider the class of 1-bounded and 1-Lipschitz functions on $[0,1]^{\nu}$, which can (up to equivalence classes) be represented by the unit ball $B^{1,\infty}$ in the Sobolev space $W^{1,\infty}_{[0,1]^{\nu}}$. We establish the following theorem, where the learning criterion is the standard one for learning real functions [73, Definition 16.1].

Theorem 20 (Sample and gate complexity lower bounds on functions given by G-gate unitaries to approximate bounded Lipschitz functions, restatement of Theorem 7)**.** *Let $\mathcal{F}^{\nu}_{G,A} \subseteq \mathbb{R}^{[0,1]^{\nu}}$ be the function class given by an architecture class A of G two-qubit unitaries. Let $\epsilon \in (0,1)$ and let $l(|h(x) - y|)$ be a loss function where l is a strictly increasing function with derivative larger than some positive constant on $[1,\infty)$. Suppose for any 1-bounded and 1-Lipschitz function $f \in B^{1,\infty}$, there exists an $h \in \mathcal{F}^{\nu}_{G,A}$ such that $\|f - h\|_{\infty} < \epsilon$. Then the smallest training data size N such that there exists a learning algorithm $H : ([0,1]^{\nu}, [0,1])^N \to \mathcal{F}^{\nu}_{G,A}$ that satisfies*

$$\mathbb{P}_{S\sim P^N}\left\{\mathbb{E}_{(X,Y)\sim P} l(|H[S](X) - Y|) - \inf_{f\in\mathcal{F}^{\nu}_{G,A}} \mathbb{E}_{(X,Y)\sim P} l(|f(X) - Y|) \leq \epsilon\right\} \geq 0.99, \tag{D.3}$$

for any probability distribution P over $[0,1]^{\nu} \times [0,1]$ must be at least

$$N \geq \Omega\left(\frac{1}{\epsilon^{\nu}}\right). \tag{D.4}$$

Moreover, we need at least

$$G \geq \tilde{\Omega}\left(\frac{1}{\epsilon^{\nu/2}}\right) \tag{D.5}$$

two-qubit unitaries if A contains variable circuit structures, or $G \geq \tilde{\Omega}(1/\epsilon^{\nu})$ if the circuit structure is fixed. The $\tilde{\Omega}$ for variable circuit structures hides logarithmic factors in ϵ as well as in the number of qubits n, while the $\tilde{\Omega}$ for fixed structure only hides logarithmic factors in ϵ.

This means that to approximate 1-bounded and 1-Lipschitz functions in ν-variables well to $\mathcal{O}(1/n^D)$ accuracy, we need at least $\tilde{\Omega}(n^{\nu D/2})$ two-qubit unitaries and $\Omega(n^{\nu D})$ samples to train on. And $\sim 1/\exp(n)$ accuracy can only be achieved with exponential-size quantum circuits and exponentially many samples. This result establishes a limitation on the maximal efficiency of using parameterized quantum circuits to approximate functions, complementary to existing works on universal approximation theorems for parameterized quantum circuits [75–78].

The exponential dependence on the number of variables N suggests that if one has an extensively large input vector (whose length scales with n), then the number of samples and gates needed to approximate such functions is exponentially large. Moreover, if the variables are encoded using amplitude encoding (e.g., via QRAM), which accommodates exponentially many variables ($\sim 2^n$), then the gate and sample requirement would grow double exponentially in $1/\epsilon$. This phenomenon, named curse of dimensionality, was also established in the theory of classical neural networks [74, Chapter 3]. We show that it still exists in quantum machine learning.

This curse can be circumvented by introducing more structure or constraints on the function class. For example, if we constrain to Fourier-integrable functions, a ν-independent number of $\mathcal{O}(1/\epsilon^2)$ parameters suffice for both classical [74, Theorem 3.9] and quantum [75] machine learning. However, the curse of dimensionality shows that many-variable 1-bounded and 1-Lipschitz functions are not physical [45, 146] because Nature cannot efficiently implement them.

In order to prove Theorem 20, we proceed in three steps. Firstly, we show that the complexity of the function class $\mathcal{F}^{\nu}_{G,A}$ is limited by the number of gates G. Then we prove that to approximate certain functions (1-bounded and 1-Lipschitz functions) well enough, the complexity must not be too small. Finally, we show that to learn a function class from data, the number of samples we need is lower bounded by the complexity of the function class.

1. Circuit complexity and function complexity

The complexity of the function class $\mathcal{F}^{\nu}_{G,A}$, measured by the pseudo-dimension or fat-shattering dimension [178, 179], is limited by the number of trainable gates G and the size of the architecture class A. This is because from the linearity of quantum mechanics, the function $f(x; \{U_i\}, a)$ is a polynomial in the matrix elements of the trainable unitaries $\{U_i\}$, and the degree of this polynomial is limited by G. Following the idea of [72], we formalize this idea into the following lemma.

Lemma 27 (Functions given by G-gate unitaries are bounded degree polynomials)**.** *Let $\mathcal{F}^{\nu}_{G,A}$ be the function class given by an architecture class A of G two-qubit unitaries. Then there exists a set of functions $P^{\nu}_{G,A}$ in $32G + \nu$ real variables with size $|P^{\nu}_{G,A}| = |A|$ such that the following two properties hold.*

1. *$\forall f \in \mathcal{F}^{\nu}_{G,A}$, there exist a $p \in P^{\nu}_{G,A}$ and an assignment of the first $32G$ variables such that p under this assignment is the same as f in the last ν variables;*
2. *Each $p \in P^{\nu}_{G,A}$ depends polynomially on the first $32G$ variables with degree at most $2G$.*

Proof. We begin by noting that for any fixed architecture $a \in A$, the function $f(x, \{U_i\}, a)$ is a function of $32G + \nu$ real variables, where the first $32G = 2 \cdot 2^2 \cdot 2^2 \cdot G$ variables are the real and imaginary parts of the matrix elements of $\{U_i \in U(2^2)\}$, and the last ν variables are the input data $x \in [0, 1]^{\nu}$.

Next, we aim to prove that f is a bounded degree polynomial in the unitary matrix elements. We follow the idea of [72, Lemma 1] and analyze the function $f(x, \{U_i\}, a)$ gate by gate. We note the following fact from linear algebra: for any state $|\psi\rangle$ and matrix U, the product $U|\psi\rangle$ is a state whose amplitudes are linear combinations of the amplitudes of $|\psi\rangle$ and of matrix elements of U. Therefore, by applying $\{U_i\}_{i=1}^{G}$ and other unitaries that do not depend on $\{U_i\}$ sequentially according to the architecture a, we get a state whose amplitude is a polynomial of the matrix elements of $\{U_i\}$ with degree at most G. Hence, the output scalar $\langle 0^n | U(x; \{U_i\}, a)^{\dagger} O U(x; \{U_i\}, a) | 0^n \rangle$ is a polynomial of the matrix elements of $\{U_i\}$ with degree at most $2G$. Fixing those $32G$ variables corresponds to fixing $\{U_i\}$ and thus specifying any particular function in $\mathcal{F}^{\nu}_{G,A}$ with this architecture a. Taking into account the dependence on x and gathering the function for each architecture $a \in A$, we arrive at the desired set of functions $P^{\nu}_{G,A}$ with $|P^{\nu}_{G,A}| = |A|$. □

The fact that these functions are of bounded degree in the variables specifying the trainable unitaries implies an upper bound on pseudo-dimension. We prove this with a reasoning analogous to [180] and [72, Theorem 2].

Proposition 14 (Pseudo-dimension upper bound for functions given by G-gate unitaries)**.** *Let $\mathcal{F}^{\nu}_{G,A}$ be the function class given by an architecture class A of G two-qubit unitaries. Then the pseudo-dimension of $\mathcal{F}^{\nu}_{G,A}$ is at most $128G \log_2(16eG|A|)$.*

Proof. Let $\{(x_i, y_i)\}_{i=1}^{m} \subseteq [0, 1]^{\nu} \times \mathbb{R}$ be a set of data points satisfying that for any $C \subseteq \{1, \dots, m\}$, there exists $f_C \in \mathcal{F}^{\nu}_{G,A}$ such that $f(x_i) - y_i \geq 0$ if and only if $i \in C$. That is, $\{(x_i, y_i)\}_{i=1}^{m}$ is pseudo-shattered by $\mathcal{F}^{\nu}_{G,A}$. From Lemma 27 we know that there exists a set of functions P in $32G + \nu$ real variables with size $|P| = |A|$ such that for every C, there is a $p_C \in P$ and an assignment Ξ_C to the first $32G$ variable that satisfies $p_C(\Xi_C, x_i) - y_i \geq 0$ if and only if $i \in C$. This means that the set of functions $\{p(\cdot, x_i) - y_i : i = 1, \dots, m, p \in P\}$ is a set of $m|A|$ polynomials of degree at most $2G$ in $32G$ real variables that has at least 2^m different consistent sign assignments[3]. Now we invoke the following technical lemma.

Lemma 28 (Bounded degree polynomials have a bounded number of consistent sign assignments, [72, 180, 181])**.** *Let P be a set of real polynomials in v variables with $|P| \geq v$, each of degree at most $D \geq 1$. Then the number of consistent sign assignments to P is at most $(8De|P|/v)^v$.*

[3] A consistent sign assignment to a set of polynomials $p_1, \dots, p_k$ is a vector $b \in \{-1, 0, 1\}^k$ such that there exists a set of input variables $z_1, \dots, z_N \in \mathbb{R}$ such that $\text{sgn}[p_i(z_1, \dots, z_N)] = b_i$ for all $1 \leq i \leq k$.

Thus we have

$$2^m \leq \left(\frac{8 \cdot 2G \cdot em|A|}{32G}\right)^{32G}. \tag{D.6}$$

Taking the logarithm yields

$$m \leq 32G(\log_2(16eG|A|) + \log_2(m/(32G))). \tag{D.7}$$

Let's first assume $m \geq 32G$. If $\log_2(16eG|A|) \geq \log_2(m/(32G))$, then we have $m \leq 64G\log_2(16eG|A|)$. Otherwise, $\log_2(16eG|A|) < \log_2(m/(32G))$ and we have $m \leq 64G\log_2(m/(32G))$, which translates into $\frac{\log_2(m/(32G))}{m/(32G)} \geq \frac{1}{2}$. Thus $m/(32G) \leq 4$ and $m \leq 128G$. In both cases, we have $m \leq 128G\log_2(16eG|A|)$. If $m < 32G$, this is also true. Therefore, we have pseudo-dimension (by definition in Definition 6) at most $128G\log_2(16eG|A|)$. □

A special case is for fixed circuit architecture $|A| = 1$, where we have pseudo-dimension at most $128G\log_2(16eG)$. On the other hand, if we allow variable structure of the trainable unitaries, then $|A| \leq \binom{n}{2}^G \leq n^{2G}$, and we have pseudo-dimension at most $128G\log_2(16eG) + 256G^2\log_2(16eGn)$.

2. Function complexity and approximation power

Now that we know the pseudo-dimension of such function class is upper bounded via the number of gates G, we can derive the minimal number of gates needed to obtain certain function approximation power. Consider the class of 1-bounded and 1-Lipschitz functions on $[0,1]^\nu$, which can be represented by the unit ball $B^{1,\infty}$ in the Sobolev space $W^{1,\infty}_{[0,1]^\nu}$. In order to approximate these functions well, the pseudo-dimension (and also the fat-shattering dimension) of our function class cannot be too small.

Lemma 29 (Pseudo/fat-shattering dimension and approximation power, variant of [179, Theorem 2.10] and [182, Theorem 4])**.** *Let $\epsilon > 0$ and $\mathcal{F} \subseteq \mathbb{R}^{[0,1]^\nu}$ be a class of functions such that for any $f \in B^{1,\infty}$, there is an $h \in \mathcal{F}$ such that $\|f - h\|_\infty < \epsilon$. Then the pseudo-dimension of $\mathcal{F}$ must be at least $1/(4\epsilon)^\nu$. The ϵ-fat-shattering dimension of $\mathcal{F}$ must be at least $1/(8\epsilon)^\nu$.*

Proof. Let $m \in \mathbb{N}$ to be chosen later. Let $x_1, \ldots, x_M \in [0,1]^d$ be $M = (m+1)^\nu$ points on a cubic lattice such that $\|x_i - x_j\| \geq 1/m$ for all $i \neq j$. Let $y \in \mathbb{R}^M$, and we will now construct a smooth function that takes the y values at these lattice points. Specifically, we define

$$f(x) = \sum_{i=1}^{M} y_i \phi(m(x - x_i)), \tag{D.8}$$

where $\phi(z) = \prod_{j=1}^{\nu} \varphi(z_j)$ and φ is a smoothed version of the triangular function that takes value 0 at $|z| \geq 1/2$ and value 1 at $z = 0$ and $|\partial_j \phi(z)| \leq C$ for any $C > 2$. In this way, we have $f(x_i) = y_i$ for all $1 \leq i \leq M$.

Next, for any $\alpha \in \{0,1\}^M$, set $y_i = \alpha_i/(Cm)$. This means that $|y_i| \leq 1/(Cm)$ and thus $f \in B^{1,\infty}$. Then by assumption there must be an $h \in \mathcal{F}$ such that $\|f - h\|_\infty < \epsilon$. In particular, we have $|f(x_i) - h(x_i)| = |y_i - h(x_i)| < \epsilon$ for all i.

Now, for the pseudo-dimension, we can choose m large enough (say, $m = \lfloor 1/(C^2\epsilon) \rfloor$) such that $\epsilon < 1/(2Cm)$. Then

$$h(x_i) \geq \frac{1}{2Cm} \iff \alpha_i = 1, y_i = \frac{1}{Cm}. \tag{D.9}$$

Therefore, by definion in Definition 6, $\{x_1, \ldots, x_M\}$ is pseudo-shattered by $\mathcal{F}$, and thus the pseudo-dimension of $\mathcal{F}$ is at least $M = (m+1)^\nu \geq 1/(C^2\epsilon)^\nu$. Taking the limit $C \to 2$ yields the desired result.

For fat-shattering dimension, we can choose m large enough (say, $m = \lfloor 1/(C^3\epsilon) \rfloor$) such that $\epsilon < 1/(4Cm)$. Then

$$\alpha_i = 1 \implies h(x_i) \geq \frac{1}{Cm} - \epsilon \geq \frac{1}{2Cm} + \epsilon, \tag{D.10}$$

and

$$\alpha_i = 0 \implies h(x_i) \leq \epsilon \leq \frac{1}{2Cm} - \epsilon. \tag{D.11}$$

Therefore, by definion in Definition 7, $\{x_1, \dots, x_M\}$ is ϵ-fat-shattered by $\mathcal{F}$, and thus the ϵ-fat-shattering dimension of $\mathcal{F}$ is at least $M = (m+1)^\nu \geq 1/(C^3\epsilon)^\nu$. Taking the limit $C \to 2$ yields the desired result. □

3. Function complexity and sample complexity

Now we aim to show that in order to learn a function class, the number of samples we need is lower bounded by its complexity. In particular, we achieve this through the fat-shattering dimension.

Proposition 15 (Sample complexity lower bound for real-valued functions by fat-shattering dimension, variant of [73, Theorem 19.5])**.** *Let $\mathcal{F} \subseteq [0,1]^{\mathcal{X}}$ with loss function $l_h(x,y) = l(|h(x)-y|)$. Suppose l is an increasing (almost everywhere) differentiable function, i.e., $C = \inf_{t\geq 1} l'(t) > 0$. For $0 < \epsilon < 1, 0 < \delta \leq 0.01$, the smallest training data size N such that there exists a learning algorithm $H : (\mathcal{X}, [0,1])^N \to \mathcal{F}$ that satisfies*

$$\mathbb{P}_{S\sim P^N}\left\{\mathbb{E}_{(X,Y)\sim P} l(|H[S](X) - Y|) - \inf_{f\in\mathcal{F}} \mathbb{E}_{(X,Y)\sim P} l(|f(X) - Y|) \leq \epsilon\right\} \geq 1-\delta, \tag{D.12}$$

for any probability distribution P over $\mathcal{X} \times [0,1]$ must be at least

$$N \geq C\frac{\mathrm{fat}(\mathcal{F}, \epsilon/\alpha) - 1}{32\alpha}, \quad \forall \alpha \in (0, 1/4). \tag{D.13}$$

Note that this contains L_p loss functions as a special case, where $l_h(x,y) = |h(x)-y|^p$, and $l'(t) = pt^{p-1} \geq p = C$.

Proof. Similarly to the proof of Theorem 19.5 in [73], the idea is to reduce the problem to a discrete classification problem. Consider the class H_d of all functions mapping from a finite set $\{x_1, \dots, x_d\} \subset \mathcal{X}$ to $\{0,1\}$. It's known that any learning algorithm for H_d has sample complexity at least $(d-1)/(32\epsilon)$ for small ϵ, δ ([73, Theorem 5.3]). Here we show that, for any fixed α between 0 and 1/4, any learning algorithm for $\mathcal{F}$ to accuracy ϵ can be used to construct a learning algorithm for H_d to accuracy α/C, where $d = \mathrm{fat}(\mathcal{F}, \epsilon/\alpha)$. Then the proposition follows.

To see this, suppose $\{x_1, \dots, x_d\}$ is ϵ/α-shattered by $\mathcal{F}$, witnessed by $r_1, \dots, r_d$. Suppose L is a learning algorithm for $\mathcal{F}$, then we can construct a learning algorithm for H_d as follows. For each labeled example (x_i, y_i), assuming y_i is deterministic given x_i, the algorithm passes to L the labeled example $(x_i, \tilde{y}_i)$, where $\tilde{y}_i = 2$ if $y_i = 1$ and $\tilde{y}_i = -1$ if $y_i = 0$. Let P be the original distribution on $\mathcal{X} \times \{0,1\}$, and $\tilde{P}$ the induced distribution on $\mathcal{X} \times \{-1, 2\}$. Then suppose L produces a function $f : \mathcal{X} \to [0,1]$, the learning algorithm for H_d then outputs $h : \mathcal{X} \to \{0,1\}$, where $h(x_i) = 1$ if and only if $f(x_i) > r_i$. Thus we only need to prove if $\mathbb{E}_{\tilde{P}} l_f - \inf_{g\in\mathcal{F}} \mathbb{E}_{\tilde{P}} l_g < \epsilon$, then $\mathbb{E}_P 1(h(x) \neq y) \leq \alpha/C$.

To show this, we claim that

$$\inf_{g\in\mathcal{F}} \mathbb{E}_{\tilde{P}} l_g = \inf_{g\in\mathcal{F}} \mathbb{E}_{\tilde{P}} l(|g(x) - \tilde{y}|) \leq \mathbb{E}_{\tilde{P}} \min\{l(|\hat{y} - \tilde{y}|), \hat{y} \in \{r(x) \pm \epsilon/\alpha\}\}, \tag{D.14}$$

where $r(x_i) = r_i$. This is because that $\tilde{P}$ is concentrated on the shattered set. Then for any assignment $\{\hat{y}_i \in \{r_i \pm \epsilon/\alpha\}, i = 1, \dots, d\}$, there exists a $g \in \mathcal{F}$ s.t. $g(x_i) \geq \hat{y}_i$ if $\hat{y}_i = r_i + \epsilon/\alpha$ and $g(x_i) \leq \hat{y}_i$ if $\hat{y}_i = r_i - \epsilon/\alpha$. In particular, we consider the assignment of $\hat{y}_i$ s.t. $l(|\hat{y}_i - \tilde{y}_i|)$ is minimized. Then there exists a function g^* staistifying the following property. If $\tilde{y}_i = -1$, then the minimizer is $\hat{y}_i = r_i - \epsilon/\alpha$, and we have $l(|g^*(x_i) - \tilde{y}_i|) \leq l(|\hat{y} - \tilde{y}_i|)$ since $\tilde{y}_i < g^*(x_i) \leq \hat{y}_i$. Similarly, if $\tilde{y}_i = 2$, then the minimizer is $\hat{y}_i = r_i + \epsilon/\alpha$, and we still have $l(|g^*(x_i) - \tilde{y}_i|) \leq l(|\hat{y} - \tilde{y}_i|)$ since $\hat{y}_i \leq g^*(x_i) \leq \tilde{y}_i$. Therefore, since $\tilde{y}_i$ and y_i is deterministic given x_i, we have found a single g^* s.t. $\mathbb{E}_{\tilde{P}} l(|g^*(x) - \tilde{y}|) \leq \mathbb{E}_{\tilde{P}} \min\{l(|\hat{y} - \tilde{y}|), \hat{y} \in \{r(x) \pm \epsilon/\alpha\}\}$. Hence, the infimum over $g \in \mathcal{F}$ $\inf_{g\in\mathcal{F}} \mathbb{E}_{\tilde{P}} l(|g(x) - \tilde{y}|) \leq \mathbb{E}_{\tilde{P}} l(|g^*(x) - \tilde{y}|) \leq \mathbb{E}_{\tilde{P}} \min\{l(|\hat{y} - \tilde{y}|), \hat{y} \in \{r(x) \pm \epsilon/\alpha\}\}$. Therefore,

$$\mathbb{E}_{\tilde{P}} l_f - \inf_{g\in\mathcal{F}} \mathbb{E}_{\tilde{P}} l_g \geq \mathbb{E}[l(|f(x) - \tilde{y}|) - \min\{l(|\hat{y} - \tilde{y}|), \hat{y} \in \{r(x) \pm \epsilon/\alpha\}\}]. \tag{D.15}$$

Consider the quantity inside the expectation, for $x = x_i$ with $y = 0$, $\tilde{y} = -1$, let $a = f(x_i) + 1, b = r_i - \epsilon/\alpha + 1$. Then by Lagrange's mean value theorem, there exists a c between a and b, such that this quantity can be written as

$$l(a) - l(b) = l'(c)(a-b) = l'(c)(f(x_i) - r_i + \epsilon/\alpha). \tag{D.16}$$

If $l(|f(x)-\tilde{y}|) - \min\{l(|\hat{y}-\tilde{y}|), \hat{y} \in \{r(x) \pm \epsilon/\alpha\}\} < C\epsilon/\alpha$, then

$$f(x_i) - r_i < \frac{\epsilon}{\alpha}\frac{C-l'(c)}{l'(c)} < 0, \tag{D.17}$$

and we have $f(x_i) < r_i$ and $h(x_i) = 0 = y_i$. Similar arguments apply for $y = 1$. Thus,

$$\begin{aligned}
\mathbb{E}_P 1(h(x) \neq y) &\leq \tilde{P}[|f(x)-\tilde{y}|^p - \min\{|\hat{y}-\tilde{y}|^p, \hat{y} \in \{r(x) \pm \epsilon/\alpha\}\} \geq C\epsilon/\alpha] && \text{(D.18)}\\
&\leq \frac{\alpha}{C\epsilon}\mathbb{E}_{\tilde{P}}[|f(x)-\tilde{y}|^p - \min\{|\hat{y}-\tilde{y}|^p, \hat{y} \in \{r(x) \pm \epsilon/\alpha\}\}] && \text{(D.19)}\\
&\leq \frac{\alpha}{C\epsilon}(\mathbb{E}_{\tilde{P}} l_f - \inf_{g\in\mathcal{F}} \mathbb{E}_{\tilde{P}} l_g) \leq \frac{\alpha}{C}. && \text{(D.20)}
\end{aligned}$$

This completes the proof of Proposition 15. □

With Proposition 14, Lemma 29 and Proposition 15, we can finally proceed to prove Theorem 20.

Proof of Theorem 20. To show the gate number lower bound, note that from Proposition 14, $\mathrm{Pdim}(\mathcal{F}^{\nu}_{G,A})$ is upper bounded by $128G\log_2(16eG) + 256G^2\log_2(16eGn)$ for variable circuit structures and by $128G\log_2(16eG)$ for fixed circuit structure. Meanwhile, from Lemma 29, we know that to approximate any ν-variable 1-bounded and 1-Lipschitz functions to ϵ error in $\|\cdot\|_\infty$, we must have $\mathrm{Pdim}(\mathcal{F}^{\nu}_{G,A}) \geq 1/(4\epsilon)^\nu$ and $\mathrm{fat}(\mathcal{F}^{\nu}_{G,A},\epsilon) \geq 1/(8\epsilon)^\nu$. Therefore, for variable circuit structures, we have

$$1/(4\epsilon)^\nu \leq \mathrm{Pdim}(\mathcal{F}^{\nu}_{G,A}) \leq 128G\log_2(16eG) + 256G^2\log_2(16eGn), \tag{D.21}$$

and thus $G \geq \tilde{\Omega}(1/(\epsilon)^{\nu/2})$. Similarly, for fixed circuit structure, we have $G \geq \tilde{\Omega}(1/\epsilon^\nu)$.

To show the sample complexity lower bound, note that from Proposition 15, we have the sample complexity $N \geq C\frac{\mathrm{fat}(\mathcal{F}^{\nu}_{G,A},\epsilon/\alpha)-1}{32\alpha}$. Setting $\alpha = 1/8$ and using the fat-shattering bound from Lemma 29, we arrive at $N \geq \Omega(1/\epsilon^\nu)$. □

Appendix E: Preliminary results on learning brickwork circuits

As stated in the outlook section, an interesting circuit structure is the brickwork circuit, which is generated by repeatedly applying the following two layers of gates (suppose n is even): (1) $U_{1,2}\otimes U_{3,4}\otimes\cdots\otimes U_{n-1,n}$ and (2) $U_{2,3}\otimes U_{4,5}\otimes\cdots\otimes U_{n-2,n-1}$, where $U_{i,j}$ denotes a 2-qubit unitary acting on the ith and jth qubit. Here we utilize the tools from unitary t-designs [120] to prove that the metric entropy of G-gate brickwork circuits is lower bounded by $\Omega(tn)$, if they can implement (approximate) unitary t-designs. Specifically, we have the following result.

Proposition 16 (Metric entropy lower bound of brickwork circuits)**.** *Let $U^{n,\mathrm{brick}}_G \subseteq U(2^n)$ be the set of n-qubit unitaries that can be implemented with G-gate brickwork circuits. Suppose that the uniform distribution over $U^{n,\mathrm{brick}}_G$ forms an ϵ-approximate t-design of $U(2^n)$ for some $\epsilon \in (0,1/2)$. Then we have*

$$\log\mathcal{M}(U^{n,\mathrm{brick}}_G, \mathrm{d}_{\mathrm{avg}}, \epsilon) \geq \Omega(tn). \tag{E.1}$$

Proof. Suppose $U^{n,\mathrm{brick}}_G$ with the uniform distribution forms an ϵ-approximate t-design $\mathcal{E}$ of $U(2^n)$. We begin by recalling a moment bound for approximate unitary designs.

Lemma 30 (Moment bound of approximate unitary designs, [28, proof of Lemma 1])**.** *Suppose $\mathcal{E}$ is an ϵ-approximate unitary t-design of $U(d)$. Then for any unitary $V \in U(d)$, we have*

$$\mathbb{E}_{U\sim\mathcal{E}}\left[|\operatorname{tr}\big(U^\dagger V\big)|^{2t}\right] \leq (1+\epsilon)t!\,. \tag{E.2}$$

Consequently, by Markov's inequality, we have the following lemma saying that a random element of a design is far apart from a fixed unitary with high probability.

Lemma 31. *(Design elements are far away from any fixed unitary). Suppose $\mathcal{E}$ is an ϵ-approximate unitary t-design of $U(d)$. Then for any unitary $V \in U(d)$, we have*

$$\mathbb{P}_{U\sim\mathcal{E}}\left[\|U-V\|_F^2 \leq 2d(1-\Delta)\right] \leq \mathbb{P}_{U\sim\mathcal{E}}\left[|\operatorname{tr}\big(U^\dagger V\big)| \geq d\Delta\right] \leq \frac{1+\epsilon}{\Delta^{2t}}\frac{t!}{d^{2t}}. \tag{E.3}$$

Proof. To prove this, we use the above moment bound and Markov's inequality:

$$\mathbb{P}_{U\sim\mathcal{E}}\left[|\operatorname{tr}(U^\dagger V)| \geq d\Delta\right] = \mathbb{P}_{U\sim\mathcal{E}}\left[|\operatorname{tr}(U^\dagger V)|^{2t} \geq d^{2t}\Delta^{2t}\right] \leq \frac{\mathbb{E}_{U\sim\mathcal{E}}\left[|\operatorname{tr}(U^\dagger V)|^{2t}\right]}{d^{2t}\Delta^{2t}} \leq \frac{1+\epsilon}{\Delta^{2t}}\frac{t!}{d^{2t}}. \tag{E.4}$$

Furthermore, since $\|U-V\|_F^2 = 2d - 2\mathrm{Re}[\operatorname{tr}(U^\dagger V)] \leq 2d(1-\Delta)$ implies $|\operatorname{tr}(U^\dagger V)| \geq \mathrm{Re}[\operatorname{tr}(U^\dagger V)] \geq d\Delta$, Lemma 31 follows. □

Now, we apply a probabilistic argument by randomly choosing M i.i.d. unitaries $U_1, \ldots, U_M$ from $\mathcal{E}$. The probability that any two of them are far away from each other is given by

$$\begin{aligned}
&\mathbb{P}_{U_1,\ldots,U_M\sim\mathcal{E}}[\forall 1 \leq i \neq j \leq M, \|U_i - U_j\|_F^2 \geq 2d(1-\Delta)] && \text{(E.5)}\\
&= 1 - \mathbb{P}_{U_1,\ldots,U_M\sim\mathcal{E}}[\exists 1 \leq i \neq j \leq M, \|U_i - U_j\|_F^2 \leq 2d(1-\Delta)] && \text{(E.6)}\\
&\geq 1 - \sum_{1\leq i\neq j\leq M} \mathbb{P}_{U_1,\ldots,U_M\sim\mathcal{E}}[\|U_i - U_j\|_F^2 \leq 2d(1-\Delta)] && \text{(E.7)}\\
&\geq 1 - \frac{M(M-1)}{2}\frac{1+\epsilon}{\Delta^{2t}}\frac{t!}{d^{2t}} && \text{(E.8)}\\
&\geq 1 - M^2\frac{1+\epsilon}{\Delta^{2t}}\frac{t!}{d^{2t}}, && \text{(E.9)}
\end{aligned}$$

where we have used the union bound in the first inequality and Lemma 31 in the last. Therefore, as long as we take $M < \sqrt{\left\lfloor \frac{\Delta^{2t}}{1+\epsilon}\frac{d^{2t}}{t!}\right\rfloor}$, we have

$$\mathbb{P}_{U_1,\ldots,U_M\sim\mathcal{E}}[\forall 1 \leq i \neq j \leq M, \|U_i - U_j\|_F^2 \geq 2d(1-\Delta)] > 0. \tag{E.10}$$

Hence there must be at least one instance $V_1, \ldots, V_M \in \mathcal{E}$ such that $\|V_i - V_j\|_F^2 \geq 2d(1-\Delta)$ for any pair V_i, V_j. These unitaries form a $\sqrt{2d(1-\Delta)}$-packing net of $U_G^{n,\mathrm{brick}}$ with respect to $\|\cdot\|_F$. Thus we have

$$\log\mathcal{M}(U_G^{n,\mathrm{brick}}, \|\cdot\|_F, \sqrt{2d(1-\Delta)}) \geq \Omega\left(\frac{1}{2}\log\left\lfloor\frac{\Delta^{2t}}{1+\epsilon}\frac{d^{2t}}{t!}\right\rfloor\right). \tag{E.11}$$

If we set $\sqrt{2d(1-\Delta)} = \sqrt{d}\epsilon$ (i.e., $\Delta = 1 - \epsilon^2/2$), we arrive at

$$\log\mathcal{M}(U_G^{n,\mathrm{brick}}, d_F, \epsilon) \geq \Omega(tn). \tag{E.12}$$

From the fact that quotienting out a global phase only changes the metric entropy by an additive $\Omega(\log(1/\epsilon))$ terms (Lemma 10) and the equivalence of d_F' and $\mathrm{d}_{\mathrm{avg}}$ (Lemma 4 Item 1), we arrive at the desired result. □

Learning pure quantum states (almost) without regret

(Dated: July 23, 2024)

We initiate the study of quantum state tomography with minimal regret. A learner has sequential oracle access to an unknown pure quantum state, and in each round selects a pure probe state. Regret is incurred if the unknown state is measured orthogonal to this probe, and the learner's goal is to minimise the expected cumulative regret over T rounds. The challenge is to find a balance between the most informative measurements and measurements incurring minimal regret. We show that the cumulative regret scales as $\Theta(\operatorname{polylog} T)$ using a new tomography algorithm based on a median of means least squares estimator. This algorithm employs measurements biased towards the unknown state and produces online estimates that are optimal (up to logarithmic terms) in the number of observed samples.

1. INTRODUCTION

Quantum state tomography is one of the most fundamental tasks in quantum learning, playing a critical role in the characterization and validation of quantum states. Given t copies of some unknown d-dimensional quantum state ρ, the goal of a quantum state tomography algorithm is to decide which measurements to perform on ρ and use classical post-processing with the outcomes of these measurements to produce an estimate $\hat{\rho}$ that is close to ρ in some distance metric. Two of the most relevant distances for this task are the trace distance and infidelity. The sample complexity of this problem (i.e., how many copies are sufficient to estimate ρ up to some precision on these distances) is well understood for both coherent measurements (allowing for joint measurements on multiple copies of the state) and incoherent measurements (only allowing measurements on single copies of the state) [9, 13, 23, 27].

For incoherent measurements, the most general algorithms are adaptive. Such algorithms can sequentially measure copies of ρ, deciding which measurement to perform based on the outcomes of the previous measurements. While adaptive algorithms are strictly more general than non-adaptive ones, it was early understood [4, 5, 11] that there is no separation in sample complexity when learning pure quantum states. Recently, it was shown in [9] that there is no separation in sample complexity between adaptive and non-adaptive algorithms for trace distance when learning both mixed and pure quantum states. The only regime where adaptive algorithms outperform non-adaptive ones is when learning "almost" pure quantum states [5, 15, 21]. For non-adaptive algorithms it was known that the rate $\Omega(1/\sqrt{t})$ is unavoidable [13]; however, in [9] they constructed an adaptive algorithm that achieves the rate $O(1/t)$ both for mixed and pure states.

In this work we take a different perspective on the adaptive incoherent setting of quantum state tomography, where we not only try to learn the state efficiently but also use measurements that only minimally disturb the state. Specifically, we have sequential access to an unknown pure quantum state $|\psi\rangle$ and at each round t we select a probe state $|\psi_t\rangle$ and perform a measurement in the direction of the probe state. The goal is to efficiently learn the unknown state while performing measurements that align well with the unknown state. Mathematically, this problem can be modelled as a bandit problem [17] since fundamentally we are interested in optimising an exploration–exploitation trade-off. The "exploration–exploitation" is one of the most fundamental concepts in reinforcement learning and decision-making captured by the bandit framework and the rigorous study was initiated almost one century ago in the early work by Thompson [26]. In our setting the exploration is related to the learning of the unknown state $|\psi\rangle$ through the selection of probes that are sufficiently informative, and the exploitation to performing measurements on the direction of $|\psi\rangle$.

Formally the measurements on the direction of the probe $|\psi_t\rangle$ are described by a two outcome rank-1 POVM $\{\Pi_t, \mathbb{I} - \Pi_t\}$ with corresponding outcomes $r_t \in \{1, 0\}$ and $\Pi_t = |\psi_t\rangle\langle\psi_t|$. In order to quantify the penalty that the learner suffers for selecting probes that are orthogonal to the unknown state we use as a figure of merit the regret, which is defined as

$$\mathrm{Regret}(T) = \sum_{t=1}^{T} 1 - \langle\psi|\Pi_t|\psi\rangle, \tag{1}$$

where $F(\Pi, \Pi_t) = \langle\psi|\Pi_t|\psi\rangle$ is the fidelity between the environment $\Pi = |\psi\rangle\langle\psi|$ and the selected probe $\Pi_t = |\psi_t\rangle\langle\psi_t|$ at time step $t \in [T]$. It is important to note that the regret is defined as the cumulative sum of infidelities $\gamma_t = 1 - \langle\psi|\Pi_t|\psi\rangle$, which means that there is a high penalty for measuring on directions orthogonal to the environment. The goal of the learners is to minimise the regret and we can frame this task as pure quantum state tomography with minimal regret since minimizing the individual contributions to the regret $1 - \langle\psi|\Pi_t|\psi\rangle$ implies finding Π_t close to Π in infidelity distance.

We note that the task of minimizing the regret (1) is captured by the multi-armed quantum bandit (MAQB) framework initiated in [6, 19], where some of the present authors consider the exploration–exploitation trade-off when learning properties of quantum states using classical algorithms. The work [19] considers a more general problem where the environment can be mixed or pure and the measurements are not only restricted to rank-1 projectors. They showed that for almost all cases the regret suffers a square root lower bound $\mathrm{Regret}(T) = \Omega(\sqrt{T})$ in a worst-case scenario. However, this bound does not apply to our case and the reason is due to the noise model of the outcomes given by Born's rule. For our particular model Born's rule gives that the outcomes become more deterministic as $|\psi_t\rangle$ gets close to $|\psi\rangle$ and the lower bounds considered in [20] rely on the fact that the variance of the outcomes r_t can not get arbitrary close to deterministic. Since our problem is closely related to the MAQB problem we name it pure state multi-armed quantum bandit (PSMAQB) and we use it to study the following questions at the intersection of the fields of quantum state tomography and linear stochastic bandits.

- **Question 1.** Can we perform single copy sample-optimal state tomography in infidelity and achieve at the same time sublinear regret? How much adaptiveness is needed for this task?

It is important to note that adaptiveness plays a huge role for algorithms that try to minimise the regret of the PSMAQB problem and peform sample-optimal state tomography. We could try to adapt one of the existing sample-optimal algorithms in the incoherent setting such as [12, 13, 16] for the PSMAQB problem but since all these algorithms use fixed basis or randomized measurements this will lead inevitably to the linear scaling $\mathrm{Regret}(T) = O(T)$ (we omit dimensional dependences). In [19] a simple algorithm with one round of adaptiveness was proposed for the PSMASQ problem that achieves $\mathrm{Regret}(T) = O(\sqrt{T})$ but gives the infidelity scaling $\gamma_t = O(1/\sqrt{T})$. Thus, it is interesting to see how adaptiveness can help in order to keep $\gamma_t = O(1/T)$ and at the same time achieve a sublinear regret.

For the qubit case we can relate the PSMAQB problem to a linear bandit with the action set being the unit sphere $\mathbb{S}^2 = \{x \in \mathbb{R}^3 : \|x\|_2 = 1\}$ and this motivates the following question that is related to fundamental bounds for linear stochastic bandits with continuous action sets.

- **Question 2.** Can we break the square root barrier of the regret for the PSMAQB problem?

In [19] it was shown that the MAQB problem can be reduced to a classical linear stochastic bandit problem [17, Chapter 19] and that we can adapt algorithms such as LinUCB [1, 10, 24] or linear Thompson sampling [2, 3] to achieve $\mathrm{Regret}(T) = \widetilde{O}(\sqrt{T})$, where we omit the dependency on the Hilbert space dimension. Classically, it is well known that linear bandits with smooth action sets such as the unit sphere have a lower bound of $\mathrm{Regret}(T) = \Omega(\sqrt{T})$ [24] [17, Chapter 24] and in particular if the unknown state is mixed the same bound applies to the quantum setting [19]. However, from [19] a lower bound for the PSMAQB problem is missing and this opens the possibility to achieve a better scaling than the $\sqrt{T}$ given by the standard classical bandit algorithms. Achieving a better scaling on the time horizon T for the PSMAQB would imply the first non-trivial linear stochastic bandit with continuous action sets that breaks the square root barrier. Breaking the square root barrier will require new algorithms and techniques that take advantage of the extra structure of the PSMAQB problem.

2. RESULTS AND TECHNICAL CONTRIBUTION

In this work, we provide affirmative answers at the same time to Questions 1 and 2 through the following Theorem.

Theorem 1 (informal)**.** *Given a PSMAQB with an unknown qubit environment $\Pi = |\psi\rangle\langle\psi|$, we can find an algorithm that achieves*

$$\mathbb{E}\left[\mathrm{Regret}(T)\right] = O\big(\log^2(T)\big). \tag{2}$$

Also, at each time step $t \in [T]$, this strategy outputs an estimator Π_t of Π with infidelity scaling

$$\mathbb{E}\left[1 - F\left(\Pi, \Pi_t\right)\right] = \widetilde{O}\left(\frac{1}{t}\right). \tag{3}$$

The above results also hold with high probability.

The proof of Theorem 1 is constructive which means that we design a qubit quantum state tomography algorithm and perform the theoretical analysis for it. The exact algorithm and Theorem can be found in Sections 4 and 5. We note that our algorithm is almost fully adaptive since it uses $O(T/\log(T))$ rounds of adaptiveness. Intuitively, our algorithm needs to be almost fully adaptive because keeping the scaling $1 - F(\Pi, \Pi_t) = O(1/t)$ and breaking the square root regret barrier implies that we want to update our measurements Π_t at each round to get as close as possible to Π. We say that our algorithm is "online" because it is able to output at each time step $t \in [T]$ an estimator with the almost optimal infidelity scaling (3). We provide numerical experiments in Section 5. Now we sketch the main idea of how our algorithm updates the measurements.

1. **Estimation.** At each time step $t \in [T]$ we use the past information of measurements $\Pi_{a_1}, ..., \Pi_{a_{t-1}}$ and associated outcomes $r_1, ..., r_{t-1} \in \{0,1\}^{\otimes t-1}$ to build a high probability confidence region $\mathcal{C}_t$ for the unknown environment $|\psi\rangle$.

2. **Exploration-exploitation.** A batch of measurements is performed, given by the directions of maximum uncertainty of $\mathcal{C}_t$ such that they give enough information to construct $\mathcal{C}_{t+1}$ (exploration) and also minimise the regret (1) (exploitation).

For the estimation part, we work with the Bloch sphere representation of the unknown state $\Pi = |\psi\rangle\langle\psi| = \frac{I+\theta\cdot\sigma}{2}$ where $\theta \in \mathbb{S}^2$ and for σ we can take the standard Pauli Basis i.e $\sigma = (\sigma_x, \sigma_y, \sigma_z)$. For each action Π_{a_t}, our algorithm performs k independent measurements using the same action, and it builds the following k online weighted least squares estimators of θ,

$$\widetilde{\theta}_{t,i} = V_t^{-1} \sum_{s=1}^{t} \frac{1}{\hat{\sigma}_s^2(a_s)} r_{s,i} a_s \quad \text{for } i \in [k], \tag{4}$$

where $r_{s,i} \in \{0,1\}$ is the outcome of the measurement (up to some renormalization) using the projector Π_{a_s} with Bloch vector $a_s \in \mathbb{S}^2$, $V_t = \mathbb{I} + \sum_{s=1}^{t} \frac{1}{\hat{\sigma}_s^2(a_s)} a_s a_s^{\mathsf{T}}$ is the design matrix and $\hat{\sigma}_s^2(a_s)$ is a variance estimator of the real variance associated to the outcome r_s. The key point where we take advantage from the structure of the PSMAQB problem is that the variance of the outcome r_a associated to the action Π_a can be bounded as $\mathbb{V}[r_a] \leq 1 - \mathrm{Tr}(\Pi\Pi_a)$. The idea is that through a careful choice of actions we can make the terms $1/\hat{\sigma}_s^2(a_s)$ arbitrarily large and "boost" the confidence on the directions a_s in the estimators (4) that are close to θ. However, this comes at a price, and is that in order to get good concentration bounds for our estimator we need to deal with unbounded random variables and finite variance. We address this issue using the new ideas of median of means (MoM) for online least squares estimators introduced in [7, 22, 25]. The construction takes inspiration from the old method of median of means [18, Chapter 3] for real random variables with unbounded support and bounded variance but requires non-trivial adaptation for online linear least squares estimators. Similarly to the real case we use the k independent estimators (4) in order to construct the MoM estimator $\widetilde{\theta}_t^{\text{wMoM}}$ such that we can build a confidence region with concentration bounds scaling as $1 - \exp(-k)$. We give the exact construction in Section 4.1.

For the exploration-exploitation part, we take the ideas that we develop in [20]. We give the precise action choice in Section 4.2, and here we sketch the main points. We take inspiration from the optimistic principle for bandit algorithms which in short tells us to choose the most rewarding actions with the available information. In order to use this idea, we use the confidence region that we build in the estimation part and we select measurements that align with the (unknown) direction of Π. See Figure 1. Our algorithm also achieves the relation $1 - F(\Pi, \Pi_{a_t}) = O\left(1/\lambda_{\min}(V_t)\right)$, where $\lambda_{\min}(V_t)$ quantifies the direction of maximum uncertainty (exploration) of our estimator. The maximum eigenvalue $\lambda_{\max}(V_t)$ quantifies the amount of exploitation. We can relate these two concepts through the Theorem we formally state and prove in [20, Theorem 3], which states that for our particular action selection choice we have $\lambda_{\min}(V_t) = \Omega(\sqrt{\lambda_{\max}(V_t)})$. Using this relation and a careful analysis, we can show that $\lambda_{\max}(V_t) = \Omega(t^2)$ which gives $\lambda_{\min}(V_t) = \Omega(t)$ and the scaling $1 - F(\Pi, \Pi_{a_t}) = O(1/t)$. We emphasize that the key point that allows to achieve the rate $\lambda_{\min}(V_t) = \Omega(t)$ is the fact that the variance estimators $\hat{\sigma}_s^2$ can get as close as possible to zero since the variance of the rewards of the PSMAQB problems goes to zero if we select measurements close to Π. To check the optimality of the regret, we derive a minimax expected regret lower bound based on the optimal quantum state tomography for pure state results in [14]. The proof does not follow directly from [14], and we have to adapt it to the bandit setting.

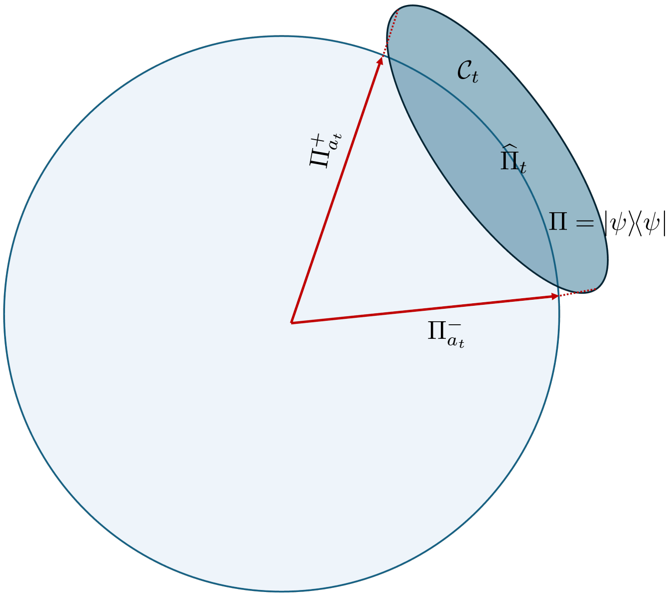

FIG. 1. The algorithm at each time step outputs an estimator $\widehat{\Pi}_t$ and builds a high-probability confidence region $\mathcal{C}_t$ (shaded region) around the unknown state $\Pi = |\psi\rangle\langle\psi|$ on the Bloch sphere representation. Then uses the optimistic principle to select projectors $\Pi_{a_t}^{\pm}$ that are close the unknown state Π projecting into the Bloch sphere the extreme points of the largest principal axis of $\mathcal{C}_t$. This particular choice allows optimal learning of Π (exploration) and simultaneously minimizes the regret (exploitation).

Theorem 2 (informal)**.** *Given a PSMAQB with a qubit environment, the cumulative expected regret for any strategy is bounded by*

$$\mathbb{E}\left[\mathrm{Regret}(T)\right] = \Omega(\log T), \tag{5}$$

where the expectation is taken over the probability distribution of rewards and actions induced by the learner strategy and also uniformly over the set of pure state environments.

This result is formally derived in Section 6. There it is also generalized to the d-dimensional PSMAQB, in which case the bound is given by $\mathbb{E}\left[\mathrm{Regret}(T)\right] = \Omega(d\log(T/d))$. The proof relies on the fact that individual actions of a strategy at time $t \in [T]$ can be viewed as quantum state tomographies using t copies of the state. A relation between the fidelity of these tomographies and the regret of the strategy allows us to convert the fidelity upper bound from [14] to a regret lower bound. We use measure-theoretic tools to adapt the proof from [14] to a more general case where the tomography can output an arbitrary distribution of states. We remark that this is a noteworthy result since in [20] they argue how regret lower bound techniques for classical linear bandits fail for noise models with vanishing variance.

3. THE MODEL

In this section first we formally state the PSMAQB problem and make a connection with a linear stochastic bandit problem. Then we define a slightly more general model where the key feature is that the variance of the rewards vanishes with the same behaviour as the PSMAQB problem.

3.1. Notation

First, we introduce some basic notation and conventions. Let $[t] = \{1, 2, ..., t\}$ for $t \in \mathbb{N}$. For real vectors $x, y \in \mathbb{R}^d$ we denote their inner product as $\langle x, y \rangle = x_1 y_1 + ... + x_d y_d$. Given a real vector $x \in \mathbb{R}^d$ we denote the 2-norm as $\|x\|_2$ and for a real semi-positive definite matrix $A \in \mathbb{R}^{d\times d}$, $A \geq 0$ the weighted norm with A as $\|x\|_A^2 = \langle x, Ax \rangle$. The set corresponding to the surface of the unit sphere is $\mathbb{S}^{d-1} = \{x \in \mathbb{R}^d : \|x\|_2 = 1\}$. For a real symmetric matrix $A \in \mathbb{R}^{d\times d}$ we denote $\lambda_{\max}(A)$, $\lambda_{\min}(A)$ its maximum and minimum eigenvalues respectively. We use the ordering $\lambda_{\min}(A) \leq \lambda_2(A), ..., \lambda_{d-1}(A) \leq \lambda_{\max}(A)$ for the i-th $\lambda_i(A)$ eigenvalue in increasing order. For a random variable X (discrete or continuous) we denote $\mathbb{E}[X]$ and $\mathbb{V}[X]$ its expectation value and variance respectively. A random variable X is *σ-subgaussian* if $\forall \lambda \in \mathbb{R}, \mathbb{E}\left[\exp(\lambda X)\right] \leq \exp\left(\lambda^2\sigma^2/2\right)$.

Let $\mathcal{S}_d = \{\rho \in \mathbb{C}^{d\times d} : \mathrm{Tr}(\rho) = 1, \rho \geq 0\}$ be the set of *quantum states* in a d-dimensional Hilbert space $\mathcal{H} = \mathbb{C}^d$ and $\mathcal{S}_d^* = \{\rho \in \mathcal{S}_d : \rho^2 = \rho\}$ the set of *pure states* or rank-1 projectors. We will use the parametrization given in [8] of a d-dimensional quantum state $\rho_\theta \in \mathcal{S}_d$,

$$\rho_\theta = \frac{\mathbb{I}}{d} + \left(\sqrt{\frac{d(d-1)}{2d^2}}\right)\theta \cdot \sigma \tag{6}$$

where $\theta \in \mathbb{R}^{d^2-1}$, and $\sigma = (\sigma_1, ..., \sigma_{d^2-1})$ is a vector of orthogonal, traceless, Hermitian matrices with the normalization condition $\mathrm{Tr}(\sigma_i\sigma_j) = 2\delta_{i,j}$. We will use the subscript θ in the quantum state ρ_θ in order to denote the vector of the parametrization (6). In particular the normalization is taken such that $\|\theta\|_2^2 \leq 1$ with equality if ρ_θ is pure. Note that the parametrization enforces $\rho_\theta^\dagger = \rho_\theta$ and $\mathrm{Tr}(\rho_\theta) = 1$. Also there are some extra conditions on the vector θ regarding the positivity of the density matrix ρ_θ but we will not use them. For two quantum states $\rho, \sigma \in \mathcal{S}_d$ the fidelity is $F(\rho, \sigma) = \left(\mathrm{Tr}(\sqrt{\sqrt{\sigma}\rho\sqrt{\sigma}})\right)^2$ and the infidelity $1 - F(\rho, \sigma)$. For a Hilbert space $\mathcal{H}$, the set of linear operators on it will be denoted by $\mathrm{End}(\mathcal{H})$. The joint state of a system consisting of n copies of a pure state $\Pi_\theta \in \mathcal{S}_d^*$ is given by the n-th tensor power $\Pi_\theta^{\otimes n} \in \mathrm{End}(\mathcal{H}^{\otimes n})$. Using Dirac notation, we can express $\Pi_\theta = |\psi_\theta\rangle\langle\psi_\theta|$ for some normalized $|\psi_\theta\rangle \in \mathcal{H}$. Then, the span of all n-copy states of the form $|\psi_\theta\rangle^{\otimes n}$ is called the symmetric subspace of $\mathcal{H}^{\otimes n}$, denoted by $\mathcal{H}_+^{\otimes n}$. Its dimension is $D_n = \binom{n+d-1}{d}$. The symmetrization operator $\Pi_n^+ \in \mathrm{End}(\mathcal{H}^{\otimes n})$ is the projector onto $\mathcal{H}_+^{\otimes n}$.

3.2. Multi-armed quantum bandit for pure states

The model that we are interested in is the general multi-armed quantum bandit model described in [19][Section 2.3] with the action set being all rank-1 projectors and with pure state environments. For completeness, we state the basic definitions for this particular case.

Definition 3. *Let $d \in \mathbb{N}$. A d-dimensional pure state multi-armed quantum bandit (PSMAQB) is given by a measurable space $(\mathcal{A}, \Sigma)$, where $\mathcal{A} = \mathcal{S}_d^*$ is the action set and Σ is a σ-algebra of subsets of $\mathcal{A}$. The bandit is in an environment, a quantum state $\Pi_\theta \in \mathcal{S}_d^*$, that is unknown.*

The interaction with the PSMAQB is done by a learner that interacts sequentially over $t \in [T]$ rounds with the unknown environment $\Pi_\theta \in \mathcal{S}_d^*$. At each time step $t \in [T]$:

1. The learner selects an action $\Pi_{a_t} \in \mathcal{A}$.

2. Performs a measurement on the unknown environment Π_θ using the two-outcome POVM

$\{\Pi_{a_t}, I_{d\times d} - \Pi_{a_t}\}$ and receives a reward $r_t \in \{0,1\}$ sampled according to the Born's rule, i.e

$$\Pr_{\Pi_\theta}(r_t|\Pi_{a_t}) = \begin{cases} \mathrm{Tr}(\Pi_\theta \Pi_{a_t}) & r_t = 1, \\ 1 - \mathrm{Tr}(\Pi_\theta \Pi_{a_t}) \quad \text{if} & r_t = 0, \\ 0 \quad \text{else.} \end{cases} \tag{7}$$

We note that the reward at time step t after selecting $\Pi_{a_t} \in \mathcal{A}$ can be written as

$$r_t = \mathrm{Tr}(\Pi_\theta \Pi_{a_t}) + \epsilon_t, \tag{8}$$

where ϵ_t is a Bernoulli random variable with values $\epsilon_t \in \{1 - \mathrm{Tr}(\Pi_\theta \Pi_{a_t}), -\mathrm{Tr}(\Pi_\theta \Pi_{a_t})\}$ such that

$$\mathbb{E}\left[\epsilon_t|\mathcal{F}_{t-1}\right] = 0, \quad \mathbb{V}\left[\epsilon_t|\mathcal{F}_{t-1}\right] = \mathrm{Tr}(\Pi_\theta \Pi_{a_t})\left(1 - \mathrm{Tr}(\Pi_\theta \Pi_{a_t})\right), \tag{9}$$

where $\mathcal{F}_{t-1} := \{r_1, \Pi_{a_1}, ..., r_{t-1}, \Pi_{a_{t-1}}, \Pi_t\}$ is a σ-filtration.

Formally the learner is described by a policy.

Definition 4. *A policy π is a set of conditional probability measures $\{\pi_t\}_{t\in\mathbb{N}}$ on the action set $\mathcal{A}$ of the form*

$$\pi_t(\cdot|r_1, \Pi_{a_1}, ..., r_{t-1}, \Pi_{a_{t-1}}) : \Sigma \to [0,1]. \tag{10}$$

Then the policy interacting with the environment Π_θ defines the probability measure over the set of actions and rewards $P_{\Pi_\theta,\Pi} : (\Sigma \times \{0,1\})^{\times T} \to [0,1]$ as

$$\int \cdots \int \Pr_{\Pi_\theta}(r_T|\Pi_{a_T})\, \pi_T(d\Pi_T|r_1, \Pi_{a_1}, ..., r_{T-1}, \Pi_{a_{T-1}}) \cdots \Pr_{\Pi_\theta}(r_1|\Pi_{a_1})\, \pi_1(d\Pi_{a_1}), \tag{11}$$

where the integrals are taken with respect to the corresponding subsets of actions.

The goal of the learner is to maximize the cumulative expected reward. This is quantified by the notion of regret that serves to compare with the best possible choice of action.

Definition 5. *Given a d-dimensional pure state multi-armed quantum bandit, a policy π and $T \in \mathbb{N}$, the cumulative regret is defined as*

$$\mathrm{Regret}(T, \pi, \Pi_\theta) := \sum_{t=1}^{T} 1 - \mathrm{Tr}(\Pi_\theta \Pi_{a_t}). \tag{12}$$

We note that since the quantity $\max_{\Pi\in\mathcal{A}} \mathrm{Tr}(\Pi_\theta \Pi)$ is maximized by $\Pi = \Pi_\theta$, then $1 = \max_{\Pi\in\mathcal{A}} \mathrm{Tr}(\Pi_\theta \Pi)$ is the maximal expected reward and the above definition quantifies how close is the chosen action to the unknown Π_θ. Moreover, expressing $\Pi_\theta = |\psi_\theta\rangle\langle\psi_\theta|$, $\Pi_{a_t} = |\psi_{a_t}\rangle\langle\psi_{a_t}|$ for normalized complex vectors $|\psi_\theta\rangle, |\psi_{a_t}\rangle \in \mathbb{C}^d$ we have

$$\mathrm{Regret}(T, \pi, \Pi_\theta) = \sum_{t=1}^{T} 1 - F(\Pi_\theta, \Pi_{a_t}) = \sum_{t=1}^{T} 1 - |\langle\psi_\theta|\psi_{a_t}\rangle|^2, \tag{13}$$

and the term $1 - |\langle\psi_\theta|\psi_{a_t}\rangle|^2$ is the infidelity between the pure quantum states $|\psi_\theta\rangle$ and $|\psi_{a_t}\rangle$.

The goal of the learner is to minimize the *expected cumulative regret* that is simply defined as $\mathbb{E}_{\Pi_\theta}[\mathrm{Regret}(T, \pi, \Pi_\theta)]$ where the expectation $\mathbb{E}_{\Pi_\theta}$ is taken over the probability measure (11). When the context is clear, we will use the notation $\mathrm{Regret}(T)$. We refer to the PSMAQB problem as the task of finding a policy that minimizes the expected regret $\mathbb{E}_{\Pi_\theta}[\mathrm{Regret}(T, \pi, \Pi_\theta)]$. Minimizing the regret means achieving sublinear regret on T since $\mathrm{Regret}(T) \le T$ holds for any policy.

3.3. Classical model

In order to study the PSMAQB it is helpful to study it using the linear stochastic bandit framework. The idea will be to express the actions and unknown quantum states as real vectors using the parametrization (6).

In the linear stochastic bandit model, the action set is a subset of real vectors i.e $\mathcal{A} \subseteq \mathbb{R}^d$, and the reward at time step $t \in [T]$ after selecting action $a_t \in \mathcal{A}$ is given by

$$r_t = \langle a_t, \theta \rangle + \epsilon_t \tag{14}$$

where $\theta \in \mathbb{R}^d$ is the unknown parameter and ϵ_t is some bounded $\sigma-$subgaussian noise that in general can depend on θ and a_t. The regret for this model is given by

$$\text{Regret}_{cl}(T, \pi, \theta) := \sum_{t=1}^{T} \max_{a \in \mathcal{A}} \langle \theta, a \rangle - \langle \theta, a_t \rangle, \tag{15}$$

where the policy π is defined analogously to Definition 4. We used the subscript *cl* to differentiate between quantum and classical model.

In order to express the PSMAQB model as a linear stochastic bandit we can use the parametrization (6) and express the expected reward for action $\Pi_{a_t} \in \mathcal{S}_d^*$ as

$$\text{Tr}(\Pi_{a_t}\Pi_\theta) = \frac{1}{d}\left(1 + (d-1)\langle a_t, \theta \rangle\right). \tag{16}$$

Inverting the above expression we have

$$\langle a_t, \theta \rangle = \frac{d\,\text{Tr}(\Pi_\theta \Pi_{a_t}) - 1}{d-1}. \tag{17}$$

Let's quickly revisit the regret expression and use the above identities in order to connect the quantum and classical versions of the regret. We denote $\Pi_{a^*} = \text{argmax}_{\Pi \in \mathcal{A}} \text{Tr}(\Pi\Pi_\theta)$ the optimal action and recall that $1 = \text{Tr}(\Pi_{a^*}\Pi_\theta)$. Then we have

$$\text{Regret}(T, \pi, \Pi_\theta) = \sum_{t=1}^{T} \text{Tr}(\Pi_{a^*}\Pi_\theta) - \text{Tr}(\Pi_{a_t}\Pi_\theta) = \frac{d-1}{d}\sum_{t=1}^{T}\langle \theta, a^* - a_t \rangle. \tag{18}$$

Note that by the normalization (6) we have that for ρ_θ and Π_{a_t} the corresponding real vecotrs are normalized $\|\theta\|_2 = \|a_t\| = 1$. Thus, since $a^* = \theta$ the regret can be written as

$$\text{Regret}(T, \pi, \Pi_\theta) = \frac{d-1}{d}\sum_{t=1}^{T}\left(1 - \langle \theta, a_t \rangle\right) = \frac{d-1}{2d}\sum_{t=1}^{T}\|\theta - a_t\|_2^2. \tag{19}$$

Now we want to formulate a classical bandit such that the environment and actions are given by the real vectors that parameterize the quantum states (6). In order to have an expected linear reward that is linear with respect to θ and a_t it is sufficient to define a renormalized reward as

$$\tilde{r}_t = \frac{dr_t - 1}{d-1} \in \left\{1, \frac{-1}{d-1}\right\}, \tag{20}$$

where we used the reward of the quantum model $r_t \in \{0, 1\}$ given by 7. Using $\mathbb{E}[r_t|\mathcal{F}_{t-1}] = \text{Tr}(\Pi_{a_t}\rho_\theta)$ and (16) it is easy to see that

$$\mathbb{E}[\tilde{r}_t|\mathcal{F}_{t-1}] = \langle \theta, a_t \rangle, \tag{21}$$

where naturally we use $\mathcal{F}_{t-1} = \{\tilde{r}_1, a_1, ..., \tilde{r}_{t-1}, a_{t-1}, a_t\}$. Thus, we can write the reward in the form (14)

$$\tilde{r_t} = \langle\theta, a_t\rangle + \epsilon_t, \quad \mathbb{E}[\epsilon_t|\mathcal{F}_{t-1}] = 0, \quad \mathbb{V}[\epsilon_t|\mathcal{F}_{t-1}] = (1 - \langle\theta, a_t\rangle)\left(1 + (d-1)\langle\theta, a_t\rangle\right), \tag{22}$$

where the expectation and variance follow from a direct calculation. Then we can study a d-dimensional PSMAQB as a linear stochastic bandit choosing the action set

$$\mathcal{A}_d^{\text{quantum}} := \{a \in \mathbb{R}^{d^2-1} : \Pi_a \in \mathcal{S}_d^*\} \tag{23}$$

with unknown parameter $\theta \in \mathbb{R}^{d^2-1}$ such that $\Pi_\theta \in \mathcal{S}_d^*$. The regret of this linear model is given by $\text{Regret}_{cl} = \frac{1}{2}\sum_{t=1}^{T} \|\theta - a_t\|_2^2$ and we have the following relation with the quantum model:

$$\text{Regret}(T, \pi, \Pi_\theta) = \frac{d-1}{d}\text{Regret}_{cl}(T, \pi, \theta), \tag{24}$$

where we take the same strategy π in both sides since we can identify the actions of both bandits through the parametrization (6) and the relation between rewards given by (20). When the context is clear we will simply use Regret(T) for both quantum and classical model.

3.4. Linear bandit with linearly vanishing variance noise

In [20] some of the present authors introduced the framework of stochastic linear bandits with linear vanishing noise where the setting is a linear bandit with action set $\mathcal{A} = \mathbb{S}^d$, unknown parameter $\theta \in \mathbb{S}^d$ and reward $r_t = \langle\theta, a_t\rangle + \epsilon_t$ such that ϵ_t is σ_t-subgaussian with $\mathbb{E}[\epsilon_t|\mathcal{F}_{t-1}] = 0$ and the property of vanishing noise $\sigma_t^2 \leq 1 - \langle\theta, a_t\rangle^2$. In order to study a PSMAQB we will relax the condition on the subgaussian noise and we will replace it by the following condition on the noise

$$\mathbb{E}\left[\epsilon_t|\mathcal{F}_{t-1}\right] = 0, \quad \mathbb{V}\left[\epsilon_t|\mathcal{F}_{t-1}\right] \leq 1 - \langle\theta, a_t\rangle^2. \tag{25}$$

As in the classical model of the previous section using that $\max_{a\in\mathcal{A}}\langle\theta, a\rangle = 1$ we have that the regret is given by

$$\text{Regret}(T) = \sum_{t=1}^{T} 1 - \langle\theta, a_t\rangle = \frac{1}{2}\sum_{t=1}^{T} \|\theta - a_t\|_2^2. \tag{26}$$

We note that finding an strategy that minimizes regret for the above model will also work for a $d = 2$ PSMAQB with unknown $\Pi_\theta \in \mathcal{S}_2^*$ using the relations of last sections since

$$\mathcal{A}_2^{\text{quantum}} = \{a \in \mathbb{R}^3 : \|a\|_2 = 1\} = \mathbb{S}^2, \tag{27}$$

and the variance of the PSMAQB (22) fullfills the relation (25).

4. ALGORITHM FOR BANDITS WITH LINEARLY VANISHING VARIANCE NOISE

In this Section we are going to present an algorithm for the linear bandit model explained in Section 3.4 that is based on the algorithm LINUCB-VN studied in [20] for linear bandits with linearly vanishing noise. Later we will show how to use this algorithm for the qubit PSMAQB problem.

4.1. Median of means for an online least squares estimator

First we discuss the medians of means method for the online linear least squares estimator introduced in [25]. We are going to use this estimator later in order to design a strategy that minimizes the regret for the model introduced in Section 3.4. The reason we need this estimator is that in the analysis of our algorithm we need concentration bounds for linear least squares estimators where the random variables have bounded variance and a possibly unbounded subgaussian parameter. The condition of bounded variance is weaker than the usual assumption of bounded subgaussian noise, however we can recover similar concentration bounds of the estimator if we implement a median of means.

In order to build the median of means online least squares estimator for linear bandits we need to sample k independent rewards for each action. Specifically given an action set $\mathcal{A} \subset \mathbb{R}^d$, an unknown parameter $\theta \in \mathbb{R}^d$, at each time step t we select an action $a_t \in \mathcal{A}$ and sample k independent rewards using a_t where the outcome rewards are distributed as

$$r_{t,i} = \langle \theta, a_t \rangle + \epsilon_{t,i} \quad \text{for } i \in [k], \tag{28}$$

for some noise such that $\mathbb{E}[\epsilon_{t,i}|\mathcal{F}_{t-1}] = 0$. We refer to k as the number of subsamples per time step. Then at time step t we define k least squares estimators as

$$\widetilde{\theta}_{t,i} = V_t^{-1} \sum_{s=1}^{t} r_{s,i} a_s \quad \text{for } i \in [k], \tag{29}$$

where V_t is the design matrix defined as

$$V_t = \lambda \mathbb{I} + \sum_{s=1}^{t} a_s a_s^{\mathsf{T}}, \tag{30}$$

with $\lambda > 0$ being a parameter that ensures invertibility of V_t. We note that the design matrix is independent of i. Then the median of means for least squares estimator (MOMLSE) is defined as

$$\widetilde{\theta}_t^{\text{MoM}} := \tilde{\theta}_{t,k^*} \quad \text{where } k^* = \operatorname*{argmin}_{j \in [k]} y_j, \tag{31}$$

where

$$y_j = \text{median}\{\|\tilde{\theta}_{t,j} - \tilde{\theta}_{t,i}\|_{V_t} : i \in [k]/j\} \quad \text{for } j \in [k]. \tag{32}$$

Using the results in [25] we have that the above estimator has the following concentration property around the true estimator.

Lemma 6 (Lemma 2 and 3 in [25])**.** *Let* $\widetilde{\theta}_t^{\text{MoM}}$ *be the MOMLSE defined* (31) *in with k subsamples with* $\{r_{s,i}\}_{(s,i)\in[t]\times[k]}$ *rewards and corresponding actions* $\{a_s\}_{s\in[t]}$*. Assume that the noise of all rewards has bounded variance, i.e* $\mathbb{E}\left[\epsilon_{s,i}^2|\mathcal{F}_{t-1}\right] \leq 1$ *for all* $s \in [t]$ *and* $i \in [k]$*. Then we have*

$$\Pr\left(\|\theta - \widetilde{\theta}_t^{MoM}\|_{V_t}^2 \leq 9\left(\sqrt{9d} + \lambda\|\theta\|_2\right)^2\right) \geq 1 - \exp\left(\frac{-k}{24}\right). \tag{33}$$

We will use a slight modification of the above result with a weighted least squares estimator like the one used in [20]. The weights will be related to a variance estimator of the noise for action $a \in \mathcal{A}$ that at each time step t can be generally defined as

$$\hat{\sigma}_t^2 : \mathcal{H}_{t-1} \times A \to \mathbb{R}_{>0}, \tag{34}$$

where $\mathcal{H}_{t-1} = \{r_{s,i}\}_{(s,i)\in[t-1]\times[k]} \cup \{a_s\}_{s\in[t-1]}$ contains the past information of rewards and actions played. For our purposes we will use only the information of the past actions and in order to simplify notation we will use $\hat{\sigma}_t^2(a)$ to denote an estimator of the variance for the reward associated action $a \in \mathcal{A}$ with the information collected up to time step $t-1$. Then the corresponding weighted versions with k subsamples are defined as

$$\widetilde{\theta}_{t,i} = V_t^{-1} \sum_{s=1}^{t} \frac{1}{\hat{\sigma}_s^2(a_s)} r_{s,i} a_s \quad \text{for } i \in [k], \tag{35}$$

with the weighted design matrix

$$V_t = \lambda \mathbb{I} + \sum_{s=1}^{t} \frac{1}{\hat{\sigma}_s^2(a_s)} a_s a_s^{\mathsf{T}}. \tag{36}$$

Then the weighted version of the median of means linear estimator is defined analogously to (31) with the corresponding weighted versions (35)(36) and we will denote it as $\widetilde{\theta}_t^{\mathrm{wMOM}}$. In our algorithm analysis we will use the following analogous concentration bound under the condition that the estimators $\hat{\sigma}_t^2$ overestimate the true variance.

Corollary 7. *Let $\widetilde{\theta}_t^{\mathrm{wMOM}}$ be the weighted version of the MOMLSE with k subsamples, $\{r_{s,i}\}_{(s,i)\in[t]\times[k]}$ rewards with corresponding actions $\{a_s\}_{s\in[t]}$ and variance estimator $\hat{\sigma}_t^2$. Define the following event*

$$G_t := \{(\mathcal{H}_{t-1}, a_t) : \mathbb{V}[\epsilon_{s,i}] \leq \hat{\sigma}^2(a_s) \forall s, i \in [t] \times [k]\}. \tag{37}$$

Then we have

$$\Pr\left(\|\theta - \widetilde{\theta}_t^{\mathrm{wMOM}}\|_{V_t}^2 \leq \beta \mid G_t\right) \geq 1 - \exp\left(\frac{-k}{24}\right), \tag{38}$$

where

$$\beta := 9\left(\sqrt{9d} + \lambda\|\theta\|_2\right)^2. \tag{39}$$

Proof. The result follows from applying Lemma 6 to the sequences of re-normalized rewards $\{\frac{r_{s,i}}{\hat{\sigma}_s(a_s)}\}_{(s,i)\in[t]\times[k]}$ and actions $\{\frac{a_{s,i}}{\hat{\sigma}_s(a_s)}\}_{s\in[t]}$. We only need to check that the sequence $\{\frac{\epsilon_{s,i}}{\hat{\sigma}_s(a_s)}\}_{(s,i)\in[t]\times[k]}$ has finite variance. Conditioning with the event G_t and the fact that by definition $\hat{\sigma}_s^2(a_s)$ only depend on the past $s-1$ action and rewards we have that the re-normalized noise has bounded variance since

$$\mathbb{E}\left[\left(\frac{\epsilon_{s,i}}{\hat{\sigma}_s(a_s)}\right)^2 \middle| \mathcal{F}_{t-1}\right] = \frac{1}{\hat{\sigma}_s^2(a_s)} \mathbb{E}[\epsilon_{s,i}^2 | \mathcal{F}_{t-1}] = \frac{\mathbb{V}[\epsilon_{s,i}]}{\hat{\sigma}_s^2(a_s)} \leq 1. \tag{40}$$

□

4.2. Algorithm

The algorithm that we design for linear bandits with linearly variance vanishing noise is LinUCB-VVN (LinUCB vanishing variance noise) stated in Algorithm 1. The algorithm runs in batches of $2(d-1)$ actions selected as

$$a_{t,i}^{\pm} := \frac{\widetilde{a}_{t,i}^{\pm}}{\|\widetilde{a}_{t,i}^{\pm}\|_2}, \quad \widetilde{a}_{t,i}^{\pm} = \theta_t^{\mathrm{wMoM}} \pm \frac{1}{\sqrt{\lambda_{\min}(V_{t-1})}}, \quad \theta_t^{\mathrm{wMoM}} := \frac{\widetilde{\theta}_t^{\mathrm{wMoM}}}{\|\widetilde{\theta}_t^{\mathrm{wMoM}}\|_2}, \tag{41}$$

for $i \in [d-1]$ and where for each action $a^{\pm}_{t,i}$ we sample $k \geq 1$ independent rewards in order to build the weighted MOMLSE defined as in Section 4.1. The design matrix V_t is updated as

$$V_t = V_{t-1} + \omega(V_{t-1}) \sum_{i=1}^{d-1} \left(a^{+}_{t,i}(a^{+}_{t,i})^{\mathsf{T}} + a^{-}_{t,i}(a^{-}_{t,i})^{\mathsf{T}} \right) \tag{42}$$

where the weights ω and variance estimator are chosen as

$$\omega(V_{t-1}) := \frac{\sqrt{\lambda_{\max}(V_{t-1})}}{12\sqrt{d-1}\beta}, \quad \hat{\sigma}^2_t(a^{\pm}_{t,i}) := \frac{1}{\omega(V_{t-1})}. \tag{43}$$

We note that the definition for $\hat{\sigma}^2_t(a^{\pm}_{t,i})$ fulfills the definition of variance estimator (34) stated in the previous section since it only depends on the past history $\mathcal{H}_{t-1}$.

Algorithm 1: LinUCB-VVN

```
Require: $\lambda_0 \in \mathbb{R}_{>0}$, $k \in \mathbb{N}$, $\omega : \mathrm{P}^d_+ \to \mathbb{R}_{\geq 0}$
Set initial design matrix $V_0 \leftarrow \lambda_0 \mathbb{I}_{d\times d}$
Choose initial estimator $\theta_0 \in \mathbb{S}^d$ for $\theta$ at random
for $t = 1, 2, \cdots$ do
    Optimistic action selection
    for $i = 1, 2, \cdots d-1$ do
        Select actions $a^{+}_{t,i}$ and $a^{-}_{t,i}$ according to Eq. (41)
        Sample k independent rewards for each $a^{\pm}_{t,i}$
        for $j = 1, ..., k$ do
            Receive associated rewards $r^{+}_{t,i,j}$ and $r^{-}_{t,i,j}$
        end
    end
    Update estimator of sub-gaussian noise for $a^{+}_{t,i}$
    $\hat{\sigma}^2_t \leftarrow \frac{1}{\omega(V_{t-1}(\lambda_0))}$ for $t \geq 2$ or $\hat{\sigma}^2_t \leftarrow 1$ for $t = 1$.
    Update design matrix
    $V_t \leftarrow V_{t-1} + \frac{1}{\hat{\sigma}^2_t} \sum_{i=1}^{d-1} \left(a^{+}_{t,i}(a^{+}_{t,i})^{\mathsf{T}} + a^{-}_{t,i}(a^{-}_{t,i})^{\mathsf{T}}\right)$
    Update LSE for each subsample
    for $j = 1, 2, ..., k$: do
        $\widetilde{\theta}^{\mathrm{w}}_{t,j} \leftarrow V_t^{-1} \sum_{s=1}^{t} \frac{1}{\hat{\sigma}^2_t} \sum_{i=1}^{d-1} (a^{+}_{s,i} r^{+}_{t,i,j} + a^{-}_{s,i} r^{-}_{t,i,j})$
    end
    Compute $\widetilde{\theta}^{\mathrm{wMOM}}_t$ using $\{\widetilde{\theta}^{\mathrm{w}}_{t,j}\}_{j=1}^k$
end
```

4.3. Regret analysis

In this Section we present the analysis of the regret for Algorithm 1. The analysis is similar to the LinUCB-VN presented in [20][Appendix C.1]. Thus, we focus on the changes respect to LinUCB-VN and although we present a complete proof we refer to [20] for more detailed computations. The main result we use from [20] is a theorem that quantifies the growth of the maximum and minimum eigenvalues of the design matrix V_t (42).

Theorem 8 (Theorem 3 in [20]). *Let $\{c_t\}_{t=0}^{\infty} \subset \mathbb{S}^{d-1}$ be a sequence of normalized vectors and $\omega : \mathrm{P}_{+}^{d} \to \mathbb{R}_{\geq 0}$ a function such that*

$$\omega(X) \leq C\sqrt{\|X\|_{\infty}}, \tag{44}$$

for a constant $C > 0$ and any $X \in \mathrm{P}_{+}^{d}$. Let $\lambda_0 \geq \max\{2, \sqrt{\frac{2}{3(d-1)}}2dC + \frac{2}{3(d-1)}\}$, and define a sequence of matrices $\{V_t\}_{t=0}^{\infty} \subset \mathbb{R}^{d\times d}$ as

$$V_0 := \lambda_0 \mathbb{I}_{d\times d}, \quad V_{t+1} := V_t + \omega(V_t)\sum_{i=1}^{d-1} P_{t,i}, \tag{45}$$

where

$$P_{t,i} := a_{t+1,i}^{+}(a_{t+1,i}^{+})^{\mathsf{T}} + a_{t+1,i}^{-}(a_{t+1,i}^{-})^{\mathsf{T}}, \quad a_{t+1,i}^{\pm} := \frac{\tilde{a}_{t+1,i}^{\pm}}{\|\tilde{a}_{t+1,i}^{\pm}\|_2}, \quad \tilde{a}_{t+1,i}^{\pm} := c_t \pm \frac{1}{\sqrt{\lambda_{t,1}}} v_{t,i}, \tag{46}$$

with $\lambda_{t,i} = \lambda_i(V_t)$ the eigenvalues of V_t with corresponding normalized eigenvectors $v_{t,1}, ..., v_{t,d} \in \mathbb{S}^{d-1}$. Then we have

$$\lambda_{\min}(V_t) \geq \sqrt{\frac{2}{3(d-1)}\lambda_{\max}(V_t)} \quad \textit{for all} \quad t \geq 0. \tag{47}$$

For the proof of the above Theorem we refer to the original reference. Then using this Theorem and the concentration bound for MOMLSE given in Corollary 7 we can provide the following regret analysis for a stochastic linear bandit with vanishing variance noise.

Theorem 9. *Let $d \geq 2$, $k \in \mathbb{N}$ and $T = 2(d-1)k\widetilde{T}$ for some $\widetilde{T} \in \mathbb{N}$, $\widetilde{T} \geq 2$. Let $\omega(X)$ defined as in (43) using λ_0 satisfying the constraints in Theorem 8. Then if we apply LinUCB-VVN 1(λ_0, k, ω) to a d dimensional stochastic linear bandit with variance as in (25) with probability at least $(1 - \exp(-k/24))^{\widetilde{T}}$ the regret satisfies*

$$\mathrm{Regret}(T) \leq 4k(d-1) + 144d(d-1)k\beta^2 \log\left(\frac{T}{2(d-1)k}\right) + 24(d-1)^{\frac{3}{2}}k\beta\log\left(\frac{T}{2(d-1)k}\right), \tag{48}$$

and at each time step $t \in [T]$ with the same probability it can output an estimator $\hat{\theta}_t \in \mathbb{S}^{d-1}$ such that

$$\|\theta - \hat{\theta}_t\|_2^2 \leq \frac{576d^2\beta^2 k + 96d\sqrt{d-1}\beta k}{t}, \tag{49}$$

with β defined as in (39).

From the above Theorem we have that if we set $k = \lceil 24\log\left(\frac{\widetilde{T}}{\delta}\right)\rceil$ for some $\delta \in (0,1)$ then with probability at least $1-\delta$ LinUCB-VNN achieves

$$\mathrm{Regret}(T) = O\left(d^4\log^2(T)\right), \quad \|\theta - \hat{\theta}_t\|_2^2 = O\left(\frac{\log(T)}{t}\right). \tag{50}$$

Proof. From the expression of the regret (26) we have that to give an upper bound it suffices to gives an upper bound between the distance of the unknown parameter θ and the actions $a_{t,i}^{\pm}$

selected by the algorithm (41). We denote the step $\tilde{t} \in [\widetilde{T}]$ to run over the batches the algorithm updates the MoM estimator $\widetilde{\theta}_{\tilde{t}}^{\mathrm{wMOM}}$. First we will do the computation assuming that the event

$$E_{\tilde{t}} := \{\mathcal{H}_{\tilde{t}} : \forall s \in [\tilde{t}], \theta \in \mathcal{C}_s\}, \tag{51}$$

holds where $\mathcal{C}_s = \{\theta' \in \mathbb{R}^d : \|\theta' - \widetilde{\theta}_{\tilde{t}}^{wMOM}\|_{V_s}^2 \leq \beta\}$. Here the history $\mathcal{H}_{\tilde{t}}$ is defined with the previous outcomes and actions of our algorithm i.e

$$\mathcal{H}_{\tilde{t}} := \left(r_{s,i,j}^{+}, a_{s,i}^{+}, r_{s,i,j}^{-}, a_{s,i}^{-}\right)_{(s,i,j)\in[\tilde{t}]\times[d-1]\times[k]} \tag{52}$$

Later we will quantify the probability that this event always hold. Using the definition of the actions (41), $\theta, \widetilde{\theta}_{\tilde{t}}^{\mathrm{wMOM}} \in \mathbb{S}^{d-1}$ and the arguments from [20][Appendix C.1, Eq. (165)] we have that

$$\|\theta - a_{\tilde{t},i}^{\pm}\|_2^2 \leq \frac{9\beta}{\lambda_{\min}(V_{\tilde{t}-1})}. \tag{53}$$

Then using that the design matrix $V_{\tilde{t}}$ (42) is updated as in Theorem 8 and the choice of weights (43) we fix

$$\lambda_0 \geq \max\left\{2, 2\sqrt{\frac{2}{3(d-1)}}\frac{d}{12\sqrt{d-1}\beta} + \frac{2}{3(d-1)}\right\} \tag{54}$$

and we have that $\lambda_{\min}(V_{\tilde{t}}) \geq \sqrt{\frac{2}{3(d-1)}\lambda_{\max}(V_{\tilde{t}})}$ applying Theorem 8. Inserting this into the above we have

$$\|\theta - a_{\tilde{t},i}^{\pm}\|_2^2 \leq \frac{12\sqrt{d-1}\beta}{\sqrt{\lambda_{\max}(V_{\tilde{t}})}}. \tag{55}$$

Thus, it remains to provide a lower bound on $\lambda_{\max}(V_{\tilde{t}})$. We note that in [20][Appendix C.1] they also had to provide an upper bound but this was because the constant β beta they use depends on t. From the definition of V_t (42) we can bound the trace as

$$\mathrm{Tr}(V_{\tilde{t}}) \geq \sum_{s=2}^{\tilde{t}} 2(d-1)\omega(V_{s-1}) \tag{56}$$

$$= \frac{\sqrt{d-1}}{6\beta}\sum_{s=1}^{\tilde{t}-1}\sqrt{\lambda_{\max}(V_s)}. \tag{57}$$

Then using the bound $\mathrm{Tr}(V_{\tilde{t}}) \geq \lambda_{\max}(V_{\tilde{t}})/d$ and some algebra we arrive at

$$\lambda_{\max}(V_{\tilde{t}}) \geq \frac{1}{1 + 6\frac{d}{\sqrt{d-1}}\beta}\sum_{s=1}^{\tilde{t}}\sqrt{\lambda_{\max}(V_s)}. \tag{58}$$

Now we have an inequality with the function $\lambda_{\max}(V_s)$ at both sides. In order to solve it we use the technique from [20][Appendix C.1, Equation (197-208)] which consist on extending $\lambda_{\max}(V_{\tilde{t}})$ to the continuous with a linear interpolation and then transforming the sum to an integral which leads to a differential inequality. Solving this leads to

$$\lambda_{\max}(V_{\tilde{t}}) \geq \frac{\tilde{t}^2}{4(1 + 6\frac{d}{\sqrt{d-1}}\beta)^2}. \tag{59}$$

Now we can insert the above into (55) and we have

$$\|\theta - a^{\pm}_{\tilde{t},i}\|_2^2 \leq \frac{24\sqrt{d-1}\beta(1 + 6\frac{d}{\sqrt{d-1}}\beta)}{\tilde{t}-1} \tag{60}$$

$$= \frac{144d\beta^2 + 24\sqrt{d-1}\beta}{\tilde{t}-1}. \tag{61}$$

Thus, we can inserted the above bound into the regret expression (26) and we have

$$\begin{aligned}
\text{Regret}(T) &= \frac{1}{2}\sum_{t=1}^{T} \|\theta - a_t\|_2^2 && (62)\\
&= \frac{1}{2}\sum_{\tilde{t}=1}^{\tilde{T}}\sum_{i=1}^{d-1}\sum_{j=1}^{k}\left(\|\theta - a^{+}_{\tilde{t},i}\|_2^2 + \|\theta - a^{-}_{\tilde{t},i}\|_2^2\right) && (63)\\
&\leq 4k(d-1) + \frac{1}{2}\sum_{\tilde{t}=2}^{\tilde{T}}\sum_{i=1}^{d-1}\sum_{j=1}^{k}\left(\|\theta - a^{+}_{\tilde{t},i}\|_2^2 + \|\theta - a^{-}_{\tilde{t},i}\|_2^2\right) && (64)\\
&\leq 4k(d-1) + (144d(d-1)k\beta^2 + 24(d-1)^{\frac{3}{2}}k\beta)\sum_{\tilde{t}=2}^{\tilde{T}}\frac{1}{t-1} && (65)\\
&\leq 4k(d-1) + 144d(d-1)k\beta^2\log\widetilde{T} + 24(d-1)^{\frac{3}{2}}k\beta\log\widetilde{T} && (66)\\
&= 4k(d-1) + 144d(d-1)k\beta^2\log\left(\frac{T}{2(d-1)k}\right) + 24(d-1)^{\frac{3}{2}}k\beta\log\left(\frac{T}{2(d-1)k}\right). && (67)
\end{aligned}$$

It remains to quantify the probability that the event $E_{\tilde{t}}$ holds. For that we will use the concentration bounds of the median of means for least squares estimator stated in Corollary 7. From the variance condition of our model (25) we have

$$\mathbb{V}[\epsilon^{\pm}_{\tilde{t},i,j}|\mathcal{F}_{\tilde{t}-1}] \leq 1 - \langle\theta, a^{\pm}_{\tilde{t},i}\rangle^2 \leq 2(1 - \langle\theta, a^{\pm}_{\tilde{t},i}\rangle) = \|\theta - a^{\pm}_{\tilde{t},i}\|_2^2, \tag{68}$$

where we used $1 + \langle\theta, a^{\pm}_{\tilde{t},i}\rangle \leq 2$. Thus from our choice of weights (43) and (60) we have that

$$\text{if } \theta \in \mathcal{C}_{s-1} \Rightarrow \mathbb{V}[\epsilon^{\pm}_{\tilde{t},i,j}|\mathcal{F}_{\tilde{t}-1}] \leq \hat{\sigma}^2_s(a^{\pm}_{s,i}). \tag{69}$$

Then in order to apply Corollary 7 we note that from the choice $\hat{\sigma}^2_s(a^{\pm}_{1,i}) = 1$ the event $G_{\tilde{t}}$ at $\tilde{t} = 1$ is always satisfied i.e $\Pr(G_1) = 1$. Then applying Bayes theorem, union bound over the events $G_1, E_1, ..., G_{t-1}, E_t$ and Corollary 7 we have

$$\Pr(E_{\widetilde{T}} \cap G_{\widetilde{T}}) \geq (1 - \exp(-k/24))^{\widetilde{T}}. \tag{70}$$

This probability also quantifies the probability that (60) holds since the only assumption we used is $\theta \in \mathcal{C}_{\tilde{t}-1}$. Then we can take simply one of the actions $a^{\pm}_{\tilde{t},i}$ as the estimator $\hat{\theta}_t$ and the result follows using the relabeling $t = 2(d-1)k\tilde{t}$ and the inequality $1/(\tilde{t}-1) \leq 2/\tilde{t}$ for $\tilde{t} \geq 2$. A more detailed analogous computation of the above probability can be found in [20][Appendix C.1]. □

In the previous Theorem we did not set a specific value for the parameter k or the number of subsamples per action. We note that the regret scales linearly with k but since the success probability scales exponentially with k it will suffice to set $k \sim \log(T)$ such that in expectation we get the $\log^2(T)$ behaviour. We formalize this in the following Corollary.

Corollary 10. *Under the same assumptions of Theorem 9 we can fix* $k = \lceil 24\log(\widetilde{T}^2)\rceil$ *and we have*

$$\mathbb{E}\left[\mathrm{Regret}(T)\right] \leq 344(d-1)\log(T) + \left(3546d(d-1)\beta^2 + 1152(d-1)^{\frac{3}{2}}\beta\right)\log^2(T) \tag{71}$$

and for $t \in [T]$,

$$\mathbb{E}\left[\|\theta - \hat{\theta}_t\|_2^2\right] \leq \frac{27648d^2\beta^2\log(T) + 4608d\sqrt{d-1}\beta\log(T)}{t} + \frac{4(d-1)\log(T)}{T}. \tag{72}$$

Using that $\beta = O(d)$ *gives*

$$\mathbb{E}\left[\mathrm{Regret}(T)\right] = O(d^4\log^2(T)), \quad \mathbb{E}\left[\|\theta - \hat{\theta}_t\|_2^2\right] = \tilde{O}\left(\frac{d^4}{t}\right). \tag{73}$$

Proof. The result of Theorem 9 holds with probability at least $(1-\exp(-k/24))^{\widetilde{T}}$. Setting $k = \lceil 24\log(\widetilde{T}^2)\rceil$ gives

$$(1-\exp(-k/24))^{\widetilde{T}} \geq \left(1 - \frac{1}{\widetilde{T}^2}\right)^{\widetilde{T}} \geq 1 - \frac{1}{\widetilde{T}}. \tag{74}$$

Then given the event R_T such that Algorithm 1 achieves the bounds given by Theorem 9 we have that the probability of failure is bounded by

$$\Pr(R_T^C) \leq \frac{1}{\widetilde{T}}, \tag{75}$$

where we used $1 = \Pr(R_T) + \Pr(R_T^C)$. Then the expectation of the bad events can be bounded as

$$\mathbb{E}\left[\mathrm{Regret}(T)\mathbb{I}\{R_T^C\}\right] \leq 4(d-1)k\widetilde{T}\Pr(R_T^C) \leq 4(d-1)k \tag{76}$$

$$\mathbb{E}\left[\|\theta - \hat{\theta}_t\|_2^2\mathbb{I}\{R_T^C\}\right] \leq 4\Pr(R_T^C) \leq \frac{4}{\widetilde{T}} \tag{77}$$

where we used $\mathrm{Regret}(T) \leq 2T = 4(d-1)k\widetilde{T}$, $\|\theta - \hat{\theta}_t\|_2^2 \leq 4$. Finally the result follows inserting the value of $k = 24\log(\widetilde{T}^2)$ into the bounds of Theorem 9 and using $\widetilde{T} \leq T$. □

5. ALGORITHM FOR QUBIT PSMAQB AND NUMERICAL EXPERIMENTS

In this Section we prove our main result that is a regret bound for LinUCB-VVN when applied to the qubit PSMAQB problem.

Theorem 11. *Let* $\widetilde{T} \in \mathbb{N}$ *and fix* $T = \lceil 96\widetilde{T}\log(\widetilde{T}^2)\rceil$. *Then given a* PSMAQB *with action set* $\mathcal{A} = \mathcal{S}_2^*$ *and environment* $\Pi_\theta \in \mathcal{S}_2^*$ *(qubits) we can apply Algorithm 1 for* $d = 3$ *and it achieves*

$$\mathbb{E}\left[\mathrm{Regret}(T)\right] \leq C_1\log(T) + C_2\log^2(T). \tag{78}$$

for some universal constants $C_1, C_2 \geq 0$. *Also at each time step* $t \in [T]$ *it outputs an estimator* $\hat{\Pi}_t \in \mathcal{S}_2^*$ *of* Π_θ *with infidelity scaling*

$$\mathbb{E}\left[1 - F\left(\Pi_\theta, \hat{\Pi}_t\right)\right] \leq \frac{C_3\log(T)}{t}, \tag{79}$$

for some universal constant $C_3 \geq 0$.

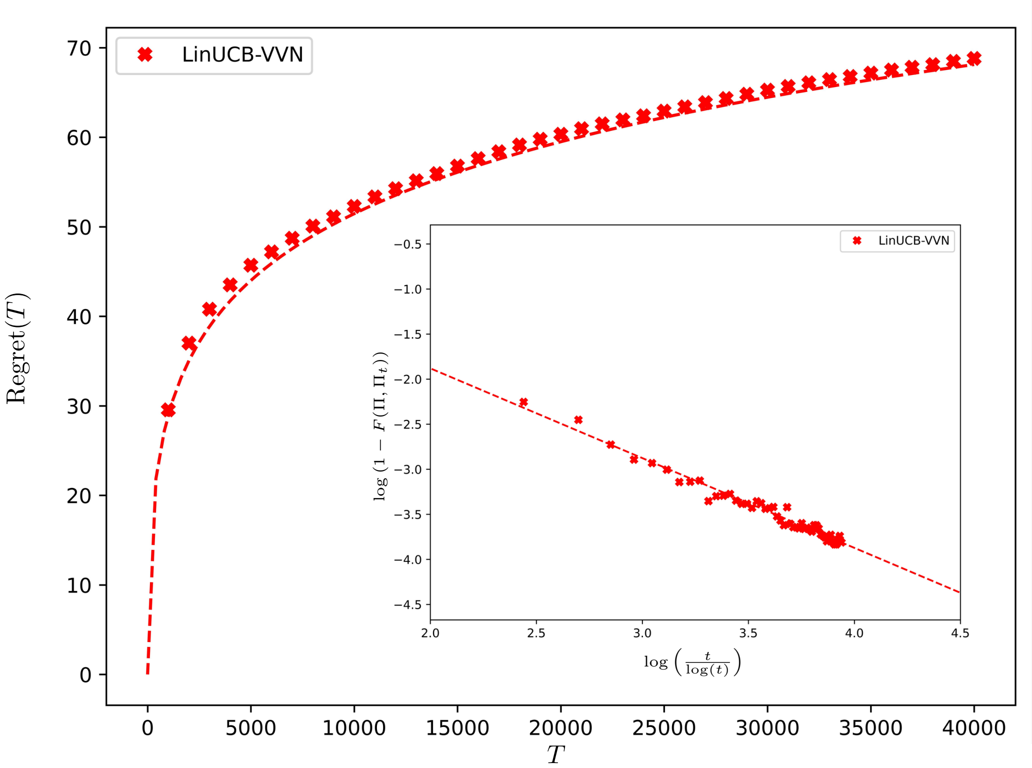

FIG. 2. Expected regret vs the number or rounds T for the LinUCB-VNN algorithm. We run $T = 4 \cdot 10^4$ rounds with $k = 10$ subsamples for the median of means construction. We use 100 independents experiments and average over them. We obtain results for each round but only plot (red crosses) few for clarity of the figure. We fit the regression $\text{Regret}(T) = m_1 \log^2 T + b_1$ with $m_1 = 3.2164 \pm 0.0009$ and $b_1 = 0.84 \pm 0.016$. In the inset plot we plot the expected infidelity of the output estimator at each rounds $t \in [T]$ versus the number of rounds t. We take $\Pi_t = \Pi_{\theta_t^{\text{wMoM}}}$ as the estimator given by the median of means linear least squares estimator. We fit the regression $1 - F(\Pi, \Pi_t) = b_2 \left(\frac{\log t}{t}\right)^{m_2}$ and we obtain $m_2 = -0.996 \pm 0.002$ $b_2 = 0.112 \pm 0.007$. We note that the number of subsamples of the theoretical results is very conservative in comparison with the value we take for the simulations.

Proof. In order to apply Algorithm 1 to a PSMAQB we set $d = 3$ (dimension for a classical linear stochastic bandit) and the actions that we select will be given by $\Pi_{a^{\pm}_{t,i}}$ where $a^{\pm}_{t,i}$ are updated as in (41). Note that they are valid action since $a^{\pm}_{t,i} \in \mathbb{S}^2$ imply $\Pi_{a^{\pm}_{t,i}} \in \mathcal{S}^*_2$. The rewards received by the algorithm follow (22) with the normalization given in (20). This model fits into the linear bandit with linearly vanishing variance noise model explained in Section 3.4 and thus we can apply the guarantees established in Theorem 9 and Corollary 10.

The algorithm is set with $k = \lceil 24 \log(\widetilde{T}^2) \rceil$ batches for the MoM construction. We set $\lambda_0 = 2$, and using $\|\theta\|_2 = 1$ we have that the constant β given in (39) has the value

$$\beta = 9\left(3\sqrt{3} + 2\right)^2 = 279 + 108\sqrt{3}. \tag{80}$$

Then we can check that for $d = 3$ the condition (54) for the input parameter λ_0 for Theorem 9 to hold is satisfied since

$$\lambda_0 = 2 \geq \max\left\{2, \frac{1}{3} + \frac{1}{2\sqrt{6}(279 + 108\sqrt{3})}\right\} = 2. \tag{81}$$

In the above we just substituted all numerical values. Then we are under the assumptions of Theorem 9 and Corollary 10 and the result follows applying both results with the relation of regrets between the classical and quantum model given in (24), the relation

$$\|\theta - \hat{\theta}_t\|_2^2 = 4\left(1 - F\left(\Pi_\theta, \Pi_{\hat{\theta}_t}\right)\right), \tag{82}$$

and substituting all numerical values. We take the estimator $\hat{\theta}_t$ given in Theorem 9 for $d = 3$. We use also the bound $\widetilde{T} \leq T$ and reabsorb all the constants into C_1, C_2, C_3. □

Remark 1. The constant dependence can be slightly improved taking the estimator for Π_θ as $\Pi_{\theta_t^{\mathrm{wMoM}}}$ with θ_t^{wMoM} defined in (41).

Remark 2. The result of Theorem 11 also holds with high probability. In particular for the choice of batches $k = 24\log(\widetilde{T}^2)$ with probability at least $1 - \frac{1}{\widetilde{T}}$.

6. REGRET LOWER BOUND FOR PSMAQB

While the algorithm for PSMAQB presented above is inspired by classical bandit theory, the lower bound on the regret that we derive is essentially based on quantum information theory. The key insight here is that a policy for PSMAQB can be viewed as a sequence of state tomographies. The expected fidelity of these tomographies is linked to the regret. Hence, existing upper bounds on tomography fidelity also provide a lower bound for the expected regret of the policy.

6.1. Average fidelity bound for pure state tomography

In its most general form, a tomography procedure takes n copies of an unknown state $\Pi \in \mathcal{S}_d^*$ and performs a joint measurement on the state $\Pi^{\otimes n}$. This is captured in the following definition. Let $(\mathcal{S}_d^*, \Sigma)$ be a σ-algebra. A *tomography scheme* is a positive operator-valued measure (POVM) $\mathcal{T} : \Sigma \to \mathrm{End}(\mathcal{H}^{\otimes n})$ such that $\mathcal{T}(\mathcal{S}_d^*) = \Pi_n^+$, where Π_n^+ is the symmetrization operator on $\mathcal{H}^{\otimes n}$. For any $\rho \in \mathrm{End}(\mathcal{H}^{\otimes n})$, this POVM gives rise to a complex-valued measure

$$P_{\mathcal{T},\rho}(A) = \mathrm{Tr}(\mathcal{T}(A)\rho) \tag{83}$$

for $A \in \Sigma$. $P_{\mathcal{T},\rho}$ becomes a probability measure if ρ satisfies $\rho \geq 0$, $\Pi_n^+\rho = \rho\Pi_n^+ = \rho$, and $\mathrm{Tr}\,\rho = 1$. Given n copies of Π, the tomography scheme produces the distribution $P_{\mathcal{T},\Pi^{\otimes n}}$ of the predicted states. Note that $\Pi^{\otimes n}$ satisfies the properties above, so $P_{\mathcal{T},\Pi^{\otimes n}}$ is indeed a probability distribution. The fidelity of this distribution is given by

$$F(\mathcal{T}, \Pi) = \int \mathrm{Tr}(\Pi\sigma) dP_{\mathcal{T},\Pi^{\otimes n}}(\sigma). \tag{84}$$

Finally, the average fidelity of the tomography scheme is defined as

$$F(\mathcal{T}) = \int F(\mathcal{T}, |\psi\rangle\langle\psi|) d\psi, \tag{85}$$

where the integration is taken with respect to the normalized uniform measure over all pure states. In the following, $\int d\psi$ will always imply this measure. We will provide a lower bound on $F(\mathcal{T})$ in terms of d and n, following the proof technique from [14]. In [14], the proof is only presented for tomography schemes producing a finite number of predictions. For our definition, we will require more general measure-theoretic tools. Before we introduce the upper bound on the fidelity, we will prove some auxiliary lemmas about the nature of the measure $P_{\mathcal{T},\rho}$.

Lemma 12. *Let (Ω, Σ) be a σ-algebra, and let $O : \Sigma \to \mathrm{End}(\widetilde{\mathcal{H}})$ be a POVM with values acting on a finite-dimensional Hilbert space $\widetilde{\mathcal{H}}$ with $\dim \widetilde{\mathcal{H}} = \tilde{d}$ s.t. $O(\Omega) \leq \mathbb{1}$, where $\mathbb{1}$ is the identity operator. Further, let $P_{O,\sigma} : \Sigma \to \mathbb{C}$ be a complex-valued measure, defined for any $\sigma \in \mathrm{End}(\widetilde{\mathcal{H}})$ as*

$$P_{O,\sigma}(A) = \mathrm{Tr}[O(A)\sigma]. \tag{86}$$

Then, there exists a set of functions $\{f_\sigma\}$ indexed by $\sigma \in \mathrm{End}\,\widetilde{\mathcal{H}}$ that are linear w.r.t. σ for all ω and that satisfy

$$f_\sigma : \Omega \to \mathbb{C} \quad s.t. \quad \forall A \in \Sigma \;\; P_{O,\sigma}(A) = \int_A f_\sigma(\omega) dP_{O,\mathbb{1}}(\omega). \tag{87}$$

We purposefully formulated this lemma with slightly more general objects than the ones used in the definition of tomography. That is, Ω does not need to be $\mathcal{S}_d^*$, and $\widetilde{\mathcal{H}}$ does not need to be the n-th power $\mathcal{H}^{\otimes n}$, although we will focus on this case.

Proof. Let $\{|i\rangle\}_{i=1}^{\tilde{d}}$ be a basis of $\widetilde{\mathcal{H}}$ We will first show that $P_{O,\sigma}$ is dominated by $P_{O,\mathbb{1}}$ for all σ. Indeed, let $A \in \Sigma$. Assume that $P_{O,\mathbb{1}}(A) = 0$. This gives us

$$\mathrm{Tr}[O(A)\mathbb{1}] = \mathrm{Tr}[O(A)] = 0, \tag{88}$$

and, because $O(A) \geq 0$, we also have $O(A) = 0$. Therefore,

$$P_{O,\sigma}(A) = \mathrm{Tr}[O(A)\sigma] = 0. \tag{89}$$

Hence, for any $|i\rangle, |j\rangle$ from the basis we can introduce the Radon-Nikodym derivatives $f_{|i\rangle\langle j|}$, which will satisfy (87). Then, for any $\sigma \in \mathrm{End}\,\widetilde{\mathcal{H}}$ we can define

$$f_\sigma(\omega) = \sum_{i,j=1}^{\tilde{d}} \langle i| \sigma |j\rangle f_{|i\rangle\langle j|}(\omega). \tag{90}$$

These f_σ are linear in σ by definition. A direct calculation shows that they also satisfy (87). □

Note that for $\sigma \geq 0$, the measure $P_{O,\sigma}$ is finite and nonnegative, but nonnegativity (and even real-valuedness) do not hold for a general $\sigma \in \mathrm{End}(\widetilde{\mathcal{H}})$. By our definition of $f_\sigma(\omega)$, it can be written as

$$f_\sigma(\omega) = \mathrm{Tr}\left[K(\omega)\sigma\right], \quad \text{where } K(\omega) = \sum_{i,j=1}^{\tilde{d}} f_{|i\rangle\langle j|}(\omega)|j\rangle\langle i|. \tag{91}$$

As the following lemma demonstrates, $K(\omega) \geq 0$ for $P_{O,\mathbb{1}}$-almost every ω:

Lemma 13. *Let (Ω, Σ, μ) be a measurable space and $V : \Omega \to \mathrm{End}(\widetilde{\mathcal{H}})$ be a measurable operator-valued function with values acting on a finite-dimensional Hilbert space $\widetilde{\mathcal{H}}$ such that*

$$\forall A \in \Sigma \quad \int_A V(\omega) d\mu(\omega) \geq 0. \tag{92}$$

Then, $V(\omega) \geq 0$ μ-almost everywhere.

Proof. Let $|\psi\rangle \in \widetilde{\mathcal{H}}$ and define

$$g_\psi(\omega) = \langle\psi| V(\omega) |\psi\rangle . \tag{93}$$

By the given condition, for any $A \in \Sigma$

$$\int_A g_\psi(\omega) d\mu(\omega) = \langle\psi| \int_A V(\omega) d\mu(\omega) |\psi\rangle \geq 0. \tag{94}$$

It follows that $g_\psi(\omega) \geq 0$ μ-almost everywhere. Let

$$Z_\psi = \{\omega \in \Omega \text{ s.t. } g_\psi(\omega) < 0\} \tag{95}$$

We have shown that $\mu(Z_\psi) = 0$. Next, since $\widetilde{\mathcal{H}}$ is finite-dimensional, it is separable. Therefore, there exists a countable set $\{|\psi_k\rangle\}_k$ dense in $\widetilde{\mathcal{H}}$. Let

$$Z = \bigcup_k Z_{\psi_k}. \tag{96}$$

We have that $\mu(Z) = 0$. Finally, let $\omega \in \Omega \setminus Z$ and $|\psi\rangle \in \widetilde{\mathcal{H}}$. Because $\{|\psi_k\rangle\}$ is dense in $\widetilde{\mathcal{H}}$, there exists a sequence $\{|\psi_{k_i}\rangle\}$ converging to $|\psi\rangle$. Then,

$$0 \leq \langle\psi_{k_i}| V(\omega) |\psi_{k_i}\rangle \xrightarrow{i\to\infty} \langle\psi| V(\omega) |\psi\rangle . \tag{97}$$

Overall, we get that

$$\forall \omega \in \Omega \setminus Z,\ |\psi\rangle \in \widetilde{\mathcal{H}} \quad \langle\psi| V(\omega) |\psi\rangle \geq 0. \tag{98}$$

Together with $\mu(Z) = 0$, this gives the desired result. □

Now we can apply this analysis to the POVM corresponding to our tomography scheme, and get the desired upper bound on the fidelity.

Theorem 14. *For any tomography scheme $\mathcal{T}$ utilizing n copies of the input state, the average fidelity is bounded by*

$$F(\mathcal{T}) \leq \frac{n+1}{n+d}. \tag{99}$$

Proof. We will introduce the density $K(\omega)$ from (91) for our tomography scheme $\mathcal{T}$ and the corresponding measure $P_{\mathcal{T},\sigma}$. Lemma 12 allows us to introduce for any $\sigma \in \mathrm{End}(\mathcal{H}^{\otimes n})$ the density $f_\sigma : \Omega \to \mathbb{C}$ s.t.

$$\forall A \in \Sigma \ \ P_{\mathcal{T},\sigma}(A) = \int_A f_\sigma(\omega) dP_{\mathcal{T},\mathbb{1}}(\omega). \tag{100}$$

This density can be written as $f_\sigma(\omega) = \mathrm{Tr}\left(K(\omega)\sigma\right)$ for some $K(\omega) \in \mathrm{End}(\mathcal{H}^{\otimes n})$. $K(\omega)$ can be considered as the operator-valued density of $\mathcal{T}$ w.r.t. $P_{\mathcal{T},\mathbb{1}}$:

$$\forall A \in \Sigma \quad \mathcal{T}(A) = \int_A K(\omega) dP_{\mathcal{T},\mathbb{1}}(\omega). \tag{101}$$

Since $\mathcal{T}(A) \geq 0$, it follows by Lemma 13 that $K(\omega) \geq 0$ for $P_{\mathcal{T},\mathbb{1}}$-almost all ω. Furthermore, as $\mathcal{T}(\mathcal{S}_d^*) = \Pi_n^+$, we have that for all $A \in \Sigma$, $\mathcal{T}(A) \leq \Pi_n^+$. Therefore, $\mathcal{T}(A)\Pi_n^+ = \Pi_n^+\mathcal{T}(A) = \mathcal{T}(A)$.

This means that $\tilde{K}(\omega) = \Pi_n^+ K(\omega) \Pi_n^+$ would also satisfy (101). In the following, we will without loss of generality assume that

$$K(\omega) = \Pi_n^+ K(\omega) = K(\omega)\Pi_n^+. \tag{102}$$

With these tools at hand, we are ready to adapt the proof from [14] to the general case of POVM tomography schemes. We begin by rewriting the expression (84) for average fidelity:

$$\begin{aligned} F(\mathcal{T}) &= \int d\psi \int dP_{\mathcal{T},(|\psi\rangle\langle\psi|)^{\otimes n}}(\sigma)\, \mathrm{Tr}(\sigma\, |\psi\rangle\langle\psi|) && (103)\\ &= \int d\psi \int dP_{\mathcal{T},\mathbb{1}}(\sigma)\, \mathrm{Tr}(|\psi\rangle\langle\psi|\, \sigma)\, \mathrm{Tr}\left(K(\sigma)(|\psi\rangle\langle\psi|)^{\otimes n}\right). && (104) \end{aligned}$$

Since fidelity is nonnegative and its average is bounded by 1, we can change the order of integration. Following [14], we introduce notation

$$\sigma_n(k) = \mathbb{1}^{\otimes(k-1)} \otimes \sigma \otimes \mathbb{1}^{\otimes(n-k)} \in \mathcal{H}^{\otimes n}. \tag{105}$$

The product of traces in (104) can be rewritten in the following manner:

$$F(\mathcal{T}) = \int dP_{\mathcal{T},\mathbb{1}}(\sigma) \int d\psi\, \mathrm{Tr}\Big((K(\sigma)\otimes \mathbb{1})(|\psi\rangle\langle\psi|)^{\otimes(n+1)}\sigma_{n+1}(n+1)\Big). \tag{106}$$

We can now take the inner integral in closed form. As shown in [14, Eq. (4)],

$$\int d\psi (|\psi\rangle\langle\psi|)^{\otimes n} = \frac{\Pi_n^+}{D_n}, \tag{107}$$

where $D_n = \binom{n+d-1}{d}$. Another useful result in this paper is [14, Eq. (8)]:

$$\mathrm{Tr}_{n+1}\left(\Pi_{n+1}^+ \sigma_{n+1}(n+1)\right) = \frac{1}{n+1}\Pi_n^+ \left(\mathbb{1} + \sum_{k=1}^{n} \sigma_n(k)\right), \tag{108}$$

where $\mathrm{Tr}_{n+1} : \mathrm{End}(\mathcal{H}^{\otimes(n+1)}) \to \mathrm{End}(\mathcal{H}^{\otimes n})$ is the partial trace on the $(n+1)$-st copy of the system. These expressions allow us to rewrite (106) as follows:

$$\begin{aligned} F(\mathcal{T}) &= \frac{1}{D_{n+1}} \int dP_{\mathcal{T},\mathbb{1}}(\sigma)\, \mathrm{Tr}\left((K(\sigma)\otimes\mathbb{1})\Pi_{n+1}^+\sigma_{n+1}(n+1)\right) && (109)\\ &= \frac{1}{D_{n+1}} \int dP_{\mathcal{T},\mathbb{1}}(\sigma)\, \mathrm{Tr}\left(K(\sigma)\, \mathrm{Tr}_{n+1}\left(\Pi_{n+1}^+\sigma_{n+1}(n+1)\right)\right) && (110)\\ &= \frac{1}{(n+1)D_{n+1}} \int dP_{\mathcal{T},\mathbb{1}}(\sigma)\, \mathrm{Tr}\left(K(\sigma)\left(\mathbb{1} + \sum_{k=1}^{n}\sigma_n(k)\right)\right). && (111) \end{aligned}$$

Finally, $\sigma_n(k) \leq \mathbb{1}$, so $\mathrm{Tr}(K(\sigma)\sigma_n(k)) \leq \mathrm{Tr}(K(\sigma))$, and we can bound the above as

$$F(\mathcal{T}) \leq \frac{1}{D_{n+1}} \int dP_{\mathcal{T},\mathbb{1}}(\sigma)\, \mathrm{Tr}\left(K(\sigma)\right) = \frac{\mathrm{Tr}\,\Pi_n^+}{D_{n+1}} = \frac{D_n}{D_{n+1}} = \frac{n+1}{n+d}. \tag{112}$$

□

6.2. Bandit policy as a sequence of tomographies

Theorem 15. *Given a d-dimensional pure state general multi-armed quantum bandit we have that for any policy π the average expected regret is bounded by*

$$\int d\psi\, \mathbb{E}_{|\psi\rangle\langle\psi|,\pi}\left[\mathrm{Regret}(T,\pi,|\psi\rangle\langle\psi|)\right] \geq (d-1)\log\left(\frac{T}{d+1}\right), \tag{113}$$

where the expectation is taken w.r.t. the measure (11) *over actions taken by the bandit, and the regret is defined in* (12).

The above Theorem gives $\mathbb{E}\left[\mathrm{Regret}(T)\right] = \Omega(d\log\frac{T}{d})$. In the case of qubit environments, we have $d=2$ and $\mathbb{E}\left[\mathrm{Regret}(T)\right] = \Omega(\log T)$.

Proof. Given a policy π, we can introduce a POVM $E_t : (\Sigma\times\{0,1\})^{\times t} \to \mathrm{End}(\mathcal{H}^{\otimes t})$ such that

$$P^t_{|\psi\rangle\langle\psi|,\pi}(A_1,r_1,\ldots,A_t,r_t) = \mathrm{Tr}\left((|\psi\rangle\langle\psi|)^{\otimes t}E_t(A_1,r_1,\ldots,A_t,r_t)\right), \tag{114}$$

where $P^t_{|\psi\rangle\langle\psi|,\pi}$ is the probability measure defined by (11), but only for actions and rewards until step t. The construction of this POVM is presented in the proof of Lemma 9 in [19]. We will also define the coordinate mapping

$$\Psi_t(\Pi_1,r_1,\ldots,\Pi_t,r_t) = \Pi_t, \tag{115}$$

where $\Pi_i \in \mathcal{A}$ are actions and $r_i\in\{0,1\}$ are rewards of the PSMAQB. Now we can for each step t define a tomography scheme $\mathcal{T}_t = E_t\circ\Psi_t^{-1}$ as the pushforward POVM from E_t to the space $(\mathcal{A},\Sigma)$. Informally, this tomography scheme takes t copies of the state, runs the policy π on them, and outputs the t-th action of the policy as the predicted state. For $A\in\Sigma$, we can rewrite the tomography's distribution on predictions as

$$P_{\mathcal{T},(|\psi\rangle\langle\psi|)^{\otimes t}}(A) = \mathrm{Tr}\left(\mathcal{T}_t(A)(|\psi\rangle\langle\psi|)^{\otimes t}\right) = \mathrm{Tr}\left(E_t(\Psi_t^{-1}(A))(|\psi\rangle\langle\psi|)^{\otimes t}\right) = \left(P^t_{|\psi\rangle\langle\psi|,\pi}\circ\Psi^{-1}\right)(A). \tag{116}$$

Then, the fidelity of $\mathcal{T}_t$ on the input $|\psi\rangle\langle\psi|$ can be rewritten as

$$F(\mathcal{T}_t,|\psi\rangle\langle\psi|) = \int\langle\psi|\rho|\psi\rangle dP_{\mathcal{T}_t,(|\psi\rangle\langle\psi|)^{\otimes t}}(\rho) \tag{117}$$

$$= \int\langle\psi|\Psi_t(\Pi_1,r_1,\ldots,\Pi_t,r_t)|\psi\rangle dP^t_{|\psi\rangle\langle\psi|,\pi}(\Pi_1,r_1,\ldots,\Pi_t,r_t) \tag{118}$$

$$= \mathbb{E}_{|\psi\rangle\langle\psi|,\pi}\left[\langle\psi|\Pi_t|\psi\rangle\right]. \tag{119}$$

Using the bound for average tomography fidelity on $\mathcal{T}_t$ from Theorem 14, we can now bound the average regret of π:

$$\int\mathbb{E}_{|\psi\rangle\langle\psi|}\left[\mathrm{Regret}(T,\pi,|\psi\rangle\langle\psi|)\right]d\psi = T - \sum_{t=1}^{T}\int\mathbb{E}_{|\psi\rangle\langle\psi|}\left[\langle\psi|\Pi_t|\psi\rangle\right]d\psi \tag{120}$$

$$= T - \sum_{t=1}^{T}F(\mathcal{T}_t) \geq \sum_{t=1}^{T}1-\frac{t+1}{t+d} \tag{121}$$

$$= \sum_{t=1}^{T}\frac{d-1}{t+d} \geq (d-1)\log\left(\frac{T}{d+1}\right), \tag{122}$$

where the last inequality follows from bounding the sum by below with the integral of the function $f(t) = 1/(t+d)$. □

7. OUTLOOK

From a quantum state tomography perspective, our work introduces completely new techniques for the adaptive setting such as the median of means online least squares estimator or the optimistic principle. We expect these techniques to find applications in other quantum learning settings where adaptiveness is needed. At a fundamental level our algorithm goes beyond traditional tomography ideas like adaptive/non-adaptive basis measurements, randomized measurements or SIC POVM's and show that is enough to project near the state in order to optimally learn it. From a bandit perspective, it is surprising that the simple setting of learning pure quantum states gives the first non-trivial example of a linear bandit with continuous action sets that achieves polylogarithmic regret. This model motivated our classical work [20] and jointly with the current work we establish the first bridge between the fields of quantum state tomography and linear stochastic bandits.

Keywords: Quantum state tomography, continuous variable systems, Bosonic systems, quantum learning theory, optimal performance guarantees, Gaussian states, t-doped Gaussian states, energy-constrained states

For the full version of this work, see Ref. [1], (arxiv.org/abs/2405.01431).

I. Overview

Quantum state tomography is a fundamental task in quantum information, aiming to construct a classical description of an unknown quantum state based on experimental data. A crucial question regarding quantum state tomography is the following: what is the minimum number of samples — copies of the unknown state — required to construct a classical description of an estimator which is ε-close in trace distance to the true state with high probability? While this question has been extensively addressed for qudit systems, this is an open question for *continuous variable* (CV) systems [2–4], characterised by an infinite-dimensional Hilbert space. The literature regarding quantum state tomography of CV systems mainly relies on phase-space approximations [5–8] which — crucially — do not provide any rigorous performance guarantees with respect to the trace distance (which is the most meaningful notion of distance between quantum states [9, 10]). This gap in the literature is particularly surprising given the pivotal role of quantum optical platforms — described by CV systems — in quantum technologies such as quantum computation, communication, and metrology. Our work fills this gap, by presenting an exhaustive analysis of quantum state tomography of CV systems in terms of the trace distance. We analyse tomography of three classes of states:

- *Energy-constrained states.* We consider energy-constrained states since, without any constraints, a tomography algorithm would inevitably require an unbounded number of resources. By assuming that the mean photon number per mode of the unknown state is upper bounded by N_s, and by denoting ε as the precision in trace distance and n as the number of modes, we establish that the sample complexity of any tomography algorithm must scale at least as $\tilde{\Omega}\left(\left(\frac{N_s}{\varepsilon^2}\right)^n\right)$ (see the preliminaries in the technical manuscript for a quick review of the asymptotic notation), which is an unfavourable scaling not only in n but also in ε. Contrary to what happens for finite-dimensional states, the sample complexity of CV tomography does not scale with $O(\varepsilon^{-2})$, but with $O(\varepsilon^{-2n})$. This establishes that, even if CV systems have to satisfy stringent energy constraints, CV tomography is extremely inefficient, much more than tomography of qudit systems. In addition, we devise a tomography algorithm for possibly mixed states with sample complexity scaling as $O\left(\left(\frac{N_s}{\varepsilon^2}\right)^{2n}\right)$. Remarkably, restricting to the pure state case, we prove that $\tilde{\Theta}\left(\left(\frac{N_s}{\varepsilon^2}\right)^n\right)$ samples are necessary and sufficient for pure state tomography.

- *Gaussian states.* We prove that tomography of (energy-constrained) Gaussian states is efficient, as there exists a tomography algorithm whose sample and time complexity scales polynomially in the number of modes. Notably, our result demonstrates that Gaussian states can be efficiently learned by estimating the first moment and the covariance matrix, a result that has been previously assumed but never rigorously proved in the literature. To conduct the complexity analysis, we investigate the following fundamental question, which is of independent interest for the field of Gaussian quantum information: if we approximate the first moment and covariance matrix of an unknown Gaussian state with precision ε, what is the resulting trace distance error on the state? In our work, we answer this question by finding an upper bound on the trace distance between two Gaussian states in terms of the distance between their first moments and their covariance matrices.

- *t-doped Gaussian states.* t-doped Gaussian states are n-mode pure states prepared by applying Gaussian unitaries and at most t non-Gaussian κ-mode unitaries on the vacuum state. We prove that, if $2\kappa t \le n$, one can turn any t-doped state into a tensor product between a $2\kappa t$-mode non-Gaussian state and the $(n-2\kappa t)$-mode vacuum state, via a suitable Gaussian unitary. By leveraging such a decomposition, we devise a tomography algorithm which has a sample and time complexity that scales polynomially in n as long as $\kappa t = O(1)$, thereby establishing that tomography of (energy-constrained) t-doped states is efficient in this regime. This establishes the robustness of tomography of Gaussian states, in the sense that, even if few non-Gaussian unitaries are applied to a Gaussian state, the resulting state remains efficiently learnable. Our results on t-doped bosonic states are derived by extending to the bosonic setting some results on t-doped fermionic states of an ongoing parallel work [?]. However, extending these results is far from trivial, since in the bosonic setting one must deal with the subtleties arising from the energy constraints and from the infinite-dimensional Hilbert space.

With these results, our work significantly advances also the field of Quantum Learning Theory [11].

II. Tomography of energy-constrained states

For a system of n qudits with local dimension d, the minimum number of samples required to achieve quantum state tomography with precision ε in trace distance scales as $\tilde\Theta\left(\frac{d^{2n}}{\varepsilon^2}\right)$ [12–14], which is exponential in the number of qudits. We generalize this result to energy-constrained CV systems.

Theorem 1 ((Informal version))**.** *Let us consider an unknown n-mode state ρ satisfying the k-th moment constraint $(\mathrm{Tr}\left[\hat N_n^k\rho\right])^{1/k} \le nN_s$, where $\hat N_n$ is the total photon number operator. The number of samples required to achieve quantum state tomography with precision ε in trace distance has to scale at least as $\tilde\Omega\left(\left(\frac{N_s}{\varepsilon^{2/k}}\right)^n\right)$. Moreover, there exists a tomography algorithm for possibly mixed states with sample complexity that scales as $O\left(\left(\frac{N_s}{\varepsilon^{2/k}}\right)^{2n}\right)$. Notably, if we assume the unknown state to be pure, then $\tilde\Theta\left(\left(\frac{N_s}{\varepsilon^{2/k}}\right)^n\right)$ samples are necessary and sufficient for tomography.*

Proof ideas. The proof of the lower bound on the sample complexity involves ε-net techniques [15–18]. For the upper bound, we devise an explicit algorithm consisting of two main steps: first, performing a two-outcome measurement to project onto a suitable finite dimensional space with a fixed maximum photon number, and, second, applying known tomography algorithms for qudits.

We note that the CV classical shadow algorithm proposed in [19], primarily designed for estimating expectation values, effectively offers an alternative tomography algorithm. However, its sample complexity scales as $O\left(\left(\frac{n^2N_s^2}{\varepsilon^{2/k}}\right)^{2n}\right)$, which, being super-exponential in n, is much worse than the scaling $O\left(\left(\frac{N_s}{\varepsilon^{2/k}}\right)^{2n}\right)$ of our algorithm. Regarding the CV classical shadow algorithm proposed in [20], it provides guarantees in terms of the operator norm rather than the trace distance, making it unsuitable for quantum state tomography.

III. Tomography of Gaussian states

It is well established that: "In order to *know* a Gaussian state it is sufficient to *know* its first moment and its covariance matrix". However, in practice, we never know the first moment and the covariance matrix *exactly*, but we can only have estimates of them, meaning that we can only approximately know the Gaussian state. It is thus a fundamental problem – yet never tackled before – of Gaussian quantum information to determine what is the error incurred in trace distance when estimating the first moment and covariance matrix of an unknown Gaussian state up to a precision ε. The forthcoming Theorem 2 addresses this problem. One might be inclined to believe that there is a simple approach to solving this problem, involving first bounding the trace distance in terms of fidelity and then employing the known formula for fidelity between Gaussian states [21]. While this approach may seem promising at first glance, it ultimately fails because the expressions involved in the fidelity formula are too complicated to allow for the derivation of a simple bound in terms of the distance between the first moments and the covariance matrices.

Theorem 2. *Let ρ_1 and ρ_2 be Gaussian states with mean total photon number upper bounded by N_s, i.e. it holds that $\mathrm{Tr}\left[\rho_1\,\hat N_n\right] \le N_s$ and $\mathrm{Tr}\left[\rho_2\,\hat N_n\right] \le N_s$. The trace distance between ρ_1 and ρ_2 can be upper bounded as*

$$\frac{1}{2}\|\rho_1-\rho_2\|_1 \le \sqrt{2(N_s+1)}\left(\|m_1-m_2\|_2+\sqrt{2}\sqrt{\|V_1-V_2\|_1}\right),$$

where m_1 and m_2 are the first moments and V_1 and V_2 are the covariance matrices of ρ_1 and ρ_2, respectively. Here, $\|\cdot\|_1$ and $\|\cdot\|_2$ denote the trace norm and the 2-norm.

Proof tools. We use non-standard properties of the Gaussian channel $\mathcal{N}_K$ that acts on the covariance matrices as $V \mapsto V+K$ and leaves the first moments unchanged, where K is a fixed positive semi-definite matrix. Specifically, leveraging results from [22], we prove that the *energy-constrained* diamond distance [23?] between N_K and the identity satisfies $\frac{1}{2}\|\mathcal{N}_K-\mathrm{Id}\|_{\diamond N_s} \le \sqrt{2(N_s+1)}\sqrt{\mathrm{Tr}\,K}$, which constitutes a new technical tool.

Theorem 2, which we regard as a significant technical contributions, establishes that an ε-estimate of the first moment and of the covariance matrix of a Gaussian state leads an $\sqrt{\varepsilon}$-estimate of the state in trace distance. Moreover, Theorem 2 allows us to analyse the sample complexity of tomography of Gaussian states.

Theorem 3 ((Informal version))**.** *Let ρ be an unknown n-mode Gaussian state with mean energy per mode upper bounded by E, i.e.* $\mathrm{Tr}\left[\rho\hat{E}_n\right] \leq nE$ *where* $\hat{E}_n := \sum_{i=1}^{n}\left(\frac{\hat{x}_i^2}{2}+\frac{\hat{p}_i^2}{2}\right) = \hat{N}_n + \frac{n}{2}\mathbb{1}$ *is the energy operator. For any* $\varepsilon, \delta \in (0,1)$, *a number* $O\left(\frac{n^7E^4}{\varepsilon^4}\log\left(\frac{n^2}{\delta}\right)\right)$ *of copies of* ρ *suffices to construct a classical description of a Gaussian state estimator* $\tilde{\rho}$ *such that* $\frac{1}{2}\|\tilde{\rho}-\rho\|_1 \leq \varepsilon$ *with probability at least* $1-\delta$.

Proof ideas. The key step of the proof involves applying Theorem 2. Moreover, note that to obtain rigorous performance guarantees on the estimate of the covariance matrix, we need to establish an upper bound on the second moment of the energy. We do this by proving that any Gaussian state ρ satisfies $\mathrm{Tr}\left[\rho\hat{E}_n^2\right] \leq 3(\mathrm{Tr}\left[\rho\hat{E}_n\right])^2$, which constitutes a new technical tool.

We can improve the trace distance bound in Theorem 2 if we assume one of the states, say ρ_1, to be a pure Gaussian state (interestingly, such an improved bound holds even if ρ_2 is not Gaussian). By exploiting this improved bound, we can show that $O\left(\frac{n^5E^3}{\varepsilon^4}\log\left(\frac{n^2}{\delta}\right)\right)$ samples suffices to achieve tomography of pure Gaussian states.

Tomography of t-doped Gaussian states.— An n-mode unitary U_t is said to be a t-doped Gaussian unitary *if it is a composition of Gaussian unitaries and at most t non-Gaussian κ-mode unitaries. In other words, U_t is of the form $U_t = G_tW_t\cdots G_1W_1G_0$, where each G_i is an n-mode Gaussian unitary and W_i is a κ-mode non-Gaussian unitary. Strictly speaking, we assume each W_i to be a unitary generated by an Hamiltonian which is a (non-quadratic) polynomial in the quadratures of at most κ modes. An n-mode state $|\psi\rangle$ is said to be a* t-doped Gaussian state *if it can be prepared by applying a t-doped Gaussian unitary to the vacuum: $|\psi\rangle = U_t\,|0\rangle^{\otimes n}$. Remarkably, the following decomposition of t-doped unitaries and states hold.*

Theorem 4 ((Non-Gaussianity compression in t-doped Gaussian unitaries and states))**.** *If $n \geq 2\kappa t$, any t-doped Gaussian unitary U_t can be decomposed as $U_t = G(u_{2\kappa t}\otimes\mathbb{1}_{n-2\kappa t})G_{passive}$, for some suitable Gaussian unitary G, passive Gaussian unitary $G_{passive}$, and $2\kappa t$-mode (non-Gaussian) unitary $u_{2\kappa t}$. In particular, any t-doped Gaussian state can be decomposed as*

$$|\psi\rangle = G\left(|\phi_{2\kappa t}\rangle \otimes |0\rangle^{\otimes(n-2\kappa t)}\right) \tag{1}$$

for some suitable Gaussian unitary G and $2\kappa t$-mode (non-Gaussian) state $|\phi_{2\kappa t}\rangle$.

Theorem 4 establishes that it is possible to compress all the non-Gaussianity of a t-doped Gaussian state via a suitable Gaussian unitary. By leveraging the decomposition in (1)*, we can design a tomography algorithm for t-doped Gaussian states, whose performance are analysed in the Theorem 5 below. The idea behind our algorithm involves first estimating the Gaussian unitary G, then applying its inverse to the state in order to compress the non-Gaussianity, and finally performing the tomography algorithm mentioned in Theorem 1 over the first $2\kappa t$ modes.*

Theorem 5 ((Informal version))**.** *Let $|\psi\rangle$ be an unknown n-mode t-doped Gaussian state with second moment of the energy per mode upper bounded by E_2, i.e.* $\sqrt{\mathrm{Tr}\left[\rho\hat{E}_n^2\right]} \leq nE_2$. *For any $\varepsilon, \delta \in (0,1)$, a number* $O\left(\left(\frac{n^2(E_2)^2}{\varepsilon^2}\right)^{\kappa t}\right)$ *of copies of $|\psi\rangle$ suffices to construct a classical description of an estimator* $\left|\tilde{\psi}\right\rangle$ *such that* $\frac{1}{2}\left\|\left|\tilde{\psi}\middle\rangle\!\middle\langle\tilde{\psi}\right| - |\psi\rangle\!\langle\psi|\right\|_1 \leq \varepsilon$ *with probability at least* $1-\delta$.

Proof tools. *We exploit concentration inequalities typically used in statistical learning theory. Moreover, we employ a variety of established tools in Gaussian quantum information while also introducing novel tools. For instance, we utilise the known perturbation bound on symplectic eigenvalues of covariance matrices established by [24]. As an example of novel tool, we introduce the inequality* $E\left(U_S\rho U_S^\dagger\right) \leq \|S\|_\infty^2 E(\rho)$, *where* $E(\rho) := \mathrm{Tr}\left[\rho\hat{E}_n\right]$ *is the mean energy of ρ, U_S is the Gaussian unitary associated with a symplectic matrix S, and $\|\cdot\|_\infty$ is the operator norm.*

Theorem 5 implies that tomography of t-doped Gaussian states is efficient in the regime $\kappa t = O(1)$, as its sample, time, and memory complexity scales polynomially in n.

Conclusions.— Our work serves as bridge between the two fields of quantum learning theory and CV quantum information. We provide the first investigation of tomography of continuous variable systems with rigorous performance guarantees in terms of the trace distance. We first investigate moment-constrained states, by showing both lower and upper bounds on the sample complexity of tomography. Remarkably, we identify the optimal sample complexity for tomography of moment-constrained pure states. Second, we rigorously prove that tomography of Gaussian states is efficient. To achieve this, in Theorem 2 we introduce an upper bound on the trace distance between Gaussian states in terms of the distance between their first moments and their covariance matrices, which constitutes a technical tool of independent interest for the community of continuous variable quantum information. Finally, we analyse t-doped Gaussian states, demonstrating a valuable decomposition in Theorem 4, which guides the development of an apt tomography algorithm.

Virtual Channel Purification

Zhenhuan Liu, Xingjian Zhang, Yue-Yang Fei, and Zhenyu Cai

The full version of this paper can be found at arXiv:2402.07866.

Introduction–Despite the rapid advances in quantum hardware in recent years, there is still an extended stretch of time ahead before we can successfully implement quantum error correction (QEC) to achieve fully fault-tolerant computation. In order to reach practical quantum advantages during this time, it is essential to develop noise suppression techniques compatible with existing quantum technologies. One key method is quantum error mitigation (QEM) [1], which can extract target information from noisy quantum circuits without physically recovering the noiseless quantum state. Due to the low hardware requirement, QEM has become a prevailing tool in many quantum computation experiments [2–4] and is expected to play a key role also in the early fault-tolerant era.

Over the years, various QEM protocols have been proposed, but each comes with its own sets of assumptions. Probabilistic error cancellation [5, 6] relies on detailed knowledge about the noise models and the assumption that the noise remains the same across different times and different qubits. Zero-noise extrapolation [5, 7] requires the ability to tune hardware noise without significantly modifying the noise model and it can only offer rigorous performance guarantee at small noise. Virtual state purification [8, 9] requires the ideal input and output state to be pure states and also the noiseless component to be the dominant component of the noisy output state. Symmetry verification [10, 11] require problem-specific knowledge about the symmetry or energy constraints on the output state.

In this article, we introduce a QEM technique called *virtual channel purification* that *removes all of the assumptions above*, i.e. it is the first QEM protocol that imposes no requirements on specific knowledge about the gate error models, the incoming and output state, and the problem we try to solve; does not require additional hardware capability beyond gate-model computation; while still offers rigorous performance guarantee for the most practical noise regime. The only assumption it makes is that the noise in the ideal unitary operation is incoherent, which is the case for most practical scenarios [12, 13], especially with the help of Pauli twirling [14–17].

Protocol–Virtual channel purification (VCP) is obtained by combining ideas from virtual state purification (VSP), Choi–Jamiołkowski isomorphism, and the circuit for flag fault-tolerance [18]. Just like how VSP uses M copies of a noisy state to virtually prepare a purified output state whose infidelity falls exponentially with M, VCP is able to use M copies of a noisy *channel* $\mathcal{U}_{\mathcal{E}} = \mathcal{E}\mathcal{U}$ with $\mathcal{E} = p_0\mathcal{I} + \sum_{i=1}^{4^N-1} p_i\mathcal{E}_i$ to virtually implement a purified channel $\mathcal{U}_{\mathcal{E}^{(M)}} = \mathcal{E}^{(M)}\mathcal{U}$ with

$$\mathcal{E}^{(M)} = \frac{1}{\sum_{i=0}^{4^N-1} p_i^M}\left(p_0^M\mathcal{I} + \sum_{i=1}^{4^N-1} p_i^M\mathcal{E}_i\right) \tag{1}$$

whose infidelity falls exponentially with M. As shown in Fig. 1(a) and (c), the circuit implementation costs of VSP and VCP are similar, but VCP removes many assumptions of VSP as mentioned and provides much stronger error suppression power, extending the applicability of such methods into deeper and noisier circuits.

Performance– Compared to its state counterpart, virtual state purification (VSP), VCP can suppress global noise exponentially stronger in the number of qubits due to the larger dimensionality of channels compared to states, as shown in Fig. 2(c). While VSP requires the ideal output state to be a pure state, VCP places no such restrictions as it directly purifies the noisy channel and thus can be applied to any input state. Furthermore, while VSP can only be applied to the entire quantum circuit as a whole, VCP can be applied in a layer-by-layer manner or even target specific gates in the circuits, as demonstrated in Fig. 1(f)-(h). This provides flexibility and, more importantly, removes the restriction in VSP that the noiseless component must be the dominant component for the noisy circuit output. In this way, VCP is applicable to much deeper and noisier circuits than VSP.

When considering the practical implementation of VCP, the single-layer variant only requires one additional layer of CSWAPs compared to VSP. Furthermore, the noise of this additional layer of CSWAP is naturally mitigated by VCP itself. We have seen in Fig. 2(d) that the errors due to CSWAPs are essentially the same for both VCP and VSP. Hence, single-layer VCP is almost always preferred over VSP due to its stronger noise suppression power at a similar implementation error cost. We can further optimise the number of VCP layers to outperform the single-layer variant. In numerical simulation across a range of circuit depths and gate error rates, optimal-layer VCP always outperform VSP and can offer up to 4 times more error suppression, shown in Fig. 2(e)-(g). The advantage is expected to be even stronger using more copies of noise channels and more qubits.

FIG. 1. (a)-(c)The logic for constructing VCP circuit, taking $M = 2$ without loss of generality. (a) The circuit for VSP, consists of two copies of the noisy input state, a single control qubit initialised as $|+\rangle$, and a CSWAP gate. By measuring the control qubit in Pauli-X basis, one can virtually prepare the purified state on the second register. (b) One possible circuit implementation of VCP, obtained from performing the VSP circuit in (a) on two copies of Choi states of the noisy channel. Each curved line at the input end stands for a $2N$-qubit maximally entangled state $\left|\Phi^+\right\rangle = \frac{1}{\sqrt{2^N}}\sum_{i=0}^{2^N-1}|ii\rangle$, which is used to prepare the Choi state of the noisy channel $\mathcal{U}_\mathcal{E}$. Then, the VSP circuit acts on two noisy Choi states to virtually obtain a purified Choi state. The curved line at the output end stands for Bell state measurement (BSM) post-selected on the all-zero result, which is for implementing the purified channel using the purified Choi state. (c) A circuit implementation of VCP, obtained from straightening the curved lines in green and red in (b). By measuring the control qubit in Pauli-X basis, one can virtually implement the purified channel on the second register. This circuit is easily generalised to a larger value of M by employing $M-1$ copies of maximally mixed state and changing SWAP to the Mth order permutation. (d) Application of channel purification in entanglement distribution. Blue circles represent two users and $\left|\Phi^+\right\rangle$ is the entangled state that is distributed. (e) The circuit for channel purification. Compared to the VCP circuit, we post-select on the measurement results of the control qubit and keep only the $|+\rangle$ outcome. The dashed blue box corresponds to the purification process in (d). (f)-(h) Comparison between VSP and VCP with $M = 2$. (f) For a quantum circuit with depth D, VCP protocol can be applied layer-by-layer. (g) VSP protocol can only be performed once at the end of the quantum circuit with one control qubit and two identical copies. (h) VCP can target specific noisy gates in the quantum circuit.

controlled qubit measurement results instead of post-processing, as shown in Fig. 1(e), we can physically (instead of virtually) obtain a purified channel, which can then be applied to many tasks in quantum networks. As shown in Fig. 1(d), in entanglement distribution, compared to previous works based on entanglement purification, our channel purification protocol does not require multipartite joint operations and multiple identical copies of the distributed states for local quantum noises. Furthermore, with a single clean channel to transmit a single clean qubit, our protocol can purify noisy channels with arbitrarily large dimensions and enable the activation of valuable quantum resources. The fact that our protocol is applicable to arbitrary incoming states and arbitrary incoherent noise also opens up the door for many other possible applications in communication.

Connection with QEC– Due to the key roles we expect QEC and QEM to both play in practical quantum computation, there is always a strong desire to develop a framework that combines the two. So far the attempts are mostly about concatenating QEM on top of QEC [19–21]. Through further generalisation of VCP and the use of the Knill-Laflamme condition [22], we are able to obtain one of the first integrated protocols that combine QEM and QEC beyond concatenation. In this protocol, by paying the same sampling cost as channel purification using two copies, we are able to *remove all noise* in the noisy channel, reaching beyond the standard bias-variance trade-off limit in pure QEM [1].

In the standard configuration of VCP, the additional copies of the noisy channels are acting on a maximally mixed input state at the ancillary registers. Using the Knill-Laflamme condition, we show that we can also perform purification using a quantum error correction (QEC) code state as the ancillary input state. Furthermore, if we are able to perform stabiliser checks on the ancillary register at the end of the circuit and post-select, we can remove *all noise* from the main register using just two copies of the noise channel. This comes with a higher sampling cost following the usual bias-variance trade-off in QEM. Now instead of post-selecting on the stabiliser check results of the ancillary register, if we perform correction on the *main register* based on these check results, we can actually remove *all noise* from the main register while paying only the sampling cost of the second-order VCP. This provides one of

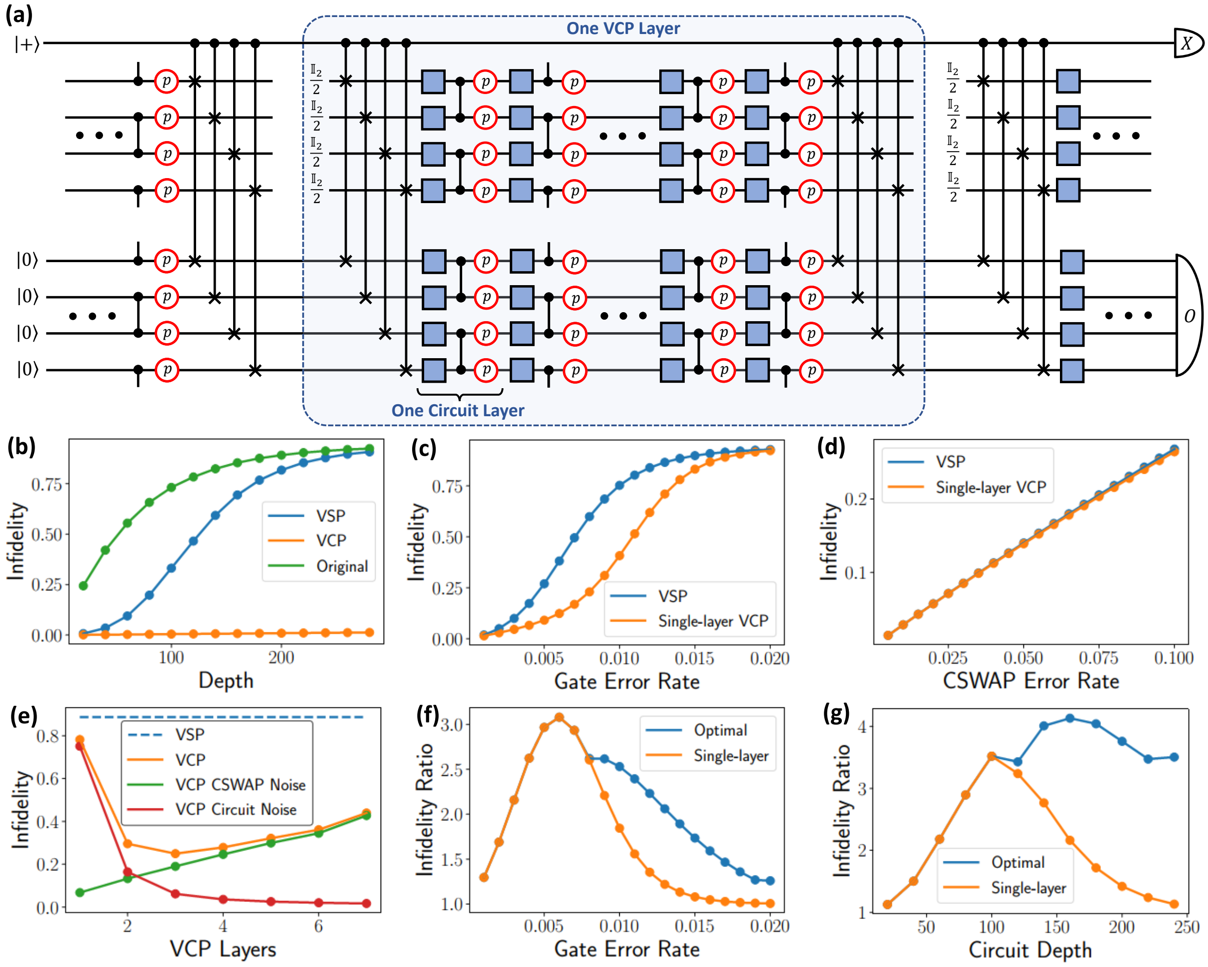

FIG. 2. (a) The circuit for our numerical simulation with VCP applied. The main circuit is a four-qubit system initialised in the all-0 state evolving through a random circuit consisting of alternating layers of random single-qubit gates (blue boxes) and CNOT gates (two dots connected by a vertical line). The CNOT gates are affected by two single-qubit depolarising channels each with an error rate p (red circles). The whole circuit is divided into L VCP layers to perform the circuit shown in 1(f). In all numerical tests besides (b), every CSWAP gate is followed by three single-qubit depolarising channels each with an error rate $5p$. (b) The infidelities after VSP and VCP for different circuit depths *without any CSWAP noise*. The gate error rate is $p = 0.005$ and the depth of each VCP layer is 20. (c) The infidelities after VSP and single-layer VCP at different values of p. The circuit depth is set to be 80. (d) The error rates caused by the CSWAP noise in VSP and single-layer VCP using the same circuit as (c), where we have removed the CNOT noise while keeping only the CSWAP noise. (e) The infidelity behaviour after VCP with different numbers of VCP layers for a circuit with a depth 240 and a gate error rate $p = 0.005$. The green and red lines represent cases without CNOT and CSWAP errors, respectively. (f) The infidelity ratios between VSP and single-layer VCP, and between VSP and VCP with the optimal number of VCP layers, at different gate noise rates with a circuit depth of 80. (g) The infidelity ratios at different circuit depths with a fixed gate error rate of $p = 0.005$.

the first frameworks that seamlessly combines QEM and QEC beyond the concatenation of QEC and QEM [19–21].

Outlook– Due to the presence of the controlled permutation operator at the beginning of the circuit which is coherently connected to the controlled permutation operator at the end, VCP actually lies outside the QEM frameworks presented for the discussion of the fundamental limits of QEM [23–25]. Hence, hopefully VCP can inspire a new range of QEM protocols outside these frameworks, like the combination with symmetry verification. One can also develop more general frameworks of QEM that incorporate VCP, which may have more desirable properties compared to the previous QEM framework. One promising way to do this is by finding deeper connections to QEC. It will also be interesting to search for other QEM methods that can be naturally merged with QEC beyond concatenation, similar to what we have done. This can be the start of a more general error suppression framework that naturally incorporates both QEM and QEC.

Abstract. Nonlocal games play a crucial role in quantum information theory and have numerous applications in certification and cryptographic protocols. Kalai et al. (STOC 2023) introduced a procedure to compile a nonlocal game into a single-prover interactive proof, using a quantum homomorphic encryption scheme, and showed that their compilation method preserves the classical bound of the game. Natarajan and Zhang (FOCS 2023) then showed that the quantum bound is preserved for the specific case of the CHSH game. Extending the proof techniques of Natarajan and Zhang, we show that the compilation procedure of Kalai et al. preserves the quantum bound for two classes of games: XOR games and d-outcome CHSH games. We also establish that, for any pair of qubit measurements, there exists a compiled XOR game such that its near-optimal winning probability serves as a robust self-test for that particular pair of measurements. Finally, we derive computational self-testing of three anticommuting qubit observables, based on the compilation of the nonlocal game corresponding to the so-called elegant Bell inequality.

Keywords: Bell non-locality, quantum cryptography

1 Introduction

Nonlocal games play a crucial role in quantum information theory and have numerous applications in certifications protocols. The first proofs of separation between classical and quantum resources are based on nonlocal games, with the most emblematic example being the Clauser-Horne-Shimony-Holt (CHSH) game [6, 10]. In such games, an honest classical referee has a 1-round classical interaction with 2 or more non-communicating players. They will then evaluate a function of the outputs and the inputs, called predicate, to establish whether to accept or not; the acceptance probability is the score of the game. The difficulty to win does not arise from the complexity of the predicate, but rather from the players' partial information. For some games the maximal score that quantum provers can achieve is strictly higher than any classical strategy, hence they can be used as proofs of quantumness. In addition to its far-reaching foundational interest, Bell nonlocality [9] enjoys a rich array of applications concerned with the certification of quantum resources and cryptographic tasks, such as device-independent quantum key distribution [1, 23, 4], certified randomness [11, 19, 2] and self-testing [17, 22].

The framework of Bell nonlocality however requires at least two non-communicating parties, and the strongest guarantees of information-theoretic security can thus only be achieved if these parties are space-like separated, which turns out to be experimentally very challenging. Moreover, from a pragmatical point of view, if one wants to certify resources on a quantum computer as it is an integral device, spatial separation and the absence of communication cannot be imposed. These are strong motivations to try to relax the constraint of spatial separation, while preserving classical verification of quantum computation.

Cryptography seems to offer a very promising tool: (quantum) homomorphic encryption, which allows to perform computations on encrypted (quantum) data without decrypting them. This could be used to mimic spatial separation by hiding to the single prover the complete knowledge of the inputs, which would otherwise make the game trivial. Kalai *et al.* formalised in [13] the idea of using quantum homomorphic encryption [16, 7] to emulate spatial separation between the nonlocal parties. They propose a procedure to compile every k-players nonlocal game into a single-prover interactive proof of $2k$-rounds, by fixing a sequential structure of the input-output requests and encrypting the first $k-1$ rounds. They then prove: (i) the *completeness* of the procedure, that is, there is an explicit and efficient quantum strategy that achieves the quantum bound of the original nonlocal game; and (ii) its *classical soundness*, that is, no classical prover can outperform the optimal classical bound up to a negligible function in the security parameter, which is the advantage of the classical adversary in the indistinguishability (IND-CPA) security game of the encryption scheme.

However Kalai *et al* do not provide an upper bound to the optimal score of a quantum prover. Indeed [13] uses classical rewinding techniques to show the soundness against classical adversaries, but this is no longer possible against quantum provers. Follow-up works by Natarajan and Zhang [18] and Brakerski *et al.* [8] prove that the quantum bound is preserved in the specific case of the compiled CHSH game. Their proofs heavily relies

Figure 1: Pictorial representation of the Kalai *et. al.* compilation protocol for 2-player nonlocal games. On the left, a general 2-player nonlocal game; the two parties are spatially separated, and only communicate to a classical verifier which is sampling questions (x, y) and collecting their answers (a, b). On the right, the single prover game resulting from the compilation procedure. In this representation, time flows downwards.

on specific properties of CHSH, providing little insight on whether Kalai *et al.* compiler preserves the quantum bound for any other nonlocal games.

2 Our Contributions

In this work, we continue this research direction and provide a partial answer for the above open question. In particular, we prove that the quantum bound is preserved for two classes of compiled games: XOR games, where the predicate depends on the logical XOR of the outputs, and d-outcome CHSH games, that generalise the CHSH game to a scenario involving many-output measurements. We also extend our results to self-testing, which relies on the fact that for specific non-local games there is a unique strategy that can achieve the optimal quantum score; then, reaching this bound is a device-independent certification of quantum resources.

The techniques we use are based on the cryptographic SOS decomposition delineated in [18]. The score of a nonlocal game is usually formulated as the expectation value of some function of the observables of the players. This is closely related to the Bell operator $\mathcal{B}$, and its shifted version $\beta\mathbb{1} - \mathcal{B}$, where β is what we call the shift. SOS decomposition - standing for sum of squares - is a method widely used in Bell nonlocality to prove quantum bounds. It consists on mathematically rearranging the terms of the shifted Bell operator as a sum of polynomials squared, whose expectation value is positive semi-definite by definition.

$$\langle\psi|\,\beta\mathbb{1} - \mathcal{B}\,|\psi\rangle = \sum_i \langle\psi|\,P_i^2\,|\psi\rangle \geq 0 \implies \langle\psi|\,\mathcal{B}\,|\psi\rangle \leq \beta$$

Hence the shifted Bell operator is also positive semi-definite, meaning that the shift β is an upper bound for the optimal quantum score. The bound becomes tight if an explicit quantum strategy achieving β is found. If the polynomials appearing in the decomposition are of degree n, then we say we have a nth-order SOS decomposition.

Elaborating on the results of [18], we define a function that maps polynomials of nonlocal observables to correlations observed in the compiled nonlocal game. This function, that we refer to as the pseudo-expectation value map $\tilde{\mathbb{E}}$, allows us to translate the SOS decomposition proof from the nonlocal to the compiled game. For polynomials of observables with a physical interpretation, we intuitively translate the probabilities using some change of variables compatible with the structure of the compiled game; therefore it acts trivially on the identity, and when applied to the Bell functional it gives the score of the compiled game. We call it pseudo-expectation because it is not a positive semi-definite function by definition. In particular, the pseudo-expectation of the polynomials squared from the SOS decomposition is not positive by definition anymore. Nevertheless, we prove that - for specific polynomials - these quantities are positive up to a negligible function in the security parameter κ of the QHE scheme.

Lemma 1 (Informal) *Consider a Bell inequality $\mathcal{B}$ with a SOS decomposition, whose polynomials can be written as $P_i = A_i - \hat{B}_i$, where $\{A_i\}_i$ are Alice's observables and $\{\hat{B}_i\}_i$ are linear sums of Bob's observables. Then there exists a negligible function $\eta_{\mathrm{QHE}}(\cdot)$ such that we have $\tilde{\mathbb{E}}\left[P_i^2\right] \geq -\eta_{\mathrm{QHE}}(\kappa)$.*

Technically, this is done by extending cryptographic arguments based on the security of the encryption scheme. Then, applying the pseudo-expectation map to the nonlocal SOS decomposition, we prove that the quantum bound of the compiled game is preserved up to a negligible function in the security parameter.

$$\begin{aligned}\tilde{\mathbb{E}}[\beta\mathbb{1} - \mathcal{B}] = \sum_i \tilde{\mathbb{E}}[P_i^2] &\geq -\eta_{\mathrm{QHE}}(\kappa) \\ \implies \tilde{\mathbb{E}}[\mathcal{B}] &\leq \beta + \eta_{\mathrm{QHE}}(\kappa)\end{aligned}$$

The pseudo-expectation map is well defined for polynomials of degree 2 in the number of observables, restricting us to work with first-order SOS decompositions. We lack of a meaningful interpretation for polynomials containing two different Alice's observables in the compiled scenario, but we can fix the shape of the SOS polynomials P_i to contain only one observable for Alice for several non-local games of interest.

In particular, in the paper we revise some known results for XOR games, and derive a new result on the decomposition of the shifted game operator. Notably, we prove that it is always possible to have a decomposition with polynomials P_i containing only one Alice's observable. This helps us to prove that the quantum score of all XOR games is preserved by Kalai *et al.* compilation.

Theorem 2 *Given an XOR game with optimal quantum bound β_q, the optimal quantum bound of the compiled XOR game is $\beta_q + \delta_{\mathrm{QHE}}(\kappa)$, where $\delta_{\mathrm{QHE}}(\cdot)$ is a negligible function.*

We also extend the pseudo-expectation map to treat higher dimensional inputs and outputs, hence generalised observables. As an example we apply it to the SATWAP inequality proposed in [20], a generalisation of CHSH for which we know it exists a SOS decomposition in our desired form [21]. We prove that the quantum score of the compiled game is preserved in this case as well. Apart from its mathematical relevance, this could lead to much more efficient certifications.

Theorem 3 *Consider the d-dimensional SATWAP Bell inequality with quantum bound $(\beta_d^{SATWAP})_q$, and its compiled version. If d is polynomial w.r.t. the security parameter κ, then the quantum bound of the compiled SATWAP inequality is $(\beta_d^{SATWAP})_q + \theta(\kappa)$, where $\theta(\cdot)$ is a negligible function.*

The SOS decomposition imposes constraints on the strategies achieving the optimal quantum score; sometimes these constraints are enough to uniquely identify these strategies, leading to self-testing protocols. From the cryptographic SOS decomposition we develop computational self-testing techniques for interactive single prover games, built on top of the nonlocal self-testing proofs. In particular, we focus on two relevant XOR games. In these cases Jordan's lemma applies, and fixing the anti-commutators of the observables is usually enough to have robust self-testing statements [14]. By achieving the optimal quantum score of some compiled XOR games, using classical interaction with a single device we can robustly self test the following resources:

- any pair of binary measurements, from the compilation of the family of Bell inequalities presented in [15, 5, 24];
- triplets of mutually unbiased base (MUB) qubit measurements, from the compilation of the elegant Bell inequality [12, 3].

To conclude, our work aims to bridge topics at the interface between quantum nonlocality, quantum cryptography and quantum complexity theory, proving fruitful combinations between these fields. Our findings reveal that the compilation procedure introduced in [13] effectively preserves the quantum bound of many interesting games, leaving the question of extending this preservation to even more nonlocal games.

Abstract

Nonlocal games play a crucial role in quantum information theory and have numerous applications in certification and cryptographic protocols. Kalai et al. (STOC 2023) introduced a procedure to compile a nonlocal game into a single-prover interactive proof, using a quantum homomorphic encryption scheme, and showed that their compilation method preserves the classical bound of the game. Natarajan and Zhang (FOCS 2023) then showed that the quantum bound is preserved for the specific case of the CHSH game. Extending the proof techniques of Natarajan and Zhang, we show that the compilation procedure of Kalai et al. preserves the quantum bound for two classes of games: XOR games and d-outcome CHSH games. We also establish that, for any pair of qubit measurements, there exists an XOR game such that its optimal winning probability serves as a self-test for that particular pair of measurements.

1 Introduction

In quantum information theory, nonlocal games are a class of games that exemplifies the separation between classical and quantum resources. In such games, a referee sends classical inputs to two or more distant parties, and the parties reply with classical outputs. A predicate on the tuples of inputs and outputs defines the winning conditions for the game. In some cases, if the distant parties have access to quantum resources, namely entangled states, they can achieve a score higher than if they only have classical resources. Building on the work of Bell [Bel64], Clauser, Horne, Shimony and Holt introduced the setting for the most famous example of such a game, the CHSH game [CHSH69]. While players with classical resources can only reach a maximal value of 0.75, players sharing entanglement can obtain a value of $\cos^2(\pi/8)$.

In addition to its far-reaching foundational interest, Bell nonlocality [BCP+14] enjoys a rich array of applications concerned with the certification of quantum resources and cryptographic tasks, such as device-independent quantum key distribution [ABG+07, VV14, AFDF+18], certified randomness [Col07, PAM+10, AM16] and self-testing [MY04, ŠB20]. The framework of Bell nonlocality however requires several non-communicating parties, and the strongest guarantees of information-theoretic security can thus only be achieved if these parties are spatially separated. Bell nonlocality is also connected to the powerful notion of multiprover interactive proof systems in quantum complexity theory, MIP*, in which two or more non-communicating provers are allowed to share quantum entanglement. In the classical setting, techniques and results from studying MIP (the classical version of MIP*) usually also find applications in the cryptographic setting, where all parties are computationally bounded, such as the celebrated PCP theorems and succinct arguments. Crucially, a series of works [ABOR00, KRR14] showed that, using a homomorphic encryption scheme, any MIP sound against non-signalling provers can be compiled into a single-prover protocol in which the single prover is computationally bounded and restrained by cryptographic tools.

In the quantum setting, recently, Kalai *et al.* [KLVY23] proposed a general method to compile nonlocal games into single-prover systems based on quantum homomorphic encryption [Mah23, Bra18], and showed that

[*] matilde.baroni@lip6.fr

the classical bound of the compiled game is preserved by their procedure. Follow-up works by Natarajan and Zhang [NZ23] and Brakerski *et al.* [BGK+23] proved that the quantum bound is also preserved in the specific case of the compiled CHSH game. Their works left open the question of whether Kalai *et al.* compiler also preserves the quantum bound for any nonlocal games. In this work, we continue this research direction and provide a partial answer for the above open question. In particular, we prove that the quantum bound is preserved for two classes of compiled games: XOR games, where the predicate depends on the XOR of the outputs, and d-outcome CHSH games, which generalize the CHSH game to the scenario involving many-output measurements.

Nonlocality serves as a tool for exploring certifiable quantum advantage, leading to the development of various quantum certification methods through self-testing, distinguished by their information-theoretic security. Notably, these certification protocols are formulated within the framework of the Bell scenario, designed for scenarios with two or more spatially separated parties. While effective for foundational proofs of quantumness, applying such setups to computing platforms faces challenges due to their incompatibility with Bell-type scenarios. In this context, gaining a deeper understanding of the additional properties of compiled nonlocal games becomes significant, as it holds the promise of translating diverse certification techniques into a single-device setting. However, this translation would come at the cost of exchanging information-theoretic security for computational security.

1.1 Outline of the paper

The paper is structured in the following way. Section 2 is dedicated to preliminary notions. We introduce nonlocal games and Bell inequalities, with a focus on a sub-class: XOR games. For these, in Section 2.3 we revise some known results and derive a new result on the decomposition of the shifted game operator. Then, we introduce quantum homomorphic encryption and Kalai's compilation protocol [KLVY23]. We elaborate on the results of [NZ23], in particular on their idea of defining a pseudo-expectation value that maps polynomials of measurement observables to correlations observed in the compiled nonlocal game.

The second part focuses on those cases for which we can prove that such a pseudo-expectation map can be used to upper bound the optimal quantum winning probabilities in compiled nonlocal games. In Section 3 we use the decomposition introduced in the preliminaries to prove the soundness of the quantum bound for any compiled XOR game. Section 4 generalizes our approach to encompass an inequality with a higher number of outputs. Finally, in section 5 we develop computational self-testing techniques for interactive single prover games, built on top of the nonlocal self-testing proofs. In particular, we show that a certain class of compiled XOR games can be used to self-test any pair of qubit measurements.

1.2 Concurrent and independent work

While finishing this manuscript we became aware of a recent work by Cui *et al.* [CMM+24] who also show that the compilation procedure of Kalai et al. [KLVY23] preserves the quantum bias of all XOR games. Even though both papers use a similar techniques based on [NZ23], [CMM+24] and our work also achieve different results. Their work shows a type of self-testing result for all compiled XOR games, while we explore the self-testing properties of carefully designed compiled XOR games, such that any pair of qubit measurements and tomographically complete sets of qubit measurements can be self-tested from the optimal winning probability. The work of Cui *et al.* explores the compilation of parallelly repeated XOR games and the Magic Square game, while we work with the compiled d-CHSH game which cannot be seen as a parallel repetition of XOR games.

2 Preliminaries

2.1 Nonlocal games and Bell inequalities

In a two-party nonlocal game, a referee randomly selects questions, also called inputs, according to a predetermined distribution and sends them to the non-communicating parties, usually called Alice and Bob. Upon receiving the answers, also called outputs, from Alice and Bob, the referee determines whether they won or lost based on the game rule, which is public. Winning is nontrivial because the players can't communicate during the game: they must generate their output solely based on their respective inputs and potentially a shared resource. $x \in \mathsf{X}$ and $y \in \mathsf{Y}$ denote the questions sent to Alice and Bob, respectively, $a \in \mathsf{A}$ and $b \in \mathsf{B}$ denote their respective answers. $|\cdot|$ denotes the cardinality of a set. The referee samples the questions from a distribution $q(x, y)$, and the game rule is a predicate $V : (a, b, x, y) \mapsto \{0, 1\}$. Alice and Bob define a strategy to answer the questions, based on the resources that they have, and the conditional probabilities of obtaining outputs a and b when inputting x and y, is denoted by $p(a, b|x, y)$. The winning probability of the game is then given by:

$$\omega = \sum_{x,y} q(x,y) V(a,b,x,y) p(a,b|x,y). \tag{1}$$

If Alice and Bob use classical resources, in the most general case they can share a random variable t sampled from a distribution $p(t)$, and they can determine their respective output based on the value of t and the received input. In the context of Bell nonlocality, such strategy corresponds to a local hidden variable model (LHV). In that case, the maximal winning probability is called the classical score of the game. Alice and Bob can always reach the maximal winning probability with deterministic response functions $f(x,t)$, $g(y,t)$ to choose their outputs [Fin82], and the maximal classical score is then equal to:

$$\omega_c = \max_{f,g} \sum_{x,y,t} p(t) q(x,y) V(f(x,t), g(y,t), x, y). \tag{2}$$

If Alice and Bob have access to quantum resources, they can share a quantum state $|\psi\rangle$ and perform quantum measurements on it. For each output, they can perform a different measurement, meaning that Alice has $|\mathsf{X}|$ different measurements, one for each for each x, characterized by $|\mathsf{A}|$ operators $\{M_{a|x}\}_a$, such that:

$$\forall x \in |\mathsf{X}|\,, \forall a \in |\mathsf{A}|\,, M_{a|x} \succeq 0, \tag{3}$$

$$\forall x \in |\mathsf{X}|\,, \sum_a M_{a|x} = \mathbb{1}. \tag{4}$$

Bob's measurements are defined similarly and denoted by $\{N_{b|y}\}_b$. The probability that Alice and Bob get outputs a and b, given inputs x and y is determined by the Born rule $p(a,b|x,y) = \langle\psi|M_{a|x} \otimes N_{b|y}|\psi\rangle$. In that case, the winning probability is equal to:

$$\omega = \sum_{x,y} q(x,y) V(a,b|x,y) \langle\psi|M_{a|x} \otimes N_{b|y}|\psi\rangle. \tag{5}$$

and the maximal quantum score is given by:

$$\omega_q = \max_{\{M_{a|x}\}_x, \{N_{b|y}\}_y, |\psi\rangle} \omega. \tag{6}$$

Note that, more generally, Alice and Bob could have access to a mixed state ρ, but since we don't impose any restriction on the dimension of the underlying Hilbert space, any score reachable with a mixed state can also be reached with a pure state by increasing the dimension of the Hilbert space.

If the players output bits, i.e. $|A| = |B| = \{0,1\}$, the game is said to be binary, and the quantum strategies can be characterised in a simpler way: their measurements are defined by the Hermitian measurement observables

$$A_x = \sum_a (-1)^a M_{a|x}, \qquad B_y = \sum_b (-1)^b N_{b|y}. \tag{7}$$

In the rest of the paper, we use the following notations:

$$|A_x\rangle = A_x|\psi\rangle, \qquad |A\rangle = \sum_x |A_x\rangle \otimes |x\rangle, \tag{8}$$

$$|B_y\rangle = B_y|\psi\rangle, \qquad |B\rangle = \sum_y |B_y\rangle \otimes |y\rangle, \tag{9}$$

which allows us to express the players' correlations through a correlation matrix as:

$$C = \sum_{x,y} c_{xy} |x\rangle\langle y| \qquad \text{with } c_{xy} = \langle A_x|B_y\rangle. \tag{10}$$

Nonlocal games are closely related to Bell inequalities [SMA08, AH12]. A Bell inequality can be defined via a linear form on the space of the conditional distributions $p(a,b|x,y) \in \mathbb{R}^{|A||B||X||Y|}$:

$$\sum_{a,b,x,y} \gamma_{a,b,x,y} p(a,b|x,y) \leq \beta_c, \tag{11}$$

which means that any nonlocal game can be seen as a Bell inequality by taking $\gamma_{a,b,x,y} = q(x,y)V(a,b,x,y)$. Importantly quantum Bell score can be written as $\beta = \langle\psi|\mathcal{B}|\psi\rangle$ where $\mathcal{B}$ is the Bell operator

$$\mathcal{B} = \sum_{a,b,x,y} \gamma_{a,b,x,y} M_{a|x} \otimes N_{b|y} \tag{12}$$

When there is a gap between the maximal classical and quantum scores, the quantum strategies that achieve a score higher than the classical value also violate a Bell inequality. For instance, the quantum state and measurements yielding the maximal value for the CHSH game also yield the maximal quantum value, known as Tsirelson's bound, for the CHSH inequality. In the remainder of this paper, we sometimes switch between the nonlocal game and the Bell inequality formulations. The local bound of a Bell inequality will be denoted with β_c, while the maximal value considering quantum strategy will be denoted as β_q. For a Bell inequality with quantum bound β_q we will often use the shifted Bell operator

$$\beta_q \mathbb{1} - \mathcal{B}, \tag{13}$$

which is by construction positive semi-definite.

2.2 Self-testing

Self-testing is a powerful technique that allows one to certify quantum resources by just looking at the correlations. To be more precise, the correlations $p(a,b|x,y)$ are said to self-test the state and measurements $|\psi'\rangle, \{M'_{a|x}\}, \{N'_{b|y}\}$ if for all states and measurements $\varrho_{\mathrm{AB}}, \{M_{a|x}\}, \{N_{b|y}\}$ compatible with $p(a,b|x,y)$ there exists

(i) local Hilbert spaces $\mathcal{H}_{\mathrm{A}}, \mathcal{H}_{\mathrm{B}}$ such that $\varrho_{\mathrm{AB}} \in \mathcal{L}[\mathcal{H}_{\mathrm{A}} \otimes \mathcal{H}_{\mathrm{B}}]$, $M_{a|x} \in \mathcal{L}[\mathcal{H}_{\mathrm{A}}]$, $N_{b|y} \in \mathcal{L}[\mathcal{H}_{\mathrm{B}}]$

(ii) a local isometry $\Phi = \Phi_{\mathrm{A}} \otimes \Phi_{\mathrm{B}}$

such that for any purification $|\psi\rangle^{\mathrm{ABP}}$ of $\varrho^{\mathrm{AB}}_{\mathrm{AB}}$ it holds

$$\begin{aligned}\Phi \otimes \mathbb{I}_{\mathrm{P}} &\left[\mathsf{M}_{a|x} \otimes \mathsf{N}_{b|y} \otimes \mathbb{I}_{\mathrm{P}} |\psi\rangle^{\mathrm{ABP}}\right] \\ &= \left(\mathsf{M}'_{a|x} \otimes \mathsf{N}'_{b|y} |\psi'\rangle^{\mathrm{A'B'}}\right) \otimes |\xi\rangle^{\mathrm{ABP}}\end{aligned}$$

for all a, x, b, y and for some state $|\xi\rangle^{\mathrm{ABP}}$. In this paper, we are especially interested in self-testing of measurements. A compact way of writing the self-testing statement for Bob's measurements from the description given above is that there exists an isometry Φ_B that maps each $M_{b|y}$ to $M'_{b|y} \otimes \mathbb{1}$.

2.2.1 Self-testing binary observables based on anti-commutation

We will be very interested in the self-testing of binary observables, for which some standard techniques have been developed.

A very relevant result is Jordan's lemma [PAB+09]. It states that two hermitian matrices with eigenvalues ±1 can always be simultaneously block-diagonalised, with blocks of size at most 2×2. Effectively this means that the correlations of n binary observables can always be simulated with n projective measurements in the Bloch sphere. Fixing the dimension, and in particular $d = 2$, is a massive simplification to the construction of self-testing protocols.

The characterisation of a set of projective measurements in the Bloch sphere has a simple geometrical intuition. Let's start considering two measurements, but it can be easily generalised to more. We need three coordinates to fix the first measurement, and two angles to define the second one with respect to the first one. Without loss of generalisation for the self-test, we can apply a local unitary to constrain the two observables to be on the XZ-plane of Bloch sphere, and the first one to be exactly σ_X. Hence, one angle is sufficient to characterise two projective measurements up to a global rotation; this unique degree of freedom is encoded in the commutator of the two observables. This is the core idea presented in [Kan17], where the author presents a self-testing protocol of binary observables based on commutation. Using this, they also find better bounds for the robustness of self-testing of some games.

In the following sections we will be often interested in robust self-testing protocols for binary measurements. We will prove that a score which is ϵ close to the quantum bound implies that the anti-commutator is ϵ close to the ideal (noisyless) value

$$\omega = \omega_q - \epsilon \implies D\big|_{|\psi\rangle}(\{B_0, B_1\}, a^{\text{ideal}}\mathbb{1}) \le \eta(\epsilon)$$

for some meaningful distance, restricted to the support of the states used in the game $|\psi\rangle$.

2.3 XOR games

XOR games are a subclass of binary games, in which the winning conditions for each outputs depend only on the parity of the two answer bits, i.e. $V(a,b,x,y)=1$ if and only if $f(x,y)=a\oplus b$. Hence, the winning probability takes the form

$$\omega=\sum_{a,b,x,y} q(x,y)p(a\oplus b=f(x,y)|x,y). \tag{14}$$

The winning probability of an XOR game is connected to its bias

$$\xi=\sum_{x,y} q(x,y)(-1)^{f(x,y)}c_{x,y}, \tag{15}$$

through the relation $\omega=(1+\xi)/2$. The term "bias" comes from the fact that in XOR games, the score $1/2$ can be achieved by players that do not use any resources, but randomly output their bits, independently of the inputs. An XOR game can be characterized by its so-called game matrix Φ:

$$\Phi=\sum_{x,y} q(x,y)(-1)^{f(x,y)}|x\rangle\langle y|. \tag{16}$$

The bias can then be compactly written as $\xi=\operatorname{Tr}\left[C^T\Phi\right]$. We can also define the operator associated to an XOR game as

$$\mathcal{B}=\sum_{x,y} q(x,y)(-1)^{f(x,y)}A_x\otimes B_y, \tag{17}$$

and the bias can then be computed as the value of the Bell operator $\xi=\langle\psi|\mathcal{B}|\psi\rangle$.

Lemma 1 ([Tsi87])**.** *Alice's optimal quantum strategy in an XOR game, encoded in the vector $|A_q\rangle$, is fully determined by Bob's optimal strategy $|B_q\rangle$ through a linear transformation:*

$$|A_q\rangle=\mathbb{1}\otimes F|B_q\rangle. \tag{18}$$

Proof. This lemma was proven by Tsirelson in [Tsi87], but we reproduce here the proof of [ECW20]. The optimal quantum bias of an XOR game can be obtained as the solution to a semidefinite program (SDP) [Weh06]. For that purpose let us define the Gram matrix $\tilde{Q}$

$$\tilde{Q}=\left[\begin{array}{c|c} R & C \\ \hline C^T & S\end{array}\right],\ \text{with } R=\sum_{x,x'}\langle A_x|A_{x'}\rangle|x\rangle\langle x'|,\ \text{and } S=\sum_{y,y'}\langle B_y|B_{y'}\rangle|y\rangle\langle y'|. \tag{19}$$

A Gram matrix is positive semidefinite and the diagonal of the Gram matrix of unit vectors contains only 1. Thus, the SDP yielding the optimal quantum bias for an XOR game takes the form

$$\begin{aligned} \xi_q &= \max_{\tilde{Q}} \operatorname{Tr}\left[\tilde{Q}\tilde{\Phi}\right], \\ \text{s.t.} \quad & \tilde{Q}_{ii}=1, \quad \text{for} \quad i=1,\cdots,|\mathsf{X}|+|\mathsf{Y}|, \\ & \tilde{Q}\succeq 0, \end{aligned} \tag{20}$$

where $\tilde{\Phi}=\frac{1}{2}\begin{pmatrix}0 & \Phi\\ \Phi^T & 0\end{pmatrix}$. From this primal form of the SDP, we can obtain the dual formulation by introducing the Lagrangian $\mathcal{L}=\operatorname{Tr}[\tilde{Q}\tilde{\Phi}]-\frac{1}{2}\sum_i\lambda_i(\operatorname{Tr}\left[|i\rangle\langle i|\tilde{Q}\right]-1)$, where λ_i are nonnegative Lagrangian multipliers. Let us define the diagonal matrix $\Lambda=\operatorname{diag}(\lambda_1,\cdots,\lambda_{|\mathsf{X}|+|\mathsf{Y}|})$. The minimal value of the Lagrangian upper bounds the solution to the primal SDP if $\frac{1}{2}\Lambda-\tilde{\Phi}\succeq 0$, so the dual SDP takes the form

$$\min \operatorname{Tr}\left[\frac{\Lambda}{2}\right], \qquad \text{s.t.} \quad \frac{\Lambda}{2}-\tilde{\Phi}\succeq 0. \tag{21}$$

As a consequence of the aforementioned construction, it can be deduced that any given pair of primal and dual feasible solutions satisfy $\operatorname{Tr}[\tilde{Q}\tilde{\Phi}]\leq\xi_q\leq\operatorname{Tr}[\Lambda]/2$. The optimal values of the primal and of the dual coincide if strong duality holds. A sufficient condition for strong duality to hold, when the primal and dual are finite, is the existence of a strictly feasible solution to the dual problem, which is satisfied here. Hence, the optimal value can be obtained if the complementary slackness condition is satisfied

$$\mathrm{Tr}\left[\tilde{Q}\left(\frac{1}{2}\Lambda - \tilde{\Phi}\right)\right] = 0. \tag{22}$$

Let us now introduce the notations $\Lambda = \Lambda_A \oplus \Lambda_B$, where Λ_A (Λ_B) is a diagonal $|\mathsf{X}| \times |\mathsf{X}|$ ($|\mathsf{Y}| \times |\mathsf{Y}|$) matrix, and $|Q\rangle = |A\rangle \oplus |B\rangle$. We can write the quantum bias as $\xi = \langle Q|\mathbb{1} \otimes \tilde{\Phi}|Q\rangle$. The slackness condition (22) gives $\mathrm{Tr}\left[\mathbb{1} \otimes \left(\frac{1}{2}\Lambda - \tilde{\Phi}\right)|Q\rangle\langle Q|\right] = 0$, or equivalently $\mathbb{1} \otimes (\frac{1}{2}\Lambda - \tilde{\Phi})|Q\rangle = 0$, since $\frac{1}{2}\Lambda - \tilde{\Phi}$ is positive semidefinite. The form of Λ and $\tilde{\Phi}$ implies the following conditions for the optimal strategies of Alice and Bob:

$$\mathbb{1} \otimes \Lambda_A|A_q\rangle = \mathbb{1} \otimes \Phi|B_q\rangle, \quad \text{and} \quad \mathbb{1} \otimes \Lambda_B|B_q\rangle = \mathbb{1} \otimes \Phi^T|A_q\rangle. \tag{23}$$

Taking $F = \Lambda_A^{-1}\Phi$ gives the desired result. □

Another convenient way to write the relations obtained above is

$$|A_x\rangle = \lambda_x^{-1}\sum_{y=1}^{m_B}\Phi_{xy}|B_y\rangle, \qquad \text{for } x = 1, \cdots, |\mathsf{X}|\,. \tag{24}$$

The matrix $\tilde{Q}$ can be seen as a moment matrix corresponding to the first level of Navascues-Pironio-Acín hierarchy (NPA) [NPA07]. The n-th level NPA moment matrix is obtained by defining all degree-n monomials S_i of the operators of the set $\{A_1, \cdots, A_{|\mathsf{X}|}, B_1, \cdots, B_{|\mathsf{Y}|}\}$ and taking $\tilde{Q}^{(n)} = \langle\psi|S_i^\dagger S_j|\psi\rangle|i\rangle\langle j|$. Upper bounds on the maximal quantum score of an arbitrary nonlocal game can be obtained as solutions to an SDP analogous to (20), but taking $\tilde{Q}^n$ instead of $\tilde{Q}$ and the appropriate game matrix $\tilde{\Phi}$. The larger n is, the tighter the upper bound is. In the case of XOR games, the moment matrix of the first level of the NPA hierarchy actually suffices to find the exact optimal value, as it was proven in [NW10]. The dual formulation can be seen as an optimization over sum-of-squares (SOS) polynomials, given the duality theory between positive semidefinite moment matrices and SOS polynomials [Lau09]. In the case of the NPA hierarchy the difference between the solutions of the dual and primal problems can be seen as the expectation value of an SOS polynomial $\sum_i S_i^\dagger S_i$, where S_i belongs to the monomials used to create the corresponding moment matrix [TPKBA24]. For XOR games, this implies that for every Gram matrix $\tilde{Q}$ obtained by measuring the state $|\psi\rangle$, the following holds:

$$\xi_q - \mathrm{Tr}[\tilde{Q}\tilde{\Phi}] = \langle\psi|\sum_i P_i^\dagger P_i|\psi\rangle, \tag{25}$$

where the P_i-s are first degree polynomials over $\{A_1, \cdots, A_{|\mathsf{X}|}, B_1, \cdots, B_{|\mathsf{Y}|}\}$, i.e. $P_i = \sum_{x,y}(\alpha_x^i A_x + \beta_y^i B_y)$. As Eq. (25) holds for all quantum realizations, it can be written as

$$\xi_q\mathbb{1} - \mathcal{B} = \sum_i P_i^\dagger P_i, \tag{26}$$

where $\xi_q\mathbb{1} - \mathcal{B}$ is usually called the shifted game operator. The following theorem stipulates that for XOR games, the shifted game operator can be written as a sum of squares, with each term containing a single Alice operator, plus a positive polynomial depending only of Bob's operators.

Theorem 1. *Let $\mathcal{B}$ be the game operator of an XOR game with optimal quantum bias ξ_q. Then the following holds:*

$$\xi_q\mathbb{1} - \mathcal{B} = \sum_x \frac{\lambda_x}{2}\left(A_x - \sum_y F_{xy}B_y\right)^2 + P\left(\{B_y\}_y\right), \tag{27}$$

where F is the matrix of Lemma 1 and $P(\{B_y\}_y)$ is a positive polynomial over Bob's measurement operators.

To prove this theorem, we first use the following lemma proven by Ostrev.

Lemma 2. *[Ost16]*

1. *Let $\lambda_1, \cdots, \lambda_{|\mathsf{X}|+|\mathsf{Y}|}$ be an optimal solution to the dual semidefinite program (21). Then there exist vectors $\{|u_i\rangle = \sum_{j=1}^{|\mathsf{X}|}u_{ij}|j\rangle\}_{i=1}^r$ and $\{|v_i\rangle = \sum_{j=1}^{|\mathsf{Y}|}v_{ij}|j\rangle\}_{i=1}^r$ such that*

$$\sum_{i=1}^r |u_i\rangle\langle u_i| = \frac{1}{2}\Lambda_A, \qquad \sum_{i=1}^r |v_i\rangle\langle v_i| = \frac{1}{2}\Lambda_B, \qquad \sum_{i=1}^r |u_i\rangle\langle v_i| = \frac{1}{2}\Phi. \tag{28}$$

2. *Let $|A\rangle$ and $|B\rangle$ be a quantum strategy for an XOR game. Let $\{|u_i\rangle = \sum_{j=1}^{|\mathsf{X}|} u_{ij}|j\rangle\}_{i=1}^{r}$ and $\{|v_i\rangle = \sum_{j=1}^{|\mathsf{X}|} v_{ij}|j\rangle\}_{i=1}^{r}$ satisfy (28). Then the following identity holds:*

$$\sum_{i=1}^{r}\left\|\sum_{j=1}^{|\mathsf{X}|} u_{ij}|A_j\rangle - \sum_{j=1}^{|\mathsf{Y}|} v_{ij}|B_j\rangle\right\|^2 = \frac{1}{2}\mathrm{Tr}[\Lambda] - \sum_{ij}\langle A_j|\Phi_{ij}|B_j\rangle. \tag{29}$$

Proof. The interested reader can find the proof of the first part in [Ost16] (Lemma 4 therein), we reproduce here the proof of the second part (Lemma 5 in [Ost16]). The l.h.s. of (29) reads

$$\begin{aligned}
&\sum_{i=1}^{r}\left\|\sum_{j=1}^{|\mathsf{X}|} u_{ij}|A_j\rangle - \sum_{j=1}^{|\mathsf{Y}|} v_{ij}|B_j\rangle\right\|^2 = \\
&= \langle A|\mathbb{1}\otimes\left(\sum_{i=1}^{r}|u_i\rangle\langle u_i|\right)|A\rangle + \langle B|\mathbb{1}\otimes\left(\sum_{i=1}^{r}|v_i\rangle\langle v_i|\right)|B\rangle - 2\langle A|\mathbb{1}\otimes\left(\sum_{i=1}^{r}|u_i\rangle\langle v_i|\right)|B\rangle = \\
&= \frac{1}{2}\langle A|\mathbb{1}\otimes\Lambda_A|A\rangle + \frac{1}{2}\langle B|\mathbb{1}\otimes\Lambda_B|B\rangle - \langle A|\left(\mathbb{1}\otimes\Phi\right)|B\rangle = \\
&= \frac{1}{2}\mathrm{Tr}[\Lambda_A] + \frac{1}{2}\mathrm{Tr}[\Lambda_B] - \langle A|\mathbb{1}\otimes\Phi|B\rangle,
\end{aligned}$$

which is exactly the second statement of the lemma, given that $\Lambda = \Lambda_A + \Lambda_B$. □

We now define a robust version of Ostrev's lemma.

Lemma 3. 1. *Let $\lambda_1, \cdots, \lambda_{|\mathsf{X}|+|\mathsf{Y}|}$ be an optimal solution to the dual semidefinite program (21). Then there exist vectors $\{|u_i\rangle = \sum_{j=1}^{|\mathsf{X}|} u_{ij}|j\rangle\}_{i=1}^{r}$ and $\{|v_i\rangle = \sum_{j=1}^{|\mathsf{Y}|} v_{ij}|j\rangle\}_{i=1}^{r}$ such that*

$$\sum_{i=1}^{r}|u_i\rangle\langle u_i| = \frac{1}{2}\Lambda_A, \qquad \sum_{i=1}^{r}|v_i\rangle\langle v_i| \preceq \frac{1}{2}\Lambda_B, \qquad \sum_{i=1}^{r}|u_i\rangle\langle v_i| = \frac{1}{2}\Phi \tag{30}$$

2. *Let $|A\rangle$ and $|B\rangle$ be a quantum strategy for an XOR game. Let $\{|u_i\rangle = \sum_{j=1}^{|\mathsf{X}|} u_{ij}|j\rangle\}_{i=1}^{r}$ and $\{|v_i\rangle = \sum_{j=1}^{|\mathsf{X}|} v_{ij}|j\rangle\}_{i=1}^{r}$ satisfy (28). Then the following identity holds:*

$$\sum_{i=1}^{r}\left\|\sum_{j=1}^{|\mathsf{X}|} u_{ij}|A_j\rangle - \sum_{j=1}^{|\mathsf{Y}|} v_{ij}|B_j\rangle\right\|^2 \leq \frac{1}{2}\mathrm{Tr}[\Lambda] - \sum_{ij}\langle A_j|\Phi_{ij}|B_j\rangle. \tag{31}$$

Proof. For the proof of the first part, we give an explicit construction of the vectors $|u_i\rangle$ and $|v_i\rangle$. We choose $u_{ij} = \sqrt{\frac{\lambda_i}{2}}\delta_{ij}$, where δ_{ij} is the Kronecker delta, and we take $|v_i\rangle = \frac{1}{\lambda_i}\sum_j \Phi_{ij}|u_j\rangle$. The first and third relations in (30) are satisfied, as $\sum_i |u_i\rangle\langle u_i| = \frac{1}{2}\mathrm{diag}(\lambda_1, \cdots, \lambda_{|\mathsf{X}|})$, and $\sum_i |u_i\rangle\langle v_i| = \frac{1}{2}\Phi$. Concerning the second relation, we get $\sum_i |v_i\rangle\langle v_i| = \frac{1}{2}\Phi^T\Lambda_A^{-1}\Phi$. To analyze it, we use the complementary slackness condition, which implies that $\Lambda - \tilde{\Phi} \succeq 0$. By Schur's complement lemma , this matrix is positive if and only if $\Lambda_B - \Phi^T\Lambda_A^{-1}\Phi \succeq 0$. This completes the proof of the first part of the lemma. The second part follows analogously to the second part of Lemma 2. □

We can now prove Theorem 1.

Proof. Taking the $|u_i\rangle$-s and $|v_i\rangle$-s used to prove the first part of Lemma 3 in (31), we get

$$\xi_q - \langle\psi|\mathcal{B}|\psi\rangle - \sum_{x=1}^{m_A}\frac{\lambda_x}{2}\left\|A_x|\psi\rangle - \lambda_x^{-1}\sum_y \Phi_{x,y}B_y|\psi\rangle\right\|^2 \geq 0. \tag{32}$$

When opening the sum of squares, we get

$$\xi_q - \sum_{x=1}^{m_A}\frac{1}{\lambda_x}\langle\psi|\sum_{y,y'}B_y\Phi_{y,x}\Phi_{x,y'}B_{y'}|\psi\rangle \geq 0, \tag{33}$$

which holds for every valid quantum state $|\psi\rangle$, implying

$$2P\left(\{B_y\}_y\right) \equiv \xi_q \mathbb{1} - \sum_{x=1}^{m_A} \frac{1}{\lambda_x} \sum_{y,y'} B_y \Phi_{y,x} \Phi_{x,y'} B_{y'} \geq 0. \tag{34}$$

The simple expansion of all the squares shows that

$$\xi_q \mathbb{1} - \mathcal{B} = \frac{\lambda_x}{2} \left(A_x - \lambda_x^{-1} \sum_y \Phi_{x,y} B_y \right)^2 + P\left(\{B_y\}_y\right), \tag{35}$$

which together with (34) proves the theorem. □

2.4 Quantum homomorphic encryption

Homomorphic encryption is a cryptographic technique that enables to execute computations directly on encrypted data, without prior decryption. The results of these computations remain in an encrypted form and, upon decryption, yield outputs identical to those obtained through operations on the unencrypted data. The term "homomorphic" draws from algebraic homomorphism, wherein encryption and decryption functions are likened to homomorphisms between plaintext and ciphertext spaces. A cryptosystem supporting arbitrary computation on ciphertexts is termed fully homomorphic encryption (FHE), representing the most robust form of homomorphic encryption. Originally conceptualized as a privacy homomorphism by Rivest, Adleman, and Dertouzous [RAD⁺78] shortly after the invention of the RSA cryptosystem [RSA78], the first plausible construction for FHE using lattice-based cryptography was presented by Gentry [Gen09]. Leveraging the hardness of the (Ring) Learning With Errors (RLWE) problem, more efficient schemes for fully homomorphic encryption have been devised [BGV14, BV14]. The possibility of quantum homomorphic encryption (QHE), allowing for quantum computations on encrypted data, was introduced by Mahadev [Mah18], with Brakerski [Bra18] subsequently enhancing it to achieve improved noise tolerance.

Before reminding the formalism of QHE, we first recall the definition of quantum polynomial time algorithms. Throughout the paper, κ denotes the security parameter.

Definition 1 (Quantum polynomial time algorithm)**.** *A quantum algorithm is quantum polynomial time (QPT) it can be implemented by a family of quantum circuits with size polynomial in the security parameter κ.*

We now reproduce the definition of QHE as it appears in [KLVY23].

Definition 2 (Quantum Homomorphic Encryption (QHE))**.** *A quantum homomorphic encryption scheme* $\mathsf{QHE} = (\mathsf{Gen}, \mathsf{Enc}, \mathsf{Eval}, \mathsf{Dec})$ *for a class of quantum circuits C consists of the following four quantum algorithms which run in quantum polynomial time in terms of the security parameter:*

- Gen *takes as input the security parameter 1^κ and outputs a (classical) secret key* sk *of size* $\mathrm{poly}(\kappa)$ *bits;*
- Enc *takes as input a secret key* sk *and a classical input x, and outputs a ciphertext* ct*;*
- Eval *takes as input a tuple $(C, |\Psi\rangle, \mathsf{ct}_{\mathrm{in}})$, where $C : \mathcal{H} \times (\mathbb{C}^2)^{\otimes n} \to (\mathbb{C}^2)^{\otimes m}$ is a quantum circuit, $|\Psi\rangle \in \mathcal{H}$ is a quantum state, and $\mathsf{ct}_{\mathrm{in}}$ is a ciphertext corresponding to an n-bit plaintext.* Eval *computes a quantum circuit* $\mathsf{Eval}_C(|\Psi\rangle \otimes |0\rangle^{\otimes \mathrm{poly}(\lambda,n)}, \mathsf{ct}_{\mathrm{in}})$ *which outputs a ciphertext $\mathsf{ct}_{\mathrm{out}}$. If C has classical output, we require that Eval_C also has classical output.*
- Dec *takes as input a secret key* sk *and ciphertext* ct*, and outputs a state $|\phi\rangle$. Additionally, if* ct *is a classical ciphertext, the decryption algorithm outputs a classical string y.*

As in [KLVY23] the following property is required from QHE, in order for it to behave “nicely" with entanglement:

Definition 3 (Correctness with auxiliary input)**.** *For every security parameter $\kappa \in \mathbb{N}$, any quantum circuit $C : \mathcal{H}_A \times (\mathbb{C}^2)^{\otimes n} \to \{0,1\}^*$ (with classical output), any quantum state $|\Psi\rangle_{AB} \in \mathcal{H}_A \otimes \mathcal{H}_B$, any message $x \in \{0,1\}^n$, any secret key* $\mathsf{sk} \leftarrow \mathsf{Gen}(1^\kappa)$ *and any ciphertext* $\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{sk}, x)$*, the following states have negligible trace distance:*

Game 1 *Start with $(x, |\Psi\rangle_{AB})$. Evaluate C on x and register A, obtaining classical string y. Output y and the contents of register B.*

Game 2 *Start with* $\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{sk}, x)$ *and* $|\Psi\rangle_{AB}$. *Compute* $\mathsf{ct}' \leftarrow \mathsf{Eval}_C(\cdot \otimes |0\rangle^{\mathrm{poly}(\lambda,n)}, \mathsf{ct})$ *on register* A. *Compute* $y' = \mathsf{Dec}(\mathsf{sk}, \mathsf{ct}')$. *Output* y' *and the contents of register* B.

In simple terms, “correctness with auxiliary input" stipulates that when QHE evaluation is employed on a register A within a joint (entangled) state in $\mathcal{H}_A \otimes \mathcal{H}_B$, the entanglement between the QHE-evaluated output and B must be maintained.

Finally, the following definition characterizes another property expected from QHE, and it is in cryptography well-known indistinguishability under chosen plaintext attack (IND-CPA).

Definition 4 (IND-CPA security against quantum distinguishers)**.** *For any two messages* x_0, x_1 *and any QPT adversary* $\mathcal{A}$*:*

$$\left|\Pr\left[\mathcal{A}^{\mathsf{Enc}(\mathsf{sk},\cdot)}(\mathsf{ct}_0) = 1 \,\middle|\, \begin{array}{l}\mathsf{sk} \leftarrow \mathsf{Gen}(1^\lambda)\\ \mathsf{ct}_0 \leftarrow \mathsf{Enc}(\mathsf{sk}, x_0)\end{array}\right] - \Pr\left[\mathcal{A}^{\mathsf{Enc}(\mathsf{sk},\cdot)}(\mathsf{ct}_1) = 1 \,\middle|\, \begin{array}{l}\mathsf{sk} \leftarrow \mathsf{Gen}(1^\lambda)\\ \mathsf{ct}_1 \leftarrow \mathsf{Enc}(\mathsf{sk}, x_1)\end{array}\right]\right| \leq \mathsf{negl}(\kappa) \ ,$$

for some negligible funcion $\mathsf{negl}(\cdot)$.

2.5 Compiled nonlocal games

In [KLVY23], Kalai *et al.* introduced a compilation technique that can be used to construct single-prover proofs of quantumness. Their procedure transforms any k-player nonlocal game into a single-prover interactive game, employing post-quantum cryptography to emulate spatial separation among the parties. The proposed protocol maintains classical soundness, ensuring that no classical polynomially-bounded prover can surpass the maximal classical score of the original game. Additionally, leveraging quantum homomorphic encryption (QHE), the authors devise an explicit and efficient quantum strategy that achieves the quantum bound of the original nonlocal game. This enables the translation of proofs of quantumness into the single-prover interactive proof framework.

In this context, we refer to a single-prover interactive game that is generated through the KLVY compilation of a nonlocal game as a compiled nonlocal game. We recall the definition of compiled nonlocal games introduced in [KLVY23]. Using the interactive proof terminology, the entity called “referee” in the nonlocal game will be referred to as the “verifier”.

Definition 5 (Compiled nonlocal game)**.** *In a compiled nonlocal game, a verifier, equipped with access to a Quantum Homomorphic Encryption (QHE) scheme as defined in Def. 2, engages with a prover. According to a probability distribution* $q(x, y)$*, the verifier samples* x *and* y*. In the first round, the verifier transmits* $\mathtt{x} = \mathsf{Enc}(x)$ *to the prover, who responds with an encrypted output* $\mathtt{a} = \mathsf{Enc}(a)$*. In the second round, the verifier sends the input* y *to the prover in the clear, and the prover replies with the answer* b*. The verifier assesses the outcome using the game predicate* $V(\mathsf{Dec}(\mathtt{a}), b|\mathsf{Dec}(\mathtt{x}), y) \in \{0, 1\}$ *to determine whether the prover has passed or failed in the game.*

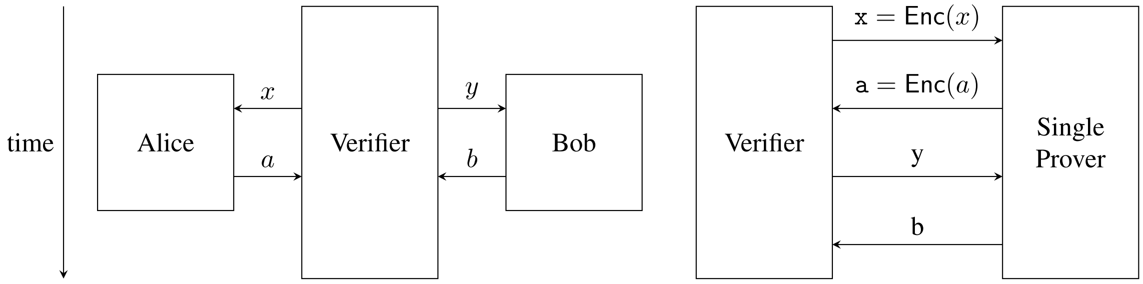

Figure 1: Pictorial representation of the Kalai *et. al.* compilation protocol for 2-player nonlocal games. On the left, a general 2-player nonlocal game; the two parties are spatially separated, and only communicate to a verifier which is sampling questions (x, y) and collecting their answers (a, b). On the right, the single prover game resulting from the compilation procedure. In this representation time flows downwards.

The following theorem (Theorem 1.1 in [KLVY23]) relates the classical and quantum score of a nonlocal game to the scores of the corresponding compiled game.

Theorem 2 ([KLVY23])**.** *Given any* 2*-player nonlocal game with quantum bound* ξ_q *and classical bound* ξ_c *and any QHE scheme (with security parameter* κ*) that satisfies correctness with auxiliary inputs and IND-CPA* *security against quantum distinguishers then, there is a 4-round single prover interactive game with completeness ξ_q realized by a quantum polynomial-time algorithm and soundness $\xi_c + negl(\kappa)$ against any classical polynomial-time algorithm.*

The classical soundness statement in this theorem guarantees that the maximal winning probability that a classical polynomial-time prover can achieve in a compiled nonlocal game is nearly identical to the optimal classical winning probability in the corresponding nonlocal game, with a negligible deviation dependent on the security parameter. The main insight in [KLVY23] is that the success of the classical prover is primarily hindered by the sequential nature of the game. This sequential structure forces the prover to commit to an answer a before receiving the input y. The combination of this sequential setup with secure QHE effectively replicates the locality requirement of a nonlocal game that is ensured by the spatial separation of the players. The quantum soundness statement ensures that a QPT prover can win the compiled nonlocal game with a probability that is at least as large as the optimal quantum winning probability in the corresponding nonlocal game.

2.5.1 Modelling the quantum prover

Let us now model the behavior of the single quantum prover, in the same way as it was done in [NZ23]. In a compiled game, denoted as per Def. 5, the prover, initially in state $|\psi\rangle$, undergoes a process involving encrypted questions and answers. Specifically, in the first round, the prover receives an encrypted question x, performs a POVM measurement, and computes an encrypted answer a. Using Naimark dilation theorem, the prover's POVM measurement is simulated by a projective measurement, denoted here with $M_{\mathsf{a}|\mathsf{x}}$. The prover's action could potentially involve a unitary operation $U_{\mathsf{x},\mathsf{a}}$ following the measurement, crucial in the sequential setting. The projectors and unitaries can be unified into a set of potentially non-Hermitian operators $\mathsf{M}_{\mathsf{a}|\mathsf{x}}$, satisfying $\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}}\mathsf{M}_{\mathsf{a}|\mathsf{x}} = M_{\mathsf{a}|\mathsf{x}}$ and hence $\sum_{\mathsf{a}} \mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}}\mathsf{M}_{\mathsf{a}|\mathsf{x}} = \mathbb{1}$. The prover's state after the first round of the game corresponds to the post-measurement state

$$|\psi_{\mathsf{a}|\mathsf{x}}\rangle = \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle, \tag{36}$$

and the probability to get output a for input x is

$$p(\mathsf{a}|\mathsf{x}) = \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle = \left\| |\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 . \tag{37}$$

In the second round, the prover's behavior is characterized by a set of projective operators $\{\{N_{b|y}\}_b\}_y$. If the second-round answers are bits, the measurements can be characterized by specifying a Hermitian observable $B_y = \sum_b (-1)^b N_{b|y}$. Similarly, if Alice's outputs in the corresponding nonlocal game are bits, we can define a "decrypted" observable

$$\begin{aligned} \mathrm{A}_x &= \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} (-1)^{\mathsf{Dec}(\mathsf{a})} \mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}}\mathsf{M}_{\mathsf{a}|\mathsf{x}} && (38)\\ &= \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} A_{\mathsf{x}}, && (39) \end{aligned}$$

where A_{x} are binary observables, while A_x in general is not. If both a and b are bits, we can define the correlators allowing to characterize the winning probability of a quantum prover in a computational single-prover game:

$$\langle \mathrm{A}_x, B_y \rangle = \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} (-1)^{\mathsf{Dec}(\mathsf{a})} \langle \psi_{\mathsf{a}|\mathsf{x}} | B_y | \psi_{\mathsf{a}|\mathsf{x}} \rangle \tag{40}$$

The correlators have the same operational meaning as in nonlocal games: when the verifier samples a question pair (x, y) in the compiled game and receives (decrypted) answers (a, b), $\langle \mathrm{A}_x, B_y \rangle$ is precisely the expected value of $(-1)^{a+b}$.

The marginals of the second-round observables in principle depends on the encrypted x of the first round and have form:

$$\langle B_y \rangle_x = \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} \langle \psi_{\mathsf{a}|\mathsf{x}} | B_y | \psi_{\mathsf{a}|\mathsf{x}} \rangle . \tag{41}$$

2.6 Technical tools for estimating quantum bounds of compiled nonlocal games

2.6.1 Block encodings

We now examine certain outcomes related to the block encoding of quantum processes. Block encoding is a method for the efficient implementation of a quantum operation. Our motivation for exploring this process stems from the contextual constraint imposed in the subsequent sections of this paper, where we address computational limitations among participants. Consequently, we aim to identify operations that can be efficiently executed by leveraging available quantum resources.

Definition 6 (Block encoding)**.** *Given a matrix $A \in \mathbb{C}^{c\times c}$, we say that $U \in \mathbb{C}^{d\times d}$ is a Q-block encoding of A if*

- *U is a unitary matrix whose quantum circuit can be implementable with $O(Q)$ gates,*
- *U has the following form $U = \begin{pmatrix} \tau A & \cdot \\ \cdot & \cdot \end{pmatrix}$, where we call τ the scale factor of the block encoding.*

We say U is QPT-implementable if Q is polynomially bounded in the size of the input.

If U is a block encoding of A, then A can be implemented by performing the following operation

$$\tau\left(\langle 0| \otimes \mathbb{1}\right) U (|0\rangle \otimes \mathbb{1})$$

where $\mathbb{1}$ is the identity matrix of the size of A.

Through the linear combination and multiplication of matrices possessing a block encoding, our anticipation is the persistence of this property in the resulting matrix. Although the explicit construction in complete generality is not immediately apparent, [GSLW19, Lemmas 52 and 53] provides a technical framework for the block encoding of linear combinations and products of matrices with block encoding. Here, we present a streamlined version of their results, tailored to our specific requirements.

First, we present a lemma about the block encoding of a linear combination of matrices that have block encoding, whose proof can be found in [GSLW19, Lemma 52].

Lemma 4 (Linear combination of block encoded matrices)**.** *Let $A = \sum_{j=1}^{m} y_j A_j$, where $y \in \mathbb{C}^m$ is a complex bounded vector $\|y\|_1 \leq \beta$ and A_j are matrices for which we know a Q_j-block encoding U_j. Then we can implement a $\left(m + \sum_{j=1}^{m} Q_j\right)$-block encoding of A.*

Corollary 1. *Let $A = \sum_{j=1}^{m} y_j A_j$, where $y \in \mathbb{C}^m$ is a complex bounded vector $\|y\|_1 \leq \beta$. If $m = \mathrm{poly}(\kappa)$ and each A_j is an operator with QPT-implementable block encodings with scale factor $O(1)$ for all j, A also has a QPT-implementable block encoding with scale factor $O(1)$.*

The subsequent lemma guarantees the presence of a block encoding for the product of matrices, each possessing its own block encoding, whose proof can be found in [GSLW19, Lemma 53].

Lemma 5 (Product of block encoded matrices)**.** *Let U and V be the Q_U and Q_V-block encodings of A and B respectively. Then we can implement a $(Q_U + Q_V)$-block encoding of AB.*

Corollary 2. *Let U and V be the Q_U and Q_V-block encodings of A and B respectively. If U and V are QPT-implementable, each with scale factor $O(1)$, AB also has a QPT-implementable block encoding with scale factor $O(1)$.*

For operators with a QPT-implementable block-encoding, the following technical lemma from [NZ23] applies.

Lemma 6 ([NZ23, Lemma 14])**.** *Let $\mathscr{B}$ be an operator with a QPT-implementable block encoding with $O(1)$ scale factor and $\|\mathscr{B}\| \leq O(1)$. Then there exists a QPT-measurable POVM $\{M_\beta\}_\beta$ such that for any state ρ, the following holds:*

$$\left| \sum_\beta \beta \cdot \mathrm{Tr}\left[M_\beta \rho\right] - \mathrm{Tr}\left[\mathscr{B}\rho\right] \right| \leq \varepsilon, \tag{42}$$

for any $\varepsilon = 1/\mathrm{poly}(\kappa)$.

These results, together with the definition of the IND-CPA security, allow us to state the following:

Lemma 7 (adapted from [NZ23, Lemmas 15-17])**.** *Let $\mathscr{B}$ be an operator with a QPT-implementable block encoding with $O(1)$ scale factor and $\|\mathscr{B}\| \leq O(1)$. Let $\mathrm{QHE} = (\mathsf{Gen}, \mathsf{Enc}, \mathsf{Eval}, \mathsf{Dec})$ be a secure quantum homomorphic encryption scheme (see Definition 2), let D_0, D_1 be any two QPT sampleable distributions over plaintext questions x, and let $|\psi\rangle$ be any efficiently preparable state of the prover. Then, for any security parameter $\kappa \in \mathbb{N}$, there exists a negligible function $\delta_{qhe}(\kappa)$ such that*

$$\left| \mathop{\mathbb{E}}_{x\leftarrow D_0} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \mathscr{B} \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle - \mathop{\mathbb{E}}_{x\leftarrow D_1} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \mathscr{B} \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \right| \leq \delta_{qhe}(\kappa). \tag{43}$$

The proof of this Lemma encompasses Lemmas 15, 16 and 17 in [NZ23]. Importantly, $\mathscr{B}$ does not have to be a binary observable, it just has to be efficiently implementable by quantum circuits. This lemma establishes a link between QPT-implementable block encodings and IND-CPA security. Looking ahead, using the fact that XOR games and SATWAP Bell inequalities have a nice form of SOS decomposition into linear combination and product of block encodings as presented in previous sections, this lemma will allow us to relate the quantum bound of the compiled nonlocal games to those of the original nonlocal games, at the expense of a negligible security loss.

2.6.2 Crypto-correlation matrix and pseudo-expectation map

In this section, we revisit and further expound upon the concepts delineated in Section 4.4 of [NZ23]. In that section, the authors introduced a compelling argument to establish the optimal quantum winning probability for the compiled CHSH game through the introduction of a cryptographic SOS decomposition. Our objective is to broaden their findings to encompass a more extensive array of games, namely XOR games and d-outcome CHSH games.

Consider a game with an optimal quantum bias ξ_q. Its game operator (17) is

$$\mathcal{B} = \sum_{x,y} \gamma^{AB}_{x,y} A_x B_y, \tag{44}$$

and the corresponding shifted game operator has an SOS decomposition

$$\xi_q \mathbb{1} - \mathcal{B} = \sum_j b_i P_i^\dagger P_i + \sum_i d_i [A_{x_i}, B_{y_i}] + \sum_i e_i (\mathbb{1} - A^2_{x_i}) + \sum_i f_i (\mathbb{1} - B^2_{y_i}), \tag{45}$$

where $b_j \in \mathbb{R}^+$ are real positive coefficients for the terms of the SOS decomposition, d_i-s could be complex numbers referring to the constraint that Alice's and Bob's operators commute, e_i-s and f_i-s multiply terms that vanish if the measurements of Alice and Bob are projective. All terms on the r.h.s. of (45) except the first one are general constraints that are usually implicitly assumed. Here, the aim is to develop an analogous procedure for bounding the optimal quantum bias of compiled games, so one has to be careful as some of the constraints satisfied in the case of nonlocal games might not be satisfied in the case of compiled games. For example, operations in two rounds of the compiled game do not necessarily commute.

Analogously to matrix $\tilde{Q}$ from Section 2.3, expounding on the ideas from [NZ23], we define a $(|\mathsf{X}| + |\mathsf{Y}|) \times (|\mathsf{X}| + |\mathsf{Y}|)$ matrix $\tilde{\mathcal{Q}}$ as follows

$$\tilde{\mathcal{Q}} = \left[\begin{array}{c|c} \mathbb{1}_{|\mathsf{X}|} & C \\ \hline C^T & S \end{array}\right], \tag{46}$$

where $\mathbb{1}_{|\mathsf{X}|}$ is the $|\mathsf{X}| \times |\mathsf{X}|$ identity matrix, where

$$C = \sum_{x,y} \langle \mathrm{A}_x, B_y \rangle |x\rangle\langle y|, \tag{47}$$

$$S = \sum_{y,y'} \mathop{\mathbb{E}}_{x \in \mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} \langle \psi_{\mathsf{a}|\mathsf{x}} | B_y B_{y'} | \psi_{\mathsf{a}|\mathsf{x}} \rangle |y\rangle\langle y'|, \tag{48}$$

and where $\langle \mathrm{A}_x, B_y \rangle$ correspond to Eq. (40). The matrix $\tilde{\mathcal{Q}}$, unlike $\tilde{Q}$, is not necessarily positive semidefinite, as there is no real consistency in assigning values to its entries. Similarly to $\tilde{Q}$, $\tilde{\mathcal{Q}}$ has ones on the diagonal, in the first block by construction and in the second because

$$\begin{aligned} S_{y,y} &= \mathop{\mathbb{E}}_{x \in \mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} \langle \psi_{\mathsf{a}|\mathsf{x}} | \mathbb{1} | \psi_{\mathsf{a}|\mathsf{x}} \rangle \\ &= \mathop{\mathbb{E}}_{x \in \mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} \langle \psi | \mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \mathsf{M}_{\mathsf{a}|\mathsf{x}} | \psi \rangle \\ &= \mathop{\mathbb{E}}_{x \in \mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \langle \psi | \psi \rangle \\ &= 1. \end{aligned}$$

Then, as in [NZ23], we define a linear operator $\tilde{\mathbb{E}}$ that maps every homogeneous degree-2 polynomial in the variables A_x, B_y to linear combinations of elements of the matrix $\tilde{\mathcal{Q}}$ in the following way:

$$\tilde{\mathbb{E}}[A_x B_y] = C_{x,y}, \qquad \tilde{\mathbb{E}}[B_y \mathrm{A}_x] = C^T_{y,x}, \tag{49}$$

$$\tilde{\mathbb{E}}[A_x A_{x'}] = \delta_{x,x'}, \qquad \tilde{\mathbb{E}}[B_y B_{y'}] = S_{y,y'}. \tag{50}$$

For $y = y'$ or $x = x'$ in Eq. (50), we get a consistent mapping of identity

$$\tilde{\mathbb{E}}[A_x A_x] = \tilde{\mathbb{E}}[\mathbb{1}] = 1, \qquad \tilde{\mathbb{E}}[B_y B_y] = \tilde{\mathbb{E}}[\mathbb{1}] = S_{y,y} = 1. \tag{51}$$

As in [NZ23], we call the map $\tilde{\mathbb{E}}$ a pseudo-expectation. Such defined pseudo-expectation maps the game operator $\mathcal{B}$ introduced in Eq. (44)) to a bias in the compiled nonlocal game:

$$\tilde{\mathbb{E}}[\mathcal{B}] = \sum_{x,y} \gamma_{x,y} \tilde{\mathbb{E}}[A_x B_y] = \sum_{x,y} \gamma_{x,y} \langle \mathrm{A}_x, B_y \rangle = \bar{\xi}. \tag{52}$$

The optimal quantum bias can be upper bounded using the SOS decomposition of the shifted game operator(eq. (45)):

$$\tilde{\mathbb{E}}\left[\xi_q \mathbb{1} - \mathcal{B}\right] = \tilde{\mathbb{E}}\left[\sum_i b_i P_i^\dagger P_i + \sum_i d_i [A_{x_i}, B_{y_i}] + \sum_i e_i (\mathbb{1} - A_{x_i}^2) + \sum_i f_i (\mathbb{1} - B_{y_i}^2)\right] \tag{53}$$

Given (49), the terms multiplied by d_i vanish because, under pseudo-expectation map, operators A_x and B_y commute. The terms multiplied by e_i and f_i also vanish because of Eq. (51). Hence

$$\tilde{\mathbb{E}}\left[\xi_q \mathbb{1} - \mathcal{B}\right] = \sum_i b_i \tilde{\mathbb{E}}\left[P_i^\dagger P_i\right] \tag{54}$$

Thus, if $\tilde{\mathbb{E}}\left[P_i^\dagger P_i\right]$ is non-negative, the bias in a compiled game cannot be larger than the optimal quantum bias of the corresponding nonlocal game.

3 Quantum bound of compiled XOR games

In Section 2.3, we established key insights into XOR games. Here, building upon the methodology outlined in [NZ23] and revisited in 2.6.2, we present our first important result: compiled XOR games exhibit a quantum bias that closely aligns with the quantum bias of the corresponding nonlocal game, fluctuating only slightly with the security parameter. The power of the quantum prover to win a compiled XOR game with a probability larger than the optimal quantum winning probability for the corresponding XOR game crucially depends on their ability to transmit from the first round information about the received plaintext input. However, inputs are encrypted in such a way that the encryption satisfies IND-CPA security, meaning that even the quantum prover cannot do better than randomly guessing its question x knowing the encryption x of x. This inability of a QPT prover to break the encryption is articulated in Lemma 7. In essence, this lemma conveys that regardless of the measurement employed by a QPT prover in the second round of the game, they are unable to differentiate between states resulting from distinct samples of plaintext questions taken in the first round.

Before stating our main result let us state two lemmas about the behavior of the XOR game operator under the pseudo-expectation map defined in Sec. 2.6.2. The first lemma is a generalization of Claims 31 and 33 from [NZ23].

Lemma 8. *Let $P_x = A_x - \sum_y F_{xy} B_y$ with$\{A_x\}_x$ and $\{B_y\}_y$ binary observables. Then there exists a negligible function $\delta_{\mathrm{QHE}}(\cdot)$ such that we have $\tilde{\mathbb{E}}\left[P_j^\dagger P_j\right] \geq -\delta_{\mathrm{QHE}}(\kappa)$, where $\tilde{\mathbb{E}}[\cdot]$ is the pseudo-expectation map defined in Sec. 2.6.2.*

Proof. Let us introduce the shortened notation $\hat{B}_x = \sum_y F_{xy} B_y$. We get

$$\begin{aligned}
\tilde{\mathbb{E}}\left[P_x^\dagger P_x\right] &= \tilde{\mathbb{E}}\left[A_x A_x\right] - 2\tilde{\mathbb{E}}\left[A_x \hat{B}_y\right] + \tilde{\mathbb{E}}\left[\hat{B}_y \hat{B}_{y'}\right] \\
&= 1 - 2\sum_y F_{xy} C_{xy} + \sum_{y,y'} F_{yx} F_{xy'} S_{yy'} \\
&= 1 - 2\sum_y F_{xy} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} (-1)^{\mathsf{Dec}(\mathsf{a})} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} B_y \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle + \\
&\qquad \sum_{y,y'} F_{yx} F_{xy'} \mathop{\mathbb{E}}_{x\in\mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} B_y B_{y'} \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&= 1 - 2 \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} (-1)^{\mathsf{Dec}(\mathsf{a})} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \hat{B}_x \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle + \mathop{\mathbb{E}}_{x\in\mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \hat{B}_x^\dagger \hat{B}_x \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\approx_{\delta_{\mathrm{QHE}}(\kappa)} 1 - 2 \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} (-1)^{\mathsf{Dec}(\mathsf{a})} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \hat{B}_x \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle + \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \hat{B}_x^\dagger \hat{B}_x \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\approx_{\delta_{\mathrm{QHE}}(\kappa)} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \left(\mathbb{1} - 2(-1)^{\mathsf{Dec}(\mathsf{a})} \hat{B}_x + \hat{B}_x^2\right) \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\approx_{\delta_{\mathrm{QHE}}(\kappa)} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} \left((-1)^{\mathsf{Dec}(\mathsf{a})}\mathbb{1} - \hat{B}_x\right)^2 \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle
\end{aligned}$$

In the first two lines, we used the linearity and the definition of the pseudo-expectation map. In the third line, we used the definition of matrices C (eq. (49)) and S (eq. (50)). In the fourth line, we just used the definition of $\hat{B}_x$. To get the fifth line we used the fact that $\hat{B}_x^\dagger \hat{B}_x$ has a QPT-implementable block encoding (Corrolaries 1 and 2) and thus we can apply Lemma 7 given above. To get the sixth line we used linearity and we grouped all terms inside of one average over $\mathsf{x} = \mathsf{Enc}(x)$; in particular we noticed that we could write the first term 1 as $\mathbb{1}$ inside this average. Finally, in the seventh line we recognised that the expression within round brackets can be expressed as the square of an operator. This is necessarely positive, implying that up to a negligible factor $\tilde{\mathbb{E}}\left[P_x^\dagger P_x\right]$ must also be positive. □

Lemma 9. *Let P be a positive semi-definite homogeneous degree-2 polynomial over binary observables $\{B_y\}_y$. Then $\tilde{\mathbb{E}}[P] \geq 0$, where $\tilde{\mathbb{E}}[\cdot]$ is the pseudo-expectation map defined in Sec. 2.6.2.*

Proof. The pseudo-expectation of P reads

$$\tilde{\mathbb{E}}[P] = \mathop{\mathbb{E}}_{x\in\mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}^\dagger_{\mathsf{a}|\mathsf{x}} P \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \geq 0 \tag{55}$$

Since all elements in the sum are positive because P is positive semi-definite the relation trivially holds. □

We can now state the main theorem, providing the quantum optimal bias of compiled XOR games.

Theorem 3. *Given an XOR game with optimal quantum bias ξ_q, the optimal quantum bias of the compiled XOR game is $\xi_q + \delta_{\mathrm{QHE}}(\kappa)$, where $\delta_{\mathrm{QHE}}(\cdot)$ is a negligible function.*

Proof. Let us recall Theorem 1 which states that for every XOR game we have

$$\xi_q \mathbb{1} - \mathcal{B} = \sum_x \frac{\lambda_x}{2}\left(A_x - \sum_y F_{xy} B_y\right)^2 + P\left(\{B_y\}_y\right),$$

By applying the pseudo-expectation map we get

$$\begin{aligned}
\tilde{\mathbb{E}}\left[\xi_q \mathbb{1} - \mathcal{B}\right] &= \tilde{\mathbb{E}}\left[\sum_x \frac{\lambda_x}{2}\left(A_x - \sum_y F_{xy} B_y\right)^2 + P\left(\{B_y\}_y\right)\right] && (56)\\
&= \sum_x \frac{\lambda_x}{2} \tilde{\mathbb{E}}\left[\left(A_x - \sum_y F_{xy} B_y\right)^2\right] + \tilde{\mathbb{E}}\left[P\left(\{B_y\}_y\right)\right] && (57)
\end{aligned}$$

To get the second line we used the linearity of the pseudo-expectation map. Based on Lemmas 8 implies that the first term on the r.h.s is up to a negligible function nonnegative, while Lemma 9 implies that the second term on the r.h.s. must be nonnegative. The pseudo-expectation map on the l.h.s. gives $\xi_q - \bar{\xi}_q$, implying that in the worst case the compiled game optimal bias can be only negligibly larger than the optimal quantum bias of the corresponding XOR game:

$$\bar{\xi}_q \leq \xi_q + \delta_{\mathrm{QHE}}(\kappa), \tag{58}$$

which completes the proof. □

4 Quantum bound of compiled nonlocal games with many outputs and conditions for self-testing of qudit measurements from a single prover

We now introduce a family of nonlocal games in which the players respond with more than two outputs. In this case, the quantum strategy involves d-outcome measurements, $\{M_{a|x}\}_{a=0}^{d-1}$ for Alice and $\{N_{b|y}\}_{b=0}^{d-1}$ for Bob. These measurements can be represented through generalized observables

$$A_x^{(k)} = \sum_{a=0}^{d-1} \omega^{ak} M_{a|x}, \qquad B_y^{(l)} = \sum_{b=0}^{d-1} \omega^{bl} N_{b|y}, \quad \forall k, l = 0, \cdots, d-1, \tag{59}$$

where $\omega = \exp\left(\frac{2\pi i}{d}\right)$. Clearly , the eigenvalues of the generalized unitary observables $A_x^{(k)}$ and $B_y^{(l)}$ are roots of unity. We will refer to the indices k and l as the orders of the generalised measurement; notice that the orders $k = 0 \mod d$ are the identity. For $d > 2$, generalized observables are not Hermitian, but still satisfy the following regular property:

$$(A^{(k)})^\dagger = A^{(-k)} \qquad (B^{(l)})^\dagger = B^{(-l)}$$

and hence $\left[A^{(k)}\right]^\dagger A^{(k)} = \mathbb{1}$ for every k. Considering only projective measurements, it is easy to check that $A^{(k)} = \left[A^{(1)}\right]^k$ and $B^{(l)} = \left[B^{(1)}\right]$; we will use these two notations interchangeably.

In this section, we adopt the perspective of Bell inequalities. The CHSH inequality is the simplest Bell inequality whose maximal violation self-tests the maximally entangled pair of qubits. Several propositions have been formulated to capture different features of the CHSH inequality, some focusing on self-testing maximally entangled shared states [SAT+17], some on self-testing mutually unbiased bases measurements for both parties [KŠT+19]. We concentrate on the Salavrakos-Augusiak-Tura-Wittek-Acin-Pironio (SATWAP) Bell inequality introduced in [SAT+17], for which a self-test of arbitrary local dimension with minimal number of measurements (2 per part) has been proposed in [SSKA21].

The SATWAP inequality is defined for two spatially separated players, each receiving a bit as input, $\mathsf{X} = \mathsf{Y} = \{1, 2\}$, and subsequently producing an output that can take one of d different values, $\mathsf{A} = \mathsf{B} = \{0, \ldots, d-1\}$. Many Bell inequalities can be expressed by conveniently defining some regular combination of probabilities given fixed inputs, called correlators. The definition of generalised correlator is:

$$\langle A_x^{(k)} B_y^{(l)} \rangle = \sum_{a=0}^{d-1} \sum_{b=0}^{d-1} \omega^{ak+bl} p(ab|xy) \tag{60}$$

The SATWAP inequality is given in terms of these

$$\beta_d^{\text{SATWAP}} = \sum_{k=1}^{d-1} \left(a_k \langle A_1^k B_1^{d-k} \rangle + a_k^* \omega^k \langle A_1^k B_2^{d-k} \rangle + a_k^* \langle A_2^k B_1^{d-k} \rangle + a_k \langle A_2^k B_2^{d-k} \rangle \right), \tag{61}$$

with the following definition of the phases $a_k = \frac{\omega^{\frac{2k-d}{8}}}{\sqrt{2}} = \frac{1-i}{2} \omega^{k/4}$ such that $a_k^* = a_{d-k}$ and $a_{\pm d} = \pm \frac{1+i}{2}$. To simplify the notation it is convenient to group Bob's observables in the following sums:

$$C_1^{(k)} = a_k B_1^{-k} + a_k^* \omega^k B_2^{-k}, \qquad C_2^{(k)} = a_k^* B_1^{-k} + a_k B_2^{-k}. \tag{62}$$

Using these definitions, the corresponding Bell operator is thus

$$\mathcal{B}_d^{\text{SATWAP}} = \sum_{k=1}^{d-1} \left(A_1^k \otimes C_1^{(k)} + A_2^k \otimes C_2^{(k)} \right). \tag{63}$$

Bell value is thus given as $\beta_d^{\text{SATWAP}} = \langle\psi|\mathcal{B}_d^{\text{SATWAP}}|\psi\rangle$. The classical and the quantum bounds of this inequality are

$$\left(\beta_d^{\text{SATWAP}}\right)_l = \frac{1}{2}\left(3\cot\left(\frac{\pi}{4}d\right) - \cot\left(\frac{3\pi}{4}d\right)\right) - 2, \qquad \left(\beta_d^{\text{SATWAP}}\right)_q = 2(d-1).$$

The quantum bound can be found by explicitly building the SOS decomposition of the shifted Bell operator, as shown in [SAT+17]. The terms of the SOS decomposition are labeled by $x \in \{1,2\}$ and $k \in \{0,\dots,d-1\}$:

$$P_{x,k} = (A_x^k)^\dagger - C_x^{(k)}.$$

A quick calculation allows us to check the correctness of the SOS decomposition :

$$\begin{aligned}
\beta_q \mathbb{1} - \mathcal{B}_d^{\text{SATWAP}} &= \frac{1}{2}\sum_{k=1}^{d-1}\left(P_{1,k}^\dagger P_{1,k} + P_{2,k}^\dagger P_{2,k}\right) && (64)\\
&= -\mathbb{B}_d^{\text{SATWAP}} + (d-1)\mathbb{1} + \frac{1}{2}\sum_{k=1}^{d-1}\left(C_1^{(d-k)}C_1^{(k)} + C_2^{(d-k)}C_2^{(k)}\right)\\
&= -\mathcal{B}_d^{\text{SATWAP}} + 2(d-1).
\end{aligned}$$

The maximal quantum violation of this inequality is a self-test of a maximally entangled pair of qudits, together with measurements that are unitarily equivalent to the measurements used to maximally violate well-known Collins-Gisin-Linden-Massar-Popescu (CGLMP) Bell inequalities [CGL+02]. We summarise this technical result in the following lemma, proven in [SSKA21].

Lemma 10 ([SSKA21])**.** *The maximal violation of the SATWAP Bell inequality certifies the following:*

- *The dimension of Alice's and Bob's Hilbert spaces is a multiple of d, and we can write their Hilbert space as the tensor products $\mathcal{H}_A = \mathbb{C}^d \otimes \mathcal{H}_{A'}$, $\mathcal{H}_B = \mathbb{C}^d \otimes \mathcal{H}_{B'}$, where $\mathcal{H}_{A'}$ and $\mathcal{H}_{B'}$ are auxiliary Hilbert spaces of finite dimension;*

- *There exist local unitary transformations $U_A : \mathcal{H}_A \to \mathcal{H}_A$ and $U_B : \mathcal{H}_B \to \mathcal{H}_B$ such that*

$$U_B B_1 U_B^\dagger = Z_d \otimes \mathbb{1}_{B'}, \qquad U_B B_2 U_B^\dagger = T_d \otimes \mathbb{1}_{B'}, \tag{65}$$

$$U_A A_1 U_A^\dagger = (a_1^* Z_d + 2(a_1^*)^3 T_d) \otimes \mathbb{1}_{A'}, \qquad U_A A_2 U_A^\dagger = (a_1 Z_d - a_1^* T_d) \otimes \mathbb{1}_{B'}. \tag{66}$$

where $Z_d = diag[1,\omega,\dots,\omega^{d-1}]$ and $T_d = \sum_{i=0}^{d-1}\omega^{i+1/2}|i\rangle\langle i| - \frac{2}{d}\sum_{j,i=0}^{d-1}(-1)^{\delta_{i,0}+\delta_{j,0}}\omega^{(i+j+1)/2}|i\rangle\langle j|$.

- *Alice and Bob share a state $|\psi_{AB}\rangle$ which is unitarily equivalent to the maximally entangled pair of qudits*

$$U_A \otimes U_B|\psi_{AB}\rangle = |\phi_d^+\rangle \otimes |\tau_{A'B'}\rangle.$$

Note that Eqs. (65) fully characterize Bob's measurements, given that they are projective and $B_y^{(k)} = B_y^k$.

For the compiled SATWAP Bell inequality, a modification in the modeling of the quantum prover is necessary. Our focus, thus far, has primarily been on compiled games with binary outputs. The prover is initiated in some quantum state $|\psi\rangle$ and its action in the first round is described in the same way, with eqs. (36) and (37) still holding. However, a generalized k-th order decrypted observable now reads:

$$\begin{aligned}
\mathsf{A}_x^{(k)} &= \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)}\sum_{\mathsf{a}}\omega^{k\mathsf{Dec}(\mathsf{a})}\mathsf{M}_{\mathsf{a}|\mathsf{x}}^\dagger\mathsf{M}_{\mathsf{a}|\mathsf{x}} && (67)\\
&= \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} A_{\mathsf{x}}^{(k)} && (68)
\end{aligned}$$

and the generalized decrypted correlator takes the form

$$\langle \mathsf{A}_x^{(k)}, B_y^{(l)}\rangle = \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x}\sum_{\mathsf{a}}\omega^{k\mathsf{Dec}(\mathsf{a})}\langle\psi_{\mathsf{a}|\mathsf{x}}|B_y^{(l)}|\psi_{\mathsf{a}|\mathsf{x}}\rangle, \tag{69}$$

with this value operationally giving the expectation value of ω^{ak+bl}, which will be directly used to asses the performance of the prover in the SATWAP game.

We generalize the modified moment matrix $\tilde{\mathcal{Q}}$ to include the expectation values of generalized observables. Recall that generalized observables are labeled not only by the input $x \in \mathsf{X}$ (or $y \in \mathsf{Y}$) but also by the degree $k \in$

$\{1, \ldots, d-1\}$ (or l). Every entry of the modified covariance matrix $\tilde{\mathcal{Q}}$ is labeled by two generalized observables, hence is a square matrix of dimension $(|\mathsf{X}| + |\mathsf{Y}|)(d-1)$. Hence, we define a generalization of the matrix $\tilde{\mathcal{Q}}$ as follows

$$\tilde{\mathcal{Q}} = \left[\begin{array}{c|c} \mathbb{1}_{(d-1)|\mathsf{X}|} & C \\ \hline C^T & S \end{array}\right] \tag{70}$$

where $\mathbb{1}_{(d-1)|\mathsf{X}|}$ is $(d-1)|\mathsf{X}| \times (d-1)|\mathsf{X}|$ identity matrix and

$$C = \sum_{x,y,k,l} \langle \mathrm{A}_x^{(d-k)}, B_y^{(l)} \rangle |(k-1)d + x\rangle\langle(l-1)d + y| \tag{71}$$

$$S = \mathop{\mathbb{E}}_{x \in \mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}:\mathsf{Dec}(\mathsf{x})=x} \sum_{\mathsf{a}} \langle \psi_{\mathsf{a}|\mathsf{x}} | B_y^{(d-l)} B_{y'}^{(l')} | \psi_{\mathsf{a}|\mathsf{x}} \rangle |(l-1)d + y\rangle\langle(l'-1)d + y'| \tag{72}$$

with $\langle \mathrm{A}_x^{(k)}, B_y^{(l)} \rangle$ being introduced in eq. (69).

As in 2.6.2, we define a linear operator $\tilde{\mathbb{E}}$ that maps every homogeneous degree-2 polynomial in the variables $\{A_x^{(k)}, B_y^{(l)}\}_{x,y,k,l}$ to linear combinations of elements of matrix $\tilde{\mathcal{Q}}$ in the following way

$$\tilde{\mathbb{E}}[A_x^{(d-k)} B_y^{(l)}] = C_{(k-1)d+x,(l-1)d+y}, \qquad \tilde{\mathbb{E}}[B_y^{(l)} \mathrm{A}_x^{(d-k)}] = C^T_{(l-1)d+y,(k-1)d+x} \tag{73}$$

$$\tilde{\mathbb{E}}[A_x^{(k)} A_{x'}^{(k')}] = \delta_{x,x'}\delta_{k,k'}, \qquad \tilde{\mathbb{E}}[B_y^{(l)} B_{y'}^{(l')}] = S_{(l-1)d+y,(l'-1)d+y'} \tag{74}$$

For $y = y'$, $l = l'$ or $x = x'$, $k = k'$ in eq. (50) we get a consistent mapping of identity

$$\tilde{\mathbb{E}}[A_x^{(d-k)} A_x^{(k)}] = \tilde{\mathbb{E}}[\mathbb{1}] = 1, \qquad \tilde{\mathbb{E}}[B_y^{(d-l)} B_y^{(l)}] = \tilde{\mathbb{E}}[\mathbb{1}] = S_{(l-1)d+y,(l-1)d+y} = 1. \tag{75}$$

With this formalism, we can prove a result equivalent to Theorem (3) for the quantum bound of the compiled SATWAP inequality. Let us first introduce the following lemma.

Lemma 11. *Let $P_{x,k} = (A_x^k)^\dagger - C_x^{(k)}$, where A_x^k is a generalised observable, and $C_x^{(k)}$ are linear sums of generalised observables defined in eq. (62). Then there exists a negligible function $\delta_{\mathrm{QHE}}(\cdot)$ such that we have $\tilde{\mathbb{E}}\left[(P_x^k)^\dagger P_x^k\right] \geq -\delta_{\mathrm{QHE}}(\kappa)$, where $\tilde{\mathbb{E}}[\cdot]$ is the pseudo-expectation map generalised above.*

Proof. The proof follows closely the arguments presented in the proof of Lemma 8, with the difference that generalised observables are not hermitian, and phases are also complex.

$$\begin{aligned}
\tilde{\mathbb{E}}\left[P_{x,k}^\dagger P_{x,k}\right] &= \tilde{\mathbb{E}}\left[(A_x^{(k)})^\dagger A_x^{(k)}\right] - \tilde{\mathbb{E}}\left[(A_x^{(k)})^\dagger C_x^{(k)}\right] - \tilde{\mathbb{E}}\left[(C_x^{(k)})^\dagger A_x^k\right] + \tilde{\mathbb{E}}\left[(C_x^{(k)})^\dagger C_x^{(k)}\right] \\
&= \tilde{\mathbb{E}}\left[A_x^{(d-k)} A_x^{(k)}\right] - \tilde{\mathbb{E}}\left[A_x^{(d-k)} C_x^{(k)}\right] - \tilde{\mathbb{E}}\left[C_x^{(d-k)} A_x^{(k)}\right] + \tilde{\mathbb{E}}\left[C_x^{(d-k)} C_x^{(k)}\right] \\
&= 1 - \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \omega^{(d-k)\mathsf{Dec}(\mathsf{a})} \langle \psi_{\mathsf{a}|\mathsf{x}} | C_x^{(k)} | \psi_{\mathsf{a}|\mathsf{x}} \rangle - \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \omega^{k\mathsf{Dec}(\mathsf{a})} \langle \psi_{\mathsf{a}|\mathsf{x}} | C_x^{(d-k)} | \psi_{\mathsf{a}|\mathsf{x}} \rangle \\
&+ \mathop{\mathbb{E}}_{i \in \mathsf{X}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(i)} \sum_{\mathsf{a}} \langle \psi_{\mathsf{a}|\mathsf{x}} | C_x^{(d-k)} C_x^{(k)} | \psi_{\mathsf{a}|\mathsf{x}} \rangle \\
&\approx_{\delta_{\mathrm{QHE}}(\kappa)} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle \psi_{\mathsf{a}|\mathsf{x}} | \left(\mathbb{1} - \omega^{-k\mathsf{Dec}(\mathsf{a})} C_x^{(k)} - \omega^{k\mathsf{Dec}(\mathsf{a})} C_x^{(d-k)} + C_x^{(d-k)} C_x^{(k)} \right) | \psi_{\mathsf{a}|\mathsf{x}} \rangle \\
&\approx_{\delta_{\mathrm{QHE}}(\kappa)} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle \psi_{\mathsf{a}|\mathsf{x}} | \left(\omega^{k\mathsf{Dec}(\mathsf{a})} \mathbb{1} - C_x^{(k)} \right)^2 | \psi_{\mathsf{a}|\mathsf{x}} \rangle \geq 0
\end{aligned}$$

In the second and in the third line we used the linearity of the pseudo-expectation map over sums of generalised observables and the definitions stated above. In the fourth step we apply Lemma 7 to the last addend and we fix the index $i = x$, at the price of a negligible function $\delta_{\mathrm{QHF}}(\kappa)$. We can apply this lemma because $C_x^{(d-k)} C_x^{(k)}$ has a QPT-implementable block encoding, since is composed by linear sums and multiplications of QPT-implementable generalised observables (Corollaries 1 and 2). Finally, using linearity we can group all the terms inside of one average over $\mathsf{x} = \mathsf{Enc}(x)$; we rephrase this sum as an operator square, which is non-negative by definition. □

Theorem 4. *Let's consider the d-dimensional SATWAP Bell inequality, with quantum bound $(\beta_d^{SATWAP})_q$, and its compiled version through Kalai protocol. If d is polynomial w.r.t. the security parameter κ, then the quantum bound of the compiled SATWAP inequality is $(\beta_d^{SATWAP})_q + \theta(\kappa)$, where $\theta(\cdot)$ is a negligible function.*

Proof. Applying the map $\tilde{\mathbb{E}}$ to the shifted SATWAP operator given in eq. (64) gives :

$$\tilde{\mathbb{E}}\left[\beta_q \mathbb{1} - \mathcal{B}_d^{\text{SATWAP}}\right] = \frac{1}{2}\sum_{k=1}^{d-1}\left(\tilde{\mathbb{E}}\left[P_{1,k}^{\dagger}P_{1,k}\right] + \tilde{\mathbb{E}}\left[P_{2,k}^{\dagger}P_{2,k}\right]\right), \tag{76}$$

In Lemma 11 we proved that all elements in the sum on the r.h.s. are non-negative up to a negligible function, *i.e.*

$$\tilde{\mathbb{E}}\left[P_{x,k}^{\dagger}P_{x,k}\right] \approx_\delta \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}_{\mathsf{a}|\mathsf{x}}^{\dagger}\left(\omega^{k\mathsf{Dec}(\mathsf{a})}\mathbb{1} - C_x^{(k)}\right)^2 \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \tag{77}$$

This implies that there exists a negligible function of the security parameter $\theta(\kappa)$ such that the maximal quantum score $\bar{\beta}_q$ in the compiled SATWAP inequality becomes

$$\bar{\beta}_q \leq 2(d-1) + \theta(\kappa). \tag{78}$$

□

Let us now explore self-testing properties, and assume that a QPT prover achieved the score $\bar{\beta}_q$ in the compiled SATWAP inequality. Given eq. (76), reaching the optimal quantum score implies

$$0 = \frac{1}{2}\sum_{k=1}^{d-1}\left(\tilde{\mathbb{E}}\left[P_{1,k}^{\dagger}P_{1,k}\right] + \tilde{\mathbb{E}}\left[P_{2,k}^{\dagger}P_{2,k}\right]\right). \tag{79}$$

By using eqs. (77) and (79) we get

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \langle\psi|\mathsf{M}_{\mathsf{a}|\mathsf{x}}^{\dagger}\left(\omega^{k\mathsf{Dec}(\mathsf{a})}\mathbb{1} - C_x^{(k)}\right)^2 \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \approx_\delta 0, \tag{80}$$

where we write δ as shorthand for δ_{QHE}. This further gives us

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \left\| C_x^{(k)}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle - \omega^{k\mathsf{Dec}(\mathsf{a})}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \right\|^2 \approx_\delta 0, \tag{81}$$

further implying that for every k, every x decrypting to x, and every a

$$C_x^{(k)}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \approx_\delta \omega^{k\mathsf{Dec}(\mathsf{a})}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle. \tag{82}$$

If we fix k' the previous relation implies

$$\begin{aligned}
\left[C_x^{(1)}\right]^{k'} \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle &\approx_\delta \left[C_x^{(1)}\right]^{k'-1} C_x^{(1)}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\approx_{2\cdot\delta} \omega^{\mathsf{Dec}(\mathsf{a})}\left[C_x^{(1)}\right]^{k'-1} \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\approx_{3\cdot\delta} \omega^{2\mathsf{Dec}(\mathsf{a})}\left[C_x^{(1)}\right]^{k'-2} \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\dots \\
&\approx_{k'\cdot\delta} \omega^{k'\mathsf{Dec}(\mathsf{a})}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\approx_{(k'+1)\cdot\delta} C_x^{(k')}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle,
\end{aligned}$$

where in the second line we used eq. (82) for $k=1$, which we used successively until the last line where we used again eq. (82) for $k = k'$. By summing over a, and noting that $k' < d$ which is polynomially bounded in the security parameter κ we get:

$$\left[C_x^{(1)}\right]^{k}|\psi\rangle \approx_{O(\delta)} C_x^{(k)}|\psi\rangle. \tag{83}$$

Now we develop the following expression for an arbitrary k

$$\begin{aligned}
C_x^{(d-k)}C_x^{(k)}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle &\approx_\delta \omega^{k\mathsf{Dec}(\mathsf{a})}C_x^{(d-k)}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&\approx_{2\delta} \omega^{k\mathsf{Dec}(\mathsf{a})}\omega^{(d-k)\mathsf{Dec}(\mathsf{a})}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&= \omega^{d\mathsf{Dec}(\mathsf{a})}\mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle \\
&= \mathsf{M}_{\mathsf{a}|\mathsf{x}}|\psi\rangle,
\end{aligned}$$

where for the first line we used eq. (82), for the second line we used the same equation by changing k to $d-k$, and the last line follows from $\omega^d = 1$. Again by summing over a we obtain

$$C_x^{(d-k)} C_x^{(k)} |\psi\rangle \approx_{O(\delta)} |\psi\rangle, \tag{84}$$

Thus, on the support of $|\psi\rangle$ the observables $C_x^{(k)}$ satisfy condition

$$\left[C_x^{(1)}\right]^k \approx_{O(\delta)} C_x^{(k)}, \qquad C_x^{(d-k)} C_x^{(k)} \approx_{O(\delta)} \mathbb{1}. \tag{85}$$

In [SSKA21] it is proven that these two equations for $O(\delta) = 0$ imply though Lemmas 1, 2, and 3 in the supplementary material therein that there exists a unitary U such that

$$U_B B_1^{(1)} U_B^\dagger = Z_d \otimes \mathbb{1}_{B'}, \qquad U_B B_2^{(1)} U_B^\dagger = T_d \otimes \mathbb{1}_{B'}, \tag{86}$$

with Z_d and T_d being given in Lemma 10. Since $B_1^{(1)}$ and $B_2^{(1)}$ are unitary we get $B_1^{(k)} = \left[B_1^{(1)}\right]^k$ and $B_2^{(k)} = \left[B_2^{(1)}\right]^k$. We conjecture that the derivation procedure is robust to noise, implying that in the case of reaching the optimal quantum violation of the compiled SATWAP inequality relations (86) hold up to a negligible function of the security parameter.

5 Computational self-test of any two binary measurements from a single prover

Let us consider first a family of correlation Bell inequalities introduced in [LMS+23], and further discussed in [BSB23]. The family of Bell inequalities is parameterized with three parameters μ, ν and χ, and the Bell operator is

$$\begin{aligned}\mathcal{B}_{\mu\nu\chi} = &\cos(\mu+\nu)\cos(\mu+\chi)(\cos(\chi)A_0 - \cos(\nu)A_1) \otimes B_0 \\ &+ \cos(\nu)\cos(\chi)(-\cos(\mu+\chi)A_0 + \cos(\mu+\nu)A_1) \otimes B_1\end{aligned} \tag{87}$$

The corresponding family of Bell inequalities involves the CHSH inequality (for $\mu = \chi = 0$ and $\nu = \pi$). A Bell inequality belonging to this family has quantum violations when $\cos(\mu+\chi)\cos(\mu+\nu)\cos(\nu)\cos(\chi) < 0$. Whenever this is the case, reaching the quantum bound

$$\beta_q = \pm \sin(\mu)\sin(\chi-\nu)\sin(\mu+\nu+\chi) \tag{88}$$

self-tests the maximally entangled pair of qubits [WBC23]. This property makes it a good candidate for our compilation procedure. The SOS decomposition of the shifted Bell operator is

$$\beta_q \mathbb{1} - \mathcal{B}_{\mu\nu\chi} = c_0 P_0^\dagger P_0 + c_1 P_1^\dagger P_1, \tag{89}$$

where

$$c_0 = -\frac{\cos(\chi)\cos(\mu+\chi)}{2\sin(\mu)}, \qquad c_1 = -\frac{\cos(\nu)\cos(\mu+\nu)}{2\sin(\mu)}$$

and

$$\begin{aligned}P_0 &= \sin(\mu)A_0 + \cos(\mu+\nu)B_0 - \cos(\nu)B_1 \\ P_1 &= \sin(\mu)A_1 + \cos(\mu+\chi)B_0 - \cos(\chi)B_1\end{aligned}$$

Given the form of the SOS decomposition (89), the optimal value of the compiled inequality $\bar{\beta}_q$ is the same as the quantum bound β_q given in (88) up to a negligible function. Taking the pseudo-expectation value of (89) we get

$$\beta_q - \bar{\beta} = c_0 \tilde{\mathbb{E}}\left[P_0^\dagger P_0\right] + c_1 \tilde{\mathbb{E}}\left[P_1^\dagger P_1\right] \tag{90}$$

As usual, we denote $\hat{B}_0 = (-\cos(\mu+\nu)B_0 + \cos(\nu)B_1)/\sin(\mu)$ and $\hat{B}_1 = -(\cos(\mu+\chi)B_0 + \cos(\chi)B_1)/\sin(\mu)$. If $\bar{\beta} = \beta_q - \varepsilon$, the equation above simply becomes

$$\varepsilon = c_0 \tilde{\mathbb{E}}\left[P_0^\dagger P_0\right] + c_1 \tilde{\mathbb{E}}\left[P_1^\dagger P_1\right]$$

where the two terms on the lhs don't have to be positive. Though, from the result of Lemma 8, we know that they must be positive up to a negligible function depending on the quantum homomorphic encryption scheme:

$$\tilde{\mathbb{E}}\left[P_x^\dagger P_x\right] \geq \underset{\mathsf{x}=\mathsf{Enc}(x)}{\mathbb{E}} \sum_{\mathsf{a}} \left\| \hat{B}_x |\psi_{\mathsf{a}|\mathsf{x}}\rangle - (-1)^{\mathsf{Dec}(\mathsf{a})} |\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 - \delta_{\mathrm{QHE}}(\kappa).$$

Using this bound on the previous equation we get the following:

$$\begin{aligned}\varepsilon + (c_0 + c_1)\delta_{\mathrm{QHE}}(\kappa) \geq & c_0 \underset{\mathsf{x}=\mathsf{Enc}(0)}{\mathbb{E}} \sum_{\mathsf{a}} \left\| \hat{B}_0 |\psi_{\mathsf{a}|\mathsf{x}}\rangle - (-1)^{\mathsf{Dec}(\mathsf{a})} |\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \\ & + c_1 \underset{\mathsf{x}=\mathsf{Enc}(1)}{\mathbb{E}} \sum_{\mathsf{a}} \left\| \hat{B}_1 |\psi_{\mathsf{a}|\mathsf{x}}\rangle - (-1)^{\mathsf{Dec}(\mathsf{a})} |\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2\end{aligned}$$

where now on the lhs we only have positive quantities. Hence, for all values of x we get this bound:

$$\underset{\mathsf{x}=\mathsf{Enc}(x)}{\mathbb{E}} \sum_{\mathsf{a}} \left\| \hat{B}_x |\psi_{\mathsf{a}|\mathsf{x}}\rangle - (-1)^{\mathsf{Dec}(\mathsf{a})} |\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \leq \frac{\varepsilon}{c_x} + \frac{c_0 + c_1}{c_x} \delta_{\mathrm{QHE}}(\kappa) \qquad \forall x \in \{0, 1\}. \tag{91}$$

As a pedagogical introduction, let us see what happens when the maximal quantum score is achieved in the noiseless case, *i.e.* $\varepsilon = 0$ and $\delta_{\mathrm{QHE}} = 0$. The equation above would imply that every addend is equal to zero:

$$\hat{B}_x |\psi_{\mathsf{a}|\mathsf{x}}\rangle = (-1)^{\mathsf{Dec}(\mathsf{a})} |\psi_{\mathsf{a}|\mathsf{x}}\rangle, \qquad \forall \mathsf{x} : \mathsf{Dec}(\mathsf{x}) = x, \forall \mathsf{a}.$$

When the quantum bound is saturated, the square of the hat operator $\hat{B}_x$ acts like identity on $|\psi_{\mathsf{a}|\mathsf{x}}\rangle$:

$$(\hat{B}_x)^2 |\psi_{\mathsf{a}|\mathsf{x}}\rangle = (-1)^{\mathsf{Dec}(\mathsf{a})} \hat{B}_x |\psi_{\mathsf{a}|\mathsf{x}}\rangle = |\psi_{\mathsf{a}|\mathsf{x}}\rangle \qquad \forall \mathsf{x} : \mathsf{Dec}(\mathsf{x}) = x, \forall \mathsf{a} \tag{92}$$

By the definition of $\hat{B}_0$, and assuming $B_0^2 = B_1^2 = \mathbb{1}$, the following is always true for every state:

$$\begin{aligned}(\hat{B}_0)^2 |\psi_{\mathsf{a}|\mathsf{x}}\rangle &= \left(\frac{\cos^2(\nu) + \cos^2(\nu + \mu)}{\sin^2(\mu)} \mathbb{1} - \frac{\cos(\nu)\cos(\nu + \mu)}{\sin^2(\mu)} \{B_0, B_1\} \right) |\psi_{\mathsf{a}|\mathsf{x}}\rangle \\ &= k_{\mathbb{1}} |\psi_{\mathsf{a}|\mathsf{x}}\rangle - k_{\{\}} \{B_0, B_1\} |\psi_{\mathsf{a}|\mathsf{x}}\rangle\end{aligned} \tag{93}$$

where in the second line we simply fixed a notation for the coefficients of the operators. Equations (92) and (93) together fix the value of the anti-commutator of Bob's observables when the maximal quantum score is achieved:

$$\{B_0, B_1\} |\psi_{\mathsf{a}|\mathsf{x}}\rangle = \frac{k_{\mathbb{1}} - 1}{k_{\{\}}} |\psi_{\mathsf{a}|\mathsf{x}}\rangle = 2\cos(\mu) |\psi_{\mathsf{a}|\mathsf{x}}\rangle \qquad \forall \mathsf{x} : \mathsf{Dec}(\mathsf{x}) = x, \forall \mathsf{a}$$

where the second inequality is a simple trigonometric identity

$$\frac{k_{\mathbb{1}} - 1}{k_{\{\}}} = \frac{\cos^2(\nu) + \cos^2(\nu + \mu) - \sin^2(\mu)}{\sin^2(\mu)} \frac{\sin^2(\mu)}{\cos(\nu)\cos(\nu + \mu)} = 2\cos(\mu).$$

Since all observables are binary, this is a self-test. Indeed, Jordan's lemma ensures that B_0 and B_1 can be simultaneously block-diagonalised such that all blocks are either of size 2×2 or 1×1. In the same way like in [ŠBCB22], we embed every 1×1 into a Hilbert space of larger dimension. This operation does not affect the correlation probabilities, and it simplifies our analysis, as we work with a Jordan decomposition in which all blocks are of the size 2×2. Without loss of generalisation, we can apply a local unitary to the observable B_0 and bring it to Pauli's σ_x in every 2×2 block:

$$U B_0 U^\dagger = \sigma_x \otimes \sum_i |i\rangle\langle i|. \tag{94}$$

We can also safely bring all the 2×2 blocks of B_1 to the XZ plane of the Bloch sphere; by fixing the value of the anti-commutator, we get that B_1 has $\cos(\mu)\sigma_x + \sin(\mu)\sigma_z$ in every block. For every $\mu \neq 0$ we can find ν and χ such that the condition $\cos(\mu + \chi)\cos(\mu + \nu)\cos(\nu)\cos(\chi) < 0$ is satisfied, implying that the quantum bound is larger than the classical. This implies that we can perform a single-prover self-test of any two observables applied by Bob, *i.e.* for every μ there is a compiled XOR game whose maximal violation self-tests Bob's measurements implying:

$$U B_0 U^\dagger = \sigma_x \otimes \mathbb{1}, \qquad U B_1 U^\dagger = (\cos(\mu)\sigma_x + \sin(\mu)\sigma_z) \otimes \mathbb{1} \tag{95}$$

The noiseless assumption is unrealistic, both from a cryptographic and experimental point of view. Assuming a finite security parameter κ and small experimental deviations ϵ, we can still prove that the anti-commutator of Bob's observables is close to the noiseless value, obtaining a robust self-test for Bob's binary observables. Let's start considering Eq. (91) with $\mathsf{x} = \mathsf{Enc}(0)$, and open the sum over a:

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \left[\sum_{\mathsf{a}=\mathsf{Enc}(0)} \left\| (\hat{B}_0 - \mathbb{1})|\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 + \sum_{\mathsf{a}=\mathsf{Enc}(1)} \left\| (\hat{B}_0 + \mathbb{1})|\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \right] \leq \frac{\varepsilon}{c_0} + \frac{c_0 + c_1}{c_0} \delta_{\mathrm{QHE}}(\kappa)$$

We call the vectors inside the norms as $|\Delta^{\pm}_{\mathsf{a}|\mathsf{x}}\rangle = (\hat{B}_0 \pm \mathbb{1})|\psi_{\mathsf{a}|\mathsf{x}}\rangle$, hence we can write:

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \left[\sum_{\mathsf{a}=\mathsf{Enc}(0)} \left\| |\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 + \sum_{\mathsf{a}=\mathsf{Enc}(1)} \left\| |\Delta^{+}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \right] \leq \frac{\varepsilon}{c_0} + \frac{c_0 + c_1}{c_0} \delta_{\mathrm{QHE}}(\kappa) \tag{96}$$

Consider again $\hat{B}_0$, its square is:

$$\begin{aligned}(\hat{B}_0)^2 &= \mathbb{1} + (\hat{B}_0 - \mathbb{1}) + \hat{B}_0(\hat{B}_0 - \mathbb{1}) = \mathbb{1} - (\hat{B}_0 + \mathbb{1}) + \hat{B}_0(\hat{B}_0 + \mathbb{1}) \\ &= k_{\mathbb{1}}\mathbb{1} - k_{\{\}}\{B_0, B_1\}\end{aligned}$$

where the first lines are trivial identities, and in the second line we rewrote Eq. (93). Rearranging the terms, and applying the observables on $|\psi_{\mathsf{a}|\mathsf{x}}\rangle$, we obtain the following formula for the anti-commutator of Bob's observables:

$$[2\cos(\mu)\mathbb{1} - \{B_0, B_1\}]\,|\psi_{\mathsf{a}|\mathsf{x}}\rangle = \pm \frac{1}{k_{\{\}}} |\Delta^{\mp}_{\mathsf{a}|\mathsf{x}}\rangle + \frac{1}{k_{\{\}}} \hat{B}_0 |\Delta^{\mp}_{\mathsf{a}|\mathsf{x}}\rangle$$

where to find $2\cos(\mu)$ we used again the trigonometric identity above. We focus first on the equation with $|\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle$. We compute its norm squared, averaging over $\mathsf{x} = \mathsf{Enc}(0)$ and summing over $\mathsf{a} = \mathsf{Enc}(0)$

$$\begin{aligned}\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(0)} \left\| [2\cos(\mu)\mathbb{1} - \{B_0, B_1\}]\,|\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 &= \frac{1}{k^2_{\{\}}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(0)} \left\| |\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle + \hat{B}_0|\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \\ &\leq \frac{1}{k^2_{\{\}}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(0)} \left(\left\| |\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 + \left\| \hat{B}_0|\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \right) \\ &\leq \frac{1}{k^2_{\{\}}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(0)} \left(\left\| |\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 + \|\hat{B}_0\|^2 \left\| |\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \right) \\ &= \frac{1 + \|\hat{B}_0\|^2}{k^2_{\{\}}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(0)} \left\| |\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2\end{aligned}$$

where we used Cauchy-Schwarz and the triangle inequality. Similarly, we can find a similar bound summing over $\mathsf{a} = \mathsf{Enc}(1)$ and using the decomposition of the anti-commutator with the vectors $|\Delta^{+}_{\mathsf{a}|\mathsf{x}}\rangle$:

$$\begin{aligned}\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(1)} \left\| [2\cos(\mu)\mathbb{1} - \{B_0, B_1\}]\,|\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 &= \frac{1}{k^2_{\{\}}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(1)} \left\| -|\Delta^{+}_{\mathsf{a}|\mathsf{x}}\rangle + \hat{B}_0|\Delta^{+}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \\ &\leq \frac{1 + \|\hat{B}_0\|^2}{k^2_{\{\}}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}=\mathsf{Enc}(1)} \left\| |\Delta^{+}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2\end{aligned}$$

Now, putting together these two result we can bound the sum over a

$$\begin{aligned}\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}} \left\| [2\cos(\mu)\mathbb{1} - \{B_0, B_1\}]\,|\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 &\leq \frac{1 + \|\hat{B}_0\|^2}{k^2_{\{\}}} \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \left[\sum_{\mathsf{a}=\mathsf{Enc}(0)} \left\| |\Delta^{-}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 + \sum_{\mathsf{a}=\mathsf{Enc}(1)} \left\| |\Delta^{+}_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \right] \\ &\leq \frac{1 + \|\hat{B}_0\|^2}{k^2_{\{\}}} \left(\frac{\varepsilon}{c_0} + \frac{c_0 + c_1}{c_0} \delta_{\mathrm{QHE}}(\kappa) \right) \\ &\leq \sin^2(\mu) \left[2\cos(\mu) + \frac{1}{\cos(\nu)\cos(\nu + \mu)} \right] \left(\frac{\varepsilon}{c_0} + \frac{c_0 + c_1}{c_0} \delta_{\mathrm{QHE}}(\kappa) \right)\end{aligned}$$

where in the second line we used the bound found in Eq. 96. The angles are fixed from the inequality, therefore in the last line we have some negligible functions in ϵ and κ multiplied by some constant factors depending on the angles. Therefore we proved that, on the support of the states used in the compiled game, the anti-commutator of Bob's observable is $2\cos(\mu)\mathbb{1}$ up to a negligible function $\eta_{anticomm}$:

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}} \left\| [2\cos(\mu)\mathbb{1} - \{B_0, B_1\}] \, |\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \leq \eta_{anticomm}(\epsilon, \kappa, \nu, \mu) \tag{97}$$

6 Computational self-test of three Pauli observables

The Elegant Bell inequality, first introduced in [Gis09], considers two parties and binary observables, with input sets $\mathsf{X} \in [4]$ and $\mathsf{Y} \in [3]$. The Bell operator has the form

$$\mathcal{B}^{el} = (A_1 + A_2 - A_3 - A_4) \otimes B_1 + (A_1 - A_2 + A_3 - A_4) \otimes B_2 + (A_1 - A_2 - A_3 + A_4) \otimes B_3$$

The quantum bound $\beta_q = 4\sqrt{3}$ self-tests a maximally entangled pair of qubits and maximally spread measurements for Alice and Bob (hence the elegance) [APVW16]. Specifically, Bob's three measurements form a set of mutually unbiased bases resembling an octahedron in the Bloch sphere, while Alice's four measurements form a dual structure, i.e. a cube.

This can be seen as an XOR game, therefore Theorem 3 applies and the quantum bound of the compiled game is preserved. In the following section we will proof that the self-testing properties of this game are also preserved by Kalai compilation. This is particularly interesting because the self-tested arrangement is not confined to a single plane on the Bloch sphere: is a triplet of MUB measurements in Bloch sphere.

The standard SOS decomposition for the shifted elegant Bell inequality in the nonlocal case is

$$\beta_q \mathbb{1} - \mathcal{B}^{el} = \frac{\sqrt{3}}{2} \sum_{i=1}^{4} P_i^2 \tag{98}$$

with the following definition for the polynomials P_i

$$P_1 = A_1 - \frac{B_1 + B_2 + B_3}{\sqrt{3}}, \qquad P_2 = A_2 - \frac{B_1 - B_2 - B_3}{\sqrt{3}},$$
$$P_3 = A_3 - \frac{-B_1 + B_2 - B_3}{\sqrt{3}}, \qquad P_4 = A_4 - \frac{-B_1 - B_2 + B_3}{\sqrt{3}}.$$

We use the standard notation $P_i = A_i - \hat{B}_i$. When the compiled game reaches the score $\bar{\beta} = \beta_q - \epsilon$, the following is true

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(x)} \sum_{\mathsf{a}} \left\| \hat{B}_x |\psi_{\mathsf{a}|\mathsf{x}}\rangle - (-1)^{\mathsf{Dec}(\mathsf{a})} |\psi_{\mathsf{a}|\mathsf{x}}\rangle \right\|^2 \leq \frac{2}{\sqrt{3}}\varepsilon + 4\delta_{\mathrm{QHE}}(\kappa) \qquad \forall x \tag{99}$$

As a pedagogical introduction we study first the noisiless case, with $\delta_{\mathrm{QHE}}(\kappa) = 0$ and $\varepsilon = 0$, implying that

$$\hat{B}_x |\psi_{\mathsf{a}|\mathsf{x}}\rangle - (-1)^{\mathsf{Dec}(\mathsf{a})} |\psi_{\mathsf{a}|\mathsf{x}}\rangle = 0, \qquad \forall \mathsf{x} : \mathsf{Dec}(\mathsf{x}) = x, \forall x$$

Once again, this proves that the square of the hat operator acts like identity on $|\psi_{\mathsf{a}|\mathsf{x}}\rangle$:

$$(\hat{B}_x)^2 |\psi_{\mathsf{a}|\mathsf{x}}\rangle = (-1)^{\mathsf{Dec}(\mathsf{a})} \hat{B}_x |\psi_{\mathsf{a}|\mathsf{x}}\rangle = |\psi_{\mathsf{a}|\mathsf{x}}\rangle \tag{100}$$

The square of the hat operator can be completely characterized in terms of the anti-commutators of the observables, assuming their projectivity $B_1^2 = B_2^2 = B_3^2 = \mathbb{1}$. Let's consider $x = 1$, then

$$(\hat{B}_1)^2 = \mathbb{1} + \frac{1}{3}\big(\{B_1, B_2\} + \{B_2, B_3\} + \{B_1, B_3\}\big)$$

Considering all possible x and Eq. 100, we obtain the following system of equations :

$$\big(+\{B_1, B_2\} + \{B_2, B_3\} + \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle = 0$$
$$\big(-\{B_1, B_2\} + \{B_2, B_3\} - \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle = 0$$
$$\big(-\{B_1, B_2\} - \{B_2, B_3\} + \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle = 0$$
$$\big(+\{B_1, B_2\} - \{B_2, B_3\} - \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle = 0$$

whose only solution is

$$\{B_1, B_2\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle = \{B_2, B_3\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle = \{B_1, B_3\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle = 0 \tag{101}$$

This completely fix the three observales: they must be unitarely equivalent to the three Pauli's. See appendix C of [Kan17] for a formal proof of this statement.

To make the self-testing cryptographically and experimentally meaningful it needs to be robust to noise, *i.e.* we need to consider a non-null ε and $\delta_{\mathrm{QHE}}(\kappa)$. We want to prove that all the anti-commutators are still null up to a negligible function depending on the noise ε and the security parameter κ:

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}} \left\|\{B_{y_1}, B_{y_2}\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 \leq \eta(\epsilon, \kappa) \qquad \forall y_1 \neq y_2$$

Using similar tricks to the section before [i can expand, but it's trivial] we get the following system of equations:

$$\begin{aligned}
\mathop{\mathrm{E}}_{\mathsf{x}=\mathsf{Enc}(0)} \sum_{\mathsf{a}} \left\|\big(+\{B_1, B_2\} + \{B_2, B_3\} + \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 &\leq 9(1+\sqrt{3})f(\varepsilon) + \delta_{\mathrm{QHE}}(\kappa)\\
\mathop{\mathrm{E}}_{\mathsf{x}=\mathsf{Enc}(1)} \sum_{\mathsf{a}} \left\|\big(-\{B_1, B_2\} + \{B_2, B_3\} - \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 &\leq 9(1+\sqrt{3})f(\varepsilon) + \delta_{\mathrm{QHE}}(\kappa)\\
\mathop{\mathrm{E}}_{\mathsf{x}=\mathsf{Enc}(2)} \sum_{\mathsf{a}} \left\|\big(-\{B_1, B_2\} - \{B_2, B_3\} + \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 &\leq 9(1+\sqrt{3})f(\varepsilon) + \delta_{\mathrm{QHE}}(\kappa)\\
\mathop{\mathrm{E}}_{\mathsf{x}=\mathsf{Enc}(3)} \sum_{\mathsf{a}} \left\|\big(+\{B_1, B_2\} - \{B_2, B_3\} - \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 &\leq 9(1+\sqrt{3})f(\varepsilon) + \delta_{\mathrm{QHE}}(\kappa)
\end{aligned}$$

Even if the averages are over different values of x, we can change them all to be the same value $\bar{x}$, paying the price of an additional $\delta_{\mathrm{QHE}}(\kappa)$. We expand the definitions of the terms inside the norms. For every equation of the system we will have something like

$$\begin{aligned}
&\left\|\big(\{B_1, B_2\} + \{B_2, B_3\} + \{B_1, B_3\}\big)|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 =\\
&= \left\|\{B_1, B_2\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 + \left\|\{B_2, B_3\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 + \left\|\{B_3, B_1\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 +\\
&+ \langle\psi_{\mathsf{a}|\mathsf{x}}|\{\{B_1, B_2\}, \{B_2, B_3\}\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle + \langle\psi_{\mathsf{a}|\mathsf{x}}|\{\{B_1, B_2\}, \{B_1, B_3\}\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle + \langle\psi_{\mathsf{a}|\mathsf{x}}|\{\{B_1, B_3\}, \{B_2, B_3\}\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle
\end{aligned}$$

with possibly different signs in the last line. We sum all of the inequalities; only the terms with the norm of the anti-commutators are going to survive, hence

$$4 \mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(\bar{x})} \sum_{\mathsf{a}} \left(\left\|\{B_1, B_2\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 + \left\|\{B_2, B_3\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 + \left\|\{B_3, B_1\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2\right) \leq 4\left(9(1+\sqrt{3})f(\varepsilon) + 2\delta_{\mathrm{QHE}}(\kappa)\right)$$

All the terms in the sum are positive, hence we obtain the desired bound for all the pairs of anti-correlators:

$$\mathop{\mathbb{E}}_{\mathsf{x}=\mathsf{Enc}(\bar{x})} \sum_{\mathsf{a}} \left\|\{B_{y_1}, B_{y_2}\}|\psi_{\mathsf{a}|\mathsf{x}}\rangle\right\|^2 \leq 9(1+\sqrt{3})f(\varepsilon) + 2\delta_{\mathrm{QHE}}(\kappa) \qquad \forall y_1 \neq y_2 \tag{102}$$

which is indeed the robust version of equation (101).

7 Open problems

Our findings reveal that the compilation procedure introduced in [KLVY23] effectively preserves the quantum bound of XOR games. However, it remains uncertain whether this preservation extends to generic nonlocal games. As demonstrated, the compilation of Bell inequalities is feasible, yet determining whether the quantum bound preservation holds for Bell inequalities not expressible as nonlocal games poses a challenge. In both scenarios, the complexity arises from the inability to find the quantum bound using a simple correlation matrix and the duality of semi-definite programming. Resolving this likely requires using the NPA hierarchy and employing moment matrices with numerous nonobservable elements. An additional open problem pertains to the quantum behavior of compiled games involving more than two players. Modeling a single quantum prover in such instances necessitates a rigorous characterization of sequential encrypted operations. Lastly, understanding the relationship between self-testing in standard nonlocal games and their compiled counterparts proves to be an instructive avenue for future exploration.

Abstract. A major challenge in fault-tolerant quantum computation (FTQC) is reducing space overhead, i.e., the large number of physical qubits per logical qubit, and time overhead, i.e., long physical gate sequences per logical gate. We prove that a protocol using finite-rate quantum LDPC codes with concatenated Steane codes achieves constant space overhead and polylogarithmic time overhead, even accounting for non-zero classical computation time. This protocol improves the time overhead upon constant-space-overhead protocols using quantum LDPC codes with polynomial time overhead and quasi-polylogarithmic time overhead using concatenated quantum Hamming codes. This result reveals the quantum LDPC code approach can achieve time-efficient FTQC while maintaining constant overhead, as well as the code-concatenation approach, and it underscores the need for a comprehensive investigation into the feasibility of physical implementation of the two approaches.

Keywords: Fault-tolerant quantum computation, Quantum error correction, Quantum LDPC codes, Quantum concatenated codes, Quantum expander codes, Steane code

1 Background

Quantum computation has promising potential for faster computation compared to classical computation [1, 2]. However, implementing quantum computation using physical qubits directly as qubits in an original circuit representing the computation may corrupt the results of the computation due to errors inherent in quantum devices. To address this problem, fault-tolerant quantum computation (FTQC) [3, 4] has been developed. FTQC enables the simulation of an original quantum circuit using the logical qubits of a quantum error-correcting code, rather than physical qubits. By employing techniques of quantum error correction, FTQC ensures accurate quantum computation even in the presence of errors that may accumulate as the size of the original circuit increases [3, 4].

Currently, there are two major FTQC schemes: one is a concatenated code scheme [5–7] and the other is a quantum low-density parity-check (LDPC) code scheme [8–19]. Both schemes have a threshold theorem [5, 6, 8, 20–26], which states that the failure probability of the fault-tolerant simulation can be arbitrarily suppressed, given that the physical error rate is below a certain threshold. However, conventional FTQC schemes, such as those using surface codes [10, 11] and concatenated Steane codes [6], require a substantial increase in the number of physical qubits per logical qubit, which scales polylogarithmically with the size of the original quantum circuit [6, 18]. This poses a challenge, as the number of physical qubits in quantum devices is limited, making the space overhead the primary obstacle to realizing FTQC. In addition to space overhead, time overhead, which refers to the ratio of the physical time step in simulating an original circuit to the time step in an original circuit, is also important to retain the speedups of quantum computation. The conventional FTQC schemes scale polylogarithmically in time overhead with the size of the original circuit [6, 18]. Reducing both space and time overhead in FTQC is of great interest from both practical and theoretical perspectives.

One of the main interests in the field of FTQC is how short a time overhead we can achieve while simultaneously maintaining a constant space overhead. In recent years, there have been advances in this problem. Reference [12] clarified the properties that a non-vanishing-rate quantum LDPC code must retain to achieve FTQC with a constant space overhead in combination with concatenated codes. Subsequently, Refs. [13, 27] showed that quantum expander codes [13, 28, 29] can be used as the quantum LDPC code for this protocol. Although this protocol keeps the space overhead constant, it sacrifices the parallelism of the gate; that is, this protocol has a limitation on the number of logical gates that can be performed per time step. As a result, sequential gate implementation was necessary for this protocol, leading to a polynomial increase in time overhead. More recently, Refs. [7, 30] resolved this bottleneck of constant-space-overhead protocols by developing a new protocol based on concatenated codes to achieve quasi-polylogarithmic time overhead while also achieving constant space overhead.

However, it still remains an open question whether it is

[*] shiro.tamiya01@gmail.com

[†] koashi@qi.t.u-tokyo.ac.jp

[‡] hayata.yamasaki@gmail.com

possible to design an even faster constant-space-overhead protocol that achieves polylogarithmic time overhead, which is shorter than the quasi-polylogarithmic time overhead and as fast as the conventional polylogarithmic-space-overhead protocols. This question relates to a trade-off relation between the space and time overheads in FTQC, originally raised in [12]. On the one hand, there exist fault-tolerant protocols where both the space overhead and time overhead are polylogarithmic [6, 18]. One the other hand, when space overhead is reduced to a constant, an ideal trade-off would be that the time overhead remains polylogarithmic, with only a higher degree polynomial, but existing constant-space-overhead protocols exhibit the polynomial or quasi-polylogarithmic time overheads [7, 12, 13, 27], resulting in apparently redundant time overhead. This issue highlights the challenge of understanding the trade-off relation of space and time overhead in FTQC.

2 Results

In this work, we demonstrate that FTQC can achieve a polylogarithmic time overhead while maintaining a constant space overhead, eliminating the redundant tradeoff between space overhead and time overhead. To achieve this goal, we analyze a hybrid fault-tolerant protocol that combines concatenated Steane code [6] and non-vanishing-rate quantum LDPC codes with an efficient decoding algorithm, in particular the quantum expander codes [13, 28, 29]. In our hybrid protocol, non-vanishing-rate quantum LDPC codes serve as registers to store and protect logical qubits, while concatenated codes serve to implement logical gate operations on logical qubits through gate teleportation [3, 31, 32] by preparing auxiliary encoded states of the non-vanishing-rate quantum LDPC codes.

Theorem 1 *Let $\{\mathrm{C}_n\}$ be a sequence of original circuits specified by an integer n. Each circuit C_n has width $W(n)$ and depth $D(n)$, where the size of C_n is polynomially bounded, i.e., $|\mathrm{C}_n| = O(W(n)D(n)) = O(\mathrm{poly}(n))$ as $n \to \infty$. Then, for all $\varepsilon > 0$, there exists a threshold $p_{\mathrm{th}} > 0$ and if the error rate $p < p_{\mathrm{th}}$, there exists a sequence of fault-tolerant circuits $\{\mathrm{C}_n^{\mathrm{FT}}\}$ and each circuit $\mathrm{C}_n^{\mathrm{FT}}$ has a width $W_{\mathrm{FT}}(n)$ and a depth $D_{\mathrm{FT}}(n)$ that satisfy*

$$\begin{aligned}\frac{W_{\mathrm{FT}}(n)}{W(n)} &= O(1),\\ \frac{D_{\mathrm{FT}}(n)}{D(n)} &= O\left(\mathrm{polylog}\left(\frac{n}{\varepsilon}\right)\right),\end{aligned} \tag{1}$$

as $n \to \infty$, and $\mathrm{C}_n^{\mathrm{FT}}$ outputs the probability distribution that is close to that of C_n with total variation distance at most ε.

The formal statement of Theorem 1 and its proof is given in Sec. V E of the technical version and the definition of circuits and the noise model is given in Sec. III.

The summaries of our contributions are as follows.

1. *Construction of fault-tolerant protocol with higher parallelization of logical gates.*— Our crucial contribution for achieving polylogarithmic-time- and constant-space-overhead fault-tolerant protocol is demonstrating our fault-tolerant protocol can achieve the higher parallelism for executing logical gates than the existing constant-space-overhead protocols with quantum LDPC codes [3, 13, 27]. The existing protocols execute the logical gates sequentially. Specifically, they execute logical gates acting on $O(W(n)/\mathrm{polylog}(n))$ logical qubits at a single time step. However, taking into account advances in the analysis of error suppression by decoding algorithms [13, 27], we show that our protocol can increase parallelism to achieve a polylogarithmic time overhead while maintaining a constant space overhead.

2. *Identification of fault-tolerance conditions for quantum LDPC codes.*— We clarify the fault-tolerance conditions for quantum LDPC codes on gadgets that intend to perform logical operations acting on logical qubits in a quantum LDPC code. For details, see the techical version in Sec. V C. Unlike the fault-tolerance conditions for protocols based on concatenated codes [6, 7], the conditions do not require transversality, i.e., gadgets can be implemented by a tensor product of gates acting individually on each physical qubit, but require gadgets to have a constant depth and for the number of physical qubits through which errors can propagate via physical operations to be constant. These conditions contribute to the explicit construction of fault-tolerant protocols using quantum LDPC codes and show the existence of a threshold.

3. *Existence of threshold considering classical computation with non-negligible runtime.*— The existing analysis of the constant-space-overhead protocol with quantum LDPC codes assumes that classical computation, which is used in such as decoding algorithms and gate teleportation [13, 27, 33], can be performed instantaneously in zero time. However, in practice, the classical computation required to perform FTQC has a non-zero runtime that grows as the size of original circuits becomes large, which cannot be ignored in achieving a scalable physical implementation of FTQC. To address this issue, our analysis explicitly takes into account the nonzero runtime of classical computation in executing the protocol. For this purpose, we employ the constant-time decoding algorithms in Ref. [27]. Our contribution is to bound the runtime of all classical computations required to perform the fault-tolerant protocol (for details, see Sec. V D of the technical version). Remarkably, even when considering the runtime of classical computations, our constant-space-overhead protocol can exhibit polylogarithmic time overhead.

4. *A threshold analysis of fault-tolerant protocol for simulating open circuits.*—We provide a threshold analysis of fault-tolerant protocol using con-

catenated Steane code to implement open quantum circuits that do not end with measurements, as in Refs. [25, 34], whereas conventional analysis of FTQC with concatenated codes is applicable only to the circuits ending with measurements [6, 7]. Our formal proof is given in Sec. IV B of the technical version. In our protocol, this protocol is not used in isolation. It is integrated into the protocol with quantum LDPC codes in such a way that we use the concatenated Steane code to prepare encoded states of quantum LDPC codes in a fault-tolerant way. The threshold theorem for open circuits is used without an explicit proof in Refs. [12, 13, 27], but we prove the theorem based on our protocol and the local stochastic Pauli error model [3], to complete the full proof of the threshold theorem for the fault-tolerant protocol using quantum LDPC codes.

3 Conclusion

Our results show our protocol using non-vanishing-rate quantum LDPC codes with concatenated Steane codes attains both constant space and polylogarithmic time overheads. Our results represent a crucial step toward FTQC achieving significant quantum speedups with a feasibly bounded number of qubits and a negligibly small slowdown. Furthermore, we have resolved the issue of redundant spacetime trade-offs present in existing constant-space-overhead FTQC protocols. This work indicates promising potential for low-overhead FTQC using a hybrid approach of non-vanishing-rate quantum LDPC codes and concatenated codes.

Technical version:
Polylog-time- and constant-space-overhead fault-tolerant quantum computation with quantum low-density parity-check codes

Technical version of "Polylog-time- and constant-space-overhead fault-tolerant quantum computation with quantum low-density parity-check codes" is organized as follows. In Sec. I, we present preliminaries for this work. In Sec. II, we describe the setting of FTQC. In Sec. III, we provide a rigorous analysis of the fault-tolerant protocol using concatenated Steane codes for implementing open quantum circuits (which do not terminate with measurements) to prepare encoded states of non-vanishing-rate quantum LDPC codes. In Sec. IV, using this protocol, we present and analyze the hybrid protocol using non-vanishing-rate quantum LDPC codes and concatenated Steane codes to achieve polylog-time and constant-space-overhead FTQC; in particular, we prove the threshold theorem for this protocol and bound its time and space overhead in Sec. IV E. Finally, in Sec. V, we conclude our work.

I. PRELIMINARIES

In this section, we present preliminaries used in our paper. In Sec. I A, we start with introducing the Pauli group and the Clifford group, along with their binary representations. In Sec. I B, we introduce the quantum error-correcting codes used in our fault-tolerant protocol.

A. Pauli group and Clifford group

We present the basics of the Pauli group and the Clifford group. The Pauli group is defined as follows.

Definition 1 (Pauli group)**.** Let X, Y, and Z be the Pauli operators defined as

$$X \coloneqq \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad Z \coloneqq \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad Y \coloneqq \mathrm{i}XZ = \begin{bmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{bmatrix}. \tag{1}$$

The Pauli group on n qubits, denoted by $\mathcal{P}_n$, consists of $2^n \times 2^n$ matrices in the form of

$$P = \alpha \bigotimes_{i=0}^{n-1} P_i, \tag{2}$$

where $\alpha \in \{\pm 1, \pm \mathrm{i}\}$ and $P_i \in \{I, X, Y, Z\}$. Here, I is an identity matrix with size 2×2 and $\mathrm{i} = \sqrt{-1}$. In particular, when specifying the dimension of the identity operator, the identity opeator with size $2^n \times 2^n$ is denoted by I_n. Also, let $\langle \mathrm{i}I_n \rangle$ be the center of the Pauli group $\mathcal{P}_n$, generated by $\mathrm{i}I_n$. The projective Pauli group is defined as the Pauli group where global phases are ignored, i.e.,

$$\tilde{\mathcal{P}}_n \coloneqq \mathcal{P}_n / \langle \mathrm{i}I_n \rangle, \tag{3}$$

where representatives of $\tilde{\mathcal{P}}_n$ are selected by fixing $\alpha = 1$.

The eigenvectors of the Pauli-Z operator serve as a particular basis for a qubit, which is referred to as the computational basis. This basis is denoted by $\{|0\rangle, |1\rangle\}$, where $|0\rangle$ and $|1\rangle$ are the eigenstates of the Pauli-Z operator, corresponding to the eigenvalues $+1$ and -1, respectively. As a special case of projective measurement, we often use the measurement of the Pauli operator $P \in \mathcal{P}_n$ whose projective operators $\{\Pi_m\}_m$ associated with the measurement outcomes $m \in \{0, 1\}$ are defined as

$$\Pi_0 \coloneqq (I_n + P)/2, \;\; \Pi_1 \coloneqq (I_n - P)/2. \tag{4}$$

For a given Pauli operator $P \in \mathcal{P}_n$, the weight of P, denoted by $|P|$, is defined as the number of qubits on which P acts non-trivially, i.e.,

$$|P| \coloneqq \#\{i \in \{1, \ldots, n\} \colon P_i \neq I\}, \tag{5}$$

where P_i is given by (2).

The Clifford group is defined as the group whose elements map Pauli operators to Pauli operators under conjugation.

Definition 2 (Clifford group)**.** Let $\mathbb{U}(d)$ be the unitary group on the set $\mathbb{C}^d$ of complex vectors. The Clifford group on n qubits is the normalizer of the n-qubit Pauli group,

$$\mathcal{C}_n \coloneqq \{C \in \mathbb{U}(2^n) \mid CPC^\dagger \in \mathcal{P}_n, \forall P \in \mathcal{P}_n\}. \tag{6}$$

where $(\cdot)^\dagger$ represents the adjoint of $(\cdot)$. The elements of the Clifford group are called Clifford operators. Furthermore, the projective Clifford group is defined as

$$\tilde{\mathcal{C}}_n \coloneqq \mathcal{C}_n / \mathbb{U}(1), \tag{7}$$

where our analysis does not need to specify the representative of $\tilde{\mathcal{C}}_n$ while the representative of $\tilde{\mathcal{C}}_n / \tilde{\mathcal{P}}_n$ will be specified later in (14).

The symplectic representation of Pauli operators allows us to perform several calculations on Pauli operators using a binary vector. The definition of the symplectic representation of Pauli operators is as follows.

Definition 3. (Symplectic representation of Pauli operators)

Let $P = \bigotimes_{i=1}^n P_i \in \tilde{\mathcal{P}}_n$ be a Pauli operator. The mapping $\phi \colon \tilde{\mathcal{P}}_n \to \mathbb{F}_2^{2n}$ provides the symplectic representation of P. In this representation, P is mapped to a pair of row vectors $x, z \in \mathbb{F}_2^n$, denoted by $\phi(P) \coloneqq [x, z] \in \mathbb{F}_2^{2n}$, according to the following rules:

$$\text{if } P_i = I,\ \ x_i = 0 \text{ and } z_i = 0, \tag{8}$$
$$\text{if } P_i = X,\ x_i = 1 \text{ and } z_i = 0, \tag{9}$$
$$\text{if } P_i = Y,\ \ x_i = 1 \text{ and } z_i = 1, \tag{10}$$
$$\text{if } P_i = Z,\ x_i = 0 \text{ and } z_i = 1. \tag{11}$$

Since $\tilde{\mathcal{P}}_n \cong \mathbb{F}_2^{2n}$, when we ignore the global phase of the Pauli operator, the multiplication in two Pauli operators $P_1, P_2 \in \tilde{\mathcal{P}}_n$ can be calculated with their symplectic representation as

$$\phi(P_1) \oplus \phi(P_2), \tag{12}$$

where $\oplus$ represents the bitwise exclusive OR (XOR). Moreover, the multiplication in $P_1, P_2 \in \tilde{\mathcal{P}}_n$ can also be expressed as

$$P_1 P_2 = (-1)^{xz'^\top + x'z^\top} P_2 P_1, \tag{13}$$

where $\phi(P_1) = [x, z] \in \mathbb{F}_2^{2n}$, $\phi(P_2) = [x', z'] \in \mathbb{F}_2^{2n}$, and $z^\top$ represents the transpose of z. Thus, the commutator between two Pauli operators corresponds to $xz'^\top + x'z^\top$ in (13), which is defined as the symplectic inner product.

The conjugation of a Pauli operator in $\tilde{\mathcal{P}}_n$ by a Clifford operator in $\tilde{\mathcal{C}}_n$ is carried out in a way that maintains the symplectic inner product. From Refs. [1, 2], we have $\tilde{\mathcal{C}}_n/\tilde{\mathcal{P}}_n \cong \mathrm{Sp}(2n, \mathbb{F}_2)$, where the equivalence relation is defined by conjugation, and $\mathrm{Sp}(2n, \mathbb{F}_2)$ represents the group of $2n \times 2n$ symplectic matrices over $\mathbb{F}_2$. In addition, the corresponding $\Gamma \in \mathrm{Sp}(2n, \mathbb{F}_2)$ can be identified by mapping $[e_i, 0] \mapsto [x, z]$ and $[0, e_j] \mapsto [x', z']$, where e_i is the standard basis vector of $\mathbb{F}_2^n$ that has an entry 1 in the i-th column and 0 otherwise [2]. These facts provide the symplectic matrix $\gamma(C) \in \mathbb{F}_2^{2n\times 2n}$ of a representative of a Clifford operator $C \in \tilde{\mathcal{C}}_n/\tilde{\mathcal{P}}_n$ [2] as

$$\gamma(C) := \begin{bmatrix} \phi(CX_n^{(1)}C^\dagger)^\top & \cdots & \phi(CX_n^{(n)}C^\dagger)^\top & \phi(CZ_n^{(1)}C^\dagger)^\top & \cdots & \phi(CZ_n^{(n)}C^\dagger)^\top \end{bmatrix}, \tag{14}$$

where $X_n^{(i)} (Z_n^{(i)}) \in \tilde{\mathcal{P}}$ represents an n-qubit Pauli operator that acts as $X (Z)$ on the i-th qubit, and as I otherwise. The conjugation of a Pauli operator $P \in \tilde{\mathcal{P}}_n$ by a Clifford operator $C \in \tilde{\mathcal{C}}_n/\tilde{\mathcal{P}}_n$ can be calculated by multiplying the matrix $\gamma(C) \in \mathbb{F}_2^{2n\times 2n}$ with the vector $\phi(P) \in \mathbb{F}_2^{2n}$ from the right, i.e.,

$$\phi(P)\gamma(C). \tag{15}$$

The group $\tilde{\mathcal{C}}_n/\tilde{\mathcal{P}}_n$ is generated by the H operator, S operator, and CNOT operator defined as

$$H := \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}, \tag{16}$$

$$S := \begin{bmatrix} e^{-\mathrm{i}\frac{\pi}{4}} & 0 \\ 0 & e^{\mathrm{i}\frac{\pi}{4}} \end{bmatrix} = R_Z\left(\frac{\pi}{2}\right), \tag{17}$$

$$\mathrm{CNOT} := \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}, \tag{18}$$

where $R_Z(\theta) := e^{-\mathrm{i}\frac{\pi}{2}\theta Z} = \begin{bmatrix} e^{-\mathrm{i}\frac{\pi}{2}\theta} & 0 \\ 0 & e^{\mathrm{i}\frac{\pi}{2}\theta} \end{bmatrix}$. A Clifford operator $C \in \tilde{\mathcal{C}}_n/\tilde{\mathcal{P}}_n$ can be decomposed into 11 rounds in a sequence, where each round uses only one type of Clifford operator in the order of H, CNOT, S, CNOT, S, CNOT, H, S, CNOT, S, CNOT [3]. In this paper, the decomposed form is chosen as a representative of $\tilde{\mathcal{C}}_n/\tilde{\mathcal{P}}_n$.

B. Concatenated Steane codes and non-vanishing-rate quantum LDPC codes

In this section, we present basics of stabilizer codes that we will use in this paper. In Sec. I B 1, we introduce stabilizer codes and Calderbank-Shor-Steane (CSS) codes. In Sec. I B 2, we explain the Steane code as an important class of CSS codes and its code concatenation. In Sec. I B 3, we explain quantum LDPC codes.

1. *Stabilizer codes and Calderbank-Shor-Steane (CSS) codes*

A quantum error-correcting code $\mathcal{Q}$ with N physical qubits is a subspace $\mathcal{Q}$ of a 2^N-dimensional Hilbert space, i.e., $\mathcal{Q} \subseteq (\mathbb{C}^2)^{\otimes N}$, where $\mathbb{C}^2 = \mathrm{span}\{|0\rangle, |1\rangle\}$ represents a qubit. We consider a stabilizer code, which is specified by its stabilizer $\mathcal{S} \subset \mathcal{P}_N$, which is an Abelian subgroup of $\mathcal{P}_N$ satisfying $-I \notin \mathcal{S}$. The centralizer $C(\mathcal{S})$ consists of all Pauli operators that commute with all elements in $\mathcal{S}$. If $\mathcal{S}$ is generated by $N - K$ independent elements, then the corresponding space $\mathcal{Q}(\mathcal{S})$ is a 2^K-dimensional subspace that is invariant under the action of $\mathcal{S}$. Logical operators are elements of the set $C(\mathcal{S}) \setminus \mathcal{S}$. For each $k \in [1, \ldots, K]$, one can choose the associated logical X and Z operators in $C(\mathcal{S}) \setminus \mathcal{S}$ that obey the Pauli commutation relation. In this case, the subspace is isomorphic to a space of K qubits, which are called the *logical qubits*. We refer to the subspace $\mathcal{Q}(\mathcal{S})$ as the *code space* and a state of logical qubits as a *codeword*. The minimum number of physical qubits that any non-trivial logical operator acts upon is referred to as the *distance*. A stabilizer code $\mathcal{Q}(\mathcal{S})$ with the parameters of the number of physical qubits N, the number of logical qubits K, and distance D is denoted by an $[[N, K, D]]$ code. Furthermore, the rate R of the code $\mathcal{Q}(\mathcal{S})$ is defined as $R \coloneqq K/N$. We refer to physical qubits that form $\mathcal{Q}$ as *data qubits*.

A Calderbank-Shor-Steane (CSS) code [4, 5] is a stabilizer code that can be constructed from a pair of classical linear codes. A classical linear code with a block length n and dimension k is a linear subspace C of a vector space $\mathbb{F}_2^n$, where $\mathbb{F}_2 = \{0, 1\}$ is a finite field with 2 elements representing a bit. A linear code C is defined as the kernel of an $m \times n$ parity-check matrix H, i.e., $C = \{x \in \mathbb{F}_2^n : Hx^\top = 0\}$, where $m \geq n - k$ holds equality when H is full rank, and x is a row vector representing a codeword. In addition, a linear subspace of a vector space $\mathbb{F}_2^n$ spanned by the set of vectors that are orthogonal to all codewords in C is known as the dual code $C^\perp$ of C defined as $C^\perp \coloneqq \{d \in \mathbb{F}_2^n : d \oplus c = 0, \forall c \in C\}$. Given a pair of classical linear codes $C_X = \ker H_X$ and $C_Z = \ker H_Z$ with a block length N satisfying $C_Z^\perp \subseteq C_X$, we can define a parity-check matrix $H \in \mathbb{F}_2^{M \times 2N}$ of the CSS code as

$$H = \begin{bmatrix} H_X & 0 \\ 0 & H_Z \end{bmatrix}, \tag{19}$$

where $M = M_X + M_Z$. The parity-check matrix $H \in \mathbb{F}_2^{M \times 2N}$ of the CSS code gives the stabilizer group $\mathcal{S}$ of the code generated by $\{g_i\}_i$ such that

$$\begin{aligned} H_X^\top &= [\phi(g_0), \ldots, \phi(g_{M_X - 1})], \\ H_Z^\top &= [\phi(g_{M_X}), \ldots, \phi(g_{M-1})]. \end{aligned} \tag{20}$$

From the construction in (19), the stabilizer generators of the CSS code can be classified into Z-type generators of

$$g_m^Z \in \left\{ \bigotimes_i P_i \colon P_i \in \{I, Z\} \right\} \text{ for } m \in \{1, \ldots, M_Z\}, \tag{21}$$

and X-type generators of

$$g_{m'}^X \in \left\{ \bigotimes_i P_i \colon P_i \in \{I, X\} \right\} \text{ for } m' \in \{M_Z{+}1, \ldots, M\}. \tag{22}$$

The condition that these generators commute with each other is equivalent to $H_Z H_X^\top = 0$, which is guaranteed by the requirement of $C_Z^\perp \subseteq C_X$. The code space of the CSS codes $\mathcal{Q}$ is

$$\operatorname{span} \left\{ \sum_{y \in C_Z^\perp} |x \oplus y\rangle : x \in C_X \right\}, \tag{23}$$

the dimension of a CSS code is $K = k_X + k_Z - N$, where k_X and k_Z are the dimension of C_X and C_Z, respectively, and the distance of the code is $D = \min\{D_X, D_Z\}$, where $D_X = \min_{x \in C_X \setminus C_Z^\perp} |x|$, $D_Z = \min_{x \in C_Z \setminus C_X^\perp} |x|$, and $|x|$ is the Hamming weight of x.

2. *Concatenated Steane codes*

A $[[7, 1, 3]]$ Steane's 7-qubit code [5], or simply the Steane code, is a CSS code whose parity-check matrices H_X and H_Z are both $[7, 4, 3]$ Hamming code [6], i.e.,

$$H_Z = H_X = \begin{bmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 & 1 \end{bmatrix}, \tag{24}$$

which satisfy $H_Z H_X^\top = 0$. The stabilizer generators of the Steane code are defined as

$$\begin{aligned} g_1^X &= X \otimes X \otimes X \otimes X \otimes I \otimes I \otimes I, \\ g_2^X &= I \otimes X \otimes X \otimes I \otimes X \otimes X \otimes I, \\ g_3^X &= I \otimes I \otimes X \otimes X \otimes I \otimes X \otimes X, \\ g_1^Z &= Z \otimes Z \otimes Z \otimes Z \otimes I \otimes I \otimes I, \\ g_2^Z &= I \otimes Z \otimes Z \otimes I \otimes Z \otimes Z \otimes I, \\ g_3^Z &= I \otimes I \otimes Z \otimes Z \otimes I \otimes Z \otimes Z, \end{aligned} \tag{25}$$

The logical Z and X operators of the Steane code acting on the logical qubit are described by the following operator acting on the 7 physical qubits, respectively,

$$\begin{aligned} I \otimes I \otimes I \otimes I \otimes Z \otimes Z \otimes Z, \\ I \otimes I \otimes I \otimes I \otimes X \otimes X \otimes X. \end{aligned} \tag{26}$$

If a logical gate can be implemented by a tensor product of gates acting individually on each physical qubit, the logical gate is called *transversal*. Transversality is important in FTQC since the logical gate can be performed in a single time step without additional qubits and, more importantly, they inherently prevent error propagation occurring in the code. The feature of the Steane code is that the logical Clifford gates H, S, and CNOT can be executed transversally by $H^{\otimes 7}$, $(S^\dagger)^{\otimes 7}$, and CNOT$^{\otimes 7}$, respectively, as well as the logical Z and X.

A decoding algorithm for the Steane code is as follows: the CSS code corrects errors using two types of stabilizer generators, X-type generators and Z-type generators, independently. The X-type generators are used for correcting phase-flip (Z) errors and the Z-type generators are used for bit-flip (X) errors, respectively. In the following, we will focus on error correction using X-type generators. By definition, the X-type generator is derived from the parity-check matrix H_Z of the $[7, 4, 3]$ Hamming code in (24), and thus we can use the same decoding algorithm for the $[7, 4, 1]$ Hamming code. Suppose that a single-qubit Z error occurs, and the syndrome bits in $\sigma(E) = (s_1, s_2, s_3) \in \mathbb{F}_2^3$ are obtained, where the i-th element corresponds to the measurement outcome $m \in \{0,1\}$ of g_i in (25). Due to the properties of the Hamming code, the syndrome bits indicate the position of the qubit where the error occurred, given by a binary representation of

$$\tilde{i} = \sum_{i=1}^{3} s_i 2^{i-1}, \tag{27}$$

which gives the Z operator on the $\tilde{i}$-th qubit as the recovering operation.

The concatenated Steane codes [7, 8] are constructed by recursively replacing each qubit composed of a code with a logical qubit of the Steane code. First, at level L, we have a qubit to be encoded. For each $l \in \{L, \ldots, 1\}$, the code is obtained by replacing each physical qubit with a logical qubits of the Steane code. This recursive structure leads to the level-L concatenated Steane code, denoted by $\mathcal{Q}^{(L)}$, with parameters,

$$[[N = 7^L, K = 1, D = 3^L]]. \tag{28}$$

3. *Quantum LDPC codes*

A family of CSS codes with parameters $[[N_i, K_i, D_i]]$ indexed by an integer i is said to be an (r, c) quantum low-density parity-check (LDPC) code if the parity-check matrices of the CSS codes in the family have at most $r = O(1)$ non-zero elements in each row and at most $c = O(1)$ non-zero elements in each column as $i \to \infty$ and $N_i \to \infty$. That is, the X-type and Z-type stabilizer generators of the quantum LDPC codes have only $r = O(1)$ weights, and only a constant number $c = O(1)$ of stabilizer generators act nontrivially on each physical qubit of the quantum LDPC codes. If the rate R_i of a family of quantum LDPC codes converges to a finite positive value R as $i \to \infty$,

$$\lim_{i \to \infty} R_i = R > 0, \tag{29}$$

a code in the family is referred to as a *non-vanishing-rate* quantum LDPC code. Conversely, if the rate R converges to zero, a code in the family is referred to as a *vanishing-rate* quantum LDPC code.

Vanishing-rate quantum LDPC codes, such as surface codes [9–14] and color codes [15–18], are capable of executing most or all logical Clifford gates transversally [13, 14, 17–19]. However, a drawback of these codes is that the number of physical qubits required to protect a single logical qubit diverges asymptotically. In contrast, non-vanishing-rate quantum LDPC codes are advantageous since such codes can be used for constant-space-overhead FTQC as the rate converges to a non-zero value [20–22]. Although implementing logical Clifford gates transversally with non-vanishing-rate LDPC codes is challenging [23–26], these codes can implement logical gates by using gate teleportation if one can prepare required auxiliary encoded states in a fault-tolerant way.

II. SETTING OF FAULT-TOLERANT QUANTUM COMPUTATION

In this section, we present the setting of fault-tolerant quantum computation used in our work. We consider *original quantum circuits* composed of a finite set of quantum operations. In our setting, an original circuit is written in terms of the following quantum operations: $|0\rangle$-state preparation, Z-basis measurements, Pauli gates (X, Y, and Z), Clifford gates (H, S, and CNOT), non-Clifford gates ($T \coloneqq R_Z(\pi/4)$ and $T^\dagger$), and a wait operation I. The operations can be executed on all qubits simultaneously, and no more than one operation acts on a single qubit at any given time step. The total number of these time steps is referred to as the *depth* of the original circuit, and the maximum number of qubits, where maximization is taken over all time steps of the original circuit, is referred to as the *width*.

In this paper, we consider original circuits that start with the $|0\rangle$-state preparation and end with the Z-basis measurements, with no measurements included in the middle of the circuit [27]. Any stabilizer circuit has an equivalent circuit comprising 11 rounds in a sequence in the order of H, CNOT, S, CNOT, S, CNOT, H, S, CNOT, S, CNOT [3], or 9 rounds of CNOT, S, CNOT, S, H, S, CNOT, S, and CNOT [28]. The layer of the m-qubit stabilizer circuit given by both decompositions has an $O(m)$ depth and $O(m^2/\log(m))$ two-qubit gates [3, 28]. Thus, given any original circuit $\mathrm{C}_n^{\mathrm{org}}$ specified by an integer n with width $W(n)$ and depth $D(n)$, we can rewrite it into an original circuit that has the following form.

Assumption 1. *Let $\mathrm{C}_n^{\mathrm{org}}$ be an original circuit in the following form:*

- *A Clifford layer described by an $W(n)$-qubit stabilizer circuit with $O(W(n))$ depth, repeated $O(D(n))$ times*
- *Each Clifford layer is sandwiched between layers of single-depth circuits composed of T and $T^\dagger$ gates and $\mathbb{1}$, which we refer to as T-gate layers.*
- *The first Clifford layer is preceded by a single-depth layer circuit composed of $|0\rangle$-state preparations, rather than a T-gate layer. Similarly, the final Clifford layer is followed by a single-depth layer circuit composed of Z-basis measurements, instead of a T-gate layer.*

Note that because original circuits satisfying Assumption 1 do not contain measurements in the middle of the computation, the width of the original circuit remains unchanged.

The goal of FTQC is to simulate an original circuit $\mathrm{C}_n^{\mathrm{org}}$, i.e., sample from a probability distribution that is close to that of $\mathrm{C}_n^{\mathrm{org}}$ with the total variation distance at most $\varepsilon > 0$. To achieve this, we provide a fault-tolerant protocol that explicitly constructs a physical circuit with fault tolerance (referred to as a *fault-tolerant circuit*) described by physically implementable operations.

We assume that the physical circuit satisfies the following conditions. These conditions follow the convention of the previous works [8, 20, 21, 25, 29].

Assumption 2 (physical circuit)**.** *A physical circuit satisfies the following conditions:*

1. *Set of physical operations:*

   A physical circuit consists of physical operations including $|0\rangle$-state preparation, Z-basis measurement, Pauli gates X, Y, and Z, Clifford gates H, S, $S^\dagger$, and CNOT*, non-Clifford gates T and $T^\dagger$, and wait operation I. Each physical operation in a physical circuit is referred to as a physical location.*

2. *No geometrical constraint on CNOT gates:*

   We assume that the CNOT gate can be applied to an arbitrary pair of physical qubits at a single time step, regardless of the location of the two physical qubits as in neutral atom systems [30, 31], trapped-ion systems [32–34], and photonic systems [35–37].

3. *Parallel physical operations:*

   The physical operations can be performed simultaneously for all qubits in a single time step as long as each qubit is involved in only one operation at any given time. The depth of the physical circuit is determined by these time steps.

4. *Allocation of qubits and bits:*

   We allocate physical qubits via $|0\rangle$-state preparation and deallocate them through Z-basis measurement. Bits are allocated in a classical register to store the measurement outcomes. Once a classical computer receives the bits of the measurement outcomes, those bits are deallocated from a classical register. The number of physical qubits and bits at any given time are those that have been allocated previously and have not yet been deallocated.

5. *Ideal classical computation with non-negligible runtime:*

   For simplicity of our analysis, we assume that classical computation can be performed without faults. Additionally, during the classical computation, we assume that the wait operations on all allocated physical qubits are performed in the physical circuit. The depth of the wait operation is determined by the runtime of the classical computation. Specifically, the depth is limited to a value less than or equal to a constant multiple of the runtime of the classical computation.

The issue in quantum computing is that when executing these physical circuits during quantum computation, the circuits are subjected to noise that may impair the results of computation. When analyzing the impact of noise on FTQC with quantum LDPC codes, the conventional approach is to consider the local stochastic Pauli error model on a physical circuit [20–22], which is also used in this paper. This error model has the stochastic property, where a Pauli error is applied to a quantum state with probability p, and the state remains unchanged with probability $1-p$. It also satisfies the locality property, where the probability of an error occurring at any given set of locations decreases exponentially with the size of the set. However, it does not impose any other constraints; errors can exhibit correlations in both time and space and may be adversarially chosen to complicate fault-tolerant simulations.

Definition 4 (Local stochastic Pauli error model on a physical circuit)**.** Let C be a physical circuit, and L be a set of physical locations in C. Let a set of faulty locations be a random variable $F \subseteq L$, where a faulty location is defined as a physical location that leads to an error resulting from the imperfect physical operation at this location. We say that C is subjected to the local stochastic Pauli error model with parameter $p_{\mathrm{loc}} \in [0,1]$ if the following conditions hold.

1. For all $A \subseteq L$, the probability that F contains A satisfies

$$\mathbb{P}[F \supseteq A] \leq p_{\mathrm{loc}}^{|A|}. \tag{30}$$

2. The physical operations in F are associated with a Pauli operator chosen adversarially that represents an error as follows.

   - If a location in F is a $|0\rangle$-state preparation operation, a Pauli operator is applied to the qubit after the $|0\rangle$-state preparation is performed.
   - If a location in F is a gate operation (including Pauli gates, Clifford gates, non-Clifford gates, and a wait), a Pauli operator is applied to each qubit(s) after the corresponding gate operation is performed.
   - If a location in F is a Z-basis measurement operation, a bit flip or identity operation is applied to the measurement outcome.

   The physical locations in $L\backslash F$ behave in the same way as the case without faults.

In this paper, we assume a physical circuit is subjected to the local stochastic Pauli error model. We refer to a physical circuit that suffers from local stochastic Pauli errors as a *faulty* physical circuit.

Assumption 3. *A physical circuit* C *is subjected to the local stochastic Pauli error with parameter* $p_{\mathrm{loc}} \in [0,1]$.

For the faulty physical circuit to implement FTQC with a quantum LDPC code, we also define the local stochastic Pauli error model on a set of data qubits and syndrome bits of a block of a quantum LDPC code, denoted by V and W, respectively. For simplicity, we remove the distinction between V and W. That is, we consider the union $X \coloneqq V \cup W$ of the two sets, and we call each element of X a wire in a circuit.

Definition 5 (Local stochastic Pauli error model on wires)**.** Let V be a set of data qubits and W be a set of syndrome bits at a given time step of a physical circuit. Let $X \coloneqq V \cup W$ be a set of wires and $H \coloneqq F \cup G \subseteq X$ be a set of erroneous wires, where F is the set of erroneous wires in V and G in W. An error model is said to be the local stochastic Pauli error model on wires with parameter $p_{\mathrm{wire}} \in [0,1]$ if the following conditions are satisfied.

1. For any $U = S \cup T \subseteq X$, the probability that H contains U satisfies,

$$\mathbb{P}[H \supseteq U] \leq p_{\mathrm{wire}}^{|U|}. \tag{31}$$

2. A Pauli operator is applied to $F \subseteq V$, and bit flip or identity operations are applied to $G \subseteq W$.

In the case where the errors on the syndrome bits are not considered, an error model on data qubits is the local stochastic Pauli error model with parameter p_{data} if for all $S \subseteq V$, the following relations are satisfied.

1. For all $S \subseteq V$, the probability that $F \subseteq V$ contains S satisfies,

$$\mathbb{P}[F \supseteq S] \leq p_{\mathrm{data}}^{|S|}. \tag{32}$$

2. A Pauli operator is applied to $F \subseteq V$.

A fault-tolerant protocol provides a fault-tolerant circuit to simulate a given original circuit. The fault-tolerant protocol replaces qubits in an original circuit with logical qubits of a quantum error-correcting code. This process requires using multiple physical qubits per logical qubit for redundancy. At the same time, operations in an original circuit are replaced by logical operations acting on the logical qubits. Implementing these logical operations in a physical circuit requires additional time steps. This procedure incurs an overhead with respect to space and time. Let $W_{\mathrm{FT}}(n)$ represent the width and $D_{\mathrm{FT}}(n)$ represent the depth of a fault-tolerant circuit. Then, the space overhead is defined as the ratio of the width of the fault-tolerant circuit $W_{\mathrm{FT}}(n)$ to the width n of the corresponding original circuit,

$$\frac{W_{\mathrm{FT}}(n)}{W(n)}. \tag{33}$$

On the other hand, the time overhead is defined as the ratio of the depth $D_{\mathrm{FT}}(n)$ of the fault-tolerant circuit, including wait operations necessary for classical computation, to the depth $D(n)$ of the original circuit,

$$\frac{D_{\mathrm{FT}}(n)}{D(n)}. \tag{34}$$

For a target error ε, the fault-tolerant protocol is said to achieve a constant space overhead if the space overhead of the fault-tolerant circuit is

$$\frac{W_{\mathrm{FT}}(n)}{W(n)} = O(1), \tag{35}$$

as $n \to \infty$ and $\varepsilon \to 0$, and is said to achieve a polylogarithmic time overhead if the time overhead of the fault-tolerant circuit is

$$\frac{D_{\mathrm{FT}}(n)}{D(n)} = O\left(\mathrm{polylog}\left(\frac{n}{\varepsilon}\right)\right) \tag{36}$$

as $n \to \infty$ and $\varepsilon \to 0$.

III. FAULT-TOLERANT PROTOCOL FOR OPEN QUANTUM CIRCUITS

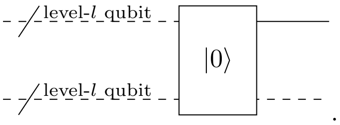
In this section, we explain a protocol based on concatenated Steane codes for simulating ideal quantum circuits that output a quantum state, rather than measurement outcomes. We refer to quantum circuits that output a quantum state as *open* quantum circuits, to distinguish them from *closed* quantum circuits that output measurement outcomes. The protocol will be used to simulate an original open circuit to produce an encoded state of a quantum LDPC code, and the encoded state is used for performing logical Clifford gates and logical T and $T^{\dagger}$ gates acting on logical qubits in a quantum LDPC code via gate teleportation [38, 39]. As discussed later in Sec. IV D, this protocol is not used in isolation. It is integrated into the protocol with quantum LDPC codes in such a way that we use the concatenated Steane code to prepare encoded states of quantum LDPC codes in a fault-tolerant way. The existing analysis [20–22] of the fault-tolerant protocol for quantum LDPC codes does not explicitly bound the error in preparing the encoded state, and one of our contributions here is to provide a thorough analysis including this part of the protocol to present a complete threshold theorem of the overall protocol.

A. Compilation from original open circuit to fault-tolerant circuit

For a given ideal open circuit, the protocol recursively constructs a level-l circuit ($l \in \{L, \ldots, 0\}$) consisting of elementary operations acting on level-l qubits. Here, a level-0 circuit is a physical circuit. We say that each elementary operation contained in the level-l circuit is a location of the level-l circuit. For the level-l circuit, we assume that at most one elementary operation can act on a single level-l qubit in a single time step. The depth of a level-l circuit is determined by the number of time steps. The set of elementary operations includes $|0\rangle$-state preparation operation, $|T\rangle$-state preparation operation, H-, S-, $S^\dagger$-, CNOT-, Pauli-gate operations, Z-basis measurement operation, and a wait operation. Here, $|T\rangle := TH|0\rangle$. We also define the T-gate abbreviation as a collection of the elementary operations to perform T gates by gate teleportation. For each elementary operation, we define the corresponding gadget that is a circuit to carry out the corresponding logical operation on a logical qubit of the Steane code. We also define an error-correction (EC) gadget, which is a circuit that performs error correction on a set of 7 qubits forming the Steane code, and a decoding interface, which is a circuit that performs the decoding operation to transform the logical state encoded in the Steane code consisting of the set of 7 qubits to the same state of an unencoded physical qubit.

The elementary operations and abbreviations are represented as in a diagram. In the diagram, the change from a dashed input line to a solid output line represents the allocation of a level-l qubit, while the change from a solid line to a dashed line represents deallocation. If both the input and output lines are dashed, it means that the corresponding level-l qubit is used as a workspace for performing elementary operations. The double output line represents the bits that the elementary operation outputs. The elementary operations are as follows.

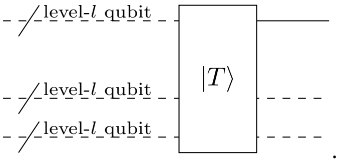
- $|0\rangle$-state preparation operation



(37)

The $|0\rangle$-state preparation operation allocates a single level-l qubit that is prepared in the state $|0\rangle$.

- $|T\rangle$-state preparation operation



(38)

The $|T\rangle$-state preparation operation allocates a single level-l qubit that is prepared in the state $|T\rangle$.

- H-gate operation

(39)

The H-gate operation applies the H gate to a level-l qubit.

- S-gate operation

(40)

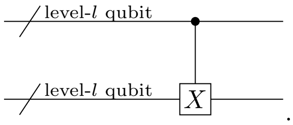
The S-gate operation applies the S gate to a level-l qubit.

- $S^\dagger$-gate operation

(41)

The $S^\dagger$-gate operation applies the $S^\dagger$ gate to a level-l qubit.

- CNOT-gate operation



(42)

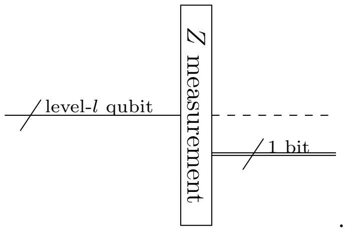
The CNOT-gate operation applies the CNOT gate between two level-l qubits.

- Pauli-gate operation

(43)

The Pauli-gate operation applies the Pauli gate $P \in \mathcal{P}_1$ to a level-l qubit [40].

- Z-basis measurement operation



(44)

The Z-basis measurement operation performs the Z-basis measurement on a level-l qubit. It deallocates the level-l qubit and outputs a 1-bit measurement outcome.

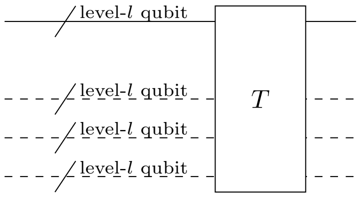
- Wait operation

(45)

The wait operation applies an I operation to a level-l qubit, which is regarded as a special case of Pauli gates.

The T-gate abbreviation is denoted as follows:

- T-gate abbreviation

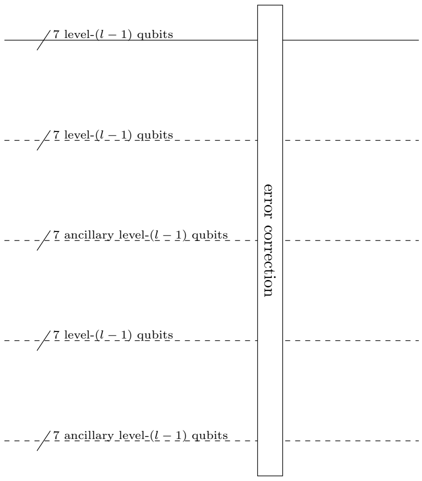


. (46)

The T-gate abbreviation performs the T-gate operation on a level-l qubit through gate teleportation.

In addition to the elementary operations and their corresponding gadgets, the EC gadget and the decoding interface are denoted as follows:

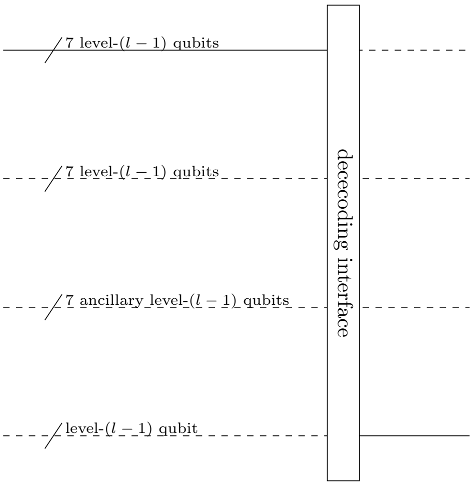
- EC gadget



. (47)

The EC gadget performs quantum error correction on a logical qubit consisting of 7 level-$(l-1)$ qubits, temporarily utilizing the other four sets of 7 level-$(l-1)$ qubits .

- Decoding interface



, (48)

A decoding interface performs the decoding operation from a logical qubit of the Steane code to an unencoded physical qubit.

The gadgets are carefully designed to satisfy the fault-tolerance conditions, which are presented in Appendix A, and their constructions are shown in Appendix B.

The procedure for compiling an original open circuit C that generates a quantum state $|\psi\rangle$ into a physical circuit, as shown in Fig. III A, is as follows. Given a target error $\delta > 0$ and an original circuit C, we first determine the concatenation level L such that the failure probability of the fault-tolerant simulation can be bounded by δ. Next, we compile the original circuit into a level-L circuit by replacing each operation in the original circuit with the corresponding elementary operation that acts on level-L qubits. As for the T and $T^\dagger$ gates in the original circuit, we replace a T gate with a T-gate abbreviation and a $T^\dagger$ gate with an $S^\dagger$-gate operation, followed by a T-gate abbreviation, respectively. In addition to each level-L qubit, we allocate $3+4=7$ auxiliary level-L qubits. Of these seven, the three auxiliary level-L qubits are used for elementary operations and the T-gate abbreviation. The other four registers are never explicitly used in the level-L circuit and not shown in Fig. III A, but these level-L qubits are used to provide workspaces for the EC gadget that will appear in the level-$(L-1)$ circuit. For each level $l \in \{L, L-1, \ldots, 1\}$, we recursively compile the level-l circuit into the corresponding level-$(l-1)$ circuit. For each level-l qubit in the level-l circuit, a set of seven level-$(l-1)$ qubits is allocated in the level-$(l-1)$ circuit, along with $3+4=7$ auxiliary level-$(l-1)$ qubits per set. As in the level-L case, three of these seven auxiliary level-$(l-1)$ qubits are used for abbreviations and elementary operations in the level-$(l-1)$ circuit. The remaining four level-$(l-1)$ qubits are never explicitly used in the level-$(l-1)$ circuit, but are used as workspaces for EC gadgets. This transformation involves replacing each elementary operation with the corresponding gadget and inserting an EC gadget between the gadgets. For simplicity of our analysis, we insert EC gadgets synchronously. This means that EC gadgets are executed only after all the gadgets for the elementary operations belonging to the same depth in the level-l circuit have been completed. Until the EC gadgets are finished, the gadgets corresponding to the elementary operations that belong to the next depth in the level-l circuit are not executed. To ensure synchronization, we incorporate wait operations after the previously completed gadgets. At this stage, the level-$(l-1)$ circuit outputs an encoded version of the quantum state $|\psi\rangle$, where each physical qubit of $|\psi\rangle$ is replaced by the 7 level-$(l-1)$ qubits forming the logical qubit of the Steane code. To obtain the unencoded state $|\psi\rangle$, we add the decoding interface to each logical qubit at the end of the level-$(l-1)$ circuit, i.e., an open circuit is always compiled into a circuit with decoding interface in the end, in place of measurements at the end of closed circuits.

By applying this procedure recursively, we obtain the

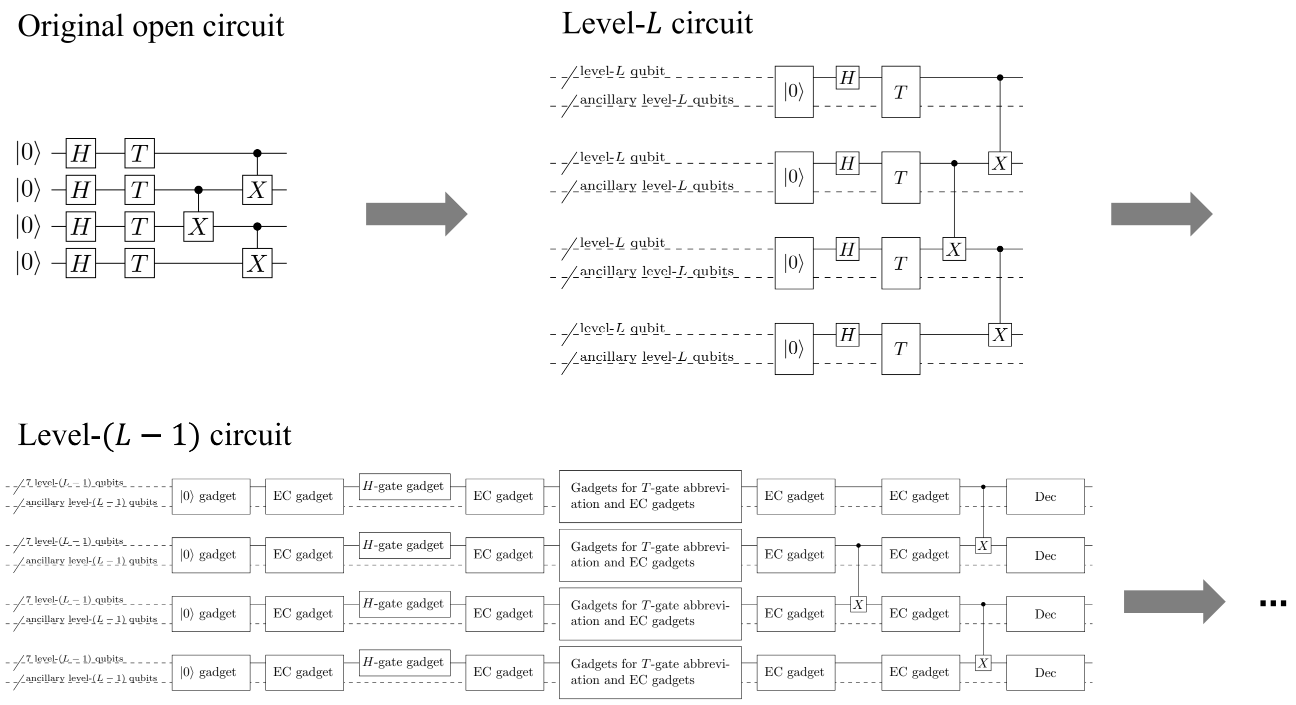


FIG. 1. Compilation procedure of our protocol for ideal open circuits. First, we compile an original open circuit into a level-L circuit that consists only of elementary operations on level-L qubits. Here, the T gate, which is implemented using gate teleportation, is an abbreviation of a sequence of elementary operations. For each level $l \in \{L, \ldots, 1\}$, we recursively compile the level-l circuit into the level-$(l-1)$ circuit by replacing each elementary operation with the corresponding gadget, inserting an EC gadget in between, and adding decoding interfaces, denoted by Dec, to every set of 7 level-$(l-1)$ qubits at the end of the level-$(l-1)$ circuit. In this way, we finally obtain a level-0 circuit, i.e., a physical circuit for an original open circuit.

level-0 circuit. However, in a level-0 circuit, Assumption 2 allows T and $T^\dagger$ gates to be implemented directly as physical operations, rather than gate teleportation using abbreviations of physical circuits. Thus, we replace T and $T^\dagger$ abbreviations in a level-0 circuit with the physical T and $T^\dagger$ gates, respectively, and elementary operations with the corresponding physical operations. As a result, the $3+4=7$ auxiliary level 0 qubits that are allocated for each level-0 qubit can be removed. After making these replacements, we finally obtain the level-0 circuit, i.e., physical circuit, denoted by $\mathrm{C}^{(L)}$, which is to be performed in quantum computation.

B. Threshold theorem for open circuits

In this section, we show the threshold theorem for simulating open circuits. Our approach is based on Ref. [41]. However, for open circuits we need a different treatment because the decoding interfaces are located at the end of the physical circuit. Thus, our proof is carried out by appropriately modifying the proof of the threshold theorem for closed circuits [41]. The threshold theorem for open circuits described below is used without an explicit proof in Refs. [20–22], but we prove the theorem based on our protocol and noise model, so as to complete the full proof of the threshold theorem for the fault-tolerant protocol using quantum LDPC codes. Although the threshold theorem for open circuits has been established in Ref. [42] as well, the noise model considered is the independent and ideally distributed (IID) Pauli error model, and thus the theorem in Ref. [42] is not applicable to our more general setting.

Theorem 6 (Threshold theorem for simulating open circuits with polylog-time and polylog-space overhead)**.** *Suppose that a physical circuit that satisfies Assumption 2 and 3 is subjected to a local stochastic Pauli error model. Let $\{\mathrm{C}_N\}$ be a sequence of original open circuits that produce a quantum state $|\psi_N\rangle$ specified by an integer N. Each circuit C_N has width $W(N)$ and depth $D(N)$ and $|\mathrm{C}_N|$ be the number of locations in C_N, where $|\mathrm{C}_N| \to \infty$ as $N \to \infty$. Let $\delta > 0$ be a constant. Suppose that we compile from the original open circuit C_N into a sequence of physical circuits $\tilde{\mathrm{C}}_N$ as explained in Sec. III A.*

Then, there exists a threshold $p_{\mathrm{loc}}^{\mathrm{th}} > 0$ and if $0 \leq p_{\mathrm{loc}} \leq p_{\mathrm{loc}}^{\mathrm{th}}/2$, the following statement holds for $N \to \infty$: there is a sequence of physical circuits $\tilde{\mathrm{C}}_N$ that produces $|\psi^{(N)}\rangle$ which is subjected to the local stochastic Pauli error with parameter $\tilde{p} \leq 2Mp_{\mathrm{loc}}$ with probability at least $1-\delta$, where M is a constant representing the number of loca-

tions in the decoding interface described in Sec. III B 1. Furthermore, $\tilde{\mathrm{C}}_N$ has width $\tilde{W}(N)$ and depth $\tilde{D}(N)$ such that

$$\begin{aligned} \frac{\tilde{W}(N)}{W(N)} &= O\left(\mathrm{polylog}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right), \\ \frac{\tilde{D}(N)}{D(N)} &= O\left(\mathrm{polylog}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right). \end{aligned} \tag{49}$$

To prove Theorem 6, the rest of this section is organized as follows. In Sec. III B 1, we present the construction of the decoding interface. In Sec. III B 2, we give the proof of Theorem. 6 based on the decoding interface explained in Sec. III B 1.

1. *Construction of the decoding interface*

The decoding interface is designed to map an encoded state of a logical qubit into the corresponding unencoded state of a physical qubit. Ideally, it behaves as the ideal decoder (50). The construction of the decoding interface is illustrated in Fig. III B 1. The interface is based on Knill's error correction [38, 39, 41, 42]. The interface uses auxiliary qubits that are in the state of a Bell state, with one side encoded in a logical state using an encoding circuit $U_{\mathrm{encode}}^{|\psi\rangle}$ as shown in Fig. 16 (b), in addition to the input logical state on which we want to decode. Then, a logical Bell measurement is performed on two sets of logical states. Based on the outcome of the 7-bit measurements in the transversal Z-basis, it is input to the decoding algorithm to calculate the outcome of the logical operator $\bar{Z}$. This classical computation is performed using the same procedure as explained in the Z-basis measurement gadget. The measurement outcome is then used to determine the correction operation for quantum teleportation. Once the Pauli correction operation is applied, the interface outputs a qubit in the desired state to be teleported.

2. *Level reduction*

Next, to prove the threshold theorem, we consider the reduction of the level of a physical circuit $\mathrm{C}^{(L)}$. The reduction is carried out by replacing each Rec in $\mathrm{C}^{(L)}$ with an equivalent level-0 gate by moving the ideal decoder 7 from the end to the start in $\mathrm{C}^{(L)}$. The definition of the ideal decoder is as follows.

Definition 7 (Ideal decoder)**.** An ideal decoder is a combined non-fauly operation that consists of a syndrome measurement, followed by a recovery operation determined by the decoding algorithm using the result of the syndrome measurement, and ending with a decoding operation that maps an encoded state to the corresponding state of a physical qubit.

The ideal decoder is shown in the diagram as

- Ideal decoder

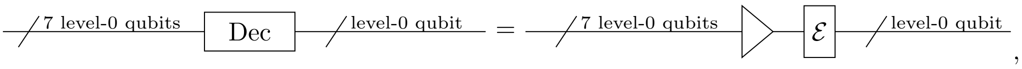
, (50)

where the bold line represents a logical qubit and the thin line represents an unencoded physical qubit.

Specifically, the proof in Ref. [41] is accomplished by recursively reducing the level of simulation by moving the ideal decoder from Z-basis measurement gadgets located at the end of a physical circuit to the front. By doing this, we obtain a level-reduced physical circuit $\mathrm{C}^{(L-1)}$ with a lower error parameter. For the concatenated code protocol for closed circuits, the level reduction procedure was established in Refs. [8, 41]. In contrast, the protocol for open circuits instructs the physical circuit to end with a decoding interface that is not fault-tolerant; a single fault could result in an error on the unencoded state. However, since the decoding interface is a stabilizer circuit [3], i.e., all operations in a stabilizer circuit are Clifford gates or Z-basis measurements, every faulty physical circuit can be transformed into the circuit that ideally executes the physical circuit and applies the Pauli error to the qubit at the final time step of the circuit. Under this transformation, due to the union bound, the output qubit is subjected to a local stochastic Pauli noise $\mathcal{E}$ with probability

$$\tilde{p} \leq M p_{\mathrm{loc}}, \tag{51}$$

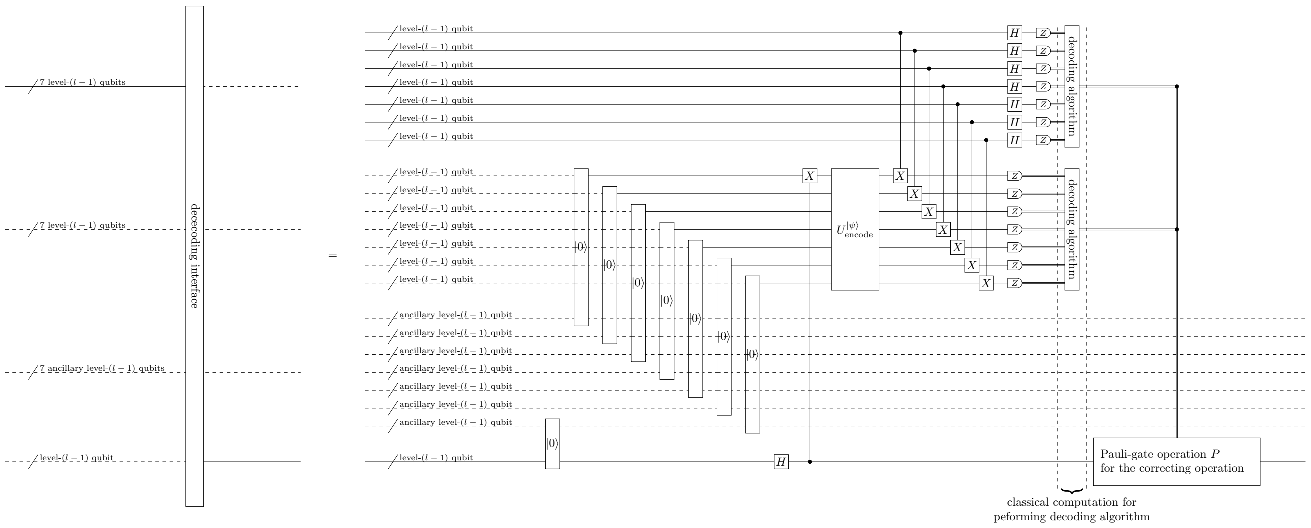
where M is the number of locations in the decoding interface. Therefore, the decoding interface, denoted by Dec, can be transformed as follows.



, (52)

where the output level-0 qubit is subjected to the local stochastic Pauli noise $\mathcal{E}$ with parameter $\tilde{p} \leq M p_{\mathrm{loc}}$, which is a completely positive and trace-preserving (CPTP) map.

Using the ideal decoder obtained from the decoding interface as in (52), the rest of the level reduction procedure can be carried out similarly as in Ref. [41]. For simplicity, we refer to a level-0 circuit comprised of gadget followed



7 level-(l − 1) qubits
7 level-(l − 1) qubits
7 ancillary level-(l − 1) qubits
level-(l − 1) qubit

by an EC gadget as a *rectangle* or *Rec*. Similarly, we call a level-0 circuit comprised of Rec, along with the preceding EC gadget, an *extended rectangle* or *ExRec*. If a gadget satisfies the fault-tolerance conditions as shown in Sec. A, then no single fault in any location of ExRec in $\mathrm{C}^{(L)}$ can cause a fault in the corresponding location in a level-1 circuit. Thus, if there is at most one fault in an ExRec in $\mathrm{C}^{(L)}$, then we can convert the Rec in $\mathrm{C}^{(L)}$ to the corresponding non-faulty level-0 operation. In contrast, if there are more than two faults in an ExRec in $\mathrm{C}^{(L)}$, the ExRec in $\mathrm{C}^{(L)}$ can be converted to an operation that acts on the corresponding non-faulty 0-operation followed by an error described by a Pauli operator. Using this relation, an ideal decoder can be reversed to convert all ExRecs in $\mathrm{C}^{(L)}$ to the corresponding level-0 operations, resulting in a physical circuit $\mathrm{C}^{(L-1)}$. Note that when the ideal decoder is moved from the end, the ideal decoder first encounters a truncated ExRec, i.e., a trailing EC gadget of a gadget is absent, but by adding an ideal trailing EC gadget to the gadget, we can apply the above procedure.

Therefore, if $\mathrm{C}^{(L)}$ is subjected to the local stochastic Pauli error model, a level-reduced circuit $\mathrm{C}^{(L-1)}$ is also subjected to the local stochastic Pauli error model, where the effective probability $p_{\mathrm{loc}}^{(1)}$ of faults occurring in $\mathrm{C}^{(L-1)}$ can be bounded by counting the number of locations in the largest ExRec, which is the one that contains the largest number of locations among all ExRecs as

$$p_{\mathrm{loc}}^{(1)} \leq A\left(p_{\mathrm{loc}}^{(0)}\right)^2, \tag{53}$$

where A is a constant representing the number of pairs of locations in the largest ExRec.

By applying this argument L times, we finally obtain a physical circuit $\mathrm{C}^{(0)}$ with parameter

$$p_{\mathrm{loc}}^{(L)} \leq p_{\mathrm{th}}\left(\frac{p_{\mathrm{loc}}^{(0)}}{p_{\mathrm{th}}}\right)^{2^L}, \tag{54}$$

where $p_{\mathrm{th}} := 1/A > 0$. Moreover, due to the union bound, the output qubits are subjected to a local stochastic Pauli error with parameter

$$\tilde{p} \leq M\sum_{l=0}^{L-1} p_{\mathrm{loc}}^{(l)} \leq M\sum_{l=0}^{\infty} p_{\mathrm{loc}}^{(l)} \leq \frac{Mp_{\mathrm{loc}}}{1-p_{\mathrm{loc}}/p_{\mathrm{loc}}^{\mathrm{th}}} \leq 2Mp_{\mathrm{loc}}, \tag{55}$$

where we used $p_{\mathrm{loc}}^{(0)} := p_{\mathrm{loc}}$ and $0 < p_{\mathrm{loc}} \leq p_{\mathrm{loc}}^{\mathrm{th}}/2$.

To achieve the target error δ, due to the union bound, it is sufficient to have $p_{\mathrm{loc}}^{(L)} \leq \delta/|\mathrm{C}_N|$. Therefore, using (54), we see that it suffices to have

$$L \geq \log_2 \log_{p_{\mathrm{loc}}^{\mathrm{th}}/p_{\mathrm{loc}}}\left(\frac{p_{\mathrm{loc}}^{\mathrm{th}}|\mathrm{C}_N|}{\delta}\right). \tag{56}$$

Therefore, to reduce the overhead of the protocol, we choose

$$L = \Theta\left(\log\left(\log\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right)\right). \tag{57}$$

This means that there exists a constant $c > 0$ such that $L \leq c\log_2\left(\log_{p_{\mathrm{loc}}^{\mathrm{th}}/p_{\mathrm{loc}}}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right)$ for large N.

Let w' be the maximum width and d' be the maximum depth of all gadgets for the elementary operations and the EC gadget. Since the compilation procedure has a recursive structure, we can obtain a physical circuit corresponding to operations in the original open circuit, except for the part of the decoding interfaces, with

$$\begin{aligned} W_{\mathrm{org}}(N) &= O\left(W(N)\times(w')^L\right) \\ &= O\left(W(N)\log^{\gamma_0}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right) \end{aligned} \tag{58}$$

and

$$D_{\mathrm{org}}(N) = O\left(D(N) \times (d')^L\right) = O\left(D(N) \log^{\gamma_1}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right), \tag{59}$$

where

$$\gamma_0 = c \log_2 w' \text{ and } \gamma_1 = c \log_2 d'. \tag{60}$$

In addition, a physical circuit corresponding to the decoding interface requires

$$D_{\mathrm{dec}}(N) = \sum_{l=1}^{L} (d'')^l = O\left(\log^{\gamma_2}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right), \tag{61}$$

where d'' is the depth of the decoding interface and $\gamma_2 = c \log_2 d''$. Thus, we have

$$\begin{aligned} \frac{\tilde{W}(N)}{W(N)} &= \frac{W_{\mathrm{org}}(N)}{W(N)} = O\left(\mathrm{polylog}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right), \\ \frac{\tilde{D}(N)}{D(N)} &= \frac{D_{\mathrm{org}}(N) + D_{\mathrm{dec}}(N)}{D(N)} = O\left(\mathrm{polylog}\left(\frac{|\mathrm{C}_N|}{\delta}\right)\right). \end{aligned} \tag{62}$$

From the above discussion, we conclude Theorem 6.

IV. DESCRIPTION OF POLYLOG-TIME CONSTANT-SPACE OVERHEAD PROTOCOL

In this section, we describe our fault-tolerant protocol that achieves polylog time and constant space overhead. We begin by explaining the compilation procedure of an original circuit into a fault-tolerant circuit in Sec. IV A. In Sec. IV B, we describe the construction of abbreviations for applying Clifford gates, and T- and $T^\dagger$-gates used in our protocol. Next, we specify the fault-tolerance conditions of gadgets for quantum LDPC codes in Sec. IV C, and the constructions of gadgets that satisfy the fault-tolerance conditions in Sec. IV D. Finally, we present the threshold theorem for our protocol in Sec. IV E.

A. Compilation of ideal quantum circuit into fault-tolerant quantum circuit

We present the compilation procedure for our fault-tolerant protocol that compiles an original quantum circuit into a fault-tolerant circuit to achieve the target error $\varepsilon > 0$ using a non-vanishing-rate CSS LDPC code $\mathcal{Q}$ in combination with the protocol with the concatenated Steane codes to simulate open circuits in Sec. III. Here, the (r, c) CSS LDPC code $\mathcal{Q}$ has parameters

$$[[N, K = \Theta(N), D = \Theta(N^\gamma)]], \tag{63}$$

where N represents the number of phyiscal qubits, K represents the number of logical qubits, D is the code distance, and $\gamma > 0$ is a constant. We choose N depending on ε and n so as to achieve the polylog-time- and constant-space-overhead fault-tolerant protocol.

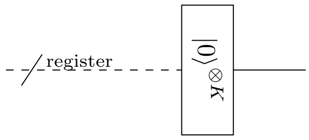
The compilation procedure consists of two steps: compiling the original circuit into an intermediate circuit and then compiling the intermediate circuit into a fault-tolerant circuit. In the compilation to the intermediate circuit, the qubits of the original circuit are grouped into registers, with each register containing at most K qubits, where K is the number of logical qubits of the quantum LDPC code $\mathcal{Q}$ in (63). Elementary operations for the quantum LDPC code will be specified as $|0\rangle^{\otimes K}$-state preparation, Clifford-state preparation operations, magic-state preparation operations, Pauli-gate operations, a CNOT-gate operation, a $Z^{\otimes K}$-measurement operation, a Bell-measurement operation, and wait operation. These elementary operations are defined as operations acting collectively on qubits in registers. By combining elementary operations, we will define abbreviations, including two-register Clifford-gate abbreviations and U_T-gate abbreviations. The intermediate circuits are described using these abbreviations and some of the elementary operations. For each elementary operation, we construct a physical circuit of the corresponding gadget that is intended to perform the corresponding logical operation acting on the logical qubits in a code block of $\mathcal{Q}$. Also, we construct an error-correcting (EC) gadget for quantum LDPC codes intended to carry out error correction on a code block of $\mathcal{Q}$ using a decoding algorithm. Here, the code $\mathcal{Q}$ must have an efficient decoding algorithm for the protocol to have a threshold, even when taking into account classical computation time. We will formally define an efficient decoding algorithm that the code $\mathcal{Q}$ should have in Sec. IV C. The gadgets are carefully designed to satisfy the fault-tolerance conditions described in Sec. IV C. The replacement of each abbreviation and elementary operation in the intermediate circuit with the corresponding gadget provides a fault-tolerant circuit for the original circuit.

1. *Compilation from original circuit to intermediate circuit*

As a first step in the compilation, we compile an original circuit into an intermediate circuit acting on K qubits within registers. First, we provide a list of elementary operations and abbreviations, along with corresponding diagrams, used in our protocol. In the diagram, a dashed input line changing to a solid output line indicates the allocation of a register, while a solid line changing to a dashed line indicates the deallocation. If both the input and output lines are dashed, the corresponding register is used as a workspace for performing elementary operations. A double output line represents the bits that the elementary operation outputs.

The elementary operations we will use are as follows.

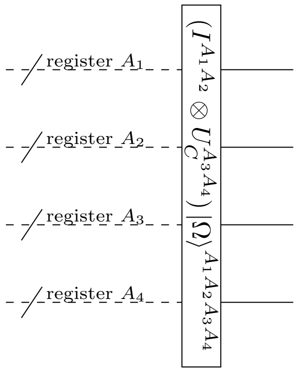
- $|0\rangle^{\otimes K}$-state preparation operation



. (64)

The $|0\rangle^{\otimes K}$-state preparation operation allocates a single register that is prepared in the state $|0\rangle^{\otimes K}$.

- Clifford-state preparation operations



register A_1
register A_2
register A_3
register A_4
$(I^{A_1A_2} \otimes U_C^{A_3A_4})\,|\Omega\rangle^{A_1A_2A_3A_4}$

. (65)

A Clifford-state preparation operation allocates four registers A_1, A_2, A_3, A_4 in the state

$$(I^{A_1A_2} \otimes U_C^{A_3A_4})\,|\Omega\rangle^{A_1A_2A_3A_4}, \tag{66}$$

where

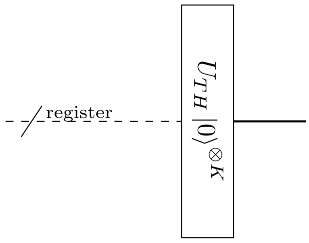
$$|\Omega\rangle^{A_1A_2A_3A_4} := |\Phi\rangle^{A_1A_3} \otimes |\Phi\rangle^{A_2A_4}, \tag{67}$$

$|\Phi\rangle^{A_iA_{i'}}$, which is a maximally entangled state between the registers A_i and $A_{i'}$, is given by

$$|\Phi\rangle^{A_iA_{i'}} = \frac{1}{\sqrt{2^K}} \sum_{m=0}^{2^K-1} |m\rangle^{A_i} \otimes |m\rangle^{A_{i'}}, \tag{68}$$

$I^{A_1A_2}$ is an identity operator acting on the qubits in the two registers A_1, and A_2 and $U_C^{A_3A_4}$ is an arbitrary Clifford operation acting on the qubits in the two registers A_3 and A_4.

- Magic-state preparation operations



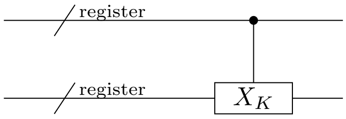
. (69)

A magic-state preparation operation allocates a single register in the state of

$$U_{TH}\,|0\rangle^{\otimes K}, \tag{70}$$

where U_{TH} is the tensor product of TH and I gates.

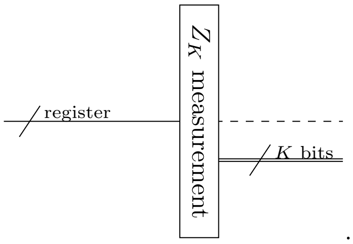
- CNOT-gate operation



. (71)

The CNOT-gate operation applies the CNOT$^{\otimes K}$ gates acting on the K qubits in the registers. Here, a controlled-X_K gate represents CNOT$^{\otimes K}$ gates on K qubits.

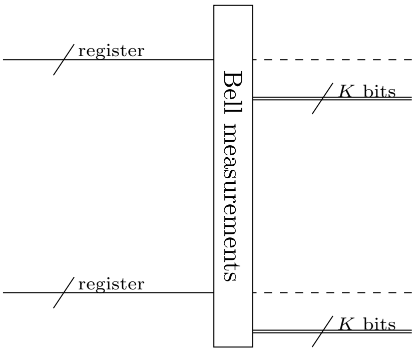
- Z_K-measurement operation



. (72)

The Z_K-measurement operation performs collective single-qubit measurements in Z basis of all K qubits contained in a register, deallocates the register, and outputs a K-bit string of the measurement outcomes. Here, Z_K represents this collective single-qubit Z-basis measurements on K qubits.

- Bell-measurement operation



. (73)

The Bell-measurement operation performs the Bell measurements on K pairs of qubits of a $X \otimes X$ operator and $Z \otimes Z$ operator, where each pair is shared by the two registers. It deallocates these registers and outputs a $2K$-bit string of the measurement outcomes. We assume that the upper register contains the K-bit string outcome of measurements of $X \otimes X$ operators and the lower register contains the outcome of measurements of $Z \otimes Z$ operators.

- Pauli-gate operations

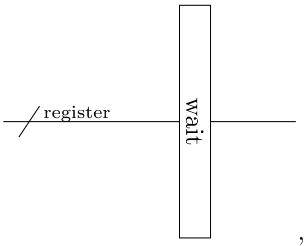
. (74)

A Pauli-gate operation performs a tensor product of arbitrary Pauli gates

$$\bigotimes_{k=1}^{K} P_k \in \tilde{\mathcal{P}}_K, \tag{75}$$

where $P_k \in \{I, X, Y, Z\}$ is a single-qubit Pauli operator acting on the k-th qubit in a register. As described below, Pauli-gate operations for quantum LDPC codes are performed by updating the Pauli frame in our protocol.

- Wait operations



, (76)

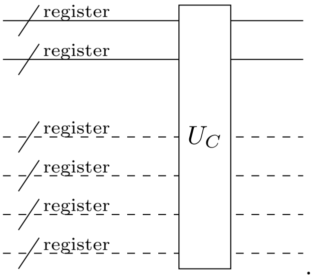
or simply

(77)

The wait operation performs the identity operator on a register, which is regarded as a special case of Pauli-gate operation.

In addition, the abbreviations are defined as follows. The explicit construction of the abbreviations (78) and (79) will be given in Sec. IV B.

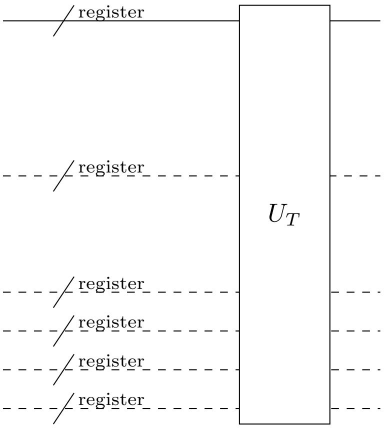
- Two-register Clifford-gate abbreviations



. (78)

A two-register Clifford-gate abbreviation applies an arbitrary Clifford operation U_C to two registers represented by solid lines. The four registers represented by dashed lines are used as workspaces.

- U_T-gate abbreviations



. (79)

A U_T-gate abbreviation applies the U_T operation to a register (solid line). Here, U_T is the tensor product of any combination of T, $T^\dagger$, and I. The five registers represented by dashed lines are used as workspaces.

Some of the elementary operations may take as input a bitstring that is determined during the execution of the quantum computation, and the specification of the elementary operation is determined on the fly by this input. Such elementary operations are called *on-demand* elementary operations. We also introduce on-demand abbreviations in a similar way. In the following, we list the on-demand elementary operations and abbreviations used in our protocol.

- On-demand Pauli gate operations

The Pauli-gate operations that are used for a correction operation required for gate teleportation in the two-register Clifford-gate abbreviation will be presented in Sec. IV B 1. The on-demand Pauli-gate operations receive a bitstring as a $2K$-bit vector of symplectic representation $\phi(P)$, where P is the K-qubit Pauli operator

$$P = \bigotimes_{k=1}^{K} P_k \in \tilde{\mathcal{P}}_K \tag{80}$$

to be applied by updating the Pauli frame as discussed in more detail below.

- On-demand two-register Clifford-gate abbreviations

The two-register Clifford-gate abbreviations used for correction operations for the gate teleportation in the U_T-gate abbreviations will be presented in

Sec IV B 2. The Clifford gate $U_C \in \tilde{\mathcal{C}}_{2K}/\tilde{\mathcal{P}}_{2K}$ we use in the U_T-gate abbreviations has the form of a tensor product of $2K$ single-qubit Clifford gates,

$$U_C = \bigotimes_{k=1}^{2K} C_k, \tag{81}$$

where $C_k \in \tilde{\mathcal{C}}_1/\tilde{\mathcal{P}}_1$ is an arbitrary single-qubit Clifford operator that acts on the k-th qubit of the first register for $k \in \{1, \ldots, K\}$ and on the $(k-K)$-th qubit of the second register for $k \in \{K+1, \ldots, 2K\}$. Thus, the on-demand abbreviations receive a bitstring as $2K$ symplectic matrices of size 2×2 of C_k as in (14).

- On-demand Clifford-state preparation

  The Clifford-state preparation operation is invoked by the on-demand two-register Clifford-gate abbreviation. The on-demand Clifford-state preparations receive bits as a $2K \times 2K$ binary matrix representing U_C.

It is essential for our protocol to perform on-demand Pauli operations classically by tracking and updating the *Pauli frame* of a quantum state [39, 43, 44]. The Pauli frame of a state relative to a specific reference state at a given time is defined as a Pauli operator

$$P_\mathrm{F} \in \tilde{\mathcal{P}}_K, \tag{82}$$

such that applying P_F to a state returns the reference state. We refer to a Pauli frame used in circuits described by elementary operations as a *elementary* Pauli frame. Note that we will also define a physical Pauli frame later in (86), which is used for physical circuits and is different from the elementary one. During the execution of quantum computation, for each register, we store a Pauli frame as a bitstring

$$\phi(P_\mathrm{F}) \in \mathbb{F}_2^{2K}. \tag{83}$$

We choose the reference state as the *corrected* state that would be obtained if the correction operation in the two-register Clifford-gate abbreviation to perform gate teleportation were applied to qubits, and the Pauli frame is tracked for the *uncorrected* state with no correction operation applied. The advantage of using Pauli frames is that it eliminates the need to physically implement on-demand Pauli operations. This means that there is no need to convert them into Pauli gadgets as described in the physical circuit, thereby eliminating the classical computation required to determine the physical Pauli-gate operation for performing a logical Pauli-gate operation and avoiding the errors that arise from physically applying the Pauli gates.

In the compilation prior to starting the execution of quantum computation, elementary operations (and abbreviations) that are not on-demand, i.e., do not require classical input, are called scheduled operations (and abbreviations) and are distinguished from on-demand ones. All scheduled elementary operations and abbreviations are determined during compilation, independently of on-demand operations, and are remain unchanged during the execution of quantum computation. This reduces the time overhead of waiting for classical computations during the execution.

In constructing an intermediate circuit, we require it shold be represented only by abbreviations (including the two-register Clifford-gate abbreviations (78), the U_T-gate abbreviations (79)), the $|0\rangle^{\otimes K}$-state preparation operation (64), the Z_K-measurement operation (72), and the wait operation (76). For simplicity, we refer to these elementary operations and abbreviations as intermediate operations. We compile the original circuit into the intermediate circuit using the following procedure. First, n qubits in the original circuit are divided into

$$\kappa(n) := \lceil n/K \rceil \tag{84}$$

registers, where each register contains at most K qubits, and $\lceil \cdot \rceil$ represents the ceiling function. For each of these registers, we also allow the intermediate circuit to use five auxiliary registers that can be allocated and used as workspace for the abbreviations. Next, we replace the operations in the original circuit with the corresponding intermediate operations. The $|0\rangle$-state preparations at the beginning of the original circuit are replaced with $|0\rangle^{\otimes K}$-state preparations. We replace the Z-basis measurements at the end of the original circuit with Z_K-measurement operations. We replace a T-gate layer in the original circuit with U_T-gate abbreviations. We replace each Clifford layer of Clifford gates in the original circuit with two-register Clifford-gate abbreviations. Even if an arbitrarily long sequence of Clifford gates acts on qubits located in the same register of the intermediate circuit, the Clifford gates can be collectively replaced with a single use of a two-register Clifford-gate abbreviation. However, we assume the intermediate circuit can perform at most one intermediate operation per register per time step, where the total number of time steps defines the depth of the intermediate circuits. Under this construction, if a one-depth part of the original circuit contains multiple Clifford gates acting on qubits in different pairs of registers, the corresponding part of the intermediate circuit requires two-register Clifford-gate abbreviations placed in series, as described in Sec. IV E. After replacing operations in the original circuit with intermediate operations, we limit the maximum number of non-trivial intermediate operations (i.e., operations other than the wait operation) that can be applied in parallel at a single time step, denoted by

$$L(n), \tag{85}$$

which will turn out to be able to be chosen as (199) later in our analysis. At the same time step, we insert wait operations for all registers where a non-trivial intermediate operation is not applied. Progressing beyond the existing analyses [20–22] with $L(n) = \Theta(W(n)/\mathrm{poly}(n))$, we

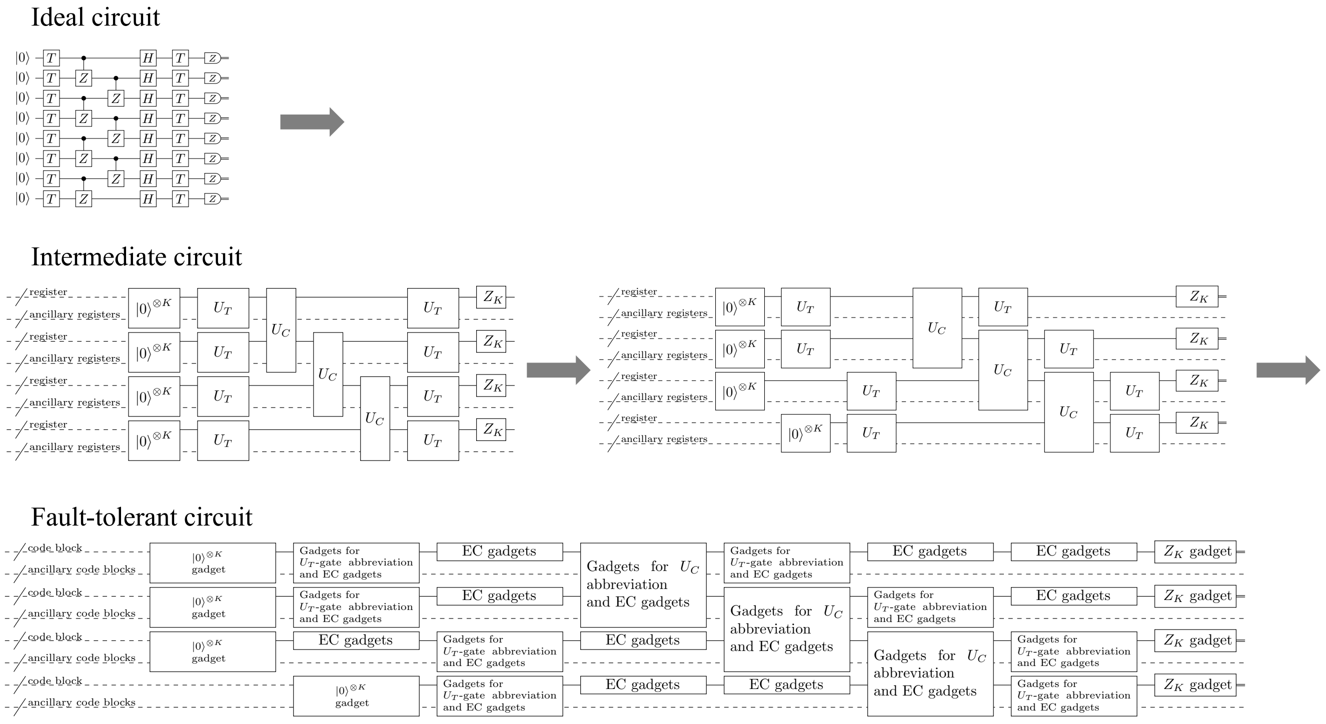


FIG. 3. Compilation procedure of our fault-tolerant protocol. First, we compile an original circuit into an intermediate circuit that consists only of intermediate operations acting on registers. Here, the two-register Clifford-gate abbreviation U_C and the U_T-gate abbreviation, which are implemented via gate teleportation, are described by a sequence of elementary operations. Then, we limit the number of intermediate operations each time step to achieve constant-space overhead. Finally, we compile the intermediate circuit with reduced parallelism into a fault-tolerant circuit by replacing each elementary operation with the corresponding gadget, inserting an EC gadget in between.

will rigorously show that $L(n) = \Theta(W(n)/\mathrm{polylog}(n))$ to prove that polylogarithmic time overhead is achievable.

2. *Compilation from intermediate circuit to fault-tolerant circuit*

As the next step in the compilation, we compile an intermediate circuit into a fault-tolerant circuit. In this step, all elementary operations in the intermediate circuit are replaced with corresponding gadgets, consisting only of physical operations.

The construction of gadgets will be described in Sec. IV D. Each gadget consists of a *quantum* part and a *classical* part. The quantum part is described by physical operations that need to be applied to the data qubits, whereas the classical part involves the necessary classical computations for executing the gadget. During the execution of the classical part, the wait operations act on the data qubits in the same way as the quantum part.

For the EC gadget, a Pauli recovery operation takes as an input bitstring that is determined by a decoding algorithm during the execution of the quantum computation, and the specification of the EC gadget is determined on the fly by this input. In this paper, the Pauli recovery operation can also be performed as a classical part by tracking Pauli frames, as well as the on-demand Pauli operation of a two-register Clifford gate abbreviation. Apart from the elementary Pauli frame in (82), we also define a *physical* Pauli frame, which is a Pauli frame for physical circuits. This physical Pauli frame

$$P_{\mathrm{F}} \in \tilde{\mathcal{P}}_N \tag{86}$$

is stored for each code block, individually. We choose the reference state as the *recovered* state that would be obtained if a recovery operation were applied to the physical qubits, and the Pauli frame is tracked for the *unrecovered* state with no recovery operation applied. The advantage of using the Pauli-frame technique is that it eliminates the need to physically implement recovery operations and simplifies the proof of the threshold theorem of the overall protocol, as explained in Sec. IV E.

Compilation from intermediate circuits to fault-tolerant circuits involves the following procedures performed sequentially for each intermediate operation within the same time step. For a given time step, if an intermediate operation is an abbreviation, the abbreviation is expanded into elementary operations (left unchanged if an intermediate operation is already an elementary operation). Next, elementary operations within the same time step in the intermediate circuit are replaced with corresponding gadgets, and EC gadgets are inserted between elementary operations. At this point, the same intermediate operation has a different circuit depth when replaced by a physical circuit. Therefore, wait operations are inserted for synchronization, so that EC gadgets should be inserted at a constant time interval from the completion of the execution of the physical circuit of the intermediate operation that finishes earlier until the completion of the execution of the intermediate operation belonging to the same time step with the greatest depth of the physical circuit. By performing this procedure at all time steps of the intermediate circuit, a fault-tolerant quantum circuit is finally obtained.

B. Construction of abbreviations

In the following, we explain the construction of abbreviations. In Sec. IV B 1, we present the construction of two-register Clifford-gate abbreviations (78). In Sec. IV B 2, we present the construction of U_T-gate abbreviations (79).

1. *Two-register Clifford-gate abbreviations*

The two-register Clifford-gate abbreviations are used to apply multiple Clifford gates acting on the same pair of registers. The construction of the abbreviations is shown in Fig. 4.

The abbreviation is based on a gate teleportation protocol [39, 45, 46]. In the beginning, we have the two registers A_1 and A_2 on which we want to perform the Clifford operation U_C, and the four auxiliary registers A_3, A_4, A_5, A_6 in the state

$$|\Psi_{U_C}\rangle^{A_3A_4A_5A_6} = (I^{A_3A_4} \otimes U_C^{A_5A_6})\,|\Omega\rangle^{A_3A_4A_5A_6}\,, \quad (87)$$

which is prepared by the Clifford-state preparation operation (65). After preparing the auxiliary states, we perform the Bell-measurement operation (73) on two pairs of registers A_1, A_3 and A_2, A_4. These Bell measurements output the pair of $2K$-bit outcomes as

$$(x^{A_1A_3}, z^{A_1A_3}) \in \mathbb{F}_2^{2K} \text{ and } (x^{A_2A_4}, z^{A_2A_4}) \in \mathbb{F}_2^{2K}, \quad (88)$$

where the K-bit string x' represents the outcomes of the measurements of $X \otimes X$, and the K-bit string z' represents the outcomes of the measurements of $Z \otimes Z$. From the $4K$-bit outcomes, we calculate the correction operation $P_{\text{corr}} \in \tilde{\mathcal{P}}_{2K}$ for the gate teleportation in the form of

$$P_{\text{corr}} := U_C^{A_5A_6}\left(\bigotimes_{k=1}^{K} P_k^{A_5} \otimes \bigotimes_{l=1}^{K} P_l^{A_6}\right)\left(U_C^{A_5A_6}\right)^{\dagger}, \quad (89)$$

where $P_k^{B_j} \in \{I, X, Y, Z\}$ with $j \in \{5, 6\}$ is a Pauli operator acting on the k-th qubit in the register B_j. From the $4K$-bit measurement outcome of the Bell measurements, the corresponding correction operation in (89) can be calculated via multiplication of the symplectic matrix $\gamma(U_C^{A_5A_6}) \in \mathbb{F}_2^{4K\times 4K}$ from the right of the row vector of the symplectic representation of $\phi\left(\left(\bigotimes_{k=1}^{K} P_k^{A_5} \otimes \bigotimes_{l=1}^{K} P_l^{A_6}\right)\right) \in \mathbb{F}_2^{4K}$ as

$$\phi(P_{\text{corr}}) = \phi\left(\left(\bigotimes_{k=1}^{K} P_k^{A_5} \otimes \bigotimes_{l=1}^{K} P_l^{A_6}\right)\right)\gamma(U_C^{A_5A_6}). \quad (90)$$

The resulting $4K$-dimensional row vector of (90) is used as an input bitstring to specify the on-demand Pauli-gate operation for the correction operation. Using $O(K^2)$ parallel processes, this classical computation can be performed within a runtime of

$$O(\log(K)). \quad (91)$$

The wait operations (76) are performed during this classical computation. Then, the Pauli-gate operation (89) for the correcting operation is applied to the registers A_5, A_6 completing this abbreviation.

However, by using the Pauli frame technique, we can avoid the need to perform an on-demand Pauli operation directly on physical qubits. Specifically, when on-demand Pauli operations are physically applied, there is no need to compute physical Pauli operations such that on-demand Pauli operations are performed as logical operations, which takes runtime $O(\log N)$ as explained in Appendix C. Instead, we can simply store the on-demand Pauli operation as an elementary Pauli frame in a classical register. Let

$$P_{\mathrm{F}}^{A_1} \in \tilde{\mathcal{P}}_K \text{ and } P_{\mathrm{F}}^{A_2} \in \tilde{\mathcal{P}}_K \quad (92)$$

be an elementary Pauli frame of the registers A_1 and A_2, respectively, at the time just before the abbreviation and

$$(x'^{A_1A_3}, z'^{A_1A_3}) \in \mathbb{F}_2^{2K} \text{ and } (x'^{A_2A_4}, z'^{A_2A_4}) \in \mathbb{F}_2^{2K} \quad (93)$$

be the measurement outcomes of the Bell measurement operation obtained from the uncorrected state, where the K-bit string x' represents the measurement outcomes of $X \otimes X$ operators, and the K-bit string z' represents the measurement outcomes of the $Z \otimes Z$ operators. The classical computer receives an input bitstring as the symplectic representation

$$\phi(P_{\mathrm{F}}^{A_1}) \in \mathbb{F}_2^{2K} \text{ and } \phi(P_{\mathrm{F}}^{A_2}) \in \mathbb{F}_2^{2K}, \quad (94)$$

and the pair of $2K$-bit strings $(x'^{A_1A_3}, z'^{A_1A_3})$ and $(x'^{A_2A_4}, z'^{A_2A_4})$ in (93). Then, the classical computer outputs a bitstring of the symplectic representation of the elementary Pauli frame

$$\phi(P_{\mathrm{F}}^{A_5}) \in \mathbb{F}_2^{2K} \text{ and } \phi(P_{\mathrm{F}}^{A_6}) \in \mathbb{F}_2^{2K}, \quad (95)$$

where $P_{\mathrm{F}}^{A_5}$, $P_{\mathrm{F}}^{A_6}$ are Pauli frames of the registers A_5 and A_6, respectively, at the final step of the abbreviation and

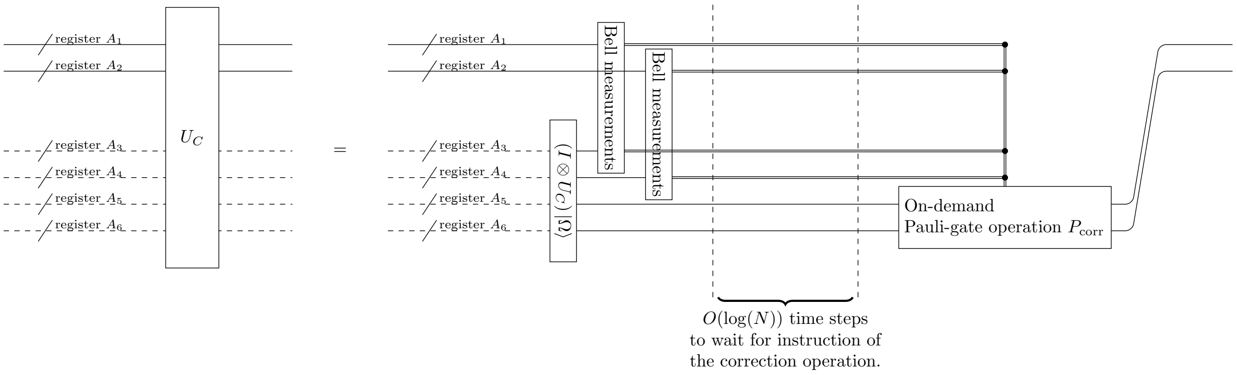

FIG. 4. The construction of the two-register Clifford-gate abbreviations (78) to perform a Clifford gate U_C applied to the two registers A_1, A_2.

provide the input for the subsequent abbreviation. To this end, we first modify the measurement outcomes (93) to (88) based on the input Pauli frame (92). For registers A_1 and A_3, this modification can be performed by taking a sum for $i \in [1, \ldots, K]$ as

$$x_i^{A_1A_3} = x_i'^{A_1A_3} \oplus \left(\phi\left(P_{\mathrm{F}}^{A_1}\right)\right)_{i+K} \oplus \left(\phi\left(P_{\mathrm{F}}^{A_2}\right)\right)_{i+K}, \tag{96}$$

and

$$z_i^{A_1A_3} = z_i'^{A_1A_3} \oplus \left(\phi\left(P_{\mathrm{F}}^{A_1}\right)\right)_{i} \oplus \left(\phi\left(P_{\mathrm{F}}^{A_2}\right)\right)_{i}. \tag{97}$$

Similarly, the same procedure can be applied to the registers A_2 and A_4. Using $O(K)$ parallel processes, the modification can be performed with runtime $O(1)$. Next, based on the modified measurement outcomes $(x^{A_1A_3}, z^{A_1A_3})$, $(x^{A_2A_4}, z^{A_2A_4})$, the classical computation for determining the Pauli correction operation (89) is performed as already explained above. This classical computation can be performed within runtime $O(\log K)$. The Pauli correction operation gives the elementary Pauli frames in (95) to be passed as the next input of the abbreviation,

$$\phi(P_{\mathrm{F}}^{A_5}) = \left((\phi(P_{\mathrm{corr}}))_{[1:K]}, (\phi(P_{\mathrm{corr}}))_{[2K+1:3K]}\right), \tag{98}$$

and

$$\phi(P_{\mathrm{F}}^{A_6}) = \left((\phi(P_{\mathrm{corr}}))_{[K:2K+1]}, (\phi(P_{\mathrm{corr}}))_{[3K+1:4K]}\right), \tag{99}$$

where $(\phi(P_{\mathrm{corr}}))_{[j:k]}$ represents a binary row vector consisting of the elements from the j-th to the k-th position of the original binary row vector $\phi(P_{\mathrm{corr}})$. Using $O(K)$ parallel processes, these computations can be performed within runtime $O(1)$. Therefore, the classical computation for calculating (95) from (94) can be performed with runtime $O(1)$.

As a result, the depth of the whole abbreviation is bounded by

$$O(\log K), \tag{100}$$

where the dominant part is the classical computation for calculating (90).

2. U_T-gate abbreviation

The U_T-gate abbreviation is used to apply the U_T gate, which is the tensor product of T, $T^\dagger$ and I acting on the qubits in a register. The construction of the U_T-gate abbreviation is shown in Fig. 5.

The U_T-gate abbreviation is also based on the gate teleportation protocol [39, 45, 46]. At the beginning of the gate teleportation protocol, we have the register A_1 containing the qubits on which we want to perform the gate U_{TH}, and the auxiliary register A_2 in the state

$$|\Psi_{U_{TH}}\rangle = U_{TH}\,|0\rangle^{\otimes K}, \tag{101}$$

which is prepared by the magic-state preparation operation (69). After preparing the auxiliary register A_2, we perform the CNOT-gate operation (71), followed by the Z_K-measurement operation (72). This Z_K-measurement operation outputs a K-bit string as

$$z \in \mathbb{F}_2^K. \tag{102}$$

From the K-bit measurement outcomes, a Clifford gate SX for the correction operation is applied to the qubits on which U_T has non-trivial support. At this point, T has been applied to the qubits where $T^\dagger$ is to be performed. Thus, an additional Clifford gate $S^\dagger$ needs to be applied to the qubit to perform $T^\dagger$. To implement these Clifford gates, we use a two-register abbreviation to perform $U_{\mathrm{corr}} \in \tilde{\mathcal{C}}_{2K}/\tilde{\mathcal{P}}_{2K}$ as in (78) that acts non-trivially only on the register A_2. Specifically, U_{corr} is expressed as a tensor product involving pairs of single-qubit Clifford gate $SX \otimes I$ and $I \otimes I$. Using the K-bit string of measurement outcome, we calculate the correction operation as

$$U_{\mathrm{corr}} = \bigotimes_{k=1}^{2K} C_k, \tag{103}$$

where $C_k \in \tilde{\mathcal{C}}_1/\tilde{\mathcal{P}}_1$ is either SX or I. This correction operation is performed with the on-demand Clifford-gate abbreviation (81), whose input consists of $2K$ symplectic matrices in (14) of size 2×2 which are either

$$\gamma(SX) \text{ or } \gamma(I). \tag{104}$$

Subsequently, this input is loaded into an on-demand two-register Clifford-gate abbreviation to execute the correction operation. Using $O(K)$ parallel processes, the runtime of classical computation to generate the input to the on-demand abbreviation can be bounded by $O(1)$.

Unlike the two-register Clifford-gate abbreviation, even if we utilize the Pauli frame technique, the correction operation of Clifford gate must be performed. If a Clifford correction operation were stored classically and a subsequent measurement operation contained in a next abbreviation was executed, it would be impossible to deterministically obtain the modified measurement results that would have been achieved with the application of the correction operation. When we utilize the Pauli frame technique, we have an elementary Pauli frame

$$P_{\mathrm{F}}^{A_1} \in \tilde{\mathcal{P}}_K \tag{105}$$

at the time just before the abbreviation and measurement outcomes

$$z' \in \mathbb{F}_2^K \tag{106}$$

of the Z_K-measurement operation obtained from the uncorrected state. The classical computer takes an input bitstirng of the symplectic representation

$$\phi(P_{\mathrm{F}}^{A_1}) \in \mathbb{F}_2^{2K} \tag{107}$$

and the K-bit string z' (106). Then, the classical computer outputs a bitstring of the symplectic representation of the elementary Pauli frame

$$\phi({P'}_{\mathrm{F}}^{A_1}) \in \mathbb{F}_2^{2K} \tag{108}$$

at the final step of the abbreviation and provide the input of the subsequent abbreviation. To this end, we modify the measurement outcomes (106) to (102) based on the input Pauli frame. The modification of the measurement outcomes z' (106) is performed by taking a sum for $i \in [1, \ldots, K]$ as

$$z_i = {z'}_i \oplus (\phi({P'}_{\mathrm{F}}^{A_1}))_i. \tag{109}$$

Using $O(K)$ parallel processes, this modification can be performed within runtime $O(1)$. Then, based on the modified measurement outcomes z_i, the classical computation for determining the Clifford correction operation is performed as already explained above. The elementary Pauli frame (108) to be passed to the next input of the abbreviation is calculated for each $i \in [1, \ldots, K]$

$$\phi(({P'}_{\mathrm{F}}^{A_1})_i) = \gamma(C_i)\phi(({P'}_{\mathrm{F}}^{A_1})_i). \tag{110}$$

Using $O(K)$ parallel processes, this classical computation can be performed with runtime $O(1)$. Therefore, the classical computations for calculating (108) from (107) can be performed with runtime $O(1)$ using $O(K)$ parallel processes.

As a result, the depth of the U_T-gate abbreviation is bounded by

$$O(\log K), \tag{111}$$

where the dominant part is the depth of the on-demand two-register Clifford-gate abbreviation.

C. Conditions of fault-tolerant gadgets on quantum LDPC codes

In this section, we define the fault-tolerance condition for gadgets for quantum LDPC codes. Before we provide the definition, we introduce a property of the decoding algorithm that is required for constructing our protocol.

The decoding algorithm used for quantum LDPC codes needs to consider cases where the syndrome bits may be erroneous, due to noise in the circuits used to measure the syndrome bits. Here, we consider a CSS LDPC code obtained from a pair of classical linear codes, $C_X = \ker H_X$ and $C_Z = \ker H_Z$, where $H_X \in \mathbb{F}_2^{M_Z \times N}$ and $H_Z \in \mathbb{F}_2^{M_Z \times N}$ are parity-check matrices. Let $e = \phi(E) \in \mathbb{F}_2^{2N}$ be a symplectic representation of a Pauli error $E \in \mathcal{P}_N$ on data physical qubits, and $\Delta = (\Delta_X, \Delta_Z) \in \mathbb{F}_2^M$ be errors on syndrome bits. The ideal syndrome bits

$$\sigma = (\sigma_X, \sigma_Z) \in \mathbb{F}_2^M \tag{112}$$

for the error $e \in \mathbb{F}_2^{2N}$ is given by

$$\sigma_X = H_Z e_X \quad \text{and} \quad \sigma_Z = H_X e_Z. \tag{113}$$

However, the ideal syndrome bits $\sigma \in \mathbb{F}_2^M$ can be corrupted by syndrome errors $\Delta \in \mathbb{F}_2^M$, resulting in noisy syndrome bits

$$\tilde{\sigma} = (\tilde{\sigma}_X, \tilde{\sigma}_Z) \in \mathbb{F}_2^M \tag{114}$$

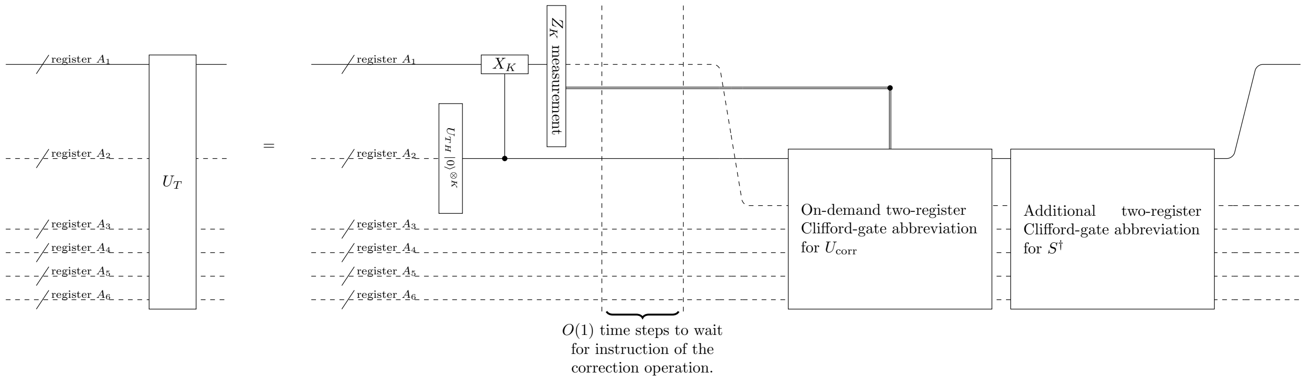
which is given by

$$\tilde{\sigma}_X = \sigma_X \oplus \Delta_X \quad \text{and} \quad \tilde{\sigma}_Z = \sigma_Z \oplus \Delta_Z. \tag{115}$$

Using the noisy syndrome $\tilde{\sigma}$, the decoding algorithm calculates the recovery operation $R \in \mathcal{P}_N$ with the symplectic representation $r = \phi(R)$.

In the analysis of the decoding algorithm, the local stochastic Pauli error model for the pair (e, Δ) is used, which is defined as follows:

Definition 8 (Local stochastic Pauli error model on data qubits and syndrome bits)**.** Let V be the set of physical qubits and $W_{X(Z)}$ be the set of $X(Z)$-type stabilizer generators. Let $e = (e_X, e_Z) \in \mathbb{F}_2^{2N}$ be a Pauli error, $\Delta = (\Delta_X, \Delta_Z) \in \mathbb{F}_2^M$ be syndrome bit errors. Let



register A_1
register A_2
register A_3
register A_4
register A_5
register A_6

$O(1)$ time steps to wait for instruction of the correction operation.

FIG. 5. The construction of the U_T-gate abbreviation (79) to perform a U_T gate on the register A_1.

$\mathrm{supp}(e_{X(Z)}) \subseteq V$ be the support of a $X(Z)$-type Pauli error and $\mathrm{supp}(\Delta_{X(Z)}) \subseteq W_{Z(X)}$ be the support of errors on syndrome bits. We say that errors (e, Δ) follow the local stochastic Pauli error model with parameters $(p_{\mathrm{data}}, p_{\mathrm{synd}})$ if for all $S \subseteq V$, $T \subseteq W_Z$, and $T' \subseteq W_X$, the following relations are satisfied.

$$\begin{aligned}\mathbb{P}\left[S \subseteq \mathrm{supp}(e_X) \text{ and } T \subseteq \mathrm{supp}(\Delta_X)\right] &\leq p_{\mathrm{data}}^{|S|} p_{\mathrm{synd}}^{|T|}, \\ \mathbb{P}\left[S \subseteq \mathrm{supp}(e_Z) \text{ and } T \subseteq \mathrm{supp}(\Delta_Z)\right] &\leq p_{\mathrm{data}}^{|S|} p_{\mathrm{synd}}^{|T|}\end{aligned} \tag{116}$$

In particular, when the errors on the syndrome bits are not considered, we say that errors follow a local stochastic Pauli error model with parameter p_{data} if for all $S \subseteq V$, the errors satisfy

$$\mathbb{P}\left[S \subseteq \mathrm{supp}(e_X)\right] \leq p_{\mathrm{data}}^{|S|} \text{ and } \mathbb{P}\left[S \subseteq \mathrm{supp}(e_Z)\right] \leq p_{\mathrm{data}}^{|S|}. \tag{117}$$

Quantum expander codes [20, 47] and quantum Tanner codes [48], which are important classes of CSS LDPC codes, each have their own decoding algorithms [20, 22, 49] such that when $\Delta \neq 0$, they can deduce a recovery operation to suppress the residual error $e^{\mathrm{re}} \in \mathbb{F}_2^{2N}$ on data physical qubits,

$$e^{\mathrm{re}} := e \oplus r. \tag{118}$$

An intriguing property of these decoding algorithms is the *single-shot* property [20, 22]. A decoding algorithm with the single-shot property works by using noisy syndrome bits $\tilde{\sigma}$, where these noisy syndrome bits are obtained from a *single* round of syndrome measurements for each stabilizer generator [20, 22, 49–53]. Using these syndrome bits obtained from the single syndrome extraction, existing single-shot decoding algorithms for finite-quantum LDPC codes [20, 22, 49] run in an iterative way, i.e., they repeat T internal loops, to output a final estimate of a recovery operation $r := r^{(T)}$. Each of the T loops can be executed with a runtime of $O(1)$, using $O(N)$ parallel processes. For each iteration $t \in [1, \ldots, T]$, the algorithm computes a temporally deduced recovery operation $r^{(t)} \in \mathbb{F}_2^{2N}$. The decoding algorithm requires that for all t, the support of the residual error, derived by using $r^{(t)} \in \mathbb{F}_2^{2N}$, should be less than or equal to the code distance D. Formally, the definition of the single-shot decoding algorithm for non-vanishing-rate quantum LDPC codes is as follows:

Definition 9 (Single-shot decoding algorithm)**.** Let $\{\mathcal{Q}_i\}_i$ be a family of CSS LDPC codes where $\mathcal{Q}_i$ is an $[[N_i, K_i, D_i]]$ code with $N_i \to \infty$ for $i \to \infty$. Let $e = (e_X, e_Z) \in \mathbb{F}_2^{2N}$ be a Pauli error, $\Delta = (\Delta_X, \Delta_Z) \in \mathbb{F}_2^M$ be syndrome bits error, and $\tilde{\sigma} = (\tilde{\sigma}_X, \tilde{\sigma}_Z) \in \mathbb{F}_2^M$ be noisy syndrome bits. For $P = \{X, Z\}$, a decoding algorithm returns the recovery operation $r_P^{(t)} \in \mathbb{F}_2^{2N}$ at each iteration $t \in \{1, \ldots, T\}$, and the final output of the recovery operation is denoted by $r_P := r_P^{(T)}$. A decoding algorithm for $\{\mathcal{Q}_i\}_i$ is said to be single-shot if, for $i \to \infty$ and for

$$u_P := e_P \oplus r_P^{(1)} \oplus \cdots \oplus r_P^{(T)}, \tag{119}$$

there exist positive constants a and b such that

$$|u_P| \leq a|e_P|_{\mathrm{R}} + b|\Delta_P| \leq D, \tag{120}$$

and then given the noisy syndrome bits $\tilde{\sigma}_P \in \mathbb{F}_2^{M_P}$ the algorithm can find a recovering operation $r_P \in \mathbb{F}_2^N$ after T steps that satisfy

$$|e_P + r_P|_{\mathrm{R}} \leq \alpha|e_P|_{\mathrm{R}} + \beta|\Delta_P|, \tag{121}$$

with

$$\alpha = 2^{-\Omega(T)}, \quad \beta = O(1). \tag{122}$$

Moreover, each iteration of the decoding algorithm can be performed within runtime $O(1)$ by using $O(N)$ parallel processes. Here $|\cdot|_{\mathrm{R}}$ denotes the stabilizer-reduced weight defined to be the minimum weight of a stabilizer-equivalent error to $e_P \in \mathbb{F}_2^N$, i.e.,

$$|e_P|_{\mathrm{R}} := \min_{g' \in C^\perp} |e_P + g'|. \tag{123}$$

In the analysis of this work, we consider the local stochastic Pauli error model on the data qubits and the syndrome bits. Under this model, the weight of errors typically scales linearly in the number of physical qubits N contained in a code $\mathcal{Q}$. It appears that a code with code distance $D = \Omega(N)$ would be required to correct errors of linear weight. However, when one uses quantum LDPC codes under the stochastic error model, there are cases where errors can be corrected with a high probability when the error parameter is below a threshold error parameter [20–22, 54] as $N \to \infty$. This is feasible because, at sufficiently low error rates, typical linear weight errors occurring in quantum LDPC codes tend to form small, separate clusters of errors that are independently correctable by using a single-shot decoding algorithm. In the following, we define two decoding algorithms that quantum LDPC codes should have: the single-shot decoding algorithm with thresholds for reducing residual errors and the decoding algorithm with threshold for recovering logical information, where these algorithms are designed to correct local stochastic Pauli errors on wires with high probability if an error parameter is below a certain threshold value. The quantum expander code has both of these decoding algorithms while it is currently unknown whether the quantum Tanner code may also have these decoding algorithms satisfying the required properties for error suppression.

Both decoding algorithms, which reduce errors and correct errors, are performed iteratively. The runtime of the classical computation depends on the number of iterations within each algorithm. It is important to note that the runtime of each loop does not grow as $N \to \infty$ when parallel processes are used. These decoding algorithms work in different situations and play different roles in our fault-tolerant protocol. Specifically, the single-shot decoding algorithm for reducing errors is capable of finding a recovery operation to keep the residual error small even if the syndrome bits are noisy, and thus we will utilize the algorithm in the EC gadget to keep the residual error small in the code block. On the other hand, the decoding algorithm for correcting errors is capable of recovering the logical state only when the syndrome bit errors are absent, and thus, we will use the algorithm in the Z_K-measurement gadget and the Bell-measurement gadget to obtain the measurement outcomes of the logical qubits in $\mathcal{Q}$. To summarize, we define the single-shot decoding algorithm for reducing errors and the decoding algorithm for correcting errors as follows.

Definition 10 (Single-shot decoding algorithm with thresholds for reducing errors)**.** Let $\{\mathcal{Q}_i\}_i$ be a family of CSS LDPC codes where $\mathcal{Q}_i$ is an $[[N_i, K_i, D_i]]$ code with $N_i \to \infty$ and $D_i \to D$ as $i \to \infty$ and $\{\mathcal{Q}_i\}_i$. Let $e = (e_X, e_Z) \in \mathbb{F}_2^{2N}$ be the data qubit errors and $\Delta = (\Delta_X, \Delta_Z) \in \mathbb{F}_2^M$ be the syndrome bit errors that are local stochastic with parameters $(p_{\text{data}}, p_{\text{synd}})$. A single-shot decoding algorithm with thresholds for $\{\mathcal{Q}_i\}_i$ has thresholds $p_{\text{dec}}^{\text{th}} > 0$, and if $p_{\text{data}} \leq p_1 < p_{\text{dec}}^{\text{th}}$, $p_{\text{synd}} \leq p_2 < p_{\text{dec}}^{\text{th}}$, for $P \in \{X, Z\}$, a single-shot decoding algorithm returns a recovery operation $r_P \in \mathbb{F}_2^{2N}$ from the noisy syndrome bits $\tilde{\sigma}$ (114) that are obtained from a single round of syndrome measurements for each stabilizer generator after T internal loops, with probability at least

$$1 - e^{-\Omega(D)}, \tag{124}$$

such that there exists a bit sequence e'_P satisfying

$$e'_P \oplus e_P \oplus r_P \in C_P^{\perp}, \tag{125}$$

where $e_P^{'}$ follows the local stochastic Pauli error model with parameter $p_{\text{data}}^{\text{re}}$ satisfying

$$p_{\text{data}}^{\text{re}} \leq p_1^{c(T)}, \tag{126}$$

where $c(T)$, which is referred to as an error suppression parameter, is a monotonically increasing function with respect to T. Each round of iteration can be executed with a runtime of $O(1)$, using $O(N)$ parallel processes.

If the decoding algorithm fails to return recovery operations r_P for both $P \in \{X, Z\}$ satisfying (125), then we say that the decoding algorithm fails.

Definition 11 (Decoding algorithm with threshold for correcting errors)**.** Let $\{\mathcal{Q}_i\}_i$ be a family of CSS LDPC codes where $\mathcal{Q}_i$ is an $[[N_i, K_i, D_i]]$ code with $N_i \to \infty$ and $D_i \to D$ as $i \to \infty$. Let $e = (e_X, e_Z) \in \mathbb{F}_2^{2N}$ be the data qubit error and $\Delta = (\Delta_X, \Delta_Z) \in \mathbb{F}_2^M$ be the syndrome bit errors that are local stochastic with parameters $(p_{\text{data}}, p_{\text{synd}})$. Suppose the syndrome bit errors are absent, i.e., $p_{\text{synd}} = 0$. A decoding algorithm has a threshold $p'^{\text{th}}_{\text{dec}} > 0$ and if $p_{\text{data}} < p'^{\text{th}}_{\text{dec}}$, for each $P \in \{X, Z\}$, the decoding algorithm returns a recovery operation $r_P \in \mathbb{F}_2^{2N}$ from the syndrome bits $\sigma \in \mathbb{F}_2^M$ as in (112) after $T = O(\log N)$ internal loops, such that the residual error $e^{\text{re}} := e \oplus r$ satisfies

$$e_P \oplus r_P \in C_P^{\perp}, \tag{127}$$

with probability at least

$$1 - e^{-\Omega(D)}. \tag{128}$$

Each loop can be executed with a runtime of $O(1)$, using $O(N)$ parallel processes.

To the best of our knowledge, the family of quantum expander codes with $D = \Theta(\sqrt{N})$ is the only non-vanishing-rate quantum LDPC code that satisfies the requirements in Defs. 10 and 11. Specifically, the small-set-flip decoding algorithm for the quantum expander codes can work as both the single-shot decoding algorithm for reducing errors with thresholds in Def. 10 and the decoding algorithm for correcting errors in Def. 11 [20, 22]. More recently, Ref. [49] showed that the family of quantum Tanner codes with $D = \Theta(N)$ also has a single-shot decoding algorithm, but there is no proof that the bounds on the error parameter of a residual error under the local stochastic error model as in (126). Although it is conceivable that quantum Tanner codes could also achieve polylogarithmic time and constantspace overhead FTQC based on our protocol, we leave the rigious proof as an open work. To summarize, we make the following assumption about the families of non-vanishing-rate quantum LDPC codes that can be used in our protocol.

Assumption 4. *A family of non-vanishing-rate CSS LDPC codes $\{\mathcal{Q}_i\}_i$ where $\mathcal{Q}_i$ is an $[[N_i, K_i, D_i]]$ code with $N_i \to \infty$ and $D_i \to D = \Theta(N^\gamma)$ with $0 < \gamma \leq 1$ for $i \to \infty$ has a decoding algorithm that can serve as both the single-shot decoding algorithm for reducing errors with thresholds in Def. 10 and the decoding algorithm for correcting errors with threshold in Def. 11.*

In order for the fault-tolerant protocol using quantum LDPC codes to exhibit fault tolerance, gadgets must be designed so that errors caused by faults occurring in a gadget do not propagate too much even when the code block size N of $\mathcal{Q}$ increases, i.e., $i \to \infty$. To achieve this, we define the following fault-tolerance conditions that each type of gadget must satisfy.

The definition of fault tolerance of the state-preparation gadgets, including the gadget of the $|0\rangle^{\otimes K}$-state preparation operation (64), the gadgets of the Clifford-state preparation operations (65), and the gadgets of the magic-state preparation operations (69), is as follows.

Definition 12 (Fault-tolerance conditions of the state preparation gadgets for quantum LDPC codes)**.** Let C be a physical circuit of a state-preparation gadget. A state-preparation gadget C is fault-tolerant if, for $i \to \infty$, the gadget successfully prepare a desired state with any target probability of at least $1 - \delta$, and data qubits at the final step of C are subjected to the local stochastic error model on data qubits with parameter

$$Mp_{\mathrm{loc}}, \tag{129}$$

where $M = O(1)$ is a constant. We say that δ is the failure probability of a state-preparation gadget.

The definition of fault tolerance of the gate gadgets, including a gadget of the CNOT-gate operation (71), the measurement gadgets, including the gadget of the Z_K-measurement operation (72) and the gadget of the Bell-measurement operation (73), and the EC gadgets are defined as follows:

Definition 13 (Fault-tolerance conditions of gate, measurement, EC gadgets for quantum LDPC codes)**.** Let C be a physical circuit of a gadget. Let L be the set of locations in C, and $X_{\mathrm{in}}, X_{\mathrm{out}}$ be the set of wires at the first and final time step of C, respectively. A wire $x \in X$ at a given time step is *connected* to another wire $x' \in X'$ at a different time step if a Pauli operator acting at x can propagate to and affect x' through physical operations. Then, let us define a bipartite graph

$$G = (L, R, E) \tag{130}$$

of C, where the i-th vertex $l_i \in L$ corresponds to the i-th wire $x_i^{\mathrm{in}} \in X_{\mathrm{in}}$, the j-th vertex $r_i \in R$ corresponds to the j-th wire $x_j^{\mathrm{out}} \in X_{\mathrm{out}}$, and an edge $e \in E$ has the endpoints $l_i \in L$ and $r_j \in R$ if and only if $x_i^{\mathrm{in}} \in X_{\mathrm{in}}$ and $x_j^{\mathrm{out}} \in X_{\mathrm{out}}$ are connected. We say that a gadget is fault-tolerant if for $i \to \infty$, C satisfies the following conditions.

1. The maximum degree of a vertex in G of C is constant.

2. The depth of the quantum part of C is constant.

By constructing gadgets that satisfy the fault-tolerance conditions in Defs. 12 and 13, we will show in Sec. IV E that if the physical error rate is below a certain threshold, the failure probability of fault-tolerant simulations can be arbitrarily suppressed.

D. Construction of fault-tolerant gadgets

In this section, we present the construction of the gadgets that satisfy the fault-tolerance conditions in Defs. 12 and 13.

1. Z_K-measurement gadget

The construction of the Z_K-measurement gadget is shown in Fig. 6 (a). The gadget is implemented by transversal Z-basis measurements of the physical operation, followed by the classical computation for performing the decoding algorithm in Def. 11. The transversal measurements give N-bit measurement outcomes

$$z \in \mathbb{F}_2^N, \tag{131}$$

where z_i corresponds to the measurement outcome of the Z-basis measurement on the i-th physical qubit and is subjected to errors.

From $z \in \mathbb{F}_2^N$, we need to estimate the K-bit logical measurement outcomes

$$\bar{z} \in \mathbb{F}_2^K, \tag{132}$$

where $\bar{z}_i$ corresponds to the measurement outcome of the logical $\bar{Z}_i$ operator on the i-th logical qubits. This can be done in the following steps:

1. From $z \in \mathbb{F}_2^N$, we calculate the syndrome bits

$$\sigma_X \in \mathbb{F}_2^{M_Z} \tag{133}$$

of the Z-type generators by using the relation,

$$(\sigma_X)_i := \bigoplus_{j \in \mathrm{supp}(g_i^Z)} z_j, \tag{134}$$

where g_i^Z is the i-th Z-type stabilizer generator, and $\mathrm{supp}(g_i^Z)$ represents the set of indices of the

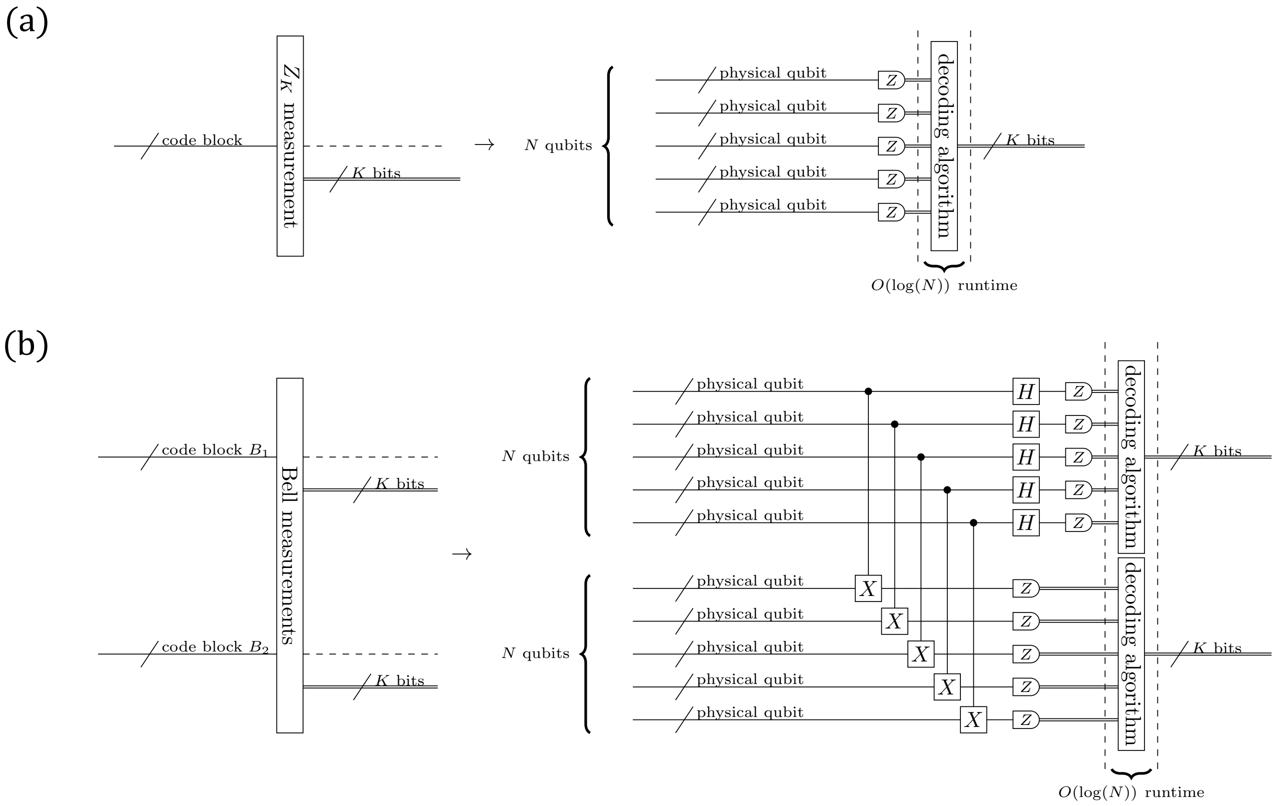

FIG. 6. (a) The physical circuit of the gadget of the Z_K-measurement operation (72) and (b) the physical circuit of the gadget of the Bell-measurement operation (73)

physical qubits on which g_i^Z acts nontrivially. Here, the syndrome bits σ_X (133) are calculated classically, and thus there are no syndrome bit errors. Using $M_Z = O(N)$ parallel processes, we can compute the syndrome bits σ_X (133) within runtime $O(\log N)$ since we use the CSS LDPC code $\mathcal{Q}$, and thus $|g_i^Z| = O(1)$ as $N \to \infty$.

2. We perform the decoding algorithm in Def. 11 that takes as input the syndrome bits $\sigma_X \in \mathbb{F}_2^{M_Z}$ and outputs the recovery operation $r_X \in \mathbb{F}_2^N$. Then, the corrected bitstring $\tilde{z} \in \mathbb{F}_2^N$ are obtained as for all $i \in [1, \ldots, N]$

$$\tilde{z}_i := z_i \oplus (r_X)_i. \tag{135}$$

Since there are no syndrome bit errors, the decoding algorithm can correct the data error. A decoding algorithm for correcting errors with threshold in Def. 11 can be performed within runtime $O(\log(N))$, and calculating (135) for all i can also be performed within runtime $O(1)$ using $O(N)$ parallel processes.

3. We calculate the measurement outcomes $\bar{z} \in \mathbb{F}_2^K$ of the logical operators as for all $i \in [1, \ldots, K]$

$$\bar{z}_i := \bigoplus_{j \in \mathrm{supp}(\bar{Z}_i)} \tilde{z}_j, \tag{136}$$

where $\bar{Z}_i$ is the logical-Z operator acting on the i-th logical qubit, and $\mathrm{supp}(\bar{Z}_i)$ represents the set of indices of the physical qubits on which $\bar{Z}_i$ acts nontrivially. Using $DK = O(N^2)$ parallel processes, we can compute (136) for all i within runtime $O(\log N)$ since $|\bar{Z}_i| = \Theta(D) = \Theta(N^\gamma)$ with $0 < \gamma \leq 1$ as $N \to \infty$.

Therefore, using $O(N^2)$ parallel processes, the classical part of the gadget can be performed within runtime

$$O(\log(N)). \tag{137}$$

For the Pauli-frame technique, we require additional classical computation. Let

$$P_{\mathrm{F}} \in \mathbb{F}_2^N \tag{138}$$

be a Pauli frame at the final step of the previous gadget and

$$z' \in \mathbb{F}_2^N \tag{139}$$

be the outcomes of the transversal Z-basis measurements obtained from the unrecovered state. The classical computer takes as input as the symplectic representation $\phi(P_{\mathrm{F}})$ and the measurement outcomes $z' \in \mathbb{F}_2^N$ of an unrecovered state and outputs the measurement outcomes $z \in \mathrm{F}_2^N$ of an recovered state as in (131). This calculation is performed for all $i \in [1, \ldots, N]$

$$z_i = z'_i \oplus (\phi(P_{\mathrm{F}}))_i \,. \tag{140}$$

Using $O(N)$ parallel processes, this additional computation can be performed within runtime $O(1)$.

The width of the quantum part in the gadget is bounded by

$$O(N), \tag{141}$$

and the depth of the quantum part is bounded by

$$O(1). \tag{142}$$

From the transversality and constant depth of the quantum part in the gadget, the gadget satisfies the fault-tolerance condition in Def. 13. The runtime of the classical part of the gadget can be bounded by runtime

$$O(\log N). \tag{143}$$

2. *Bell-measurement gadget*

The construction of the Bell-measurement gadget is shown in Fig. 6 (b). The gadget is implemented by the transversal CNOT gates between the controlled block B_1 and the target block B_2, the transversal H gates on B_1, followed by the transversal Z-basis measurements on B_1 and B_2. The transversal measurements on B_1 and B_2 yield a pair of N-bit strings of measurement outcomes, respectively, as

$$(x, z) \in \mathbb{F}_2^{2N} \tag{144}$$

where $x \in \mathbb{F}_2^N$ represents the outcomes from B_1 and $z \in \mathbb{F}_2^N$ represents those from B_2. Here, x_i and z_i correspond to the measurement outcome of the $X_i \otimes X_i$ and $Z_i \otimes Z_i$ operators, respectively, on N pairs of physical qubits. From $(x, z) \in \mathbb{F}_2^{2N}$, we deduce a pair of K-bit string of logical measurement outcomes as

$$(\bar{x}, \bar{z}) \in \mathbb{F}_2^{2K}, \tag{145}$$

where $\bar{x}_i$ and $\bar{z}_i$ correspond to the measurement outcomes of $\bar{X}_i \otimes \bar{X}_i$ and $\bar{Z}_i \otimes \bar{Z}_i$, respectively, on K pairs of logical qubits. To obtain K-bit outcomes of $\bar{z} \in \mathbb{F}_2^K$ from the noisy measurement outcomes $z \in \mathbb{F}_2^N$, we follow the procedure as described for the case of the Z_K-measurement gadget. The K-bit outcomes of $\bar{x} \in \mathbb{F}_2^K$ can also be estimated by replacing the Z-basis with the X-basis and performing the presented procedure since we consider the CSS code.

Based on the Pauli-frame technique, we require additional classical computation. Let

$$P_{\mathrm{F}}^{B_1} \otimes P_{\mathrm{F}}^{B_2} \in \mathbb{F}_2^{2N} \tag{146}$$

be a Pauli frame at the final step of the previous gadget and

$$(x', z') \in \mathbb{F}_2^{2N} \tag{147}$$

be the outcomes of transversal Z-basis measurements obtained from the unrecovered state, where $x' \in \mathbb{F}_2^N$ and $z' \in \mathbb{F}_2^N$ correspond to the outcomes from B_1 and B_2, respectively. The classical computation takes as input the symplectic representation $\phi(P_{\mathrm{F}}^{B_1} \otimes P_{\mathrm{F}}^{B_2})$ and the measurement outcomes $z' \in \mathbb{F}_2^N$ and outputs the measurement outcomes $z \in \mathrm{F}_2^N$ of a recovered state as in (144). This calculation is performed for all $i \in [1, \ldots, N]$

$$z_i = z'_i \oplus \left(\phi(P_{\mathrm{F}}^{B_1})\right)_i \oplus (\phi(P_{\mathrm{F}}^{B_2}))_i, \tag{148}$$

and

$$x_i = x'_i \oplus \left(\phi(P_{\mathrm{F}}^{B_1})\right)_{i+N} \oplus \left(\phi(P_{\mathrm{F}}^{B_2})\right)_{i+N} . \tag{149}$$

Using $O(N)$ parallel processes, this additional computation can be performed within runtime $O(1)$.

The width of the quantum part in the gadget is bounded by

$$O(N), \tag{150}$$

and the depth of the quantum part is bounded by

$$O(1). \tag{151}$$

The same analysis as in the Z-measurements gadget bounds the runtime of the classical part of the Bell-measurement gadget as

$$O(\log N). \tag{152}$$

From the transversality and constant depth of the quantum part in the gadget, the gadget satisfies the fault-tolerance conditions in Def. (13).

3. *CNOT-gate operation gadget*

The CNOT-gate gadget is designed to perform the logical CNOT gate between logical qubits in different code blocks B_1, B_2. The construction of the gadget is shown in Fig. 7. The gadget is implemented by transversal CNOT-gate operations of the physical operations.

For the Pauli-frame technique, we require additional classical computation for updating the physical Pauli frame. Let $P_{\mathrm{F}}^{B_1} \in \tilde{P}_N$ and $P_{\mathrm{F}}^{B_2} \in \tilde{P}_N$ be a physical Pauli frame at the final step of the previous gadget. The classical computation takes the two $2N$-bit strings as input, which represent the symplectic representation of the

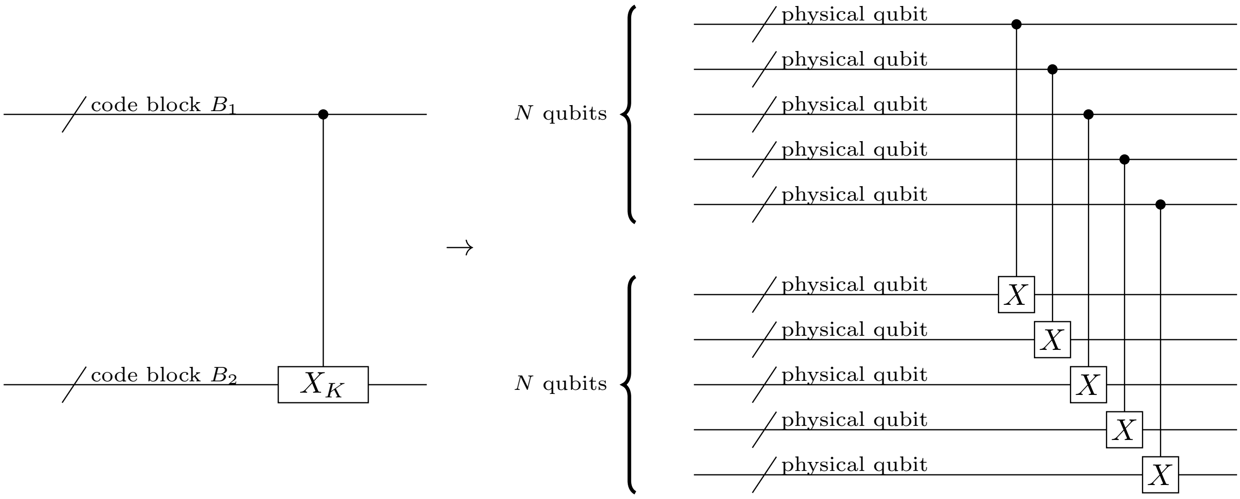

FIG. 7. The physical circuit of the gadget of the CNOT-gate operation (71).

Pauli frames, $\phi(P_{\mathrm{F}}^{B_1}) \in \mathbb{F}_2^{2N}$ and $\phi(P_{\mathrm{F}}^{B_2}) \in \mathbb{F}_2^{2N}$. The computation outputs two $2N$-bit strings representing the symplectic representation of the Pauli frames ${P'}_{\mathrm{F}}^{B_1} \in \tilde{P}_N$ and ${P'}_{\mathrm{F}}^{B_2} \in \tilde{P}_N$ at the final time step of this gadget. The updated Pauli frames can be calculated for $i \in [1, \ldots, N]$ as

$$\left(\phi\left({P'}_{\mathrm{F}}^{B_1}\right)\right)_i = \left(\phi(P_{\mathrm{F}}^{B_1})\right)_i \oplus \left(\phi(P_{\mathrm{F}}^{B_2})\right)_{i+N}, \tag{153}$$

and

$$\left(\phi\left({P'}_{\mathrm{F}}^{B_2}\right)\right)_i = \left(\phi(P_{\mathrm{F}}^{B_1})\right)_i \oplus \left(\phi(P_{\mathrm{F}}^{B_2})\right)_i. \tag{154}$$

Using $O(N)$ parallel processes, this calculation can be performed within runtime $O(1)$.

Therefore, the depth of the gadget is

$$O(1), \tag{155}$$

and the width is

$$O(N). \tag{156}$$

Due to the transversality and constant depth of the quantum part in the gadget, the gadget satisfies the fault-tolerance conditions in Def. 13.

4. $|0\rangle^{\otimes K}$-state preparation gadget

The $|0\rangle^{\otimes K}$-state preparation gadget is designed to prepare the code block initialized in the logical state $|\overline{0}\rangle^{\otimes K}$ encoded in the quantum LDPC code.

A physical circuit $\tilde{U}_{\mathrm{encode}}$ of this gadget is generated by the protocol for open circuits, as explained in Sec. III. In the gadget, the protocol simulates an original open circuit U_{encode} as shown in Fig. 8 (a) that encodes an arbitrary K-qubits state $|\psi\rangle$ into a logical state $|\overline{\psi}\rangle$ encoded in $\mathcal{Q}$ with parameters (63) as

$$U_{\mathrm{encode}}(|\psi\rangle \otimes |0\rangle^{\otimes(N-K)}) = |\overline{\psi}\rangle. \tag{157}$$

For stabilizer codes, there exists such encoding circuit U_{encode} described by a stabilizer circuit [55]. Furthermore, any n-qubit stabilizer circuit has an equivalent stabilizer circuit that has $O(n^2/\log n)$ one- or two-qubit gates and $O(n)$ depth [3, 28]. This gives the encoding circuit U_{encode} with width

$$O(N), \tag{158}$$

depth

$$O(N), \tag{159}$$

and locations

$$O(N^2/\log N). \tag{160}$$

From Theorem 6, there exists a physical circuit $\tilde{U}_{\mathrm{encode}}$ to output $|\overline{0}\rangle^{\otimes K}$ with probability at least $1-\delta$, where the data qubits of $|\overline{0}\rangle^{\otimes K}$ are subjected to the local stochastic Pauli error model with parameter at most $2Mp_{\mathrm{loc}}$ with $M = O(1)$, where M is the number of locations in the decoding interface in Sec. III B 1. Thus, the gadgets satisfy the fault-tolerance condition in Def. 12.

As a result, if we take $\delta = O(\varepsilon/\mathrm{poly}(n))$, due to (158), (159), and $|U_{\mathrm{encode}}| = O(N^2/\log N)$ in (160), both the width and the depth of the physical circuit $\tilde{U}_{\mathrm{encode}}$ are bounded by

$$O\left(N\mathrm{polylog}\left(\frac{|U_{\mathrm{encode}}|}{\delta}\right)\right) = O\left(N\mathrm{polylog}\left(\frac{n}{\varepsilon}\right)\right), \tag{161}$$

where ε is the target error probability of the protocol based on the quantum LDPC code.

5. Clifford-state preparation gadget

The Clifford-state preparation gadgets are designed to prepare the four code blocks B_1, B_2, B_3, and B_4 initialized in the logical state $\left|\overline{\Psi_{U_C}}\right\rangle^{B_1B_2B_3B_4}$ of $\mathcal{Q}$, where

$$|\Psi_{U_C}\rangle^{A_1A_2A_3A_4} = (I^{A_1A_2} \otimes U_C^{A_3A_4})(|\Phi\rangle^{A_1A_3} \otimes |\Phi\rangle^{A_2A_4}). \tag{162}$$

Here, $|\Phi\rangle^{A_iA_{i'}}$ is a maximally entangled state between the registers A_i and $A_{i'}$ as

$$|\Phi\rangle^{A_iA_{i'}} = \frac{1}{\sqrt{2^K}} \sum_{m=0}^{2^K-1} |m\rangle^{A_i} \otimes |m\rangle^{A_{i'}}. \tag{163}$$

A physical circuit $\tilde{V}$ of this gadget is also generated by the protocol for open circuits, as explained in Sec. III. The protocol simulates the ideal open circuit V as shown in Fig. 8 (b) that consists of a circuit to generate the state $|\Psi_{U_C}\rangle$, followed by the parallel use of encoding circuits U_{encode} as in (157) for preparing $\left|\overline{\Psi_{U_C}}\right\rangle$. Since the original circuit V consists of the Clifford gates, V has an equivalent stabilizer circuit [3, 28] with width

$$O(N), \tag{164}$$

depth

$$O(N), \tag{165}$$

and locations

$$O(N^2/\log N). \tag{166}$$

From Theorem 6, there exists a physical circuit $\tilde{V}$ outputting $\left|\overline{\Psi_{U_C}}\right\rangle^{B_1B_2B_3B_4}$ with probability at least $1-\delta$, where the data qubits are subjected to the local stochastic Pauli error model with the parameter at most $2Mp_{\mathrm{loc}}$ with $M = O(1)$. Therefore, the gadgets satisfy the fault-tolerance condition in Def. 12.

As a result, if we take $\delta = O(\varepsilon/\mathrm{poly}(n))$, due to (164), (165), and $|V| = O(N^2/\log N)$ in (166), both the width and the depth of the physical circuit $\tilde{V}$ are bounded by

$$O\left(N\mathrm{polylog}\left(\frac{|V|}{\delta}\right)\right) = O\left(N\mathrm{polylog}\left(\frac{n}{\varepsilon}\right)\right), \tag{167}$$

where ε is the target error probability of the protocol based on the quantum LDPC code.

6. Magic-state preparation gadget

The magic-state preparation gadgets are designed to prepare the code block initialized in the logical state $\left|\overline{\Psi_{U_{TH}}}\right\rangle$ of $\mathcal{Q}$, where

$$|\Psi_{U_{TH}}\rangle = U_{TH}\,|0\rangle^{\otimes K}. \tag{168}$$

Here, U_{TH} is the tensor product of TH gate or the I gate, where TH is applied to the logical qubits to which T gate or $T^\dagger$ gate will be applied using the U_T-gate abbreviation explained in Sec. IV B 2.

A physical circuit $\tilde{W}$ of this gadget is also generated by the protocol for open circuits, as explained in Sec. III. The protocol simulates the ideal open circuit W as shown in Fig. 8 (c) that consists of a circuit to generate the state $|\Psi_{U_{TH}}\rangle$, followed by the encoding circuit U_{encode} for creating the encoded state $\left|\overline{\Psi_{U_{TH}}}\right\rangle$.

Since the original circuit W consists of constant-depth gates TH, followed by Clifford gates U_{encode}, W has width

$$O(N), \tag{169}$$

depth

$$O(N), \tag{170}$$

and locations

$$O(N^2/\log N). \tag{171}$$

From Theorem 6, there exists a physical circuit $\tilde{W}$ outputting $\left|\overline{\Psi_{U_{TH}}}\right\rangle$ with probability at least $1-\delta$, where the data qubits are subjected to the local stochastic Pauli error model with parameter at most $2Mp_{\mathrm{loc}}$ with $M = O(1)$. Thus, the gadgets satisfy the fault-tolerance condition in Def. 12.

As a result, if we take $\delta = O(\varepsilon/\mathrm{poly}(n))$, due to (169), (170), and $|W| = O(N^2/\log N)$ in (171), both the width and the depth of the physical circuit $\tilde{W}$ are bounded by

$$O\left(N\mathrm{polylog}\left(\frac{|W|}{\delta}\right)\right) = O\left(N\mathrm{polylog}\left(\frac{n}{\varepsilon}\right)\right), \tag{172}$$

where ε is the target error probability of the protocol based on the quantum LDPC code.

7. Error-correction gadget

An EC gadget is designed to keep residual errors in the code block small using the decoding algorithm in Def. 10. For each code block, $N - K = O(N)$ auxiliary physical qubits are used to perform the syndrome measurement. Each auxiliary physical qubit is assigned to a corresponding stabilizer generator. We perform the circuit as shown in Fig. 9 to measure a specific stabilizer generator and obtain the syndrome bits,

$$\tilde{\sigma} = (\tilde{\sigma}_X, \tilde{\sigma}_Z) \in \mathbb{F}_2^{N-K}, \tag{173}$$

as in (114).

The measurements of all generators make up the syndrome measurement circuit of the EC gadget as shown in Fig. 10. Note that Ref. [21] uses Shor's error correction [56], which utilizes a cat state consisting of multiple qubits for each stabilizer generator, where the number

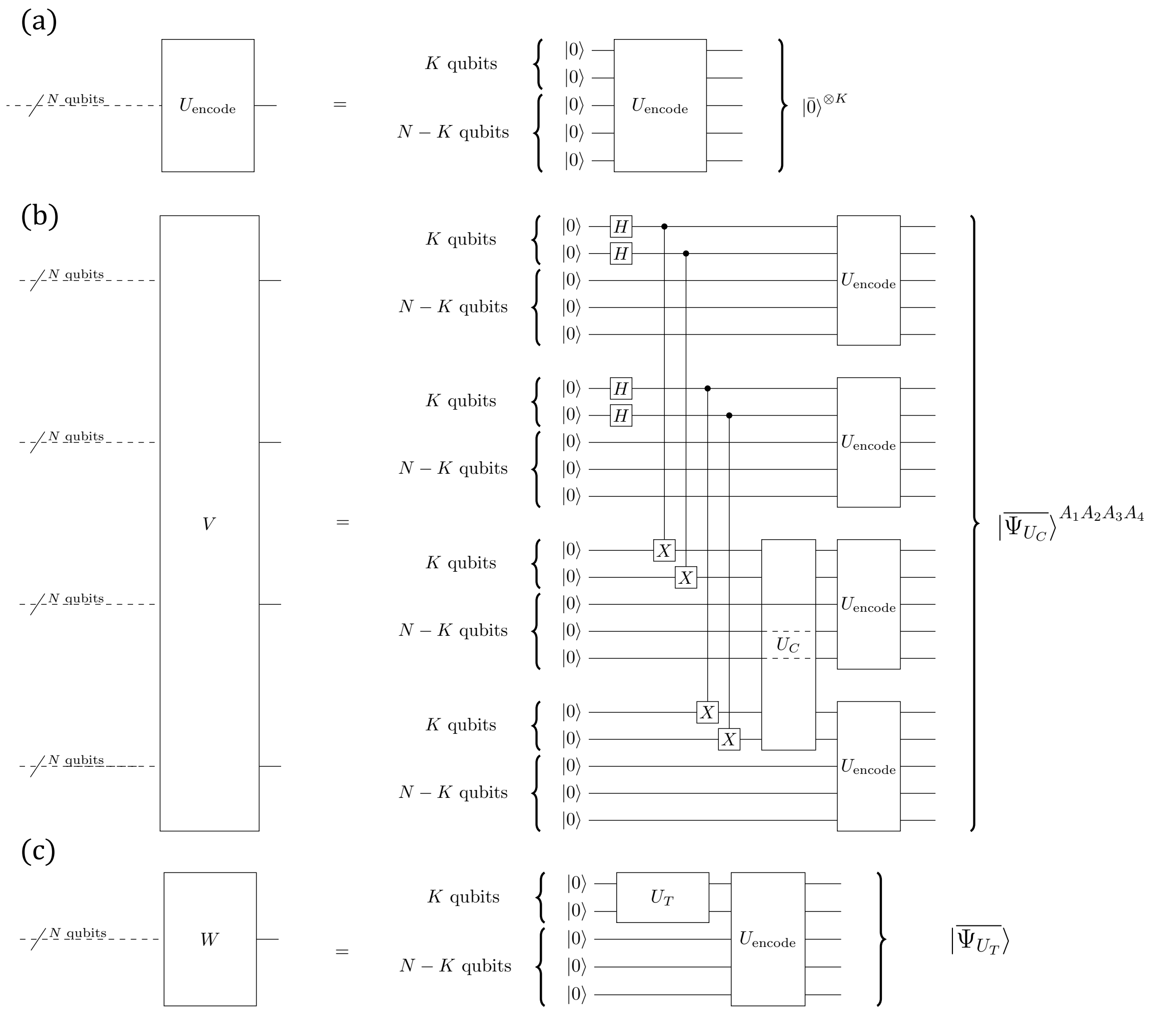

FIG. 8. (a) An original open circuit U_{encode} to create an encoded state of $|0\rangle^{\otimes K}$, (b) an original open circuit V to create an encoded state of $|\Psi_{U_C}\rangle$ and (c) an original open circuit W to create an encoded state of $|\Psi_{U_T}\rangle$. A physical circuit of the state-preparation gadgets are obtained from the protocol for simulating open circuits, as explained in Sec. III

of qubits in the cat state corresponds to the weights of the stabilizer generator. However, the EC gadgets only need to satisfy our fault-tolerance conditions in Def. 13; therefore, a single auxiliary physical qubit per stabilizer generator is sufficient. Using the noisy syndrome bits $\tilde{\sigma}$, a single-shot decoding algorithm with thresholds in Def. 10 with T internal loops deduces the recovery operation, and then the recovery operation is applied to the data qubits in the EC gadget to keep the residual error on the data qubits small. Here, we choose T to satisfy

$$c(T) > 2\Delta^{\text{synd}}, \tag{174}$$

where $c(T)$ is a monotonically increasing function, meaning that $T = O(1)$, and $\Delta^{\text{synd}} = O(1)$ is the maximum degree in (130) of the syndrome measurement circuit. The condition of (174) is required to show the existence of a threshold in our protocol, as will be explained in Lemma 16.

If we use the Pauli frame, the EC gadget consists of the syndrome measurement circuit to extract syndrome bits of unrecovered data qubits,

$$\tilde{\sigma}' = (\tilde{\sigma}'_X, \tilde{\sigma}'_Z) \in \mathbb{F}_2^{N-K}, \tag{175}$$

followed by the classical computation for modifying the syndrome bits to obtain the syndrome bits $\tilde{\sigma}$ of recovered data qubits as in (173) based on an input physical Pauli frame (more specifically, the syndrome bits that would be obtained if an ideal recovery operation would be applied to the data qubits at the next time step of a syndrome measurement circuit) and performing the decoding algorithm. During the modification of the syndrome bits and the execution of the decoding algorithm, the wait operation is performed on the data qubits. If we have a physical Pauli frame at the final time step of a previous

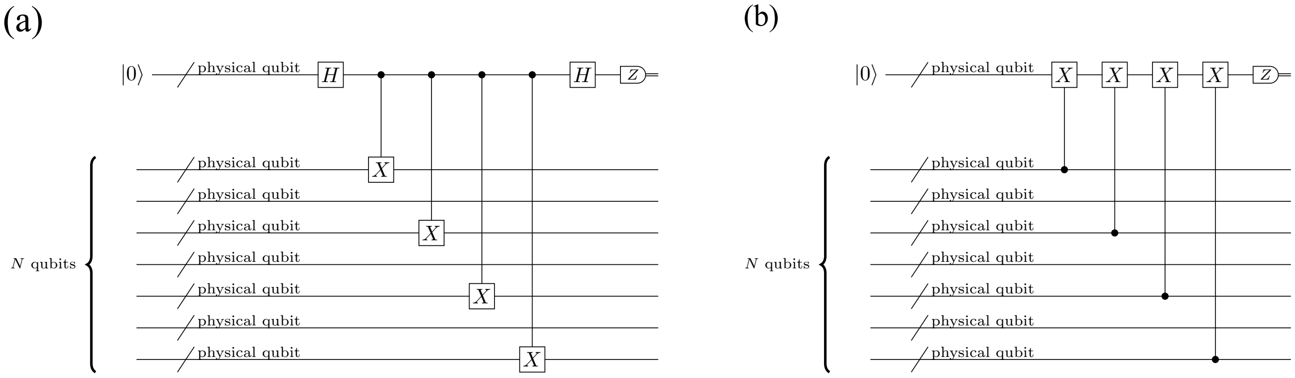

FIG. 9. The circuit for measuring the X-type stabilizer generator (a) and the Z-type stabilizer generator (b). The CNOT gate's support corresponds to the stabilizer generator's support. The syndrome measurement circuit is the circuit for measuring all stabilizer generators, each of which consists of the circuit shown in this figure.

gadget

$$P_{\mathrm{F}} \in \tilde{\mathcal{P}}_N, \tag{176}$$

we calculate the recovered syndrome bits as in (173) in the following way. First, a classical computer receives bitstrings $\tilde{\sigma}' \in \mathbb{F}_2^{N-K}$ and $\phi(P_{\mathrm{F}}) \in \mathbb{F}_2^{2N}$ as input. Considering how the physical Pauli frame P_{F} propagates through the syndrome circuit, the modification of the syndrome bits corresponding to the Z-type stabilizer generators is executed as, for $i \in [0,\ldots,M_Z-1]$,

$$(\tilde{\sigma}_X)_i = (\tilde{\sigma}'_X)_i \oplus \left(\bigoplus_{j\in\mathrm{supp}(g_i^Z)} (\phi(P_{\mathrm{F}}))_j \right), \tag{177}$$

and for the syndrome bits corresponding to the X-type stabilizer generators, that is, for $i \in [0,\ldots,M_X-1]$,

$$(\tilde{\sigma}_Z)_i = (\tilde{\sigma}'_Z)_i \oplus \left(\bigoplus_{j\in\mathrm{supp}(g_i^X)} (\phi(P_{\mathrm{F}}))_{j+N} \right). \tag{178}$$

This classical computation can be performed in runtime $O(1)$, using $O(N)$ parallel processes. Using recovered syndrome bits $\tilde{\sigma}$, a single-shot decoding algorithm with thresholds in Def. 10 with $T = O(1)$ internal loops deduces the recovery operation, and then the recovery operation $R \in \tilde{\mathcal{P}}_N$ updates the physical Pauli frame as for $i \in [1,\ldots,N]$

$$(\phi(P'_{\mathrm{F}}))_i = (\phi(R))_i \oplus (\phi(P_{\mathrm{F}}))_i\,. \tag{179}$$

The update of the physical Pauli frame can be performed in runtime $O(1)$ with $O(N)$ parallel processes.

Recall that each code block is encoded with a nonvanishing-rate (r,c) quantum LDPC code. The measurements can be performed in parallel for generators that act on disjoint data qubits; thus, the depth of the quantum part of the syndrome measurement is bounded by

$$O(rc) = O(1). \tag{180}$$

In addition, the width of the quantum part of the syndrome measurement circuit is bounded by

$$O(N+M) = O(N+(N-K)) = O(N), \tag{181}$$

where $M = N-K$ is the number of auxiliary physical qubits for measuring stabilizer generators. The runtime of the classical part is bounded by

$$O(1). \tag{182}$$

Since the width of the gadget is $O(N)$, even if the gadgets are executed for all code blocks simultaneously, it does not pose an obstacle in constructing the constant-space overhead fault-tolerant protocol. Even if the classical part of the gadget is included, the EC gadget is fault-tolerant in the sense of Def. 13 because the depth of the gadget is constant. From the property of quantum LDPC codes and the constant depth of the quantum part in the gadget, the EC gadgets satisfy the fault-tolerance conditions, as shown in Def. 13.

E. Threshold theorem

In the following, we prove the threshold theorem of our protocol.

Theorem 14. *(Fault-tolerant quantum computation with polylogarithmic time and constant space overhead). Let $\{\mathrm{C}_n^{\mathrm{org}}\}$ be a sequence of original closed circuits as described in Assumption 1 specified by an integer n, and $\mathrm{C}_n^{\mathrm{org}}$ has width $W(n)$ and depth $D(n)$, where*

$$|\mathrm{C}_n^{\mathrm{org}}| = O(W(n)D(n)) = O(\mathrm{poly}(n)), \tag{183}$$

as $n\to\infty$. Suppose that we compile an original circuit $\mathrm{C}_n^{\mathrm{org}}$ into a physical circuit $\mathrm{C}_n^{\mathrm{FT}}$ that is subjected to a local stochastic Pauli error with parameter $p_{\mathrm{loc}} > 0$ as described in Sec. IV A. The gadgets are constructed as described in Sec. IV D, i.e., state-preparation, gate, and

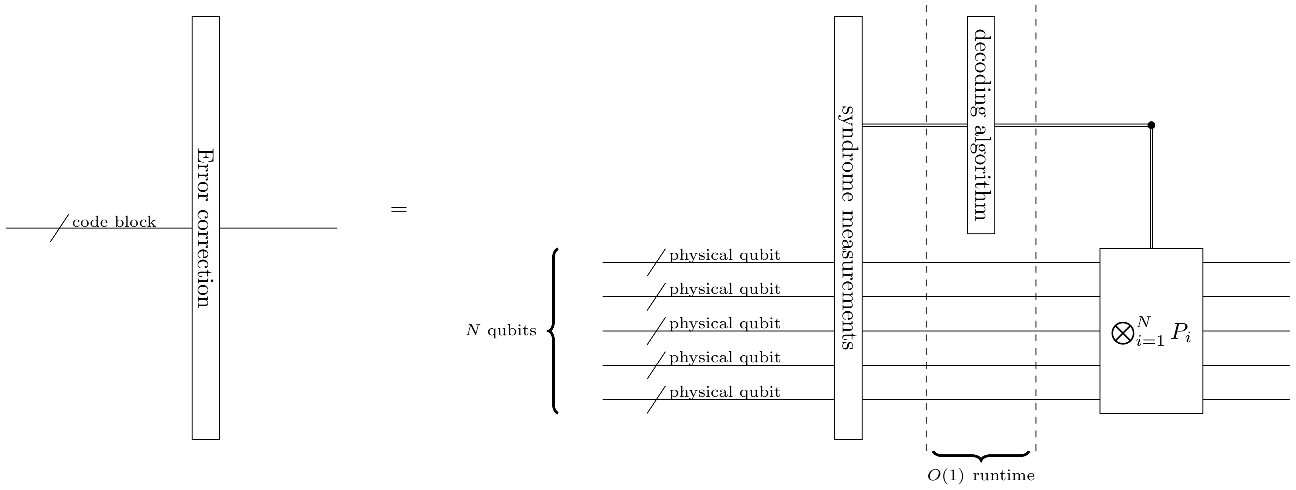

FIG. 10. A physical circuit of the EC gadget. The classical part of the gadget consists of modifying the syndrome bits based on an input Pauli frame and performing the decoding algorithm.

measurement, EC gadgets satisfy the fault-tolerance conditions in Defs. 12 and 13, where each code block is based on a non-vanishing-rate quantum CSS LDPC code

$$\mathcal{Q} \tag{184}$$

with parameters

$$[[N, K = \Theta(N), D = \Theta(N^{\gamma})]] \tag{185}$$

satisfying Assumption 4, i.e., a single-shot decoding algorithm for reducing errors in Def. 10 has a threshold $p_{\mathrm{dec}}^{\mathrm{th}} > 0$ *and a decoding algorithm for correcting errors in Def. 11 has threshold* $p'^{\mathrm{th}}_{\mathrm{dec}} > 0$.

Let $p_{\mathrm{loc}}^{\mathrm{th}} > 0$ *be a threshold of the concatenated-code protocol to simulate open circuits as explained in Sec. III B. Then, for all* $\varepsilon > 0$*, there exists a threshold* $q_{\mathrm{loc}}^{\mathrm{th}} > 0$ *and if* $0 \leq p_{\mathrm{loc}} < \min\{q_{\mathrm{loc}}^{\mathrm{th}}, p_{\mathrm{loc}}^{\mathrm{th}}/2\}$*, the following statement holds: there exists a sequence of physical circuits* $\{\mathrm{C}_n^{\mathrm{FT}}\}$*, where* $\mathrm{C}_n^{\mathrm{FT}}$ *has width* $W_{\mathrm{FT}}(n)$ *and depth* $D_{\mathrm{FT}}(n)$ *such that*

$$\begin{aligned} \frac{W_{\mathrm{FT}}(n)}{W(n)} &= O(1), \\ \frac{D_{\mathrm{FT}}(n)}{D(n)} &= O\left(\mathrm{polylog}\left(\frac{n}{\varepsilon}\right)\right), \end{aligned} \tag{186}$$

as $n \to \infty$*, and* $\mathrm{C}_n^{\mathrm{FT}}$ *outputs the probability distribution that is close to that of* $\mathrm{C}_n^{\mathrm{org}}$ *with total variation distance at most* ε.

In the following, we will show that there exists a threshold based on the fault-tolerant construction of the gadgets presented in Sec. IV D. Next, we will show that our protocol achieves a constant space overhead and a polylogarithmic time overhead.

First, we fix the parameters of the protocol. We choose the number of physical qubits N of $\mathcal{Q}$ in (184) as

$$N = \Theta\left(\log^{\alpha}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right), \tag{187}$$

where $\alpha > 1/\gamma$ is a constant, the number of registers κ as

$$\kappa(n) \coloneqq \frac{W(n)}{K} = \Theta\left(\frac{W(n)}{\log^{\alpha}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)}\right). \tag{188}$$

Let $\delta > 0$ be the failure probability of a state-preparation gadget, and we choose the probability as

$$\delta = O\left(\frac{\varepsilon}{|\mathrm{C}_n^{\mathrm{org}}|^2}\right). \tag{189}$$

We consider a sequence of original open circuits $\{\mathrm{C}_N^{\mathrm{prep}}\}$ to prepare $|0\rangle^{\otimes K}$, Clifford, and magic states encoded in $\mathcal{Q}$ in (184), as explained in Secs. IV D 4, IV D 5, and IV D 6, respectively. Here, N corresponds to the number of physical qubits in (187), and $\mathrm{C}_N^{\mathrm{prep}}$ has width

$$W_{\mathrm{prep}}(N) = O(N) \tag{190}$$

as in (158), (164), and (169), depth

$$D_{\mathrm{prep}}(N) = O(N) \tag{191}$$

as in (159), (165), (170), and locations

$$|\mathrm{C}_N^{\mathrm{prep}}| = O(N^2/\log N) \tag{192}$$

as in (160), (166), (171). From Theorem 6, we have a corresponding sequence of physical circuits $\{\tilde{\mathrm{C}}_N^{\mathrm{prep}}\}$ with

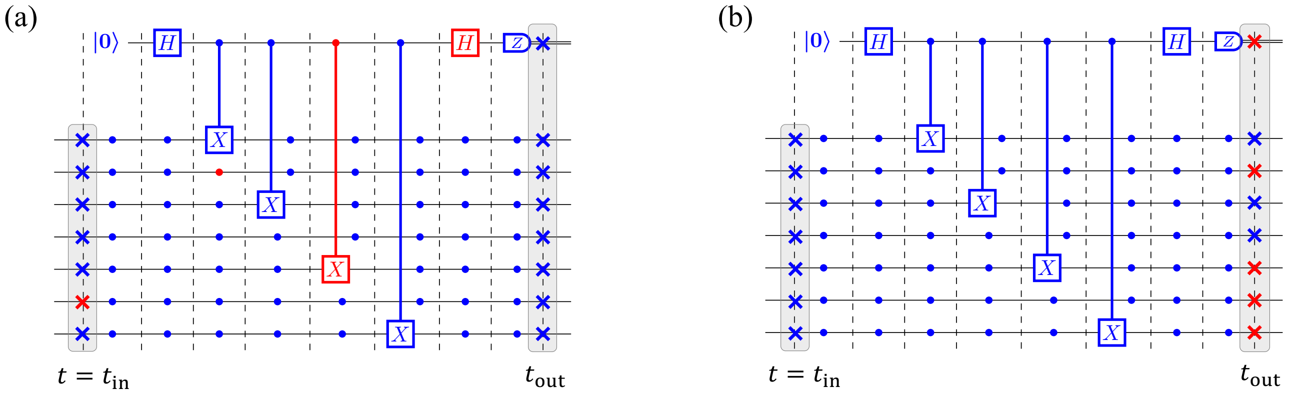

FIG. 11. A set of input wires, X_{in}, at time step $t = t_{\text{in}}$ and output wires, X_{out}, at time step $t = t_{\text{out}}$, along with a set of locations L of a physical circuit for measuring X-type stabilizer generators, as shown in Fig. 9. (a) Each cross represents a wire in X_{in} or X_{out}, where a red cross indicates an erroneous wire, and each operation (with a wait operation represented by a circle) represents a location in L, where a red operation indicates a faulty location. (b) A possible equivalent non-faulty circuit can be obtained by propagating Pauli errors that occurred in the erroneous wires at $t = t_{\text{in}}$ and Pauli errors that occurred due to the faulty locations in (a), where these errors result in erroneous wires that correspond to the red crosses at $t = t_{\text{out}}$.

width $\tilde{W}_{\text{prep}}(N)$ and depth $\tilde{D}_{\text{prep}}(N)$. The prepared states are subjected to the local stochastic Pauli error with parameter

$$\tilde{p} \leq M' p_{\text{loc}}, \tag{193}$$

where M' is defined as

$$M' := 2M, \tag{194}$$

and M is a constant representing the number of locations in the decoding interface as explained in Sec. III B 1. Moreover, the width of the physical circuits satisfies

$$\frac{\tilde{W}_{\text{prep}}(N)}{W_{\text{prep}}(N)} = O\left(\log^{\gamma_1}\left(\frac{|\mathrm{C}_N^{\text{prep}}|}{\delta}\right)\right) \tag{195}$$

$$= O\left(\log^{\gamma_1}\left(\frac{|\mathrm{C}_n^{\text{org}}|}{\varepsilon}\right)\right), \tag{196}$$

where we use (187), (192), and (189), and $\gamma_1 > 0$ is a constant. Similarly, the depth of the physical circuits satisfies

$$\frac{\tilde{D}_{\text{prep}}(N)}{D_{\text{prep}}(N)} = O\left(\log^{\gamma_2}\left(\frac{|\mathrm{C}_N^{\text{prep}}|}{\delta}\right)\right) \tag{197}$$

$$= O\left(\log^{\gamma_2}\left(\frac{|\mathrm{C}_n^{\text{org}}|}{\varepsilon}\right)\right), \tag{198}$$

where $\gamma_2 > 0$ is a constant. Then, we choose the number of non-trivial intermediate operations $L(n)$ in (85) that we apply in a one-depth part of an intermediate circuit as

$$L(n) = \Theta\left(\frac{W(n)}{\log^{\alpha+\gamma_1}\left(\frac{|\mathrm{C}_n^{\text{org}}|}{\varepsilon}\right)}\right). \tag{199}$$

We begin with obtaining a bound on the error parameter on output wires of a faulty physical circuit C. Let

$$X_{\text{in}} \tag{200}$$

be a set of input wires at the first step of C,

$$X_{\text{out}} \tag{201}$$

be a set of output wires at the final step of C, and

$$L \tag{202}$$

be a set of locations in C as shown in Fig. 11. As stated in Lemma 15, the output wires X_{out} in (201) undergo the local stochastic Pauli error model if the locations L in (202) and the input wires X_{in} in (200) also undergo the local stochastic Pauli error model. The lemma provides an upper bound on the error parameter p'_{wire} of the output wires, given the error parameters p_{wire} and p_{loc} of X_{in} and C, respectively. This bound is obtained by considering possible configurations of erroneous input wires in X_{in} and faulty locations in L that can produce erroneous wires in X_{out}. For simplicity, we denote the union of X_{in} and L by

$$\tilde{L} := X_{\text{in}} \cup L. \tag{203}$$

In addition, for a given set $U \subseteq X_{\text{out}}$,

$$A(U) \subseteq \tilde{L} \tag{204}$$

denotes the set of locations or wires of input wires that are connected to at least one wire in U. Similarly, for a given set $\tilde{R} \subseteq \tilde{L}$,

$$B(\tilde{R}) \subseteq X_{\text{out}} \tag{205}$$

denotes a set of wires that connect to at least one location or one input wire in $\tilde{R}$.

Lemma 15. *Suppose we have a physical stabilizer circuit* C *that undergoes the local stochastic Pauli error model with parameter p_{loc}, and input wires X_{in} in* (200) *and output wires X_{out} in* (201) *of* C *that undergo to the local stochastic Pauli error model with parameter p_{wire} and p'_{wire}, respectively. Let G be a bipartite graph of* C *as in* (130)*, where Δ be the maximum degree of a vertex of G and d be the depth of* C*.*

Then, output wires X_{out} undergo the local stochastic Pauli error model with parameter p'_{wire} satisfying

$$p'_{\text{wire}} \leq \frac{2^{d\Delta} q^{1/\Delta}}{1-q}, \tag{206}$$

where $q \coloneqq \max\{p_{\text{wire}}, p_{\text{loc}}\}$.

Proof. For any $U \subseteq X_{\text{out}}$ and $\tilde{R} \subseteq \tilde{L}$, we have

$$|A(U)| \leq d\Delta|U|, \quad |B(\tilde{R})| \leq \Delta|\tilde{R}|. \tag{207}$$

Given a set of the union of erroneous input data qubits and faulty locations, denoted by $\tilde{F} \subseteq \tilde{L}$, the set of erroneous wires $H \subseteq X$ satisfies $H = B(\tilde{F})$. Then, we have

$$\begin{aligned}\mathbb{P}[H \supseteq U] \leq& \mathbb{P}\left[\exists \tilde{R} \subseteq A(U) \colon \tilde{F} \supseteq \tilde{R}, B(\tilde{R}) = U\right] \\ \leq& \sum_{r \geq |U|/\Delta} \left[\sum_{\tilde{R} \subseteq A(U) \colon |\tilde{R}| = r} \mathbb{P}[\tilde{F} \supseteq \tilde{R}]\right] \\ \leq& \sum_{r \geq |U|/\Delta} \binom{|A(U)|}{r} q^r.\end{aligned}$$

Using the upper bound for the binomial coefficient

$$\binom{|A(U)|}{r} \leq 2^{|A(U)|}, \tag{208}$$

and $|A(U)| \leq d\Delta|U|$, we have

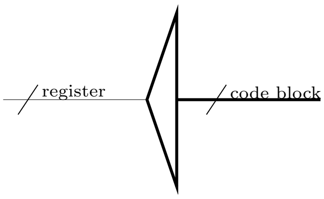
$$\begin{aligned}\mathbb{P}[H \supseteq U] \leq& 2^{d\Delta|U|} \sum_{r \geq |U|/\Delta} q^r \\ \leq& \left(\frac{2^{d\Delta} q^{1/\Delta}}{1-q}\right)^{|U|}.\end{aligned}$$

Moreover, since a physical circuit C is a stabilizer circuit, there exists a Pauli operator that represents errors on the set of fautly wires H. Therefore, the set of wires is subjected to the local stochastic Pauli error model on wires with parameter

$$p_{\text{wire}} \leq \frac{2^{d\Delta} q^{1/\Delta}}{1-q}. \tag{209}$$

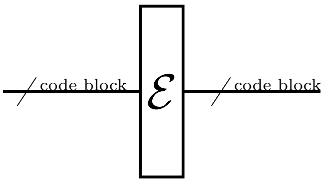
□

Next, we show that there exists a positive threshold value with respect to p_{loc}, and if p_{loc} is below the threshold, we can probabilistically transform a gadget with trailing EC gadget(s) into the corresponding elementary operation. When p_{loc} is sufficiently low, due to the fault-tolerance conditions in Defs. 12 and 13 and Lemma 15, propagation of errors between EC gadgets is suppressed, allowing EC gadgets to keep the error rate low in the code blocks. The transformations are described by the following diagrams. Let



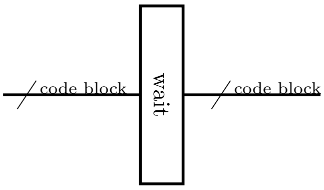
(210)

be an ideal encoder from K qubits in a register to K logical qubits of a code block $\mathcal{Q}$,



(211)

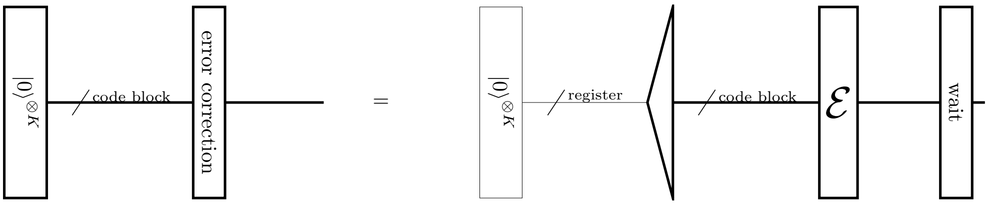
be a local stochastic Pauli noise $\mathcal{E}$, which is a CPTP map, acting on data qubits, and



(212)

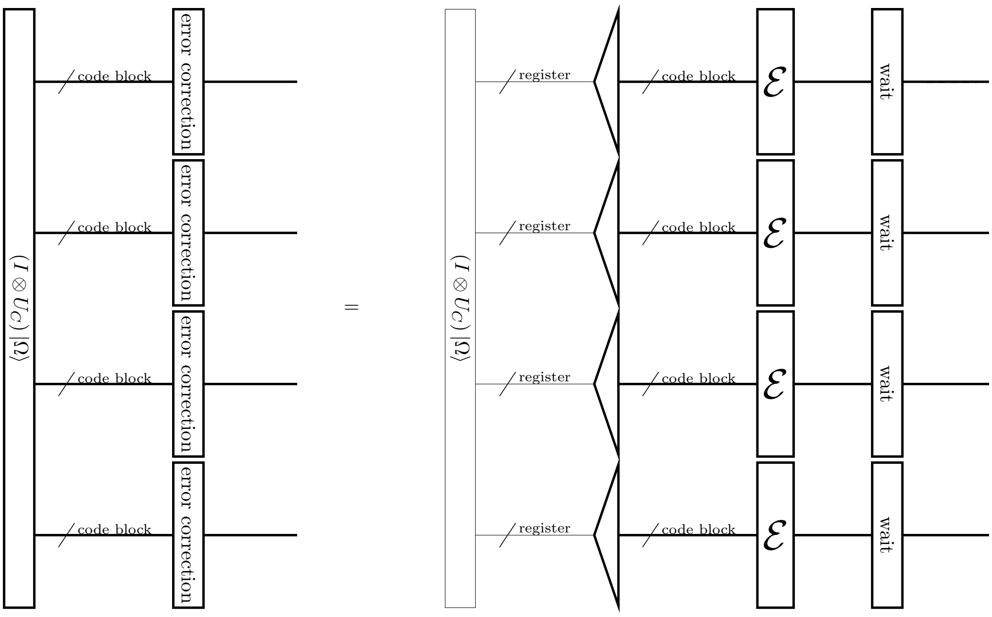
be a wait operation during performing classical computation in an EC gadget. Here, the box surrounded by a bold line represents a gadget. Then, each gadget can be transformed as follows.

1. state-preparation gadgets
   - $|0\rangle^{\otimes K}$-state preparation gadget



, (213)

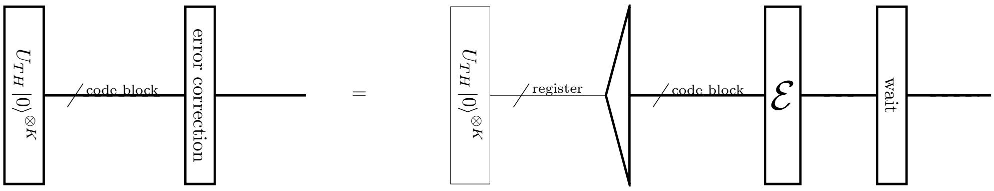
- Clifford-state preparation gadgets



$(I \otimes U_C)\,|\Omega\rangle$
code block
error correction
=
$(I \otimes U_C)\,|\Omega\rangle$
register
code block
$\mathcal{E}$
wait

, (214)

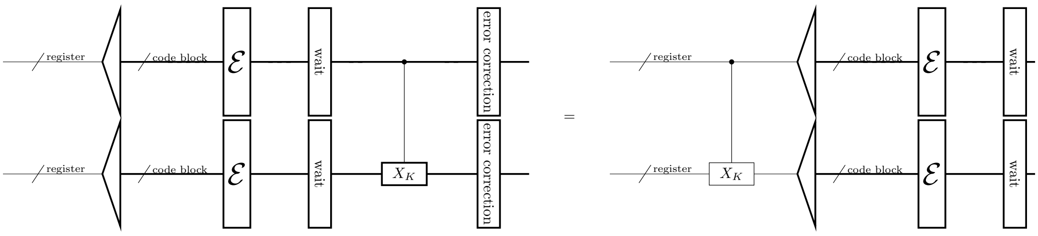
- magic-state preparation gadgets



$U_{TH}\,|0\rangle^{\otimes K}$
code block
error correction
=
$U_{TH}\,|0\rangle^{\otimes K}$
register
code block
$\mathcal{E}$
wait

, (215)

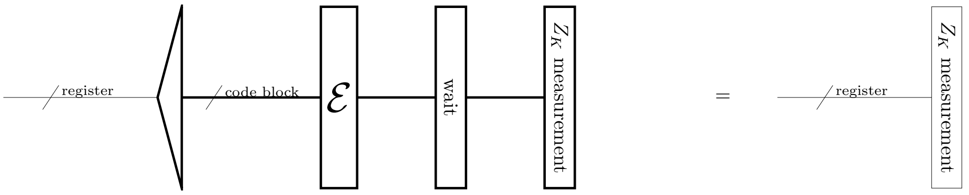
2. gate gadget
   - CNOT-gate gadget



, (216)

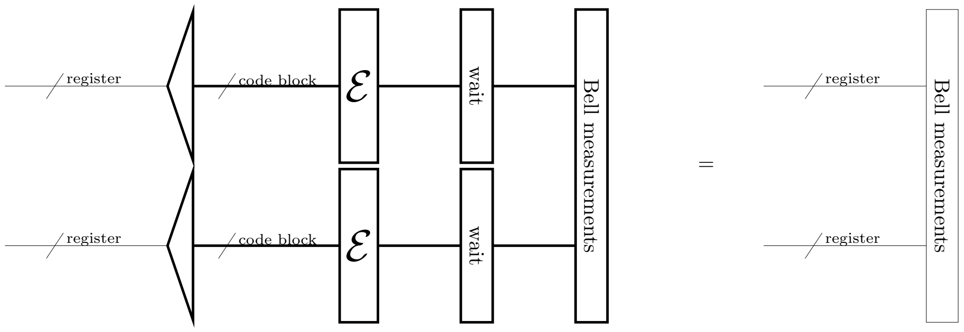
3. measurement gadgets

- Z_K-measurement gadget



, (217)

- Bell-measurement gadget



. (218)

From Lemma 16, we can probabilistically transform a sequence of gadgets into a corresponding sequence of elementary operations from the state-preparation gadgets to the measurement gadgets as in (213), (214), (215), (216), (217), and (218) by pushing the ideal encoder (210) forward.

Lemma 16. *Suppose that we have a physical circuit* C *that undergoes the local stochastic Pauli error model with parameter* p_{loc}*, and we have a single-shot decoding algorithm for reducing errors in Def. 10 with threshold* $p_{\mathrm{dec}}^{\mathrm{th}} > 0$ *and a decoding algorithm for correcting errors in Def. 11 with threshold* ${p'}_{\mathrm{dec}}^{\mathrm{th}} > 0$*. We have a sequence of gadgets, starting with the state-preparation gadgets and ending with the measurement gadgets, with the EC gadget inserted between each gadget. Suppose the state-preparation, gate, measurement, and EC gadgets satisfy the fault-tolerance conditions in Defs. 12 and 13.*

Then, there exists a threshold $q_{\mathrm{loc}}^{\mathrm{th}} > 0$*, and if* $p_{\mathrm{loc}} < \min\{q_{\mathrm{loc}}^{\mathrm{th}}, p_{\mathrm{loc}}^{\mathrm{th}}/2\}$*, each gadget with trailing EC gadget(s) can be transformed into the corresponding elementary operation as in (213), (214), (215), (216), (217), and (218) with probability at least*

$$1 - \Omega(\varepsilon / |\mathrm{C}_n^{\mathrm{org}}|^2). \tag{219}$$

Moreover, the parameter of the local stochastic Pauli noise $\mathcal{E}$ *in (213), (214), (215), (216), (217), and (218) is bounded by*

$$p_{\mathrm{data}} \leq M' p_{\mathrm{loc}}, \tag{220}$$

where $M' \coloneqq 2M$ *in (194).*

Proof. Let $\mathrm{C}^{\mathrm{synd}}$ be the syndrome measurement circuit in the EC gadget with a maximum degree $\Delta^{\mathrm{synd}} = O(1)$ and depth $d^{\mathrm{synd}} = O(1)$, and $\mathrm{C}^{\mathrm{wait}}$ be a circuit of wait operations for classical computation in the EC gadget with a maximum degree $\Delta^{\mathrm{wait}} = 1$ and depth $d^{\mathrm{wait}} = T = O(1)$ as in Def. 13.

First, we consider the transformation of state-preparation gadgets, i.e., the $|0\rangle^{\otimes K}$-state preparation (213), the Clifford-state preparation gadgets (214) and the magic-state preparation gadgets (215). From Theorem 6, the data qubits at the final step of the state-preparation gadgets are subjected to the local Pauli stochastic error model with parameter $p_{\mathrm{data}} \leq M' p_{\mathrm{loc}}$. By applying Lemma 15 to $\mathrm{C}^{\mathrm{synd}}$, the wires at the final step of $\mathrm{C}^{\mathrm{synd}}$ are subjected to the local stochastic Pauli error model with parameter

$$p_{\mathrm{wire}} \leq \frac{2^{d^{\mathrm{synd}} \Delta^{\mathrm{synd}}} (M' p_{\mathrm{loc}})^{1/\Delta^{\mathrm{synd}}}}{1 - M' p_{\mathrm{loc}}}. \tag{221}$$

Since the function $f(x) = x/(1-x)$ for $x \in [0,1)$ is monotonically increasing, by lowering p_{loc}, we have p_{loc} such that

$$\frac{2^{c_1^{\mathrm{synd}}} (M' p_{\mathrm{loc}})^{1/\Delta^{\mathrm{synd}}}}{1 - M' p_{\mathrm{loc}}} < p_{\mathrm{dec}}^{\mathrm{th}}. \tag{222}$$

With p_{loc} satisfying (222), due to (126), a residual error is applied after a recovery operation to data qubits that are subjected to the local stochastic Pauli error model with parameter

$$p_{\mathrm{data}} \leq \left(\frac{2^{d^{\mathrm{synd}} \Delta^{\mathrm{synd}}} (M' p_{\mathrm{loc}})^{1/\Delta^{\mathrm{synd}}}}{1 - M' p_{\mathrm{loc}}} \right)^{c(T)}, \tag{223}$$

where $c(T)$ is an error suppression parameter of a decoding algorithm (126), and $T = O(1)$ is the number of iterations of the decoding algorithm, determined by (174). Under this choice, there is a positive value of p_{loc} that satisfies

$$p_{\mathrm{data}} \leq \left(\frac{2^{d^{\mathrm{synd}} \Delta^{\mathrm{synd}}} (M' p_{\mathrm{loc}})^{1/\Delta^{\mathrm{synd}}}}{1 - M' p_{\mathrm{loc}}} \right)^{c(T)} \leq M' p_{\mathrm{loc}}, \tag{224}$$

and after the ideal encoding circuit is moved to the final step of the trailing syndrome measurement circuit using the Pauli frame, the parameter of the residual Pauli noise $\mathcal{E}$ can be bounded by

$$M' p_{\mathrm{loc}}. \tag{225}$$

Due to the union bound taking into account the failure probability of the single-shot decoding algorithm for reducing errors in Def. 10 and the failure probability of a state-preparation gadget in Def. 12, this transformation fails with probability at most

$$\begin{aligned} \exp(-\Omega(D)) + \delta &= \exp(-\Omega(N^{\gamma})) + \delta \\ &= O\left(\frac{\varepsilon}{|\mathrm{C}_n^{\mathrm{org}}|^2} \right), \end{aligned} \tag{226}$$

where we use (187) and (189).

Next, we consider the transformation of the gate gadget, i.e., the CNOT-gate gadget (216). Here, we consider a circuit $\mathrm{C}^{\mathrm{CNOT}}$ of the CNOT-gate gadget with a maximum degree $\Delta^{\mathrm{CNOT}} = 2$ and depth $d^{\mathrm{CNOT}} = O(1)$. Then, by applying Lemma 15 to a sequence of $\mathrm{C}^{\mathrm{wait}}$, $\mathrm{C}^{\mathrm{CNOT}}$ and $\mathrm{C}^{\mathrm{synd}}$, the parameters of the wire in the final step of the syndrome measurement circuit are suppressed, taking into account the wait operation during the classical part of the previous EC gadget as

$$p_{\mathrm{wire}} \leq \frac{2^{(d^{\mathrm{synd}} \Delta^{\mathrm{synd}} + d^{\mathrm{CNOT}} \Delta^{\mathrm{synd}} + \Delta^{\mathrm{CNOT}} \Delta^{\mathrm{synd}} T)} (M' p_{\mathrm{loc}})^{1/(\Delta^{\mathrm{CNOT}} \Delta^{\mathrm{synd}})}}{1 - M' p_{\mathrm{loc}}} =: p_{\mathrm{wire}}^{\mathrm{CNOT}}. \tag{227}$$

If we have p_{loc} such that

$$p_{\mathrm{wire}} \leq p_{\mathrm{wire}}^{\mathrm{CNOT}} \leq p_{\mathrm{dec}}^{\mathrm{th}}, \tag{228}$$

then, since we choose T such that $c(T) > 2\Delta^{\mathrm{synd}}$ as in (174), there is a positive value of p_{loc} satisfying

$$p_{\mathrm{data}} \leq \left(p_{\mathrm{wire}}^{\mathrm{CNOT}} \right)^{c(T)} \leq M' p_{\mathrm{loc}}, \tag{229}$$

after the ideal encoding circuit is moved to the final step of the syndrome measurement circuit, we can again bound p_{data} at the final step of the syndrome measurement circuit as

$$p_{\mathrm{data}} \leq M' p_{\mathrm{loc}}. \tag{230}$$

Under the condition that the previous decoding algorithm succeeds, the single-shot decoding algorithm for reducing errors in Def. 10 fails with probability at most

$$\exp(-\Omega(D)) = O\left(\frac{\varepsilon}{|\mathrm{C}_n^{\mathrm{org}}|^2} \right), \tag{231}$$

where we use (185).

Finally, we consider the transformation of the measurement gadgets, i.e., the Z_K-measurement gadget (217) and the Bell-measurement gadget (218). Here, we consider a circuit C^{Z_K} of the Z_K-measurement gadget with a maximum degree $\Delta^{Z_K} = 1$ and depth $d^{Z_K} = O(1)$ and a circuit $\mathrm{C}^{\mathrm{Bell}}$ of the Bell-measurement gadget with a maximum degree $\Delta^{\mathrm{Bell}} = 2$ and depth $d^{\mathrm{Bell}} = O(1)$. By applying Lemma 15 to C^{Z_K}, the parameter of the local stochastic Pauli error at the final time of the quantum part is bounded by

$$p_{\mathrm{data}} \leq \frac{2^{(d^{Z_K} \Delta^{Z_K} + d^{\mathrm{wait}} \Delta^{Z_K})} (M' p_{\mathrm{loc}})^{1/\Delta^{Z_K}}}{1 - M' p_{\mathrm{loc}}} =: p_{\mathrm{wire}}^{Z_K}. \tag{232}$$

If we have p_{loc} such that

$$p_{\mathrm{data}} \leq p_{\mathrm{wire}}^{Z_K} \leq p'^{\mathrm{th}}_{\mathrm{dec}}, \tag{233}$$

then the decoding algorithm in Def. 11 fails to return the measurement results of the logical operators with probability at most

$$\exp(-\Omega(D)) = O\left(\frac{\varepsilon}{|\mathrm{C}_n^{\mathrm{org}}|^2} \right), \tag{234}$$

where we use (185). For the Bell-measurement gadget $\mathrm{C}^{\mathrm{Bell}}$, by applying Lemma 15, the parameter of the local stochastic Pauli error at the final time is bounded by

$$p_{\mathrm{data}} \leq \frac{2^{(d^{\mathrm{Bell}} \Delta^{\mathrm{Bell}} + d^{\mathrm{wait}} \Delta^{\mathrm{Bell}})} (M' p_{\mathrm{loc}})^{1/\Delta^{\mathrm{Bell}}}}{1 - M' p_{\mathrm{loc}}} =: p_{\mathrm{loc}}^{\mathrm{Bell}}. \tag{235}$$

If we have p_{loc} such that

$$p_{\mathrm{data}} \leq p_{\mathrm{loc}}^{\mathrm{Bell}} \leq p'^{\mathrm{th}}_{\mathrm{dec}}, \tag{236}$$

then the decoding algorithm in Def. 11 fails to return the measurement results of the logical operators with probability at most

$$\exp(-\Omega(D)) = O\left(\frac{\varepsilon}{|\mathrm{C}_n^{\mathrm{org}}|^2}\right), \tag{237}$$

where we use (185). Therefore, (222), (224), (227), (228), (233), and (235) determine the threshold $q_{\mathrm{loc}}^{\mathrm{th}} > 0$ of the overall protocol. □

If an error parameter is below the threshold, we can transform a sequence of gadgets into a sequence of elementary operations using Lemma 16. Note that even without the Pauli frame technique, since each gadget is a stabilizer circuit, a faulty physical circuit can be transformed into a physical circuit without faulty locations where Pauli errors are applied on wires just before the Z-basis measurements in syndrome measurement circuits. Then, the above argument holds without modification.

Finally, we show that our fault-tolerant protocol can achieve an arbitrary target error $\varepsilon > 0$ with a polylogarithmic time and constant space overhead.

We begin by bounding the depth of the physical circuit $\mathrm{C}_n^{\mathrm{FT}}$ compiled from $\mathrm{C}_n^{\mathrm{org}}$. We replace the operations in the original circuit with the intermediate operations for each one-depth part of the original circuit. For the Clifford layer, a single use of the two-register Clifford-gate abbreviation allows the simultaneous application of an arbitrarily long sequence of Clifford gates to a single pair of different registers. However, since a single register contains multiple qubits, even if the ideal quantum circuit could perform a different two-qubit Clifford gate in a single depth, the two-register Clifford-gate abbreviation cannot perform a different pair of two-qubit Clifford gates in a single depth.

To bound the depth of the intermediate circuit required for performing all combinations of the two-qubit Clifford gates in a one-depth part of the Clifford layer of $\mathrm{C}_n^{\mathrm{org}}$, we obtain the combinations of two-qubit Clifford abbreviations that can be executed simultaneously from a solution of the following edge coloring problem. We consider an undirected graph $G = (V, E)$, where each vertex in V corresponds to one of the registers, and each edge in E connects vertices representing registers on which a two-qubit Clifford gate acts in a single-depth part of the Clifford layer (if the gate acts on the same register, the edge forms a self-loop). To simplify the analysis, we additionally define a graph G' by removing all self-loops from G. In the graph G', when each pair of adjacent edges is assigned a different color such that no two neighboring edges have the same color, the two-qubit Clifford gates assigned to each color are implemented as one-depth executable two-qubit Clifford-gate abbreviations in the intermediate circuit. Since each register has K qubits, a qubit in a register can be connected to at most K qubits in other registers by a two-qubit Clifford gate. In this case, since G' is a simple graph and the degree of G' is at most K, G' is $(K+1)$-edge colorable [57, 58]. Thus, G is $(K+2)$-edge colorable because adding another color allows all self-loops to be colored with this color. Note that the algorithm for constructing the $(K+1)$-edge coloring of G' can be performed in polynomial time with respect to the number of vertices and edges [59], and therefore the computation of the $(K+2)$-edge coloring of G can also be performed efficiently. Thus, any possible combination of Clifford gates can be performed in each one-depth part of the original circuit by using two-qubit Clifford abbreviations of up to $(K+2)$-depth in the intermediate circuit. For a T-gate layer, we can perform the T, $T^\dagger$, and I gate in a single-depth part by using a single use of the U_T-gate abbreviation (the same for a single-depth layer of Z-basis-measurement operations, and $|0\rangle$-state-prepration operations).

In the following, by counting the number of EC gadgets in the fault-tolerant circuit, we show that the error probability of our protocol can be suppressed to ε. Subsequently, we demonstrate that our protocol achieves a constant space overhead and a polylogarithmic time overhead. We restrict the number of non-trivial intermediate operations $L(n)$ that we apply in a one-depth part of the intermediate circuit to (199). The intermediate circuit compiled from a one-depth part of the original circuit has depth

$$(K+2) \times \frac{\kappa(n)}{L(n)} = \Theta\left(\log^{\alpha+\gamma_1}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right), \tag{238}$$

where we use (185), (187), (188), and (199). If we replace all the elementary operations contained in the intermediate operation with the corresponding gadget, then the depth of a physical circuit compiled from a one-depth part of the intermediate circuit is bounded by

$$\begin{aligned} O(\tilde{D}_{\mathrm{prep}}(N)) &= O\left(D_{\mathrm{prep}}(N)\log^{\gamma_2}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right) \\ &= O\left(\log^{\alpha+\gamma_2}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right), \end{aligned} \tag{239}$$

where the dominant parts are the state-preparation gadgets as explained in Secs. IV D 4, IV D 5, and IV D 6, and we use (187), (190), and (198). Thus, the physical circuit compiled from the original circuit has depth $D_{\mathrm{FT}}(n)$ bounded by

$$\begin{aligned} &D_{\mathrm{FT}}(n) \\ &= O\left(D(n)\log^{\alpha+\gamma_1}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\log^{\alpha+\gamma_2}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right) \\ &= O\left(D(n)\log^{2\alpha+\gamma_1+\gamma_2}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right) \end{aligned} \tag{240}$$

where we use (238) and (239). Since we allocate five auxiliary registers for each register, the number of EC gadgets in the physical circuit is bounded by

$$
\begin{aligned}
&6\kappa(n) \times O\left(D(n)\log^{2\alpha+\gamma_1+\gamma_2}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right) \\
&\quad = O\left(W(n)D(n)\log^{\alpha+\gamma_1+\gamma_2}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right).
\end{aligned}
\tag{241}
$$

Therefore, the total error probability of the fault-tolerant protocol can be bounded by

$$
\begin{aligned}
&O\left(W(n)D(n)\log^{\alpha+\gamma_1+\gamma_2}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right) \times O\left(\frac{\varepsilon}{|\mathrm{C}_n^{\mathrm{org}}|^2}\right) \\
&= O(\varepsilon),
\end{aligned}
\tag{242}
$$

where we use (183) and (219) in Lemma 16.

Next, the width of a physical circuit compiled from a single non-trivial intermediate operation is bounded by

$$
\begin{aligned}
O(\tilde{W}_{\mathrm{prep}}(N)) &= O\left(W_{\mathrm{prep}}(N)\log^{\gamma_1}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right) \\
&= O\left(\log^{\alpha+\gamma_1}\left(\frac{|\mathrm{C}_n^{\mathrm{org}}|}{\varepsilon}\right)\right),
\end{aligned}
\tag{243}
$$

where the dominant parts are the state-preparation gadgets, as explained in Secs. IV D 4, IV D 5, and IV D 6, and we use (187), (188), and (199). Thus, the width of the physical circuit can be bounded by

$$
\begin{aligned}
&W_{\mathrm{FT}}(n) \\
&= O\left(\tilde{W}_{\mathrm{prep}}(N) \times L(n) + (N + (N-K)) \times (\kappa(n) - L(n))\right) \\
&= O(W(n)),
\end{aligned}
\tag{244}
$$

where $N-K$ is the number of auxiliary physical qubits for measuring stabilizer generators in a EC gadget as explained in Sec. IV D 7, and we use (183), (185), (187), (188), and (199), and (243). Therefore, the fault-tolerant protocol can achieve the constant-space overhead as

$$
\frac{W_{\mathrm{FT}}(n)}{W(n)} = O(1). \tag{245}
$$

On the other hand, the depth $D_{\mathrm{FT}}(n)$ of $\mathrm{C}_n^{\mathrm{FT}}$ is bounded by (240). Therefore, the fault-tolerant protocol can achieve the polylog-time overhead as

$$
\frac{D_{\mathrm{FT}}(n)}{D(n)} = O\left(\mathrm{polylog}\left(\frac{n}{\varepsilon}\right)\right), \tag{246}
$$

where we use (183). From the above discussion, we conclude Theorem 14.

V. CONCLUSION

In this work, we present a hybrid fault-tolerant protocol that combines concatenated codes for gate operations with a non-vanishing-rate quantum LDPC code (in particular, the quantum expander codes [20, 60, 61]) for state preservation. Our protocol achieves polylogarithmic time overhead while maintaining constant space overhead. Thus, our protocol improves the time overhead of existing constant-space-overhead protocols, i.e., the protocols based on non-vanishing-rate quantum LDPC codes [20–22], as well as the protocol based on concatenated quantum Hamming codes [25]. This improvement is achieved by increasing the parallelism for executing logical gates from $O(W(n)/\mathrm{poly}(n))$ to $O(W(n)/\mathrm{polylog}(n))$, improving on Ref. [21], due to advances in the analysis of error suppression by decoding algorithms [20, 22]. Moreover, we show that our protocol has a threshold even when accounting for the runtime of classical computation required to perform the fault-tolerant circuit, whereas existing analyses of protocols for quantum LDPC codes assume that such classical computation can be instantaneous [20–22]. Our protocol eliminates redundant spacetime trade-offs present in existing constant-space-overhead FTQC protocols [20–22, 25].

These results highlight that the quantum LDPC code approach can achieve time-efficient FTQC while maintaining a constant space overhead, as well as the code-concatenation approaches [25, 26]. Our work contributes to the fundamental understanding of low-overhead FTQC, and more importantly, it underscores the need for a comprehensive investigation to determine which of the two approaches holds more promise for future physical implementations of FTQC.

[40] In our protocol for the concatenated code, we apply the Pauli gates directly rather than updating the Pauli frame for simplicity of the presentation. It would also be possible to use the updates of Pauli frame here. By contrast, in the protocol for the quantum LDPC code, we always apply Pauli gates by updating the Pauli frame, which is convenient for bounding the error rate right after each decoding of the quantum LDPC code.

Appendix A: Conditions of fault-tolerant gadgets on concatenated Steane codes

In this section, we provide the fault-tolerance conditions for concatenated Steane codes [29, 41]. For the argument, we introduce the notion of r-filter. The r-filter is a mathematical object used for analysis and does not correspond to any physical operation during quantum computation. The r-filter is used to ensure that the weight of an error occurring on a codeword at a given time is not too large. It is defined as follows:

Definition 17 (r-filter)**.** An r-filter is a projector onto the subspace spanned by all states of the form $E\left|\bar{\psi}\right\rangle$, where $E \in \mathcal{P}_N$ with a weight of at most r and $\left|\bar{\psi}\right\rangle \in \mathcal{Q}$ is a codeword. If the ideal syndrome bits of an encoded state were hypothetically obtained and the syndrome bits indicate a Pauli error with a weight of at most r, then the

r-filter leaves the encoded state unchanged. Conversely, if the indicated error exceeds the weight r, the r-filter rejects the encoded state, terminating the computation.

Reference [41] provides the definition for $[[N, 1, 2t+1]]$ codes where $0 \leq r \leq t$. However, for the Steane code with $t = 1$, we can easily interpret the r-filter for $r = 0, 1$. The 0-filter is defined as a projector onto the code space, i.e.,

$$\Pi_{\mathcal{Q}} := \prod_i \frac{I + g_i}{2}, \tag{A1}$$

where $\{g_i\}_i$ is a set of stabilizer generators as given in (25). The 0-filter is illustrated in the diagram as,

- 0-filter

(A2)

The 1-filter for the Steane code becomes the identity operator I acting on the whole Hilbert space because all the $X(Z)$-type errors that appear in the Steane code can be decomposed into logical $X(Z)$ errors plus weight-1 $X(Z)$ errors. The 1-filter is not shown in the diagram because it is trivial.

Then, the fault-tolerance conditions for preparation, gate, and measurement gadgets are presented below with diagrams using ideal decoder in Def. 7 and the 0-filter in Def. 17. In the diagrams, an operation surrounded by thin lines and acting on thin wires represents a non-fauly operation. The variable s shown in the upper right of a gadget represents the number of faults in the gadget.

The $|0\rangle$-state preparation gadget is fault-tolerant if it satisfies

Appendix B: Construction of abbreviations and gadgets

In this section, we present the explicit construction of an abbreviation and gadgets that satisfy the fault-tolerance condition presented from (A3) to (A18).

1. T-gate abbreviation

The construction of the T-gate abbreviation is shown in Fig. 12. The abbreviation is based on gate teleportation. Implementation is assisted by a single auxiliary qubit in the state $|T\rangle$ from the $|T\rangle$-state preparation gadget. We subsequently perform the CNOT-gate gadget followed by the Z-basis measurement. To implement the T gate, a Clifford gate SX for the correction operation is applied to the qubit if the measurement outcome is $m = 1$.

2. Z-basis measurement gadget

The Z-basis measurement gadget is constructed as shown in Fig. 13. The gadget is implemented by transversal Z-basis measurements, followed by the execution of the decoding algorithm by classical computation.

We present the explicit procedure for performing the Z-basis measurement. Specifically, we give the procedure for calculating the measurement outcome $\bar{z} \in \{0, 1\}$ of the Pauli operator Z on a level-l qubit from the noisy measurement outcomes $z_i \in \mathbb{F}_2$ of Z_i on the i-th level-$(l-1)$ qubits for $i \in \{1, \ldots, 7\}$. The procedure is as follows:

1. We measure the 7 level-$(l-1)$ qubits on the Z-basis. The outcomes are $z \in \mathbb{F}_2^7$, where each bit $z_i \in \mathbb{F}_2$ is the noisy measurement outcome on the i-th level-$(l-1)$ qubit.

2. We calculate the syndrome bits $\sigma_X \in \mathbb{F}_2^3$ of the Z-type generators from the 7-bit outcomes of the Z-basis measurement of the level-$(l-1)$ qubits by using the relation,

$$(\sigma_X)_i = \bigoplus_{j \in \mathrm{supp}(g_i^Z)} z_j, \tag{B1}$$

where $\mathrm{supp}(g_i^Z)$ denotes the set of qubit indices where g_i^Z has non-trivial support.

3. We execute the decoding algorithm (27) which takes the syndrome bits $\sigma_X \in \mathbb{F}_2^3$ as input and outputs the recovery operation of an X-type Pauli operator, denoted by $\hat{F} \in \mathcal{P}_N$. Then, the corrected

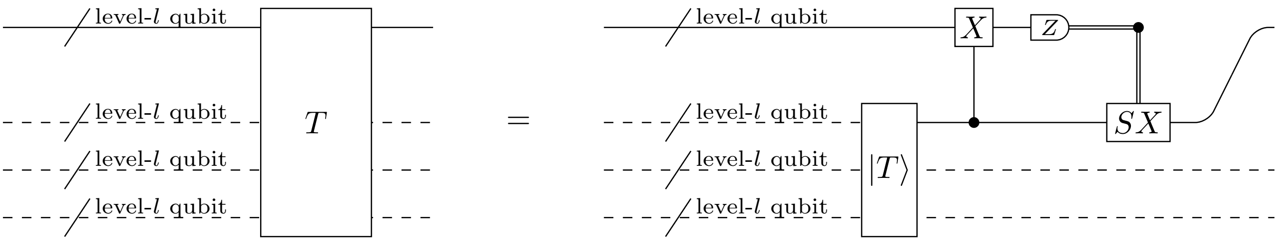

FIG. 12. The level-l circuit of the T-gate abbreviation for performing the T gate through gate teleportation.

bits $\tilde{z} \in \mathbb{F}_2^7$ are obtained for $i \in \{1, \ldots, 7\}$ as

$$\tilde{z}_i := z_i \oplus (\phi(\hat{F}))_i, \tag{B2}$$

where $(\phi(\hat{F}))_j$ represents the j-th element of the row vector $\phi(\hat{F})$.

4. We calculate the noiseless measurement outcome $\bar{z} \in \mathbb{F}_2$ of Z on the level-l qubit as

$$\bar{z} := \bigoplus_{i \in \mathrm{supp}(\bar{Z})} \tilde{z}_i, \tag{B3}$$

where $\bar{Z}$ is the logical-Z operator of the Steane code as given in (26), and $\mathrm{supp}(\bar{Z})$ denotes the set of indices of the physical qubits on which the logical-Z operator acts nontrivially.

The fault tolerance of the Z-basis measurement gadget defined as in (A14) and (A15) is ensured by transversality.

3. Gate gadgets

The constructions of the Pauli-, H-, S-, $S^\dagger$ and CNOT-gate gadgets are shown in Fig. 14. The Pauli-, H-, S-, $S^\dagger$- and CNOT-gate gadgets are implemented by the transversal Pauli, H, $S^\dagger$, S and CNOT gates acting on the level-$(l-1)$ qubits, respectively. The fault tolerance of the gate gadgets defined as (A7), (A8), (A9), (A10), (A11), (A12) and (A13) is ensured by transversality.

4. $|0\rangle$-state preparation gadget

The construction of the $|0\rangle$-state preparation gadget is shown in Fig. 15 (a). We first prepare 7 qubits in the state $|0\rangle^{\otimes 7}$ using the $|0\rangle$-state preparation operations. Then, we use an encoding circuit $U_{\mathrm{encode}}^{|0\rangle}$ to transform the state $|0\rangle^{\otimes 7}$ into the logical state of $|0\rangle$. The encoding circuit $U_{\mathrm{encode}}^{|0\rangle}$ is shown in Fig. 15 (b), presented in Ref. [63].

The issue here is that the encoding circuit is non-fault-tolerant, meaning a single fault occurring during the encoding circuit may lead to an error with a weight greater than one by the end of the encoding circuit. Thus, verification is essential to detect such errors, ensuring that the $|0\rangle$-state preparation gadget satisfies the fault-tolerance conditions specified in (A3) and (A4). In the verification process, the gadget executes the same encoding circuit $U_{\mathrm{encode}}^{|0\rangle}$ to prepare another set of 7 qubits in the logical state of $|0\rangle$. Subsequently, the gadget performs the transversal CNOT gate targeting the newly prepared qubits. This is followed by the transversal Z-basis measurements on these qubits. From these Z-basis measurements, we obtain the syndrome bits for all Z-type stabilizer generators in (25) and the measurement outcome of the logical Z operator on the level-l qubit in (26) through classical computation described in the Z-basis measurement gadget. These are crucial for detecting badly propagated X-type errors. The verification passes if and only if all the syndrome bits are trivial and the measurement outcome m of the logical Z operator is $m = 0$. If verification fails, the gadget discards the resulting state and repeats the encoding circuit $U_{\mathrm{encode}}^{|0\rangle}$ without verification in the second run. Note that the detection of the Z-type errors is unnecessary for verifying $|0\rangle$ since multiple Z-type errors at the end of the encoding circuit may lead to a logical Z error but do not transform the state, i.e., $Z|0\rangle = |0\rangle$.

We check that the above gadget construction satisfies the fault-tolerance condition defined in (A3) and (A4). In the case where $s = 0$, i.e., no fault occurs during the gadget, the gadget successfully outputs 7 qubits in the logical state of $|0\rangle$, and thus the conditions (A3) and (A4) are satisfied. Next, we discuss the case where $s = 1$, i.e., only a single fault occurs in the gadget. If the verification succeeds, the gadget successfully outputs 7 qubits in the logical state of $|0\rangle$ in the first run. If the verification fails in the first run, i.e., an error is detected, then the gadget discards the resulting state. Then, the gadget restarts and executes the encoding circuit to prepare 7 qubits in the logical state of $|0\rangle$ in the second run without verification. In this scenario, since a single fault occurred in the first run, no fault occurred during the part for preparing 7 qubits in the logical state of $|0\rangle$ in the second run, given that we consider the condition where $s = 1$. Therefore, the fault-tolerance conditions (A3) and (A4) of the gadget are satisfied.

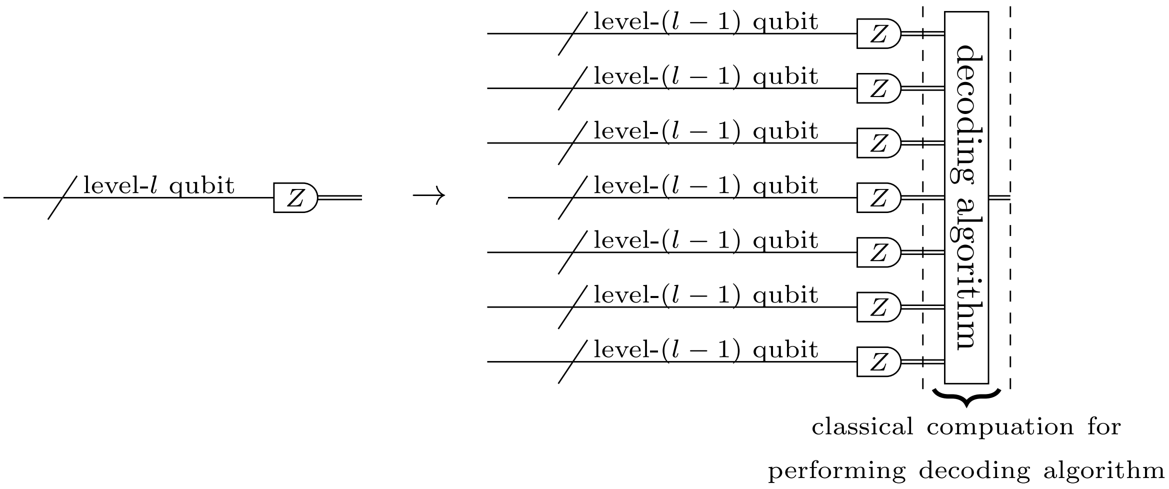

FIG. 13. The level-$(l-1)$ circuit of the Z-basis measurement gadget. The gadget is implemented by transversal Z-basis measurements, followed by the decoding algorithm.

5. $|T\rangle$-state preparation gadget

The $|T\rangle$-state preparation gadget is constructed as shown in Fig. 16 (a). The gadget starts with the preparation of the logical state of $|T\rangle := TH|0\rangle$ from the 7 qubits in the state $|T\rangle \otimes |0\rangle^{\otimes 6}$. We utilize the non-fault-tolerant encoding circuit $U_{\text{encode}}^{|\psi\rangle}$ to transform an arbitrary state $|\psi\rangle$ into an logical state of $|\psi\rangle$, as shown in Fig. 16 (b), presented in Ref. [63]. A single fault that occurs during or before the encoding circuit $U_{\text{encode}}^{|\psi\rangle}$ leads to an error with a weight greater than one, as well as for the $|0\rangle$-state preparation gadget. Thus, verification is essential to detect such errors for the $|T\rangle$-state preparation gadget to satisfy the fault-tolerance conditions given by (A5) and (A6). For verification, we perform a measurement of the operator $TXT^\dagger$, followed by error detection. The measurement of the operator $TXT^\dagger$ is needed for verification, since the $|T\rangle$ state we want to prepare is stabilized by the operator $TXT^\dagger$, i.e.,

$$TXT^\dagger|T\rangle = |T\rangle \tag{B4}$$

Since $TXT^\dagger = SX$ is a Clifford operator, we can measure the logical operator $TXT^\dagger$ by performing transversal measurements of $T^\dagger XT = S^\dagger X$. This measurement can be performed with controlled $T^\dagger XT$ gates controlled by the auxiliary A as shown in Fig. 16. The auxiliary qubit is measured to obtain the measurement outcome of the operator $T^\dagger XT$. If the measurement outcome of the operator $TXT^\dagger$ is $m = 1$, indicating that the state is projected onto the state orthogonal to $|T\rangle$, then we consider the verification to be failed, and the gadget discards the state. To measure the logical operator $TXT^\dagger$ in a fault-tolerant way, we additionally use a qubit as the flag qubit [64, 65], where the flag qubit corresponds to the auxiliary qubit B in Fig. 16. A single fault on the auxiliary qubit A may result in an error with a weight greater than one on the code block, which consists of the 7 qubits. However, in such a case, if the measurement outcome of the auxiliary qubit B, serving as the flag qubit, is $m = 1$ in the Z basis, the verification is deemed to have failed, and the gadget discards the state. To verify that the state is in the code subspace, we perform error detection at the end of $|T\rangle$-state preparation gadget based on the gate teleportation as shown in Fig. 16. If at least one non-trivial syndrome bit is detected during the execution of the gate teleport protocol, then we consider the verification to be failed, and the gadget discards the state. Therefore, the verification is successful only if the measurement outcome m of $TXT^\dagger$ is $m = 0$, the measurement outcome m of the flag qubit is $m = 0$, and all the syndrome bits obtained during the gate teleportation protocol are trivial. If the verification fails, the gadget discards the resulting state at the point of failure. Afterwards, the gadget repeats the encoding circuit to prepare the logical state $|T\rangle$ without verification in the second run.

We show that the $|T\rangle$-state preparation gadget satisfies the fault-tolerance condition defined by (A5) and (A6). If $s = 0$, indicating no fault in the gadget, the gadget successfully outputs the logical state $|T\rangle$, satisfying conditions (A5) and (A6) are satisfied. Next, we consider the case where $s = 1$, indicating a single fault in the gadget, and show that condition (A6) is satisfied. We divide the $|T\rangle$-state preparation gadget, which may cause a single fault, into three parts: (1) preparing the logical state of $|T\rangle$, (2) measuring the logical operator $TXT^\dagger$, and (3) error detection. Here, we show that the fault-tolerance condition is satisfied if a single fault occurs in any of the three parts.

1. A fault occurs during the preparation of the logical state $|T\rangle$.

   In this scenario, since we assume that only a single

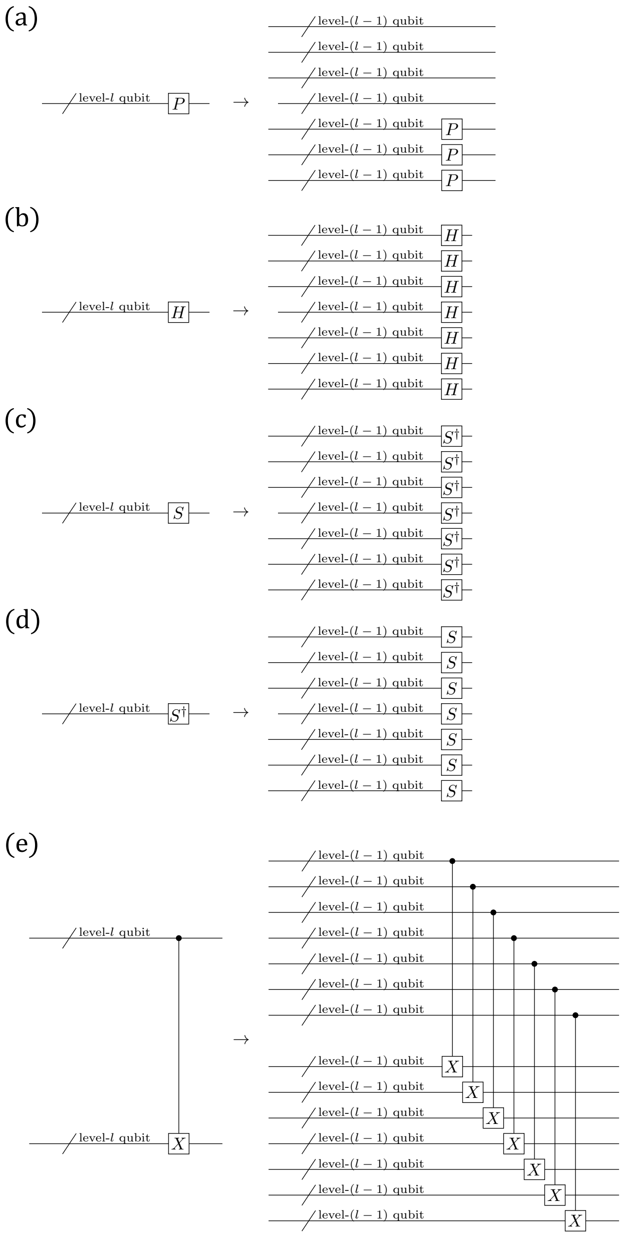

FIG. 14. A level-$(l-1)$ circuit of the Pauli-gate gadget (a), the H-gate gadget (b), the S-gate gadget (c), the $S^\dagger$-gate gadget (d), and the CNOT-gate gadget (e).

fault occurs during the gadget, the measurement of the operator $TXT^\dagger$ and the error detection are performed ideally. If the verification succeeds, the gadget successfully outputs the logical state $|T\rangle$. If the verification fails, the gadget discards the state obtained in the first run and then re-executes the encoding circuit in the second run. In this second run, the gadget outputs the logical state $|T\rangle$ without further verification because a single fault occurred in the first run. After completing the encoding circuit in the second run, the gadget successfully outputs the logical state $|T\rangle$. With this gadget construction, the condition (A6) is satisfied.

2. A fault occurs during the measurement of the logical operator $TXT^\dagger$.

   In this case, since there is no fault in the first part (i) of the gadget, the encoding circuit outputs the logical state $|T\rangle$. The problem arises when a single fault occurs in the auxiliary qubit A, as the fault-induced error may propagate to the code block of 7 qubits, resulting in an error with a weight greater than one. However, even if such a fault occurs, the error resulting from the fault is also propagated to the auxiliary qubit B, causing a measurement outcome of $m = 1$, which can be detected through verification. For example, if a fault occurs on the auxiliary qubit A, resulting in a Pauli-X or -Y error, this error affects the code block, leading to an error with multiple weights. Subsequently, this error propagates to the auxiliary qubit B through the CNOT gates, resulting in a measurement outcome of $m = 1$ on qubit B. Therefore, a Pauli error that produces an error with multiple weights on the code block can be effectively detected through the verification process. If the verification process fails, the gadget discards the state obtained from the first run and performs the encoding circuit again in the second run without verification. This construction of the gadget ensures that the condition (A6) is satisfied.

3. A fault occurs during error detection.

   Since there are no faults in (i) and (ii) of the gadget, the state before executing the error detection is a logical state of $|T\rangle$. If a single fault occurs that can be detected by the error detection procedure, the gadget discards the state. In the second run, it executes the encoding circuit again, satisfying the condition (A6). Even if a single fault occurs that is cannot be detected through error detection, from (A18), the condition (A6) is also satisfied.

Therefore, the fault tolerance of the $|T\rangle$-state preparation gadget defined as (A5) and (A6) is satisfied.

6. Error-correction gadget

The error-correction gadget is constructed as in Fig. 17. This gadget is based on Knill's error correction [38, 39, 41]. The gadget uses two sets of 7 auxiliary qubits initialized to the logical state of $|0\rangle$ using the $|0\rangle$-state preparation gadget, in addition to the input 7 qubits on which we want to perform error correction. By using these two sets of 7 auxiliary qubits, we perform quantum teleportation of the input level-l qubit. The two 7-bit outcomes from the Z-basis measurements are fed

to the decoding algorithm to calculate the measurement outcomes of the logical Z, which is the same procedure explained in the Z-basis measurement gadget. The measurement outcome is used to decide the correction operation for the quantum teleportation. The fault tolerance of the EC gadget defined by conditions (A16), (A17), and (A18) follows from transversality.

Appendix C: Pauli-gate gadgets for quantum LDPC codes

The Pauli-gate gadget for quantum LDPC codes is intended to perform a logical operation $\bar{P}$ acting on logical qubits in a code block of a Pauli-gate operation

$$P = \bigotimes_{k=1}^{K} P_k \in \tilde{\mathcal{P}}_K \tag{C1}$$

as in (75), where $P_k \in \{I, X, Y, Z\}$ is a Pauli operator acting on the k-th qubit. The construction of the gadget is shown in Fig. 18.

A logical Pauli operator $\bar{P}_k$ of P_k in (C1) is described as a tensor product of a N-qubit Pauli operator acting on physical qubits; thus, $\bar{P}$ can be described by a N-qubit Pauli operator as

$$\bar{P} = \bigotimes_{k=1}^{K} \bar{P}_k = \bigotimes_{k=1}^{K} \bigotimes_{n=1}^{N} P_{n,k} \in \tilde{\mathcal{P}}_N, \tag{C2}$$

where $\bar{P}_k = \bigotimes_{n=1}^{N} P_{n,k}$, and $P_{n,k} \in \{I, X, Y, Z\}$ is a Pauli operator acting on the n-th physical qubit.

When we perform a on-demand Pauli-gate gadget (80) for executing a two-register Clifford-gate abbreviation (78), we require an on-demand calculation of (C2). A classical computer receives a bitstring of a $2K$-bit string of the symplectic representation of a K-qubit Pauli operator $P \in \tilde{\mathcal{P}}_K$ in (C1) and outputs a $2N$-bit string of the symplectic representation of $\bar{P} \in \tilde{\mathcal{P}}_N$ in (C2). The runtime for calculating (C2) can be bounded in the following. Based on the input $2K$-bit string, we obtain K $2N$-bit strings, where the k-th $2N$-bit string is the symplectic representation of $\bar{P}_k$. Here, calculating (C2) corresponds to taking a sum of the K bitstrings as in (12). Thus, if for $n \in \{1, \ldots, N\}$, each n-th bit can be calculated simultaneously with $O(N)$ parallel processes, and the sums of the n-th positions of the K bitstrings

Abstract. Quantum machine learning using qubit system attracts extreme research interest during the last decade, as it is does not require fault-tolerant quantum computer at the noisy intermediate-scale quantum era. In general, the theoretical and experimental works so far focus on universal quantum computation theory and solid state systems, for example superconducting qubits and trapped ions. Meanwhile, photon featuring long coherent time and convenient operation, has not been well studied in the term quantum machine learning. Here, we propose the quantum kernel estimation based on boson nature which is fundamental for other quantum machine learning protocols. In our experiment, we demonstrate the quantum kernel estimation using quantum interference which is extinct in photonic systems. Furthermore, we benchmark our methods with other classical kernel methods showing quantum kernel can outperform classical kernel methods at some datasets.

Keywords: quantum machine learning, quantum optics, integrated photonic circuits

1 Introduction

Quantum machine learning is potential advantageous in noisy quantum computers, for example variational quantum estimation for quantum Quantum approximate optimization algorithm for factorization, and quantum kernel estimation for classification. Besides, quantum kernel methods can map data points in the original space, which are hard to recognize, to a high-dimensional *feature space*. This nonlinear mapping can extract data features effectively and help the machine learning tasks. Once the suitable mapping is performed, it is possible to identify the hyperplane through a support vector machine [1] (SVM), according to the inner product of the mapped data. Such a hybrid classical-quantum model would benefit from the quantum feature maps that utilize the evolution of quantum systems, which can be hard to simulate on classical computers, and hence outsource the hardest part of the computation to the quantum hardware.

In this paper, we give an experimental demonstration of quantum kernel estimation, where data points are mapped in the feature space through the unitary evolution of two-boson Fock states (see Fig. 1). Such encoding can arbitrarily tune the dimension of the feature space and provide enough of a non-linearity to achieve a high classification accuracy with data which are only non-linearly classifiable. Furthermore, we show that for given tasks, this algorithm leads to an enhancement in the performance of quantum kernels with respect to their classical counterparts.

2 Photonic quantum kernel estimation

A kernel method relies on a function that maps N input data points x_i, from a space $\mathcal{X} \subseteq \mathbb{R}^d$ into a feature space $\mathcal{H}$. Here, d is the dimension of each data point. This is done through a feature map $\Phi : \mathcal{X} \to \mathcal{H}$. Then, a SVM can be used to produce a *prediction* function $f_K : \mathcal{X} \to \mathbb{R}$ as $f_K(x) = \sum_i \alpha_i K(x, x_i)$, where these α_i coefficients are obtained by solving a linear optimization problem. The inputs of the optimization are the labels y and the matrix obtained by computing the pairwise distances between data points is $K_{i,j} = K(x_i, x_j) = \langle \Phi(x_j) | \Phi(x_i) \rangle$, the so-called *Gram matrix*.

In this work, we implement a quantum version of the kernel method by sampling from the output probability distribution arising from the unitary evolution of a Fock input state. The pairwise distances are estimated between data points, which belong to a class y taking values $+1$ or -1. This process is depicted in Fig. 1a. Therefore, our feature map plugs the data that needs to be classified into the free parameters defining a unitary evolution applied to a fixed Fock state of dimension m and whose sum of occupational numbers is n: $x \mapsto |\Phi(x)\rangle = U_x|\psi\rangle$. Here, $|\psi\rangle$ is the encoding state which is free to choose. Then, as shown in Fig. 1c, the pairwise inner products of the feature points are experimentally evaluated, as $|\langle\psi|U(x_i)^\dagger U(x_j)|\psi\rangle|^2$. Such unitaries can be effectively implemented by a programmable photonic circuit

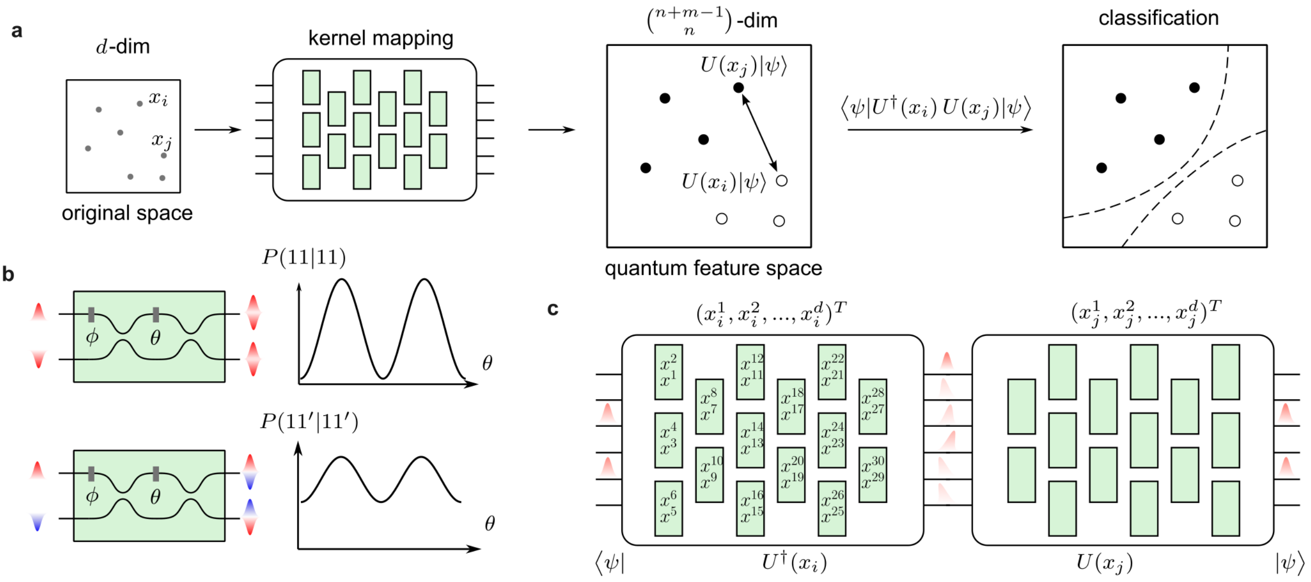

Figure 1: **Photonic quantum kernel estimation.** **a**. The photonic quantum kernel maps each data point x_i to be classified from a d-dimensional space into a quantum state $|\Phi\rangle_i$, living in a Hilbert feature space. In detail, the classical data x_i is encoded into a unitary evolution $U(x_i)$ applied on a fixed input state $|\psi\rangle$. After mapping all the data points in the dataset, we perform the classification finding the hyperplane best separating the classes, i.e. through a classical support vector machine (SVM). **b.** Pairs of indistinguishable photons and distinguishable photons show a different behavior when injected in a Mach-Zehnder interferometer (MZI). **c.** Estimation of the inner product of two data points x_i and x_j by encoding them in two unitaries $U(x_i)$ and $U(x_j)$.

consisting of an array of Mach-Zehnder interferometers (MZIs)[2]. At this point, the SVM finds the hyperplane separating the training data points through the aforementioned optimization process [3, 4] and, at the end, the binary classification of unknown points x is given by the following relation:

$$y = \text{sign}\left(\sum_{i=1}^{N} \alpha_i y_i K(x, x_i)\right) \tag{1}$$

where α_i are, as before, the coefficients optimized in the training process and y_i is the class of the i-th point in the training. This model is defined *implicitly*, as the labels are assigned by weighted inner products of the encoded data points [5, 6, 7, 8, 9, 10, 11, 12, 13].

If the Fock state contains indistinguishable bosons, they will exhibit quantum interference, as shown in Fig. 1b. In this case, the output probability distribution is given by the permanents of sub-matrices of the matrix representing the unitary evolution of the input [14]. More specifically, considering an input configuration s, the probability of detecting the output configuration t is given by $|\text{per}(U_{s,t})|^2/\Pi_i^m s_i!\Pi_i^m t_i!$. Here, per$(\cdot)$ denotes the permanent matrix operation, s_i and t_i are the occupational numbers at the i-th mode and $U_{s,t}$ is the sub-matrix obtained by selecting the rows/columns corresponding to the occupied modes of the input/output Fock states. On the other hand, if the bosons are distinguishable, they will not exhibit quantum interference. In this case the probability will amount to $\text{per}(|U_{s,t}|^2)/\Pi_i^m s_i!\Pi_i^m t_i!$.

3 Experiment and Results

In our experiment, we adopt a programmable integrated photonic processor containing laser-written waveguides and 27 thermal phase phases shifters as shown in Fig .2a. By arranging the Mach-Zehnder interferometer, it is able to perform any arbitrary 6x6 unitary matrices. The two photons are generated by a ppKTP nonlinear crystal and yield 97% on-chip indistinguishability. After evolution on the chip, all the output photons are detected by 6 superconducting nanowire single photon detectors and sequentially recorded in 15 different coincidence counting.

We test the performance of two photonic kernels in several different configurations. Firstly, we consider two different inputs, $|1,1,0,0,0,0\rangle$ and $|0,0,1,1,0,0\rangle$. Second, we are able to tune the indistinguishability to implement the quantum kernel and the coherent kernel.

For both input states, we test datasets of four different sizes: 40, 60, 80 and 100. We use the setup depicted in Fig.2a to evaluate all of the pairwise products between the unitaries $U(x_i)^\dagger U(x_j)$. Hence, $|\langle\psi|U(x_i)^\dagger U(x_j)|\psi\rangle|^2$ is given by the probability of detecting the photons on the same modes from which they were injected.

For each dataset, we use 2/3 of the data points for the training of the SVM, and the remaining 1/3 as a test set. The accuracy is defined as the number of correctly classified points over the total size of the test set. Let us note that values lower than 0.5 indicate that the model was not able to learn the features of the training set and generalize to unknown data.

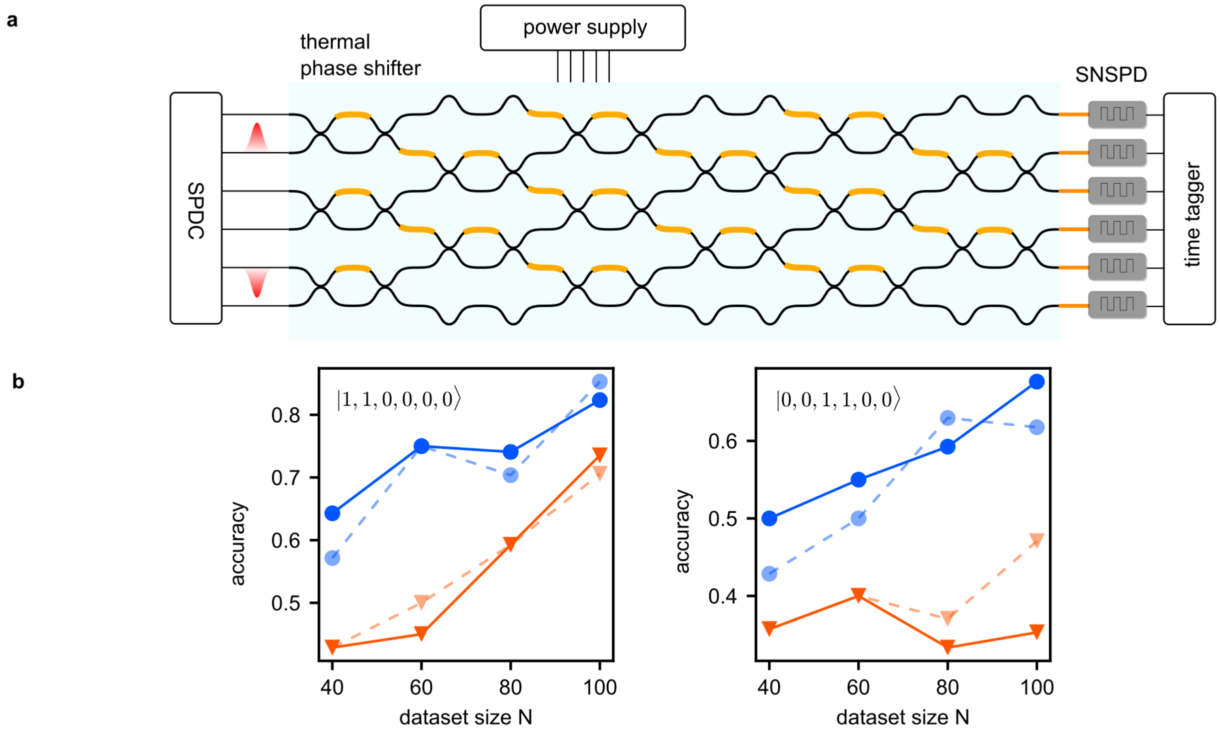

Figure 2: **Implementation of photonic quantum kernel estimation. a.** Experimental setup consisting of two parts, the off-chip single photon source and the programmable integrated photonic processor. **b.** We tested our method on datasets of different sizes (40, 60, 80, 100) and for two different input states ($|1,1,0,0,0,0\rangle$ and $|0,0,1,1,0,0\rangle$) respectively.

In Fig. 2b, we show the test accuracies obtained by injecting two input states for four different dataset sizes, where the quantum kernel performs significantly better than the coherent kernel at both experiments. The dashed lines indicate the results of numerical simulations, while the solid lines indicate experimental results.

4 Discussion

In this work, we show the first experimental demonstration of quantum kernel estimation, based on the unitary evolution of Fock states through an integrated photonic processor. In our implementation, data is mapped into a feature space by encoding it into the evolution of a fixed two-photon input state over six modes. The sampled output distribution is then fed into an SVM, which performs the classification. To achieve this, we adopt an integrated photonic processor realized by femtosecond laser writing in a borosilicate glass substrate [15].

Our method can find a wide range of promising near-term applications in quantum machine learning tasks such as information retrieval, natural language processing and medical image classification [16, 17, 18, 19], where kernel methods have been proposed a foundational keystone [20]. Our experimental results demonstrate that our quantum-enhanced kernels can outperform classical ones on datasets resulting from quantum observations, it also opens the door to hybrid methods where photonic processors are used to enhance the performance of deep neural networks.

In recent years, machine learning has had a remarkable impact on standard computation, with applications ranging from scientific to everyday-life scopes. Meanwhile, as the complexity of the addressed task grows, energy consumption and computational power requirements become a bottleneck. In this context, it has been shown that quantum (or quantum-inspired) computation might lower the amount of required resources. However, whether such enhancements can be achieved with state-of-the-art quantum technologies and for practically relevant tasks is still an open question. Here, we demonstrate a kernel method on a photonic integrated processor to perform a binary classification task, by exploiting quantum interference. We benchmark our protocol against standard algorithms and show that it outperforms them for the given tasks. A significant improvement with respect to standard algorithms is shown, even in a regime that does not display quantum interference and exploits only the coherence of single photons. This implies that we do not need entangling gates and can readily raise the dimension of our system through additional circuit modes and/or injected photons. Our result opens the way to more efficient computing algorithms and for the formulation of tasks where quantum effects enhance the effectiveness of standard methods.

INTRODUCTION

The past decades have witnessed a swift development of technologies based on quantum mechanical phenomena, which have opened up new perspectives in a wide spectrum of applications. These range from the realization of a global-scale quantum communication network, the Quantum Internet [1, 2], to the simulation of quantum systems [3], to quantum computing [4]. In particular, the interest towards the last field has been fueled by some milestone discoveries, such as Shor's factorization and Grover's search algorithm [5, 6], which have promised that quantum processors can outperform their classical counterparts. However, a clear advantage of quantum computation has been experimentally demonstrated only recently and on different computational tasks, boson sampling [7–12] and random circuit sampling [13], which do not have clear practical applications.

Given these premises, it is crucial to investigate the tasks in which quantum computing can bring added value and enhance the operation of classical computers. Moreover, the question is whether this can be achieved for problems that are now within the reach of state-of-art technology, where only noisy intermediate-scale quantum computers are available [14, 15]. In this context, a flurry of interest has been devoted to the open question of whether the new paradigm of quantum computing can have an impact on machine learning [16–18], which has revolutionized classical computation, granting new possibilities and changing our everyday lives, from email filtering to artificial intelligence. The two main directions that have been investigated are, on one side, whether quantum computation could improve the efficiency of the learning process, allowing us to find better optima with the need of a lower number of inquiries [19–22] and, on the other, how quantum behaviours can enhance the expressivity of the input encoding, exploiting correlations between variables that are hard to reproduce through classical computation [23, 24]. In particular, regarding the latter aspect, a straightforward application of quantum computing on kernel models has become evident. Kernel methods are widely used tools in machine learning [25, 26], that base their functioning on the fact that patterns for data points, which are hard to recognize in their original space, can become easy to identify once nonlinearly mapped to a (high-dimensional) *feature space*. Once the suitable mapping is performed, it is possible to identify the hyperplane which best separates the classes of feature data points, through a support vector machine [27] (SVM), according to the inner product of the mapped data. Let us note that the only part of the

FIG. 1. **Photonic quantum kernel estimation. a**. The photonic quantum kernel maps each data point x_i to be classified from a d-dimensional space into a quantum state $|\Phi\rangle_i$, living in a Hilbert feature space. In detail, the classical data x_i is encoded into a unitary evolution $U(x_i)$ applied on a fixed input state $|\psi\rangle$. This implies $|\Phi\rangle_i = U(x_i)|\psi\rangle$. After mapping all the data points in the dataset, from the inner pairwise products, we perform the classification finding the hyperplane best separating the classes, i.e. through a classical support vector machine (SVM), according to Eq. (1). **b.** Pairs of indistinguishable photons and distinguishable photons show a different behaviour when injected in a Mach-Zehnder interferometer (MZI). Here, input states 11 and 11$'$ indicate, respectively, two indistinguishable and distinguishable photons being injected in the circuit and being detected at the output modes. **c.** Estimation of the inner product of two data points x_i and x_j by encoding them in two unitaries $U(x_i)$ and $U(x_j)$. The inner product $\langle\phi_j|\phi_i\rangle$ amounts to $\langle\psi|U^\dagger(x_i)U(x_j)|\psi\rangle$. This is equivalent to projecting the evolved state $U^\dagger(x_j)U(x_i)|\psi\rangle$ onto $|\psi\rangle$. Each box represents a programmable MZI with two free parameters (namely a beam splitter with tunable reflectivity and phase), as shown in **b**.

model that is trained is the SVM, whose training and resulting classification can be performed efficiently, once the inner products are available. Hence, an interesting question is whether using a quantum apparatus to perform the data mapping and evaluate the inner products among the resulting feature points can lead to an enhanced performance. Such a hybrid classical-quantum model would benefit, on one hand, from the quantum feature maps that result from the evolution of quantum systems (which can be hard to simulate on classical computers) and, on the other, it would outsource the hardest part of the computation to the quantum hardware. This question was theoretically answered in the affirmative by [28], where a machine learning task inspired by cryptography was constructed that is provably hard for classical computers to learn and can be solved efficiently with a quantum kernel. However, the implementation of this task remains far out of reach for current experimental capabilities. Moreover, a risk that one encounters in quantum kernel estimation is that, once the feature space is too large, all data points are mapped into orthogonal states, resulting in an ineffective classification. Hence, a moderately-sized quantum feature space can prove more suitable, to preserve the similarity among data belonging to the same class.

In this paper, we give an experimental demonstration of quantum kernel estimation, where data points are mapped in the feature space through the unitary evolution of two-boson Fock states (see Fig. 1). Such encoding allows us to arbitrarily tune the dimension of the feature space and, even for relatively small dimensions, it provides enough of a non-linearity to achieve a high classification accuracy with data which are only non-linearly classifiable.

Furthermore, we show that for given tasks, this algorithm leads to an enhancement in the performance of quantum kernels with respect to their classical counterparts. These tasks were selected by maximizing the so-called *geometric difference*, which measures the separation in performance between a pair of kernels [29]. To experimentally demonstrate this method, we exploit a photonic platform and, in particular, an integrated photonic processor [30] where we inject two-boson Fock states to map the data to be classified (see Fig. 1a). This photonic platform is particularly suitable for this task, as it allows us to encode and manipulate our input data with high fidelity.

To benchmark our enhanced performance, we compare

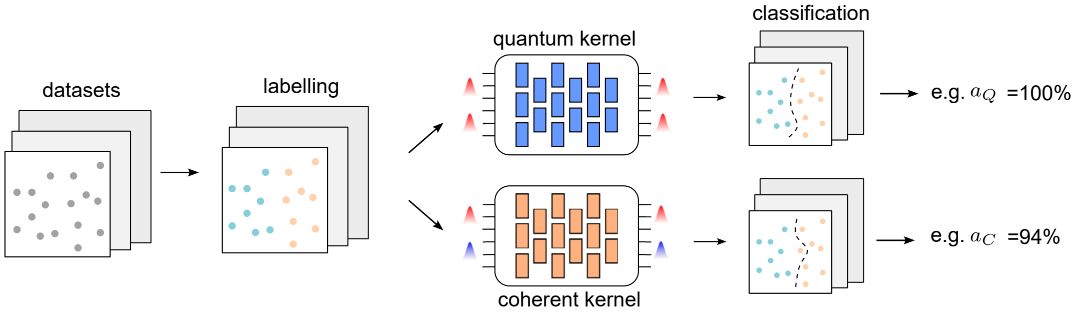

FIG. 2. **Classification tasks for photonic kernel methods.** The datasets are randomly generated and consist in d-dimensional vectors, with entries between 0 and 1. Then, we randomly assign labels to each point as belonging to class +1 or -1 and we test the ability of our photonic kernels, displaying and not displaying quantum interference (respectively indicated as *quantum kernel* and *coherent kernel*), to correctly classify the data. This is quantified by the accuracy of our models, which we indicate as a_Q and a_C.

our classification accuracies to the case in which the photonic inputs display no quantum interference, that is using distinguishable photons [31]. We also compare to conventional kernels, including Gaussian and polynomial kernels [25], optimizing their performance by using a grid search over their hyperparameters. We show that for given tasks, both the photonic kernels, with and without quantum interference, outperform standard methods.

PHOTONIC QUANTUM KERNEL ESTIMATION

A kernel method relies on a function that maps N input data points x_i, on which we wish to perform binary classification, from a space $\mathcal{X} \subseteq \mathbb{R}^d$ into a feature space $\mathcal{H}$. Here, d is the dimension of each data point. This is done through a feature map $\Phi : \mathcal{X} \to \mathcal{H}$. Then, a SVM can be used to produce a *prediction* function $f_K : \mathcal{X} \to \mathbb{R}$ as $f_K(x) = \sum_i \alpha_i K(x, x_i)$, where these α_i coefficients are obtained by solving a linear optimization problem. The inputs of the optimization are the labels y and the matrix obtained by computing the pairwise distances between data points is $K_{i,j} = K(x_i, x_j) = \langle\Phi(x_j)|\Phi(x_i)\rangle$, the so-called *Gram matrix* (for further information about kernel methods, see Supplementary Note 1).

In this work, we implement a quantum version of the kernel method, in which the aforementioned pairwise distances between data points, which belong to a class y taking values +1 or −1, are estimated by sampling from the output probability distribution arising from the unitary evolution of a Fock input state. This process is depicted in Fig. 1a. Therefore, our feature map plugs the data that needs to be classified into the free parameters defining a unitary evolution applied to a fixed Fock state of dimension m and whose sum of occupational numbers is n: $x \mapsto |\Phi(x)\rangle = U_x|\psi\rangle$. Here, $|\psi\rangle$ is the encoding state which is free to choose. Then, as shown in Fig. 1c, the pairwise inner products of the feature points are experimentally evaluated, as $|\langle\psi|U(x_i)^\dagger U(x_j)|\psi\rangle|^2$. Such unitaries can be effectively implemented by a programmable photonic circuit consisting of an array of Mach-Zehnder interferometers (MZIs)[32]. Hence, the dimension of the feature Hilbert space $\mathcal{H}$ will be $\binom{n+m-1}{n}$. At this point, the SVM finds the hyperplane separating the training data points through the aforementioned optimization process [33, 34] and, at the end, the binary classification of unknown points x is given by the following relation:

$$y = \text{sign}\left(\sum_{i=1}^{N} \alpha_i y_i K(x, x_i)\right) \quad (1)$$

where α_i are, as before, the coefficients optimized in the training process and y_i is the class of the i-th point in the training. This model is defined *implicitly*, as the labels are assigned by weighted inner products of the encoded data points [35–43].

If the Fock state contains indistinguishable bosons, they will exhibit quantum interference, as shown in Fig. 1b. In this case, the output probability distribution, which in general is hard to compute on classical processors, is given by the permanents of sub-matrices of the matrix representing the unitary evolution of the input [44]. More specifically, considering an input configuration s, the probability of detecting the output configuration t is given by $|\text{per}(U_{s,t})|^2/\Pi_i^m s_i!\Pi_i^m t_i!$. Here, per($\cdot$) denotes the permanent matrix operation, s_i and t_i are the occupational numbers at the i-th mode and $U_{s,t}$ is the sub-matrix obtained by selecting the rows/columns corresponding to the occupied modes of the input/output Fock states. On the other hand, if the bosons are distinguishable, they will not exhibit quantum interference and their output distribution is always efficiently computable [7, 10, 11, 45]. In this case the probability will amount to per($|U_{s,t}|^2$)$/\Pi_i^m s_i!\Pi_i^m t_i!$.

In the following, we will refer to a kernel implemented with indistinguishable bosons as a *quantum kernel*, K_Q, and with distinguishable ones as a *coherent kernel*, K_C.

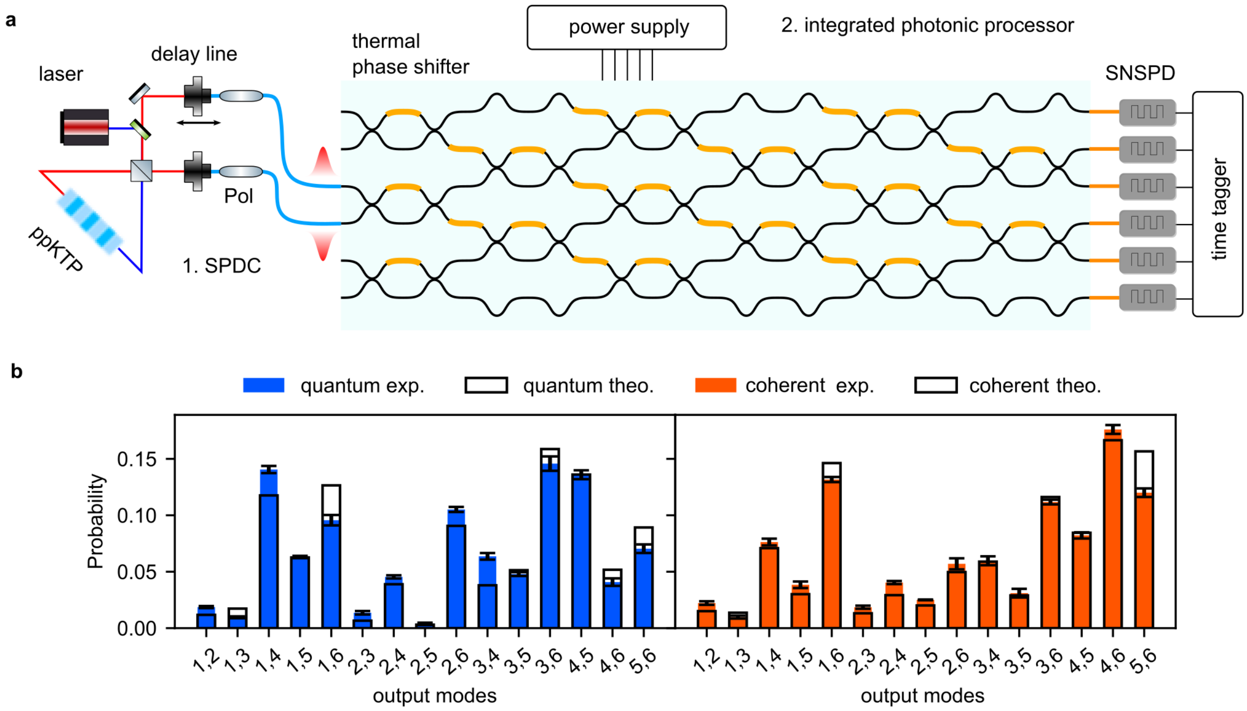

FIG. 3. **Implementation of photonic quantum kernel estimation. a.** Experimental setup consisting of two parts, the off-chip single photon source and the programmable integrated photonic processor. The frequency degenerate photons are generated by a type-II spontaneous parametric down-conversion source. Afterwards, the two photons are made indistinguishable in their polarization and arrival time. Then, we inject these photons in two modes of an integrated photonic processor with 6 input/output modes [30]. Detection is performed by superconducting nanowire single-photon detectors (SNSPDs). The degree of indistinguishability can then be tuned through a delay line, changing their relative temporal delay. **b.** Probability distribution of photon detection events. We show two instances of the experimental photon detection probability, compared to the theoretical calculation. The quantum and coherent kernel measurements are obtained respectively by injecting two indistinguishable and distinguishable photons into the third and fourth modes of the circuits, i.e. $|0,0,1,1,0,0\rangle$. The x axis shows all the circuit channels which output two photons simultaneously. Thus, all 15 possible photon detection configurations are accessible.

CLASSIFICATION TASK

To select a classification task that would benefit from the described model, we use a quantifier called the *geometric difference* [29], which compares two kernels K_a and K_b, which we will denote as $g_{a,b}$. Given a set of data points $\{x_i | x_i \in \mathcal{X}\}$ without any labels, the geometric difference provides the binary labels $\{y_i\}$ that maximise the expected difference in prediction error between two kernels – in our case, we consider K_Q and K_C, as depicted in Fig. 2. Therefore, we obtain this optimal labelling by solving the following minimisation problem:

$$y^\star = \arg\min_{y\in\mathbb{R}^d}\left(\frac{s_{K_Q}(y)}{s_{K_C}(y)}\right) \qquad (2)$$

where $s_K(y) = y^T K y$ is the model complexity of the pair K and y, i.e. the number of features that the model needs to make accurate predictions (see the Supplementary Note 2). To saturate the following inequality [29]:

$$\exists y \quad \cdot \quad s_{K_C}(y) \quad \leq \quad g^2_{CQ}\, s_{K_Q}(y) \qquad (3)$$

we take $y^T K_C^{-1} y = g^2_{CQ} y^T K_Q^{-1} y$, and obtain the relation

$$g_{CQ} = \sqrt{\left\|\sqrt{K_Q}\,(K_C)^{-1}\sqrt{K_Q}\right\|_\infty} \qquad (4)$$

where $\|\cdot\|_\infty$ denotes the spectral norm and g_{CQ} is the so-called *geometric difference.*

We can now use Eq. (4) to generate the classification task that, given a pair of kernels K_Q, K_C and a set of data points $\{x_i\}$, produces the labels $\{y_i\}$ that maximise the difference in prediction error bound. This can be done through the following procedure: (i) evaluate the Gram matrices K_Q and K_C over a set of non-labelled data points $\{x_i\}$; (ii) compute the positive definite matrix $M = \sqrt{K_Q}\,(K_C)^{-1}\sqrt{K_Q}$; (iii) compute the eigenvalues and eigenvectors of M by spectral decomposition; (iv) find the maximum eigenvalue g and its corresponding eigenvector v; (v) assign the labels $y = \sqrt{K_Q}v$. From a practical point of view, we start with the two aforementioned kernels, K_C and K_Q, and then, by maximizing the geometric difference, we find the tasks for which the latter brings an enhanced accuracy of the classification. For more details regarding the algorithm to define the classification task, see the Supplementary Note 4. Let us note that the implemented tasks constitute instances of problems that can be naturally implemented with high accuracy on our quantum platform. As such they constitute a first stepping stone towards the identification of practical tasks for which quantum machine learning can enhance the performance of classical models.

EXPERIMENT

Our experimental setup consists of two parts, a single-photon source generating the input states and a programmable integrated photonic processor depicted in Fig. 3a. First, to generate the input state, we use a type II spontaneous parametric down-conversion source, which generates frequency degenerate single-photon pairs at 1546 nm in a periodically poled K-titanyl phosphate crystal. The two photons are then made indistinguishable in their polarization and arrival time, respectively, via wave retarders and a delay line, which we also use to tune the degree of indistinguishability of the generated photons.

For the implementation of photonic kernels, which map our input data to a feature space, we require an apparatus able to perform arbitrary unitary transformations on a given input state. As mentioned before, our feature map sends each data point x_i onto the state resulting from the evolution $U(x_i)$ of a fixed input Fock state $|\psi\rangle$. Then, for the application of the SVM, which finds the best hyperplane separating the data, we need to evaluate the inner products between all of the points x_i, x_j in the feature space, which amounts to $\langle\psi|U(x_i)^\dagger U(x_j)|\psi\rangle$. This implies that, if we take $|\psi\rangle$ as a Fock state of n photons over m modes, the inner product $\langle\Phi(x_i)|\Phi(x_j)\rangle$ is given by projecting the evolved state $U(x_i)^\dagger U(x_j)\,|\psi\rangle$ onto $|\psi\rangle$.

To this aim, we employ an integrated photonic processor [30] fabricated on a borosilicate glass substrate, in which optical waveguides are inscribed through femtosecond laser writing [46–48]. The circuit features six input/output modes and it is based on a rectangular mesh of 15 programmable MZIs [32], as depicted in Fig. 3a. Each interferometer is equipped with two thermal phase shifters [49] in order to provide tunable reflectivity and phase. By properly choosing the values of the phase shifters, such arrangement allows us to perform any unitary transformation on the input photon states. Given this property, our device is also referred to as a universal photonic processor. Design, fabrication and calibration of the integrated photonic circuit are described in [30].

Specifically, the data were encoded in the values of the phase shifts, as follows: $x_i = (x_i^1, x_i^2, ..., x_i^{30}) \rightarrow \theta_i = (2\pi x_i^1, 2\pi x_i^2, ..., 2\pi x_i^{30})$, where θ_i are the phase shifts introduced by the phase shifters of a universal interferometer. This implies that, in principle, we would need a sequence of two of such circuits (as in the scheme of Fig. 1c), to first implement $U^\dagger(x_i)$ and then $U(x_j)$ on our inputs. However, in our implementation, we adopt only one universal circuit and directly implement the unitary corresponding to the product $U(x_i)^\dagger U(x_j)$. This reduces the experimental complexity and the propagation losses within the circuit itself.

At the output, detection is performed by superconducting nanowire single-photon detectors (SNSPDs). Due to the fact that these detectors are not photon-number resolving, we post-select the output events to those featuring two detectors clicking the *collision-free* events (see Supplemental Information Note 3). To test the role of quantum interference in the accuracy of the classification, we tune the indistinguishability of the two photons by changing their relative temporal delay. An instance of the probability distribution of the same unitary is shown in Fig. 3b, indicating the high experiment fidelity. The optimal classification task is chosen for each data set according to the algorithm explained in the previous section.

RESULTS

We test the performance of two photonic kernels in several different configurations. Firstly, we consider two different inputs, $|\psi_L\rangle = |1,1,0,0,0,0\rangle$ and $|\psi_C\rangle = |0,0,1,1,0,0\rangle$. This amounts to either injecting the photons into the first two modes or the central two modes. Second, we are able to tune the indistinguishability to implement the quantum kernel and the coherent kernel (see Supplementary Note 5). The maximal achieved indistinguishability between the photons is 0.9720±0.0044, by measuring the on-chip Hong-Ou-Mandel interference [50].

For both input states, we test datasets of four different sizes: 40, 60, 80 and 100. We then use the setup depicted in Fig.3a to implement all of the pairwise products between the unitaries $U(x_i)^\dagger U(x_j)$. Hence, $|\langle\psi|U(x_i)^\dagger U(x_j)|\psi\rangle|^2$ is given by the probability of detecting the photons on the same modes from which they were injected.

For each size N, we perform $N(N-1)/2$ unitaries to compute all of the inner products. The distance between the unitaries experimentally realized and the target ones can be estimated as $\sum_i \sqrt{P_i^{\text{theo}} \cdot P_i^{\text{exp}}}$, where P_i^{exp} is the experimental detection frequency for the i-th output configuration, while P_i^{theo} is the one estimated based on the theory[51]. The mean fidelity of all datasets is

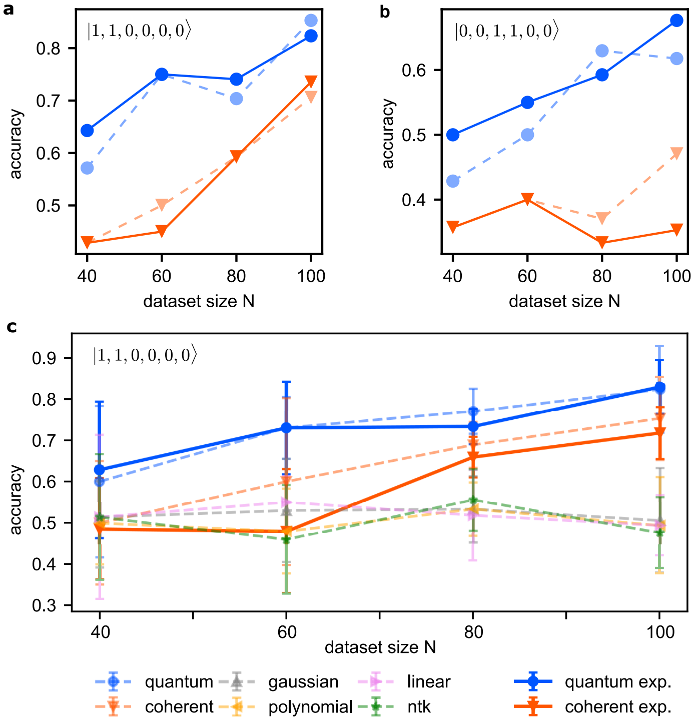

FIG. 4. **Experimental classification accuracies. a-b.** We tested our method on datasets of different sizes (from 40 to 200) and for two different input states ($|1,1,0,0,0,0\rangle$ and $|0,0,1,1,0,0\rangle$) respectively. For each dataset, 2/3 of the datapoints were used for training the support vector machine (SVM) and 1/3 for test. **c.** The average classification accuracies on 5 different sets for the quantum kernel (blue curves) and the coherent (orange curve) kernel, along with the following computational kernels: Gaussian (grey curve), polynomial (yellow) and linear (purple). The dashed line indicates the results of numerical simulations, while the solid ones the experimental results. The error bar shows the standard deviation of the classification accuracies on 5 datasets for all the kernels.

0.9816±0.0148 and 0.9934±0.0048, for the quantum kernel and coherent kernel respectively (for additional details regarding intermediate degrees of indistinguishability, see Supplementary Note 5). For each dataset, we use 2/3 of the data points for the training of the SVM, and the remaining 1/3 as a test set. The accuracy is defined as the number of correctly classified points over the total size of the test set. Let us note that values lower than 0.5 indicate that the model was not able to learn the features of the training set and generalize to unknown data.

In Fig. 4a and b, we show the test accuracies obtained by injecting two input states for four different dataset sizes, where the quantum kernel performs significantly better than the coherent kernel at both experiments. In Fig. 4c, we report the average test accuracy obtained for five different datasets with the same size, varying the dataset sizes from 40 to 100 as well. Moreover, the results obtained with the quantum kernel (blue curves) and the coherent kernel (orange curve) are compared with the following numerical kernels: Gaussian (grey curve), polynomial (yellow) and linear (purple). For the latter three kernel methods, we consider the maximal accuracy obtained by optimizing their hyperparameters (for further details, please see the Supplemental Information Note 4). Although the task is built only comparing the performance of the kernels based on indistinguishable and distinguishable photons, the obtained accuracy is higher also than commonly used classical kernels [25, 26]. The dashed lines indicate the results of numerical simulations, while the solid lines indicate experimental results.

DISCUSSION

In this work, we show the first experimental demonstration of quantum kernel estimation, based on the unitary evolution of Fock states through an integrated photonic processor. In our implementation, data is mapped into a feature space by encoding it into the evolution of a fixed two-photon input state over six modes. The sampled output distribution is then fed into an SVM, which performs the classification. To achieve this, we adopt an integrated photonic processor realized by femtosecond laser writing in a borosilicate glass substrate [30]. It is noteworthy that, although our apparatus only features linear optical elements, i.e. phase shifters and beam splitters, the chosen encoding produces a sufficient nonlinearity to achieve high accuracy in the classification of non-linearly separable datasets. This constitutes a difference of our method from implementations on superconducting qubits platforms, where entangling gates are typically needed for quantum kernel estimation [29, 52]. Furthermore, in our case, it is not necessary to increase the dimension of the feature Hilbert space to achieve a good accuracy. This is a crucial feature which allows us to avoid the typical difficulty of quantum kernels whereby all data points are encoded in orthogonal states, leading to null inner products and, therefore, to an ineffective classification [53]. Another novelty of our approach lies on the fact that we are not using the photonic platform to reproduce classical kernels, as in [54], because our kernel function is given by the natural evolution of bosons through a quantum circuit.

The task we implement is artificially designed by arbitrarily assigning binary labels to randomly generated data points, which we encode in the phase shifts introduced by an optical circuit. To assign the labels, we exploit as our metric the so-called *geometric difference*. This allows us to select the task for which the presence of quantum interference yields a better classification accuracy with respect to the case where the photons constituting the input state are fully distinguishable (and hence no interference is displayed). Despite the fact that the geometric difference compares the performance of a pair of kernels (in our case kernels implemented with indistinguishable versus distinguishable bosons), the selected tasks are performed significantly better by both the bosonic kernels than commonly used kernels, such as the Gaussian, polyonomial and linear ones. Our results indicate that, for these tasks, a kernel estimation performed on photonic hardware enhances the overall performance, even for medium-size problems, which are reachable by the state-of-art of quantum technologies. Moreover, the possibility of using distinguishable bosons to have a (smaller) performance enhancement represents an intriguing possibility, as it circumvents the difficulty of single photons states generation. This strategy can prove especially convenient to reduce the impact of photon losses on the experimental time required to collect significant statistics.

Despite being overshadowed by deep neural networks, kernels are still widely used in a large number of tasks, due to their simplicity, and ability to learn from small datasets [55, 56]. Indeed, they have also had a recent revival in classical machine learning, where they have been used as a theoretical framework that subsumes state-of-the-art neural network architectures such as transformers [57?]. Another recent trend, consists in merging neural networks and kernels, by introducing kernel-like layers inside the structure of neural networks. Notable examples are attention modules in natural language processing, and Hopfield layers [58].

Our method can find a wide range of promising near-term applications in quantum machine learning tasks such as information retrieval, natural language processing and medical image classification [59–62], where kernel methods have been proposed a foundational keystone [63]. Our experimental results demonstrate that our quantum-enhanced kernels can outperform classical ones on datasets resulting from quantum observations, it also opens the door to hybrid methods where photonic processors are used to enhance the performance of deep neural networks.

Moreover, these results open the way for further investigations related to the non-linearities that can be achieved through photonic platforms [64, 65], which are crucial elements for machine learning purposes and, in particular, for neuromorphic computation models, such as *reservoir computing* [66, 67]. This may be of particular importance when considering difficulties related to energy consumption, as it has been proved that partially optical networks can be adopted to reduce the overall energy requirements with respect to electronic ones [68]. In addition, we envisage further studies related to the combination of this kind of non-linearity with those brought by the implementation of feedback loops, as in the case of quantum memristor [69] and the exploitation of quantum interference in the implementation of feature maps.

ACKNOWLEDGEMENTS

The authors would like to thank Anna Pearson for her active involvement in the first stages of this project. This research was funded by the European Union Horizon 2020 and Horizon Europe research and innovation programme under grant agreement No 899368 (EPIQUS), and the Marie Skłodowska-Curie grant agreement No 956071 (AppQInfo), and the QuantERA II Programme under Grant Agreement No 101017733 (PhoMemtor). I.A. acknowledges financial support from the Österreichischer Wissenschaftsfonds FWF, through the ”Early-Stage Program: Research – Innovation – Training” post-doctoral fellowship No ESP 205-N (PREQUrSOR). Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or the European Research Council. Neither the European Union nor the granting authority can be held responsible for them. Further funding was received from the Austrian Science Fund (FWF) through BeyondC (F7113). Research Group 5 (FG5) and I 6002-N,; and from the Austrian Federal Ministry for Digital and Economic Affairs, the National Foundation for Research, Technology and Development and the Christian Doppler Research Association. G.d.F would like to thank Konstantinos Meichanetzidis and Tommaso Salvatori for insightful discussions on the project. The integrated photonic processor was partially fabricated at PoliFAB, the micro- and nanofabrication facility of Politecnico di Milano (https://www.polifab.polimi.it/). C.P., F.C. and

R.O. wish to thank the PoliFAB staff for the valuable technical support. For the purpose of open access, the author has applied a CC BY public copyright licence to any Author Accepted Manuscript version arising from this submission.

AUTHOR CONTRIBUTIONS

Z.Y. and I.A. designed and conducted the experiment and G.d.F., D.B. and A.T. developed the theory and algorithm. C.P., S.P., A.C. and F.C. conducted the design, fabrication and calibration of the integrated photonic processor. Z.Y., I.A. and G.d.F. wrote the first draft of the manuscript. R.O., B.C. and P.W. supervised the whole project. All authors discussed the results and reviewed the manuscript.

METHODS

The two photon input states are generated by a type-II spontaneous parametric down-conversion source, which generates frequency degenerate single-photon pairs at 1546 nm via a periodically poled K-titanyl phosphate (ppKTP) crystal. Afterwards, the two photons are made indistinguishable in their polarization, which is rotated through paddles, and arrival time, through a delay line, which we use also to tune the degree of indistinguishability of the generated photons. Then, we inject these photons in two modes of an integrated photonic processor with 6 input/output modes [30]. This circuit features 27 thermal phase shifters and its architecture follows the rectangular scheme presented in [32], to implement arbitrary unitary evolution on any input Fock state. The current source is supplied to each phase shifter independently to avoid electrical crosstalk. In the end, detection is performed by superconducting nanowire single-photon detectors (SNSPDs) housed in a 1K cryostat. We postselect the detected events to the cases in which two detectors click simultaneously in a temporal window of 1 ns. A time tagger with a 15.63 ps resolution is used to process the real-time coincidence counting for all 15 postselection patterns.

Abstract. In quantum mechanics, measuring a general observable involves statistical uncertainty, which can be reduced by averaging samples. Minimizing the number of samples is crucial in future quantum computing, especially when we desire to explore numerous observables in large systems. This work presents an adaptive extension of the quantum gradient estimation algorithm to estimate the expectation values of M observables within root mean squared error ε using $\mathcal{O}(\varepsilon^{-1}\sqrt{M}\log M)$ queries to a state preparation oracle. That is, the method achieves Heisenberg-limited scaling $\mathcal{O}(\varepsilon^{-1})$ and the sublinear scaling with M, offering a resource-efficient implementation with space overhead of $\mathcal{O}(M)$ and avoiding numerical instability in quantum signal processing techniques for large-scale tasks.

Keywords: Quantum computation, Quantum metrology, Observable estimation

1 Overview and summary

Achieving quantum enhancement in the estimation of unknown parameters is a fundamental goal in quantum technology. In particular, the gap between the standard quantum limit (SQL) and the Heisenberg limit (HL) in such estimation tasks has been getting a significant focus since the late 20th century. The SQL represents the scaling of measurement counts as $\mathcal{O}(1/\varepsilon^2)$ for target accuracy ε, while the HL scales as $\mathcal{O}(1/\varepsilon)$ due to quantum uncertainty relations that are usually quantified by a natural metric called the mean squared error (MSE). The HL can theoretically be reached using entanglement or coherence in quantum probes without noise [14, 15], while its experimental verification has not been realized for a long time until the quantum phase estimation procedure by Higgins *et al.* with use of a novel adaptive measurement [19].

The quest for quantum-enhanced measurement extends to multiple observables, a topic crucial for various applications of quantum computing like quantum simulation [26, 1, 8, 13, 3, 39], quantum machine learning [4, 25, 20], and quantum finance [33, 6]. Although modified amplitude estimation algorithms [34, 37, 36] can individually achieve HL scaling for multiple observables, we here seek a protocol that achieves both the HL scaling and the sublinear scaling with respect to M in estimating all of M observables. Some approaches based on the gradient estimation [22] have reported nearly Heisenberg-limited scaling with logarithmic corrections [35, 21], but no method has yet achieved ultimate precision scaling as defined by the HL. Specifically, existing works often rely on confidence intervals to quantify the estimation error, which do not bound the worst-case scenario as effectively as MSE. As well known in the field of quantum metrology [15, 18], the MSE successfully bounds other measures of uncertainty [2], while the converse does not hold in general. Considering that any quantum algorithm to estimate observables queries the state preparation oracle whose complexity usually scales with the target system size, it is crucial to design an estimation algorithm that achieves the Heisenberg-limited scaling in terms of MSE.

Driven by such a situation, we make a significant contribution to multiple observables estimation of number M with root MSE of ε. Concretely, we explicitly construct an adaptive estimation scheme as summarized as Algorithm 1 that satisfies the following features (each correspond to Theorem 1, 2, and 3, respectively):

- *Heisenberg-limited scaling with sublinear scaling on M.* The proposed method achieves the pure HL scaling with root MSE ε as $\mathcal{O}(\varepsilon^{-1}\sqrt{M}\log M)$ in query to the state preparation. Also, this scaling indicates a nearly quadratic improvement regarding M, compared to the (modified) quantum amplitude estimation [5, 24, 32, 34, 37, 36].

- *Constant space overhead.* The quantum circuits in the proposed scheme require additional $\mathcal{O}(M)$ qubits, which is independent of ε.

- *Robustness in high-precision regime.* When the high precision $\varepsilon \ll 1$ is required, the quantum circuits in our method have at most $\mathcal{O}(\log(1/\varepsilon))$ parameterized gates for QSVT [13], which can be tuned by $\mathcal{O}(\text{polylog}(1/\varepsilon))$ classical computation, while the previous method [35] requires to tune $\mathcal{O}(1/\varepsilon)$ gates with $\mathcal{O}(\text{poly}(1/\varepsilon))$ classical computation. This significant reduction in classical compu-

Further applications of the HL scheme	[23, 11, 10, 17]	Future work

tation allows us to avoid the numerical instability problem [16, 7, 9, 38, 30] that spoils the quantum enhancement.

In our algorithm, we sample from an $\mathcal{O}(M + \log_2 d)$-qubit circuit with an alternating sequence of a global interaction to encode the expectation values of target observables and a controlled rotation over the target $\log_2 d$-qubit system (and some ancillary system). The global interaction and the total circuit length are adaptively adjusted to read out the expectation values in high resolution, keeping the space overhead small. Then, we classically process the samples similarly to the adaptive phase estimation algorithms [18, 23, 11] and use the processing results to construct the next quantum circuit. The sublinear scaling on M comes from the spectral amplification process [27, 13] embedded in the global interaction. Importantly, the proposed algorithm is the first adaptive extension of quantum gradient estimation [22, 12], which allows us to evaluate the M-dimensional gradient of a real scalar function $f(\boldsymbol{x})$ on $\mathbb{R}^M$ with sublinear scaling on M; see Table 1 for the comparison with phase estimation algorithms.

We remark that the classical computation in the third point is required for the circuit construction, especially for quantum signal processing (QSP) [29, 28]. QSP provides a systematic way to operate a 1-qubit system under a wide range of polynomial functions of degree n, using $\mathcal{O}(n)$ parameterized quantum gates. In the framework of QSP (or its extension QSVT [13]), we need to tune the parameterized gates classically for a desired polynomial. Although finding this parameter for a degree-n polynomial can be achieved in $\mathcal{O}(\mathrm{poly}(n))$ classical computation time, it exhibits numerical instability for large n, posing a central challenge in the practical application of QSVT [30]. In the previous method for multiple observables estimation [35], the number of parameterized gates is given by $n = \tilde{\mathcal{O}}(\sqrt{M}/\varepsilon)$, leading to a quite large runtime in classical computation e.g., $\sim M/\varepsilon^2$ [sec] when we use the method in Ref. [9] (assuming it works in such a large n). In contrast, our method requires tuning only $\mathcal{O}(\sqrt{M}\log(M/\varepsilon))$ gates under a certain condition by partially using a special polynomial whose parameters are analytically derived.

Algorithm 1 Adaptive observables estimation

```
Input: $\log_2 d$-qubit state preparation unitary $U_\psi$; observables $\{O_j\}_{j=1}^M$ with the spectral norm $\|O_j\| \le 1$ such that $M > \mathcal{O}(\log d)$ holds; confidence parameter $c \in (0, 3/8(1+\pi)^2]$; target root MSE $\varepsilon \in (0,1)$.
Set a fixed precision parameter $p := 3$ and temporal estimates $\tilde{u}_j^{(0)} := 0$ for all $j$.
for $q = 0, 1, ..., q_{\max} := \lceil \log_2(1/\varepsilon) \rceil$ do
    Measure $\mathcal{O}(\log M/\delta^{(q)})$ approximate copies of the probing state $|\Upsilon(q)\rangle$ in Eq. (1) after $p$-qubit inverse quantum Fourier transformations.
    Here, $\delta^{(q)} := c/8^{q_{\max}-q}$ is a failure probability.
    Set the coordinate-wise median of the measurement outputs as $g_j^{(q)}$.
    Update $\tilde{u}_j^{(q+1)} := \tilde{u}_j^{(q)} + \pi 2^{-q} g_j^{(q)}$
    Truncate $\tilde{u}_j^{(q+1)}$ in $[-1, 1]$
end for
return final estimates $\tilde{u}_j := \tilde{u}_j^{(q_{\max}+1)}$
```

2 Main idea of algorithm

Let us state the concrete problem setup and provide the main idea of the proposed algorithm (see Algorithm 1 for the pseudocode). We consider estimating quantum expectation values of given d-dimensional M Hermitian operators $\{O_j\}_{j=1}^M$ ($\|O_j\| \le 1$) regarding a quantum state $|\psi\rangle$, which is prepared by a state preparation oracle U_ψ. Here, the observables are assumed to be accessed by some block-encoding unitaries. The key idea of the proposed scheme is to adaptively prepare the following *probing state*, from which the approximated expectation values can be extracted via gradient estimation algorithm [22]:

$$|\Upsilon(q)\rangle := \frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x} \in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j 2^q \pi^{-1} \langle O_j - \tilde{u}_j^{(q)} \mathbf{1} \rangle} |\boldsymbol{x}\rangle \tag{1}$$

where $q = 0, 1, \cdots, \lceil \log_2(1/\varepsilon) \rceil$ denotes a iteration step, p denotes a fixed precision parameter, $\langle O_j \rangle := \langle \psi | O_j | \psi \rangle$ and G_p^M is a set of 2^{pM} grid points in $\mathbb{R}^M$. In the technical manuscript, we will show that $p = 3$ is sufficient for our algorithm to successfully work. Because there is a one-to-one correspondance between G_p^M and 2^{pM}-qubit computational base, we label the computational basis by $\boldsymbol{x} = (x_1, ..., x_M) \in G_p^M$. The quantity $\tilde{u}_j^{(q)} \in [-1, 1]$ are temporal estimated values for $\langle O_j \rangle$ at the qth iteration.

As rigorously shown in Ref. [12], the gradient estimation algorithm [22] can simultaneously extract the values $2^q \pi^{-1} \langle O_j - \tilde{u}_j^{(q)} \mathbf{1} \rangle$ from the quantum state (1) with an additive error specified by p and a certain success probability. Thus, using the successful results from the gradient estimation, we can update $\tilde{u}_j^{(q)}$ to $\tilde{u}_j^{(q+1)}$ such that $\tilde{u}_j^{(q+1)}$ is more close to the target value $\langle O_j \rangle$. More precisely, this update yields a $q+1$ binary-bit accurate estimate $\tilde{u}_j^{(q+1)}$ for $\langle O_j \rangle$ because of the enhanced resolution $2^q \langle O_j - \tilde{u}_j^{(q)} \mathbf{1} \rangle$ in the probing state $|\Upsilon(q)\rangle$. Consequently, we can obtain ε-close estimates at the end of the iteration step, if the gradient estimation at every step is successfully performed.

3 Performance guarantee of algorithm

HL multiple observables estimation. We prove the rigorous performance guarantee for estimation efficiency of the proposed protocol as follows.

Theorem 1 (Theorem 2 in the technical manuscript). *Let $\varepsilon \in (0, 1)$ be a target precision. For given M observables $\{O_j\}_{j=1}^M$ and a state preparation U_ψ, there exists a quantum algorithm that samples estimators $\{\hat{u}_j\}_j$ for $\{\langle \psi | O_j | \psi \rangle\}_{j=1}^M$ satisfying*

$$\max_{j=1,2,...,M} \mathbb{E}\left[(\hat{u}_j - \langle \psi | O_j | \psi \rangle)^2 \right] \leq \varepsilon^2$$

using $\mathcal{O}(\varepsilon^{-1}\sqrt{M} \log M)$ queries to the state preparation U_ψ and $U_\psi^\dagger$ in total.

The scaling $1/\varepsilon$ of queries to U_ψ with respect to root MSE ε achieves the same scaling to the Heisenberg limit in the gradient estimation; see the technical manuscript. The squared root dependence regarding M originates from the uniform amplification of block-encoded (sum of) observables [27], which is consistent with the idea used in the previous method [35]. As for the $\log M$ term, its origin is the repetition of the measurement to (1) in each iteration step, in order to boost the success probability by taking median of estimates.

Constant space overhead. In addition to the HL scaling in query complexity, our scheme has a significant improvement in space complexity compared to the previous non-iterative counterparts [35, 21]. While the previous methods determine all of the $\mathcal{O}(\log(1/\varepsilon))$ binary bits of $\langle O_j \rangle$ by a quantum circuit with $\mathcal{O}(M \log(1/\varepsilon))$ readout qubits, our scheme determines only 1 binary bit of $\langle O_j \rangle$ at each iteration step. Therefore, by the help of the adaptive procedure, our scheme requires quantum circuits with $\mathcal{O}(M)$-qubits overhead, to prepare $|\Upsilon(q)\rangle$ with the fixed precision parameter $p = 3$. This can be summarized as follows:

Theorem 2 (Theorem 7 in the technical manuscript). *Suppose that we have access to block-encoded d-dimensional observables $\{O_j\}_{j=1}^M$, a $\log_2 d$-qubit state preparation U_ψ, and its inverse $U_\psi^\dagger$, such that $M > \mathcal{O}(\log d)$. Then, we can approximately prepare the probing state $|\Upsilon(q)\rangle$ for any integer $q \geq 0$ and $\tilde{u}_j^{(q)} \in [-1, 1]$, using an*

$$\mathcal{O}(M + \log_2 d)\text{-}qubit$$

circuit. Furthermore, each quantum circuit with q requires $\mathcal{O}(\mathrm{poly}(2^q\sqrt{M \log d}) + \mathrm{poly}(\sqrt{M}(q + \log M)))$ classical computation for finding circuit parameters, and it consists of $\mathcal{O}(2^q\sqrt{M \log d})$ uses of U_ψ and $U_\psi^\dagger$, $\mathcal{O}(2^q M(q + \log M))$ uses of unitary gates for block-encoded observables.

Robustness in high-precision regime. The quantum circuit employed in Theorem 2 requires classical tuning of $\tilde{\mathcal{O}}(\sqrt{M}/\varepsilon)$ circuit parameters (more precisely, $\tilde{\mathcal{O}}(2^q\sqrt{M})$ parameters in step q) for QSP. The classical computation for finding $\tilde{\mathcal{O}}(\sqrt{M}/\varepsilon)$ parameters is also required in the existing work by Ref. [35]. However, it is challenging to find such a large number of circuit parameters in a stable way as pointed out in previous works [30].

To avoid the numerical instability, we here provide an alternative way to prepare the probing state (1) using the *Grover-like repetition*, which is a special case of QSP such that the corresponding quantum circuit parameters are analytically derived.

Theorem 3 (Theorem 8 in the technical manuscript). *Suppose the same conditions on $\{O_j\}_{j=1}^M$ and U_ψ as in Theorem 2. If the iteration step $q \geq 0$ satisfies the following condition ($\delta' := 2^{-14}$)*

$$q \geq \log_4 \left[\frac{2^3 \cdot 33^3}{625 \ln(2d/\delta')} \frac{\left\lceil \sqrt{2(M+1)\ln(2d/\delta')} \right\rceil}{\sqrt{\ln(2d/\delta')}} \right], \quad (2)$$

and for given $\tilde{u}_j^{(q)} \in [-1, 1]$, $|\langle O_j - \tilde{u}_j^{(q)} \mathbf{1} \rangle| \leq 2^{-q}$ holds for all j, then we can approximately prepare the probing state $|\Upsilon(q)\rangle$, with the success probability at least 0.462 with ancilla qubits measurement result indicating success, using an $\mathcal{O}(M + \log_2 d)$-qubit circuit. Furthermore, each quantum circuit with q requires

$$\mathcal{O}(\mathrm{poly}(\sqrt{M}(q + \log M)))$$

classical computation, and it has the same gate complexity as that of Theorem 2.

Although this method cannot deterministically prepare the probing state, the success probability can be increased with a constant number of circuit repetitions, thus maintaining the same total query complexity when using Grover-like repetition instead of Theorem 2. We remark that the condition $|\langle O_j - \tilde{u}_j^{(q)} \mathbf{1} \rangle| \leq 2^{-q}$ is trivially satisfied in Algorithm 1; see the technical manuscript. In particular, if the number of target observables satisfies $M = \mathcal{O}((\log_2 d)^2)$, then the right hand side in Eq. (2) becomes constant, and therefore, the alternative scheme is valid in a wide range of ε.

In quantum mechanics, measuring a general observable has an inherent statistical uncertainty such as variance or mean squared error. While the uncertainty can be reduced by averaging several samples, the number of samples should be minimized when each sample is very costly; this is precisely the case in future quantum computing. Meanwhile, one of the goals of quantum computing is to explore numerous observables in large quantum systems that are beyond the capabilities of classical computers. In this work, we provide an adaptive quantum algorithm for estimating the expectation values of M general observables within root mean squared error ε simultaneously, using $\mathcal{O}(\varepsilon^{-1}\sqrt{M}\log M)$ queries to state preparation oracle; the total queries achieves the scaling of Heisenberg limit $1/\varepsilon$, a fundamental bound on the estimation precision, and the sublinear scaling of the number of observables M. The proposed method is an adaptive version of the quantum gradient estimation algorithm and has a resource-efficient implementation due to its adaptiveness. Specifically, the space overhead in the proposed method is $\mathcal{O}(M)$ which does not depend on the estimation precision ε. In addition, our method can avoid the numerical instability problem of constructing quantum circuits in a large-scale task (e.g., $\varepsilon \ll 1$ in our case), which appears in the actual application of many quantum algorithms relying on quantum signal processing techniques.

I. INTRODUCTION

A. Background

Attaining a quantum enhancement in unknown parameter estimation lies as one of the most fundamental tasks in quantum technology. It has been noticed in the quantum metrological community from the late 20th century that there exists a gap between the standard quantum limit (SQL), the statistical scaling of the measurement count $\mathcal{O}(1/\varepsilon^2)$ for target accuracy of ε that is based on the central limit theorem, and the Heisenberg limit (HL), the scaling $\mathcal{O}(1/\varepsilon)$ due to quantum uncertainty relations that are quantified by a natural metric called the mean squared error (MSE). The HL can theoretically be achieved using entanglement or coherence (i.e., sequential applications of a sensing channel) in quantum probes under the absence of noise [1, 2], while its experimental verification has not been realized for a long time until the quantum phase estimation procedure by Higgins *et al.* that uses a novel adaptive measurement [3]. Aside from Ref. [3], intensive quest for experimental realization of the scaling beyond the SQL has provoked numerous interesting ideas such as the use of quantum error correction [4–7], exploiting the non-Markovianity of the environment [8, 9].

The preceding pursuit for the fundamental limitation by quantum mechanics naturally pertains to the quantum-enhanced measurement of multiple observables. This long-standing question has been posed mainly in the community of quantum computing, since an overwhelming numbers of quantum algorithms estimate the expectation values of local and/or global observables; not to mention scientific application of quantum computers for quantum simulation of many-body systems in natural science [10–15], such a task is also ubiquitous in industrial use such as quantum machine learning [16–18] and quantum finance [19, 20]. Note that, while one may employ the modified amplitude estimation algorithm [21–23] individually for M observables to simply obtain the HL scaling of $\mathcal{O}(M/\varepsilon)$ in terms of root MSE ε, here we seek for simultaneous improvement on the target accuracy ε and observable count M. Simply put, our goal is to construct a protocol that achieves both the HL scaling and the sublinear scaling with respect to M in estimating all of M observables.

Indeed, some previous works based on the gradient estimation algorithm [24, 25] have reported nearly Heisenberg-limited scaling, although with multiplicative logarithmic correction $\log(1/\varepsilon)$ [26, 27]; there is no work that achieves the ultimate precision scaling following the HL in light of its definition. Furthermore, existing works argue the estimation accuracy in terms of confidence intervals, which crucially fails to bound the worst-case behavior of a single run, unlike the MSE. As is well known in the field of quantum metrology [2, 28–30], the MSE successfully bounds other measures of uncertainty, while the converse does not hold in general. Considering that any

FIG. 1. Graphical summary of the proposed method. Our algorithm estimates the expectation values of quantum observables $\{\langle O_j \rangle\}_{j=1}^{M}$ regarding a quantum state $|\psi\rangle$ prepared by a unitary U_ψ, with an adaptive procedure. In each iteration step q, we first encode the values of estimation errors $\{\langle O_j - \tilde{u}_j^{(q)}\mathbf{1}\rangle\}$ for a unitary gate, where $\tilde{u}_j^{(q)} \in [-1, 1]$ denotes a temporal estimated value from the previous step, for the target value $\langle O_j \rangle$. Then, we coherently amplify the estimation errors by the factor of 2^q via Grover-like repetition (or Hamiltonian simulation) on the encoding unitary and read out *zoomed-in* values $\{2^q \langle O_j - \tilde{u}_j^{(q)}\mathbf{1}\rangle\}$ simultaneously by gradient estimation protocol with a fixed measurement precision. From the measurement results, we update the temporal estimates $\tilde{u}_j^{(q)}$ to $\tilde{u}_j^{(q+1)}$. By repeating this procedure for $q = 0, 1, ..., \lceil \log_2(1/\varepsilon) \rceil$, this algorithm estimates the M observables simultaneously within at most root MSE ε. The algorithm uses $\mathcal{O}(\varepsilon^{-1}\sqrt{M}\log M)$ queries to the state preparation unitary U_ψ that indicates the scaling of Heisenberg limit, that is, the inverse of root MSE ε, together with the nearly squared root dependence on the number of observables M, which comes from the spectral amplification process in the encoding of $\{\langle O_j - \tilde{u}_j^{(q)}\mathbf{1}\rangle\}$.

quantum algorithm to estimate observables queries the state preparation oracle of target quantum state whose complexity usually scales with the system size, it is crucial to design an estimation algorithm that achieves the HL scaling in terms of the MSE.

A key insight for enhancement can be borrowed from the history of phase estimation algorithm [31]. It has been well-recognized that the textbook style of the phase estimation algorithm [32] encounters two major bottlenecks that prevents the algorithm from practical benefit; the large ancilla consumption of $\mathcal{O}(\log(1/\varepsilon))$ and the poor query complexity scaling with the target root MSE ε, i.e., only obeying the SQL $\mathcal{O}(1/\varepsilon^2)$ [3, 33, 34]. While the former can be addressed by the iterative phase estimation [31], it was not until the work by Higgins *et al.* that proposed to overcome both issues by utilizing adaptive measurement scheme to achieve the HL with a constant number of ancilla [3]. Although a followup work has shown that HL scaling can be achieved even without relying on the adaptive scheme, there is in practice an increase in the estimation variance by a constant factor [29]. On the other hand, if the large ancilla consumption is acceptable, it is known that the quantum phase estimation algorithm with an entangled ancillary state, instead of a uniform superposition state, can achieve the HL [33–36]. From the above observations, we argue that adaptive strategy is crucial for resource-efficient implementation of quantum estimation that saturates the ultimate scaling limited by purely fundamental principles of quantum physics.

B. Summary of results

Driven by such a situation, we make a significant contribution to multiple observables estimation of number M with root MSE of ε. Concretely, we explicitly construct an adaptive estimation scheme as summarized as Algorithm 1, which satisfies the following features (each correspond to Theorem 2, 7, and 8, respectively):

- *Heisenberg-limited scaling with sublinear scaling on M.* The proposed observable estimation achieves the pure HL scaling with root MSE ε as

$$\mathcal{O}(\varepsilon^{-1}\sqrt{M}\log M)$$

in query to the state preparation. Also, this scaling indicates a nearly quadratic improvement regarding M, compared to the parallel use of the (modified) quantum amplitude estimation [21–23, 37–39].

- *Constant space overhead.* The quantum circuits in the proposed scheme require at most additional $\mathcal{O}(M)$ qubits, which is independent of the target root MSE ε.

- *Robustness in high-precision regime.* When the high precision $\varepsilon \ll 1$ is required, the quantum circuits in our method have at most $\mathcal{O}(\log(1/\varepsilon))$ parameterized gates for QSVT [13], which can be tuned by $\mathcal{O}(\mathrm{polylog}(1/\varepsilon))$ classical computation, while the previous method [26] requires to tune $\mathcal{O}(1/\varepsilon)$ gates with $\mathcal{O}(\mathrm{poly}(1/\varepsilon))$ classical computation. This significant reduction in classical computation allows us to avoid the numerical instability problem [40–44] that spoils the quantum enhancement.

The first feature is a mathematical guarantee of estimation performance, and the other features highlight ease of practical implementation of our method.

In our algorithm, we sample from an $\mathcal{O}(M + \log_2 d)$-qubit circuit with an alternating sequence of a global interaction to encode the expectation values of target observables and a controlled rotation over the target $\log_2 d$-qubit system (and some ancillary system). The global interaction for observables and the total circuit length are adaptively adjusted to read out the expectation values in high resolution, keeping the space overhead small. Then, we classically process the samples similarly to the adaptive (iterative) phase estimation algorithms [29, 30, 45, 46] and use the processing results to construct the quantum circuit at the next step. The sublinear scaling in the number M of observables comes from the spectral amplification process [13, 47] embedded in the global interaction. This reason for the speedup on M is the same as the previous method [26]. Importantly, the proposed algorithm is the first adaptive extension of quantum gradient estimation [24, 25], which allows us to evaluate the M-dimensional gradient of a real scalar function $f(\boldsymbol{x})$ on $\mathbb{R}^M$ with sublinear scaling on M.

We remark that the classical computation in the third point is required for the circuit construction, especially for quantum signal processing (QSP) [48, 49]. QSP provides a systematic way to operate a 1-qubit system under a wide range of polynomial functions of degree n, using $\mathcal{O}(n)$ parameterized quantum gates, and it is also a key component of a more general technique for quantum matrix polynomials, called quantum singular value transformation (QSVT) [13]. In the framework of QSP (also QSVT), we need to tune the parameterized gates classically for a desired polynomial. Although finding this parameter for a degree-n polynomial can be achieved in $\mathcal{O}(\mathrm{poly}(n))$ classical computation time, it exhibits numerical instability for large n; this instability leads to undesired algorithmic errors in the resulting quantum circuit, posing a central challenge in the practical application of QSVT [40]. To resolve this, various optimization techniques have been investigated [40–44], and currently, they require 10^2–10^4 seconds to tune $n \sim 10^4$ parameters. In the previous method for multiple observables estimation [26], the number of circuit parameters is given by $n = \tilde{\mathcal{O}}(\sqrt{M}/\varepsilon)$, leading to a quite large runtime in classical computation e.g., $\sim M/\varepsilon^2$ [sec] when we use the method in Ref. [42] (assuming it works in such a large n). In contrast, our method requires to tune only $\mathcal{O}(\sqrt{M}\log(M/\varepsilon))$ parameters under a certain condition, by partially using a special polynomial whose parameters can be analytically determined. This exponential improvement in classical computation time, regarding estimation accuracy $1/\varepsilon$, significantly lowers the barrier of the practical implementation of our method.

II. PROBLEM SETUP

We consider estimating quantum expectation values of given d-dimensional M Hermitian operators $\{O_j\}_{j=1}^M$ with the spectral norm $\|O_j\| \leq 1$, regarding a quantum state $|\psi\rangle$. Here, d is a power of 2. The target state $|\psi\rangle$ is assumed to be prepared by a state preparation oracle $U_\psi : |\mathbf{0}\rangle \mapsto |\psi\rangle$ and an initial state $|\mathbf{0}\rangle := |0\rangle^{\otimes \log_2 d}$, and we assume oracular access to U_ψ and $U_\psi^\dagger$. The observables are assumed to be accessed by some block-encoded unitaries over the d-dimensional system and some ancilla system; that is, for each observable O_j, we assume access to a unitary gate B_j whose top-left block matrix is O_j. (Precise definition of this encoding is provided in Sec. IV.) In this setup, our goal is to *efficiently* obtain samples from estimators for the target values $\langle O_j\rangle := \langle\psi| O_j |\psi\rangle$ within the root mean squared error (MSE) ε. In particular, we aim to simultaneously achieve the HL scaling regarding ε and the sublinear scaling regarding M, for estimating all $\langle O_j\rangle$.

The performance of quantum algorithms for this task is usually quantified by the total number of queries to the state preparation U_ψ and $U_\psi^\dagger$. This is because U_ψ has complexity that usually scales with the system size, and as a result, the state preparation U_ψ is the most dominant factor in the total execution time for various settings. Under the natural assumption that $U_\psi^\dagger$ has the same cost as U_ψ, it is crucial to design an estimation algorithm that minimizes the statistical uncertainty using a limited number of queries to U_ψ and $U_\psi^\dagger$.

III. ADAPTIVE GRADIENT ESTIMATION FOR MULTIPLE QUANTUM OBSERVABLES

Our adaptive estimation algorithm is given in Algorithm 1. This algorithm can be seen as an extension of the adaptive (iterative) phase estimation [3, 29, 31, 45,

Algorithm 1 Adaptive observables estimation

```
Input: $\log_2 d$-qubit state preparation unitary $U_\psi$; observables $\{O_j\}_{j=1}^M$ with the spectral norm $\|O_j\| \leq 1$ such
    that $M > \mathcal{O}(\log d)$ holds; confidence parameter $c \in (0, 3/8(1+\pi)^2]$; target root mean squared error (MSE)
    $\varepsilon \in (0,1)$.
Output: A sample $(\tilde{u}_1, ..., \tilde{u}_M)$ from an estimator $\hat{\boldsymbol{u}} = (\hat{u}_1, ..., \hat{u}_M)$ whose $j$-th element estimates $\langle\psi|O_j|\psi\rangle$ within
    the MSE $\varepsilon^2$ as
        $\max_{j=1,2,...,M} \mathbb{E}\left[(\hat{u}_j - \langle\psi|O_j|\psi\rangle)^2\right] \leq \varepsilon^2$
Set a fixed precision parameter $p := 3$ and temporal estimates $\tilde{u}_j^{(0)} := 0$ for all $j$.
for $q = 0, 1, ..., q_{\max} := \lceil\log_2(1/\varepsilon)\rceil$ do
    Measure $\mathcal{O}(\log M/\delta^{(q)})$ approximate copies of the probing state
        $|\Upsilon(q)\rangle := \frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x} \in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j 2^q \pi^{-1} \langle O_j - \tilde{u}_j^{(q)} \mathbf{1}\rangle} |\boldsymbol{x}\rangle$
    after $p$-qubit inverse quantum Fourier transformations.
    Here, $\delta^{(q)} := c/8^{q_{\max}-q}$ is a failure probability.
    Set the coordinate-wise median of the measurement outputs as $g_j^{(q)}$.
    Update $\tilde{u}_j^{(q+1)} := \tilde{u}_j^{(q)} + \pi 2^{-q} g_j^{(q)}$
    Truncate $\tilde{u}_j^{(q+1)}$ in $[-1,1]$
end for
return final estimates $\tilde{u}_j := \tilde{u}_j^{(q_{\max}+1)}$
```

46] to the quantum gradient estimation [24, 25], which efficiently estimates the gradient ∇f of a smooth real scalar function $f(\boldsymbol{x})$ that is assumed to be encoded in an oracle; see Appendix A for the review of the gradient estimation. In the following, we focus on the estimation performance and the total query complexity regarding the use of U_ψ and $U_\psi^\dagger$ in Algorithm 1. Also, we provide its high-level overview in Fig. 1. Appendix B gives complete proof of theorems together with showing concrete implementation method for the algorithm.

The key idea of the proposed adaptive algorithm is to prepare the following *probing* state $|\Upsilon(q)\rangle$ at each iteration step q, from which the approximated expectation values can be extracted via the gradient estimation algorithm [24, 25]:

$$|\Upsilon(q)\rangle := \frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x} \in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j 2^q \pi^{-1} \langle O_j - \tilde{u}_j^{(q)} \mathbf{1}\rangle} |\boldsymbol{x}\rangle\,, \tag{1}$$

where $\mathbf{1}$ denotes the identity operator. Also, p denotes a fixed precision parameter and G_p^M is defined as a set of grid points:

$$G_p := \left\{\frac{\mu}{2^p} - \frac{1}{2} + \frac{1}{2^{p+1}} : \mu \in \{0, 1, \cdots, 2^p - 1\}\right\}.$$

Note that we label the pM-qubit computational basis $|\mu_1\rangle|\mu_2\rangle ... |\mu_M\rangle$ ($\mu_j \in \{0, 1, ..., 2^p - 1\}$) by each grid point $\boldsymbol{x} = (x_1, x_2, ..., x_M)$ in G_p^M via one-to-one correspondence between G_p and the computational basis set. The quantities $\tilde{u}_j^{(q)} \in [-1, 1]$ in the probing state Eq. (1) are temporal estimated values for $\langle O_j\rangle$ at the iteration step q. Later we will show that $p = 3$ is sufficient for our algorithm to successfully work.

The probing state $|\Upsilon(q)\rangle$ can be prepared by first intializing the pM-qubit probe system, the $\log_2 d$-qubit target system, and some ancilla systems to encode the observables. Then, applying a q-dependent interaction unitary on the whole system and then performing a postselection on the target-ancilla systems, we approximately obtain the probing state. The query complexity regarding U_ψ and $U_\psi^\dagger$ of this state preparation process is given as follows.

Corollary 1 (Probing state preparation)**.** *Suppose that we have access to block-encoded $d \times d$ observables $\{O_j\}_{j=1}^M$ via some unitaries, a $\log_2 d$-qubit state preparation U_ψ, and its inverse $U_\psi^\dagger$, such that $M > \mathcal{O}(\log d)$ holds. Then, we can prepare the probing state $|\Upsilon(q)\rangle$, up to 1/12 Euclidean distance error, for (any) integer $q \geq 0$ and $\tilde{u}_j^{(q)} \in [-1, 1]$, using $\mathcal{O}(2^q\sqrt{M \log d})$ queries to U_ψ and $U_\psi^\dagger$ in total.*

This corollary directly follows from Theorem 7 and 8 shown in the next section, both of which give methods to prepare the probing state $|\Upsilon(q)\rangle$: one is based on the Hamiltonian simulation protocol (Theorem 7), and the other is based on the Grover-like repetition (Theorem 8).

Suppose we have the probing state $|\Upsilon(q)\rangle$ at the qth iteration, with a temporal estimate $\tilde{u}_j^{(q)}$ for $\langle O_j\rangle$. Then, on the phase of $|\boldsymbol{x}\rangle$ in $|\Upsilon(q)\rangle$, the estimation error $\langle O_j - \tilde{u}_j^{(q)} \mathbf{1}\rangle$ is amplified by the factor of 2^q; this means that when $\tilde{u}_j^{(q)}$ matches $\langle O_j\rangle$ in the first q binary (fraction) digits as

$$\left|\langle O_j\rangle - \tilde{u}_j^{(q)}\right| \leq \frac{1}{2^q}, \tag{2}$$

the 2^q-fold amplification *zooms in* on the significant digits of $\langle O_j\rangle - \tilde{u}_j^{(q)}$ to shift the values toward upper digits. As proved in Ref. [25], the gradient estimation for $|\Upsilon(q)\rangle$ can simultaneously extract these zoomed-in values $2^q \langle O_j - \tilde{u}_j^{(q)} \mathbf{1}\rangle$ (with $1/\pi$) or equivalently the gradient of the linear function on the phase:

$$f(\boldsymbol{x}) := \frac{1}{\pi} \sum_j x_j 2^q \langle O_j - \tilde{u}_j^{(q)} \mathbf{1}\rangle\,,$$

with an additive error specified by the precision parameter p and a certain success probability (see Lemma 9).

Note that, in our case, the gradient estimation algorithm is simply to perform the computational basis measurement (with rewriting $|\mu\rangle$ as $|x\rangle$) on the probing state after applying a slightly modified version of p-qubit inverse quantum Fourier transformation, which is defined in Eq. (A6).

In step 4 of Algorithm 1, we use the measurement outputs $\boldsymbol{k}^{(1)}, \boldsymbol{k}^{(2)}, ..., \boldsymbol{k}^{(\mathcal{O}(\log M/\delta^{(q)}))}$ obtained in Step 3 to construct the coordinate-wise median $g_j^{(q)}$; that is, $g_j^{(q)}$ is defined as the middle value separating the greater and lesser halves of $\{k_j^{(1)}, k_j^{(2)}, ...\}$. Then, under the condition of Eq. (2), we can prove that the median $g_j^{(q)}$ satisfies

$$\left| g_j^{(q)} - \frac{2^q \langle O_j - \tilde{u}_j^{(q)} \mathbf{1} \rangle}{\pi} \right| \le \frac{1}{2\pi}, \tag{3}$$

for all $j = 1, 2, ..., M$ with success probability bigger than $1 - \delta^{(q)}$; later we will carefully choose the probability $\delta^{(q)}$ in order that a final estimator has the minimal statistical uncertainty. Using the successfully obtained $g_j^{(q)}$ satisfying Eq. (3), we update the temporal estimate as

$$\tilde{u}_j^{(q+1)} := \tilde{u}_j^{(q)} + \pi 2^{-q} g_j^{(q)}.$$

Then, it is straightforward to prove

$$\left| \langle O_j \rangle - \tilde{u}_j^{(q+1)} \right| \le \frac{1}{2^{q+1}},$$

for all j. Thus, using the outcomes from the gradient estimation algorithm at each step, we can iteratively determine one binary fraction digit of the target value $\langle O_j \rangle$ by updating $\tilde{u}_j^{(q)}$ to $\tilde{u}_j^{(q+1)}$. Repeating this iteration step $q_{\max} := \lceil \log_2(1/\varepsilon) \rceil$ times, we obtain estimates for $\{\langle O_j \rangle\}_j$ within the root MSE ε.

Now, we describe the above result in a precise way. A more detailed proof is given in Appendix B 2.

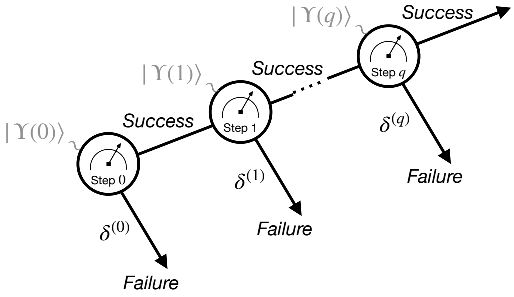
Theorem 2 (Heisenberg-limited multiple observables estimation). ***Let*** *$\varepsilon \in (0, 1)$ be a target precision. For given M observables $\{O_j\}_{j=1}^M$ and a state preparation U_ψ, there exists a quantum algorithm that outputs a sample from estimators $\{\hat{u}_j\}_{j=1}^M$ for $\{\langle O_j \rangle\}$ satisfying*

$$\max_{j=1,2,...,M} \text{MSE}[\hat{u}_j] \le \varepsilon^2, \tag{4}$$

using $\mathcal{O}(\varepsilon^{-1}\sqrt{M}\log M)$ queries to the state preparation U_ψ and $U_\psi^\dagger$ in total. Here, the mean squared error of an estimator $\hat{u}_j$ is defined as

$$\text{MSE}[\hat{u}_j] := \mathbb{E}\left[(\hat{u}_j - \langle O_j \rangle)^2 \right].$$

Sketch of the proof. The outline of the proof is similar as that of the previous methods for Heisenberg-limited phase estimation or its application [29, 45, 46, 50], but it is required to carefully check the condition for gradient estimation at each iteration step. Specifically, this condition is given by Eq. (2) for all j. If this condition holds and the precision parameter p is taken as $p = 3$, then a single shot measurement result $\boldsymbol{k} := (k_1, ..., k_M) \in G_p^M$ in Step 3 of Algorithm 1 follows



: Gradient estimation at step q

FIG. 2. Probability tree diagram in Algorithm 1.

$$\Pr\left[\left| k_j - \frac{2^q(\langle O_j \rangle - \tilde{u}_j^{(q)})}{\pi} \right| > \frac{1}{2\pi} \right] < \frac{1}{3}, \tag{5}$$

for every $j = 1, 2, \cdots, M$. The derivation of this inequality is based on our numerical finding; see Appendix B 2. We remark that the failure probability represented by the left hand side of Eq. (5) can be exponentially suppressed to $\delta^{(q)}/M$ by using the coordinate-wise median $g_j^{(q)}$ of the measurement results over $\mathcal{O}(\log M/\delta^{(q)})$ copies of the (approximate) probing state, instead of the single shot result k_j. This repetition is the origin of the $\log M$ term in the total query complexity.

In the first iteration step $q = 0$, the condition Eq. (2) is trivially satisfied, and the gradient estimation can yield $1/2\pi$-close estimates of the target quantities for all j. This probability is at least $1 - \delta^{(0)}$ due to the union bound. As for the iteration step $q \ge 1$, if all of the previous steps succeed in the gradient estimation, we can show that Eq. (2) holds for all j at the iteration step q. On the other hand, if the gradient estimation fails at the iteration step q (while all processes have been successfully executed up to the $(q-1)$th step), the condition Eq. (2) is not satisfied; as a result, outputs of the gradient estimation may not improve the temporal estimate in the subsequent processes. However, in this case, it can be shown that the additive error $|\tilde{u}_j - \langle O_j \rangle|$ of the final estimate $\tilde{u}_j := \tilde{u}_j^{(q_{\max}+1)}$ is at most $(1+\pi)/2^q$ because the outputs of gradient estimation are always in $[-1/2, 1/2]$ from the definition of G_p^M. From the above analysis, we can bound the additive error of the final estimate for all branches in Fig. 2.

The failure probability $\delta^{(q)}$ should be very small at the beginning of iteration steps q because the error of top fraction bits have a significant impact on the MSE of the final estimator. From the analysis in Ref. [50], the choice of $\delta^{(q)} := c/8^{q_{\max}-q}$ $(c \in (0, 3/8(1+\pi)^2))$ is sufficient, and then the MSE of the final estimator $\hat{u}_j$ (its realization is $\tilde{u}_j$) is calculated as at most ε^2 for all $j = 1, 2, ..., M$, from the tree diagram Fig. 2 and the above error evaluation in each branch.

To derive the query complexity for the state preparation U_ψ, we use the result in Corollary 1. In the iteration step q, preparing $\mathcal{O}(\log M/\delta^{(q)})$ copies of the probing state Eq. (1) uses $\mathcal{O}(2^q \sqrt{M \log d} \log(M/\delta^{(q)}))$ queries to the state preparation unitary U_ψ and its inverse. Thus, the summation of the queries over $q = 0, 1, ..., q_{\max}$ ($q_{\max} := \lceil \log_2(1/\varepsilon) \rceil$) is directly calculated as $\mathcal{O}(\varepsilon^{-1} \sqrt{M \log d} \log M)$, which completes the proof of Theorem 2. □

In Theorem 2, the scaling $1/\varepsilon$ of queries to U_ψ with respect to the root MSE ε achieves the same scaling to the Heisenberg limit (HL) in the gradient estimation, which is derived in Appendix A. We remark that, to the best of our knowledge, this is the first derivation of the HL in gradient estimation in terms of MSE, while the previous work [25] shows a similar lower bound (additionally, including $\sqrt{M}$ dependency) on queries to an oracle for a target function $f(\boldsymbol{x})$ on $\boldsymbol{x} \in G_p^M$, in another metric of statistical uncertainty (i.e., a confidence interval). Also, in the stringent measure of statistical uncertainty, the root MSE ε [28], all the existing works [26, 27] in multiple observables estimation only proves the nearly HL scaling that includes logarithmic terms on ε such as $\log(M/\varepsilon)$.

In addition to the Heisenberg-limited scaling regarding ε, our protocol has the nearly squared root dependence regarding the total number of observables M. This is a nearly quadratic improvement regarding M compared to the standard method (i.e., quantum amplitude estimation) of estimating the expectation values of observables. Furthermore, when we focus on another metric of statistical uncertainty — a confidence interval comprised of estimators with an additive error $\pm\epsilon_{\rm add}$ for some confidence level, which is considered in Refs. [26, 27], the query complexity of our method is essentially optimal in terms of M and $\epsilon_{\rm add}$ as well as these previous methods. Here, the query lower bound in multiple observables estimation in terms of a confidence interval is proved in Ref. [27] as follows.

Lemma 3 (Corollary 3 in Ref. [27])**.** *Let M be a positive integer power of 2 and let $\epsilon_{\rm add} \in (0, 1/3\sqrt{M})$. Let $\mathcal{A}$ be any algorithm that takes as an input an arbitrary set of M observables $\{O_j\}_{j=1}^M$. Suppose that, for every quantum state $|\psi\rangle$, accessed via a state preparation oracle U_ψ, $\mathcal{A}$ outputs estimates of each $\langle\psi| O_j |\psi\rangle$ to within additive error $\epsilon_{\rm add}$ with high probability at least $2/3$. Then, there exists a set of observables $\{O_j\}_{j=1}^M$ such that $\mathcal{A}$ applied to $\{O_j\}_{j=1}^M$ must use $\Omega(\epsilon_{\rm add}^{-1}\sqrt{M})$ queries to U_ψ.*

The proposed algorithm can be easily extended to an estimation protocol that outputs an $\epsilon_{\rm add}$-close estimate of $\{\langle O_j \rangle\}_j$ with high probability ($\geq 2/3$) at the cost of a slight increase of the total query complexity (i.e., $\mathcal{O}(\epsilon_{\rm add}^{-1}\sqrt{M}\log^2 M)$) [51]. Consequently, we establish from the Lemma 3 that this extended protocol achieves the worst-case query optimality (up to the $\log^2 M$ correction) in the high-precision regime $\epsilon_{\rm add} \in (0, 1/3\sqrt{M})$.

Finally, we remark that the preparation and measurement for multiple copies of the probing state in step 3 of Algorithm 1 can be performed in parallel if we are allowed to use multiple quantum computers, which may practically important to reduce the total execution time.

IV. STATE PREPARATION FOR ADAPTIVE GRADIENT ESTIMATION

In this section, we provide two quantum algorithms to prepare the probing state Eq. (1), using the state preparation U_ψ, $U_\psi^\dagger$, and the unitary gates $\{B_j\}_{j=1}^M$ that encode the target observables $\{O_j\}_{j=1}^M$ with the help of some ancilla system. The two methods are summarized in Theorems 7 and 8; Theorem 7 provides a method based on Hamiltonian simulation protocol, and Theorem 8 provides a method based on Grover-like repetition. Both Theorems 7 and 8 prove that the total space complexity to prepare the probing state $|\Upsilon(q)\rangle$ is $\mathcal{O}(M + \log_2 d)$. In addition, Theorem 8 shows an exponential improvement in the classical computation time for constructing explicit quantum circuits under a certain condition, compared to Theorem 7.

In the following, we first review an efficient quantum computation method of block-encoded matrices. Then, we describe the two methods for the probing state preparation.

A. Preliminary

Here, we review some important results in efficiently calculating block-encoded matrices on a quantum computer. The basic tool to represent matrices by unitary operators of dilated quantum systems is *block encoding*:

Definition 1 (Block encoding)**.** For positive values α, ε and a non-negative integer a, we say that an $(n + a)$-qubit unitary U is an (α, a, ε)-block-encoding of an n-qubit operator A, if

$$\|A - \alpha(\langle 0|^{\otimes a} \otimes \mathbf{1})U(|0\rangle^{\otimes a} \otimes \mathbf{1})\| \leq \varepsilon.$$

For simplicity, we shorten the perfect (i.e., $\alpha = 1$ and $\varepsilon = 0$) block encoding of A as a-block-encoding of A.

For instance, any unitary operator (e.g., a Pauli operator $X \otimes Z \otimes \cdots$) is trivially a 0-block-encoding of itself. There are various ways to construct block encodings; see Ref. [13]. Specifically, we here focus on the method called the linear combination of unitaries (LCU) [52, 53]. Let $A := \sum_{i=1}^m c_i U_i$ be a linear combination of unitary operators $\{U_i\}_{i=1}^m$ with real coefficients $c_i \in \mathbb{R}$. Without loss of generality, we assume $c_i > 0$ because -1 can be absorbed into U_i. In order to implement A, we use the

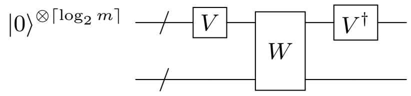


FIG. 3. Linear combination of unitaries (LCU) method. The circuit is a $\lceil\log_2 m\rceil$-block-encoding of $\|c\|_1^{-1}\sum_{i=1}^m c_iU_i$ ($c_i > 0$). PREPARE $V : |0\rangle^{\otimes\lceil\log_2 m\rceil} \mapsto \sum_{i=1}^m \sqrt{\frac{c_i}{\|c\|_1}}|i\rangle$ and SELECT $W = \sum_{i=1}^m |i\rangle\langle i| \otimes U_i$.

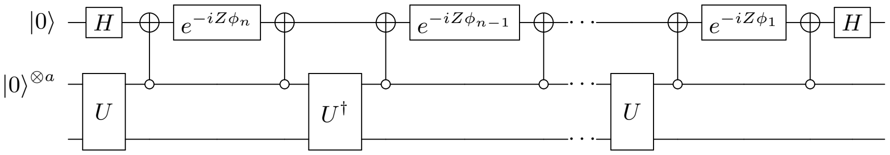

FIG. 4. Quantum circuit for quantum singular value (eigenvalue) transformation for real polynomials P of odd degree n. U denotes an a-block-encoding of a Hermitian operator A. The NOT gate is controlled by $|0\rangle^{\otimes a}$ of the a qubits, which is represented by the white circle $\circ$. For a given real polynomial P of degree n, the n circuit parameters $\{\phi_i\}_{i=1}^n$ are calculated in $\mathcal{O}(\text{poly}(n))$ classical computation time.

following two unitary operations. The first one, called PREPARE, encodes the positive coefficients $\{c_i\}_{i=1}^m$ as

$$V : |\mathbf{0}\rangle \mapsto \sum_{i=1}^m \sqrt{\frac{c_i}{\|c\|_1}}|i\rangle,$$

where $\|\bullet\|_1$ denotes L^1-norm, and $|\mathbf{0}\rangle$ and $|i\rangle$ denote an initial state and the computational basis in a $\lceil\log_2 m\rceil$-qubit ancilla system, respectively. The other, called SELECT, encodes the unitary operartors U_i conditioned by the $\lceil\log_2 m\rceil$-qubit ancilla system:

$$W = \sum_{i=1}^m |i\rangle\langle i| \otimes U_i.$$

Using the two operations V and W, it can be shown that the unitary operator $(V^\dagger \otimes \mathbf{1})W(V \otimes \mathbf{1})$ is a $(\|c\|_1, \lceil\log_2 m\rceil, 0)$-block-encoding of A, as in Fig. 3. Note that if the coefficients in LCU are controlled by other qubit registers, it may be useful to modify the PREPARE operator instead of including the phase of c_i to the SELECT operator, in order to save the number of controlled operations.

Once we have a block encoding of a target operator, we can systematically transform the block encoding to perform various tasks. Here, we show examples of such transformations that will be used in the following subsection.

Lemma 4 (Uniform singular value amplification [13, 47])**.** *Let $\gamma > 1$ and let $\delta, \varepsilon \in (0, 1/2)$. Suppose we have an a-block-encoding U of A, $(\|A\| \le (1-\delta)/\gamma)$. Then, we can implement a $(1, a{+}1, \varepsilon)$-block-encoding of γA with $m = \mathcal{O}(\gamma\delta^{-1}\log(\gamma/\varepsilon))$ queries to U or $U^\dagger$, $2m$ uses of NOT gates controlled by a-qubit, $\mathcal{O}(m)$ single-qubit gates, and $\mathcal{O}(\text{poly}(m))$ classical computation to find quantum circuit parameters.*

Lemma 5 (Quantum eigenvalue transformation by Chebyshev polynomials [13])**.** *Let m be a positive integer, and let U be an a-block-encoding of a Hamiltonian H. Then, for the m-th Chebyshev polynomial of the first kind $T_m(x)$, we can implement a $(1, a, 0)$-block-encoding of $T_m(H)$, with m uses of U or $U^\dagger$ and m uses of reflection on $|0\rangle^{\otimes a}$.*

Lemma 6 (Optimal block-Hamiltonian simulation [49])**.** *Let $t \in \mathbb{R}\backslash\{0\}$, $\varepsilon'' \in (0, 1)$, and let U be a $(1, a, 0)$-block-encoding of a Hamiltonian H. Then, we can implement a $(1, a+2, \varepsilon'')$-block-encoding of e^{itH}, with $4Q$ queries to controlled U or its inverse, $2Q$ uses of NOT gates controlled by $(a+1)$-qubit, $\mathcal{O}(Q)$ uses of single-qubit or two-qubit gates, and $\mathcal{O}(\text{poly}(Q))$ classical computation to find quantum circuit parameters, where $Q = \mathcal{O}(t+\log(1/\varepsilon''))$.*

Lemma 4 and Lemma 5 can be implemented with a quantum circuit in Fig. 4. Also, we can implement the optimal Hamiltonian simulation Lemma 6 with a similar circuit as Fig. 4; the explicit circuit constructions are provided in Refs. [13, 49, 54].

Importantly, the quantum circuit in Fig. 4 reflects the underlying structure that are common in the above lemmas; this quantum circuit implements a general method, called the quantum singular value transformation (QSVT), to transform singular values (eigenvalues) of a block-encoded matrix based on a large class of polynomials [13]. The QSVT uses the idea of quantum signal processing (QSP) [48, 49] that characterizes achievable 1-qubit unitary transformations comprised of an alternating 1-qubit gate sequence of the *signal* rotation with

FIG. 5. Preparation of the probing state $|\Upsilon(q)\rangle$ at the qth iteration. The blue unitary gate in (a) and (b) denotes a block-encoding of the Hamiltonian $\mathbf{H}$ or $\mathbf{H}_{\mathrm{G}}$ in Eq. (6) or (17), respectively, and the green unitary gate in (b) is a controlled rotation (or reflection) gate. The blue and green unitary gates contain parameterized gates for QSP, and the total number of circuit parameters scales as in (c) with respect to the target root MSE ε. As the graph in (c) indicates, the method in Theorem 8 has a much smaller number of circuit parameters for QSP compared to that of Theorem 7.

a unknown angle and the *processing* rotation with a controllable angle. To bridge the gap between QSP and QSVT, *Qubitization* [49] is a crucial technique that splits (a part of) ancilla-target systems into some qubits labeled by the eigenvalue (singular values [13]) and constructs parallel signal rotations over the qubits (e.g., U and $U^\dagger$ in Fig. 4). Here, the rotation angle depends on the corresponding singular value. Then, using additional processing rotations with controllable parameters $\{\phi_i\}$ (likewise the controlled rotation between U and $U^\dagger$ in Fig. 4), we can transform the singular values in parallel by a polynomial that depends on the controllable parameters $\{\phi_i\}$; the achievable polynomials in QSVT are characterized by QSP. See the review [55] for details of the theoretical perspective of QSVT.

In practice, a typical flow of QSVT consists of two steps: (i) finding the circuit parameter $\{\phi_i\}_{i=1}^n$ (called the phase sequence) for a given degree-n real polynomial P on classical computers, (ii) running the $\mathcal{O}(n)$-depth quantum circuit in Fig. 4 on a quantum computer, using the classically tuned parameters. Note that in the process (ii), we may need a post-selection on ancilla qubits. For a given degree-n polynomial P that has definite parity and $P(x) \in [-1, 1]$ for $x \in [-1, 1]$, the n circuit parameters $\{\phi_i\}_{i=1}^n$ in Fig. 4 can be found by $\mathcal{O}(\mathrm{poly}(n, \log(1/\delta)))$ classical computation for some error δ. Then, using the parameters this circuit results in an $(a + 1)$-block-encoding of $P(A)$. In Lemma 4, we can take an odd real polynomial $P(x)$ with degree $m = \mathcal{O}(\gamma\delta^{-1} \log(\gamma/\varepsilon))$ such that $P(x) \approx \gamma x$ holds [13, 47]. In particular, the phase sequence $\{\phi_i\}$ for the Chebyshev polynomial of the first kind T_n is analytically calculated and has a unique structure (Lemma 9 in Ref. [13]); as a result, we can eliminate the additional ancilla qubit and replace the $2n$ controlled NOT gates with n reflections on $|0\rangle^{\otimes a}$ in the circuit of Fig. 4.

B. Probing state preparation

Before proceeding to the proof of Theorems 7 and 8, we first provide an overview of our method to prepare $|\Upsilon(q)\rangle$ in Fig. 5. As seen in the figure, the proposed two methods to prepare $|\Upsilon(q)\rangle$ have a similar structure: Fig. 5(a) shows the block encoding of a Hamiltonian that encodes the expectation values of observables $\langle O_j - \tilde{u}_j^{(q)}\mathbf{1}\rangle$ and Fig. 5(b) shows alternating applications of the block encoding and a processing operation with a tuned parameter, which is based on Lemma 5 or Lemma 6. In the proof of Theorems 7 and 8, we depict the circuit for (a) and (b), respectively; then we evaluate the approximation error between the final state of the circuit and the probing state $|\Upsilon(q)\rangle$.

More detailed proofs and explicit quantum circuit diagrams for these Theorems are provided in Appendix B.

1. *Hamiltonian simulation*

Theorem 7 (Informal. Lemma 13)**.** *Suppose that we have access to block-encoded $d \times d$ observables $\{O_j\}_{j=1}^M$, a $\log_2 d$-qubit state preparation U_ψ, and its inverse $U_\psi^\dagger$, such that $M > \mathcal{O}(\log d)$. Then, we can prepare the probing state $|\Upsilon(q)\rangle$ for any integer $q \geq 0$ and $\tilde{u}_j^{(q)} \in [-1, 1]$ up to $1/12$ Euclidean distance error, using an*

$$\mathcal{O}(M + \log_2 d)\text{-}qubit$$

circuit regardless of q. Furthermore, each quantum circuit with q requires

$$\mathcal{O}(\mathrm{poly}(2^q\sqrt{M \log d}) + \mathrm{poly}(\sqrt{M}(q + \log M)))$$

classical computation for finding circuit parameters, and it consists of

$$\mathcal{O}(2^q\sqrt{M\log d}) \ \ \textit{uses of} \ \ U_\psi \ \textit{and} \ U_\psi^\dagger,$$

$\mathcal{O}(2^qM(q+\log M))$ uses of unitary gates for block-encoded observables, and $\mathcal{O}(2^qM(q+\log M)\log dM)$ uses of single-qubit and two-qubit gates.

Sketch of the proof. In this Theorem, we take the Hamiltonian $\mathbf{H}$ to encode the observables $\{O_j\}$ as

$$\mathbf{H} := \sum_{\boldsymbol{x}\in G_p^M} \tilde{f}(\boldsymbol{x})\,|\boldsymbol{x}\rangle\langle\boldsymbol{x}|\,, \tag{6}$$

where the target observables are approximately encoded in the eigenvalues $\tilde{f}(\boldsymbol{x})$ as

$$\tilde{f}(\boldsymbol{x}) \approx \frac{1}{\sigma}\sum_{j=1}^{M} x_j\,\langle\tilde{O}_j^{(q)}\rangle\,, \quad \sigma = \mathcal{O}(\sqrt{M\log d}), \tag{7}$$

Here, σ denotes the rescaling factor of the Hamiltonian $\mathbf{H}$ such that $\mathbf{H}$ can be encoded in a unitary operator. Also, we defined $\tilde{O}_j^{(q)} := (O_j - \tilde{u}_j^{(q)}\mathbf{1})/2$ for the identity $\mathbf{1}$. The approximation error in Eq. (7) is specified below.

Setting aside the details for now, we suppose that we have a (perfect) block encoding of the Hamiltonian $\mathbf{H}$ that acts on the pM-qubit probe system, $\log_2 d$-qubit target system, and ancilla systems (specified below), as illustrated in Fig. 5. Then, the optimal Hamiltonian simulation protocol Lemma 6 yields a quantum circuit W for an ϵ'-precise block encoding of time evolution operator

$$e^{i\mathbf{H}t} = \sum_{\boldsymbol{x}\in G_p^M} e^{i\tilde{f}(\boldsymbol{x})t}\,|\boldsymbol{x}\rangle\langle\boldsymbol{x}| \tag{8}$$

with time $t > 0$, using $\mathcal{O}(t + \log(1/\epsilon'))$ queries to the block encoding of $\mathbf{H}$. Note that in the case $t = 2\sigma t'$ for some positive integer t', the resulting time evolution operator approximates t' times applications of the *phase oracle* for an affine linear function $f(\boldsymbol{x}) = \sum_j x_j\,\langle O_j\rangle$ in the theory of gradient estimation. Then, applying W for

$$t := 2^{p+q+2}\sigma$$

to the uniform superposition state $|+\rangle^{\otimes pM}$ in the probe system and the initial state $|\mathbf{0}\rangle$ in the ancilla-target systems, we can approximately prepare the target state:

$$\begin{aligned} &W\,|+\rangle^{\otimes pM}\,|\mathbf{0}\rangle \\ &\quad\approx \frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j 2^q \pi^{-1}\langle O_j - \tilde{u}_j^{(q)}\rangle}\,|\boldsymbol{x}\rangle\,|\mathbf{0}\rangle\,. \end{aligned} \tag{9}$$

From the triangle inequality, this approximation error is given by the sum of ϵ' (more precisely, $\epsilon' + \sqrt{2\epsilon'}$ in Euclidean distance) from the transformation $\mathbf{H} \mapsto e^{i\mathbf{H}t}$ and the error from the observable encoding in Eq. (7), that is,

$$\epsilon' + \sqrt{2\epsilon'} + \left\|\frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x}\in G_p^M} e^{i\tilde{f}(\boldsymbol{x})t}\,|\boldsymbol{x}\rangle - |\Upsilon(q)\rangle\right\|. \tag{10}$$

To quantify the error of the third term in Eq. (10) (or the error of Eq. (7)), we here construct the block encoding of the Hamiltonian $\mathbf{H}$ from the state preparation U_ψ ($U_\psi^\dagger$) and unitary gates $\{B_j\}$ that are a-block-encodings of observables $\{O_j\}$ for some $a \in \mathbb{N}$. First, we can construct a quantum circuit $U^{(\boldsymbol{x})}$ for a block encoding $M^{-1}\sum_{j=1}^M x_j\tilde{O}_j^{(q)}$ (with the rescaling factor M, instead of σ) for a given $\boldsymbol{x} \in G_p^M$, via the LCU method with the controlled version of each B_j. The LCU requires additional $\mathcal{O}(\log M)$ qubits to encode the coefficients $\{x_j/M\}$. Using controlled versions of $U^{(\boldsymbol{x})}$, we can obtain a quantum circuit for

$$U'_{\mathrm{SEL}} := \sum_{\boldsymbol{x}\in G_p^M} |\boldsymbol{x}\rangle\langle\boldsymbol{x}| \otimes U^{(\boldsymbol{x})}. \tag{11}$$

Here, we remark that the resulting quantum circuit for Eq. (11) has at most $\mathcal{O}(pM\log(1/\delta))$-depth for some implementation error δ that comes from the encoding of the coefficients $\{x_j/M\}$; see Remark 11.

Then, the circuit

$$\left(\mathbf{1}\otimes U_\psi^\dagger\right)\cdot U'_{\mathrm{SEL}}\cdot(\mathbf{1}\otimes U_\psi) \tag{12}$$

is a block encoding of the following Hamiltonian:

$$\mathbf{H}' := \sum_{\boldsymbol{x}}\left(\sum_j x_j\cdot\frac{\langle\tilde{O}_j^{(q)}\rangle}{M}\right)|\boldsymbol{x}\rangle\langle\boldsymbol{x}|\,.$$

This Hamiltonian $\mathbf{H}'$ has the normalization factor M that is quadratically larger than σ in $\mathbf{H}$. In estimating the expectation value $\langle\tilde{O}_j^{(q)}\rangle$ via gradient estimation, we need to amplify $\mathbf{H}'$ by the factor M to prepare Eq. (1). This means that we need the time evolution operator $e^{i\mathbf{H}'t}$ of $t = 2^{p+q+2}M$, which results in no speedup for the total queries to U_ψ regarding the number M of observables. To obtain the quadratic speedup regarding M, the method in Ref. [26] uses the singular value amplification Lemma 4. Importantly, this amplification can be performed with no use of U_ψ. From the random matrix series inequality, we can show that for a large part of G_p^M (more precisely, for a subset $F \subset G_p^M$ such that $|F| \geq (1-\delta')|G_p^M|$ for any $\delta' > 0$), the condition of the amplification is satisfied for $\gamma = M/\sigma = \mathcal{O}(\sqrt{M})$, as well as the analysis in Ref. [26]. Therefore, we can amplify the block encoding $U^{(\boldsymbol{x})}$ by γ for such $\boldsymbol{x} \in F$; as a result, we have a quantum circuit for

$$U_{\mathrm{obs}} := \sum_{\boldsymbol{x}\in G_p^M} |\boldsymbol{x}\rangle\langle\boldsymbol{x}| \otimes U_{\mathrm{obs}}^{(\boldsymbol{x})}, \tag{13}$$

where $U_{\text{obs}}^{(\boldsymbol{x})}$ is an ϵ''-precise block encoding of the Hamiltonian $\sigma^{-1}\sum_j x_j \tilde{O}_j^{(q)}$ if $\boldsymbol{x} \in F$. By multiplying U_ψ and $U_\psi^\dagger$ into U_{obs} as well as Eq. (12), we finally arrive at the block encoding of the Hamiltonian $\mathbf{H}$. We note that the amplification is valid when $\sigma = \mathcal{O}(\sqrt{M \log_2 d})$ is smaller than M, and this is satisfied by the condition $M > \mathcal{O}(\log d)$.

Since the block encoding $\mathbf{H}$ consists of (i) the LCU method, (ii) adding the pM-qubit control to $U^{(\boldsymbol{x})}$, (iii) the singular value amplification, and (iv) multiplying the conjugation of U_ψ, the main contribution to the space complexity comes from the steps (i) and (ii). The other processes (iii), (iv), and the Hamiltonian simulation protocol $\mathbf{H} \mapsto e^{i\mathbf{H}t}$ introduce constant or no ancilla qubits. The LCU method (i) introduces $\mathcal{O}(\log M)$-qubit registers, and thus the number of qubits of U'_{SEL} scales as $pM + \log M + \log d$. Recalling that the precision parameter p is fixed to a constant (i.e, $p = 3$) in the probing state $|\Upsilon(q)\rangle$, we conclude that the total space complexity is $\mathcal{O}(M + \log_2 d)$, which is independent of the root MSE ε.

As for the gate complexity, we here focus on the number of queries to U_ψ (or $U_\psi^\dagger$) and U'_{SEL}. A comprehensive analysis on the total gate complexity is provided in Lemma 13. Here, we need to carefully choose the parameters $\varepsilon', \varepsilon''$, and δ' so that the entire approximation error Eq. (10) is smaller than $1/12$; in particular, this is achieved by taking ε' and δ' as some constants, and $\varepsilon'' = \mathcal{O}(1/(2^q\sigma))$. Since the block encoding of $\mathbf{H}$ consists of two uses of U_ψ and $U_\psi^\dagger$ and $m := \mathcal{O}(M\sigma^{-1}\log(M/(\sigma\varepsilon'')))$ uses of control-U'_{SEL}, then the total queries can be evaluated by multiplying $\mathcal{O}(t)$ for the Hamiltonian simulation protocol, which proves the gate complexity in Theorem 7. In addition, the number of circuit parameters for the singular value amplification (iii) and the Hamiltonian simulation protocol are given by m and t, respectively. Thus, we need to tune the parameters in classical $\mathcal{O}(\text{poly}(m))$ and $\mathcal{O}(\text{poly}(t))$ time, as discussed in Sec. IV A. □

Our scheme has a significant improvement in space complexity compared to the previous non-iterative counterparts [26, 27]. While the non-iterative methods determine all of the $\mathcal{O}(\log 1/\varepsilon)$ binary fraction bits of $\langle O_j \rangle$ by a single quantum circuit with additional $\mathcal{O}(M\log(1/\varepsilon))$ (or $\mathcal{O}(M\log(M/\varepsilon))$) qubits to read out the observables, our scheme determines only 1 binary fraction bit of $\langle O_j \rangle$ at each iteration step. Specifically, the previous non-iterative method [26] uses the Hamiltonian simulation with $t = 2^p$ in Eq. (8), where the number of read-out qubits is $p = \mathcal{O}(\log(\sqrt{M\log d}/\varepsilon))$ (i.e., $q = 0$). In contrast, by the adaptive nature of our scheme, space overhead of quantum circuits for the probing states $|\Upsilon(q)\rangle$ is $\mathcal{O}(M)$ ($\mathcal{O}(M + \log_2 d)$ in total), and this is independent of the estimation precision ε. Here, a similar improvement of space overhead can be found in the previous works on the adaptive (iterative) versions of quantum phase estimation [3, 29, 31, 45, 46]. Also, we remark that the significant reduction of space overhead directly leads to the reduction of the number of controlled operations, which is also crucial in practical implementation.

2. *Grover-like repetition*

The quantum circuit employed in Theorem 7 requires classical tuning of $\tilde{\mathcal{O}}(\sqrt{M}/\varepsilon)$ circuit parameters (more precisely, $\tilde{\mathcal{O}}(2^q\sqrt{M})$ parameters in step q) for QSP. The classical computation for finding $\tilde{\mathcal{O}}(\sqrt{M}/\varepsilon)$ parameters is also required in the existing work by van Apeldoorn *et al.* [26]. However, it is challenging to find such a large number of circuit parameters in a stable way as pointed out in previous works [40–44], while the n-parameter finding can be performed by $\mathcal{O}(\text{poly}(n, \log(1/\delta)))$ classical computation for some error δ in theory [13].

To avoid the numerical instability, we here provide an alternative way to prepare the probing state (1) using the *Grover-like repetition*, which is a special case of QSP such that the corresponding quantum circuit parameters are analytically derived.

Theorem 8 (Informal. Lemma 14)**.** *Suppose we have access to block-encoded $d \times d$ observables $\{O_j\}_{j=1}^M$, a $\log_2 d$-qubit state preparation U_ψ, and its inverse $U_\psi^\dagger$, such that $M > \mathcal{O}(\log d)$. If the iteration step $q \geq 0$ satisfies the following condition ($\delta' := 2^{-14}$)*

$$q \geq \log_4 \left[\frac{2^3 \cdot 33^3}{625 \ln(2d/\delta')} \frac{\left\lceil \sqrt{2(M+1)\ln(2d/\delta')} \right\rceil}{\sqrt{\ln(2d/\delta')}} \right], \quad (14)$$

and for given $\tilde{u}_j^{(q)} \in [-1, 1]$,

$$\left| \langle\psi| \left(O_j - \tilde{u}_j^{(q)} \mathbf{1} \right) |\psi\rangle \right| \leq 2^{-q} \quad \textit{for all} \quad j = 1, 2, ..., M, \quad (15)$$

holds, then we can successfully prepare the probing state $|\Upsilon(q)\rangle$ up to $1/12$ Euclidean distance error, with probability at least 0.462 with ancilla qubits measurement result indicating success, using an

$$\mathcal{O}(M + \log_2 d)\textit{-qubit}$$

circuit regardless of q. Furthermore, each quantum circuit with q requires

$$\mathcal{O}(\text{poly}(\sqrt{M}(q + \log M)))$$

classical computation, and it has the same gate complexity as that of Theorem 7.

Here, we remark that the condition Eq. (15) is trivially satisfied at the iteration step q in Algorithm 1 when all the previous gradient estimations are successfully performed, as discussed in Sec. III.

Sketch of the proof. This method uses eigenvalue transformation of (a slightly modified version of) the Hamiltonian $\mathbf{H}$ in Eq. (6) based on the Chebyshev polynomial of the first kind $T_t(x)$, that is, Lemma 5. Here, the degree t is given by $t = 2^{p+q+2}\sigma$. We note that since the resulting operator $T_t[\mathbf{H}]$ is non-unitary, post-selection of ancilla qubits in the block encoding is required to implement $T_t[\mathbf{H}]$, meaning that the state preparation by this method is stochastic. As mentioned in Sec. IV A, the eigenvalue transformation based on the Chebyshev polynomials $T_t(x)$ can be considered as a special case in QSVT; that is, it has an analytical solution of circuit parameters (or phase sequence). Therefore, in this alternative method, the circuit parameter finding is required only for the construction of the Hamiltonian $\mathbf{H}$; the total runtime for the classical computation is at most $\mathcal{O}(\mathrm{polylog}(1/\varepsilon))$ (more precisely, $\mathcal{O}(\mathrm{poly}(\sqrt{M}(q + \log M)))$ at step $q \leq \lceil \log_2(1/\varepsilon) \rceil$).

Now, we consider the action of the resulting operator $T_t[\mathbf{H}]$. Applying $T_t[\mathbf{H}]$ to the uniform superposition state $|+\rangle^{\otimes pM}$, we obtain an unnormalized state proportional to

$$\sum_{s=\pm1} \sum_{\boldsymbol{x} \in G_p^M} e^{ist \arccos\left[\tilde{f}(\boldsymbol{x})\right]} |\boldsymbol{x}\rangle \,. \tag{16}$$

Therefore, we need to correct the phase of $|\boldsymbol{x}\rangle$ from $e^{\pm it \arccos[\tilde{f}(\boldsymbol{x})]}$ to $e^{it\tilde{f}(\boldsymbol{x})}$ in order to match the probing state $|\Upsilon(q)\rangle$.

As for the sign $s = \pm 1$ of the phase, we can correct it by slightly modifying the Hamiltonian $\mathbf{H}$ with the help of an additional 1-qubit ancilla system. Let $\mathbf{H}_{\mathrm{G}}$ be a Hamiltonian defined as

$$\mathbf{H}_{\mathrm{G}} := \sum_{(\boldsymbol{x},y) \in G_p^M \times G_1} \tilde{f}'(\boldsymbol{x}, y) \, |\boldsymbol{x}, y\rangle \langle \boldsymbol{x}, y| \,, \tag{17}$$

where $|y\rangle$ denotes a computational basis on the additional ancilla system and

$$\tilde{f}'(\boldsymbol{x}, y) \approx \frac{1}{\sigma'} \left(y \, \langle O_{M+1} \rangle + \sum_{j=1}^{M} x_j \, \langle \tilde{O}_j^{(q)} \rangle \right) . \tag{18}$$

Here, O_{M+1} denotes a 1-qubit observable proportional to the identity that acts on the additional ancilla system, and $\sigma' = \mathcal{O}(\sqrt{M \log d})$ is the rescaling factor for block encoding. The block encoding of $\mathbf{H}_{\mathrm{G}}$ can be constructed in a similar way to that of the Hamiltonian $\mathbf{H}$; the corresponding circuit has the same complexity as that of $\mathbf{H}$. Then, applying $T_t[\mathbf{H}_{\mathrm{G}}]$ to the uniform superposition state $|+\rangle^{\otimes pM+1}$, we can show that the following holds: (for simplicity, we write O_{M+1} as $\tilde{O}_{M+1}^{(q)}$)

$$\begin{aligned} \frac{1}{\mathcal{N}_t \sqrt{2^{pM}}} \sum_{\boldsymbol{x},y} T_t \left(\tilde{f}'(\boldsymbol{x}, y) \right) |\boldsymbol{x}, y\rangle &\approx \frac{1}{2\sqrt{2^{pM}}} \sum_{s=\pm1} \sum_{(\boldsymbol{x}, x_{M+1}) \in G_p^M \times G_1} e^{ist\left(\pi/2 - (\sigma')^{-1} \sum_{j=1}^{M+1} x_j \langle \tilde{O}_j^{(q)} \rangle\right)} |\boldsymbol{x}\rangle \, |x_{M+1}\rangle \\ &= \frac{1}{\sqrt{2}} \sum_{s=\pm1} \left(\frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x} \in G_p^M} e^{2\pi i 2^p \sum_{j=1}^{M} (s x_j) \pi^{-1} 2^{q+1} \langle \tilde{O}_j^{(q)} \rangle} |\boldsymbol{x}\rangle \otimes \frac{1}{\sqrt{2}} \sum_{k \in G_1} e^{2\pi i 2k(s/4)} |k\rangle \right) , \end{aligned} \tag{19}$$

where $\mathcal{N}_t$ is the normalization factor. In the second equality, we chose the constant factor of O_{M+1} as

$$O_{M+1} := \frac{\pi(1/4 + 4l)}{2^{p+q}} I,$$

where l is an arbitrary integer satisfying $\|2^{q+1} O_{M+1}\| \leq 1$ and I denotes the 1-qubit identity. In the next paragraph, we explain the approximation of the first line in Eq. (19) in detail. The sign $s = \pm 1$ in Eq. (19) can be corrected as follows. By applying the inverse quantum Fourier transformation to the 1-qubit additional ancila system in the state Eq. (19), followed by controlled $X^{\otimes pM}$ gate (which flips the sign as $X^{\otimes pM} |\boldsymbol{x}\rangle = |-\boldsymbol{x}\rangle$), we obtain the probing state Eq. (1) in the pM-qubit registers.

The approximation in the first line of Eq. (19) comes from the non-linearity of the phase function $\arccos x$ in Eq. (16). Here, we recall that $\tilde{f}'(\boldsymbol{x}, y)$ is approximately given by the linear combination of $\langle O_j - \tilde{u}_j^{(q)} \mathbf{1} \rangle$. Using this fact, we can show that $|\tilde{f}'(\boldsymbol{x}, y)|$ scales as $\mathcal{O}(2^{-q})$ for a large part of $G_p^M \times G_1$ from the assumption of $|\langle \tilde{O}_j^{(q)} \rangle| \leq 1/2^{q+1}$ and the Hoeffding's inequality. Moreover, the error between the function $\arccos(x)$ and a linear function $\pi/2 - x$ can be upper bounded by $\mathcal{O}(|x|^3)$. As a result, the non-linearity of $\arccos x$ in Eq. (16) can be ignored for a large part of $G_p^M \times G_1$:

$$\left| \arccos\left[\tilde{f}'(\boldsymbol{x}, y)\right] - \left(\frac{\pi}{2} - \tilde{f}'(\boldsymbol{x}, y) \right) \right| = \mathcal{O}(2^{-3q}),$$

and it decreases much faster than the amplification $t = \mathcal{O}(2^q \sigma)$, as the iteration step q proceeds. Then, we prove the approximation error in Eq. (19) is at most $1/12$ in Euclieadn distance error under the assumption of this theorem. At the same time, we can evaluate the normalization factor as $|\mathcal{N}_t - 1| \leq 2\sqrt{6\delta'}$, thereby proving the post-selection probability $\mathcal{N}_t^2/2 > 0.462$.

Finally, we mention the space and gate complexity of this Theorem. As well as in the proof of Theorem 7, we can count the number of qubits in the block encoding of $\mathbf{H}_{\mathrm{G}}$, and it scales as $pM + \log M + \log d$ in total. Thus, the method has the space complexity $\mathcal{O}(M+\log_2 d)$ that is also independent of the target precision ε. As for the gate complexity, the main contribution comes from the eigenvalue transformation $\mathbf{H}_{\mathrm{G}} \mapsto T_t[\mathbf{H}_{\mathrm{G}}]$, which uses $t = \mathcal{O}(2^q\sigma')$ queries of the block encoding of $\mathbf{H}_{\mathrm{G}}$. This indicates that the gate complexity of the method is the same as that of the method in Theorem 7. □

In the alternative method, we require finding $\tilde{\mathcal{O}}(q\sqrt{M})$ circuit parameters, which comes from the singular value amplification to construct the Hamiltonian Eq. (17) than the Grover-like repetition. Thus, the alternative method shows an exponential improvement of runtime in classical computation with respect to the iteration q (or ε), compared to the method in Theorem 7 and the previous method [26], if certain conditions on the iteration step q are satisfied. Recalling that the iteration step is upper bounded by $q_{\max} := \lceil \log_2(1/\varepsilon) \rceil$ for the target root MSE ε, the alternative method can be used if there exists the iteration steps q satisfying $q \leq q_{\max}$ and the inequality Eq. (14). In Sec. IV B 3, we numerically investigate the range of iteration steps q for the use of Theorem 8, especially for the case of $M = \mathcal{O}((\log_2 d)^k)$ for some k.

Finally, we mention the success probability of Theorem 8. While we cannot prepare the probing state $|\Upsilon(q)\rangle$ deterministically in the alternative method, the success probability can be easily boosted by a constant number of repetitions of the circuit runs. Therefore, the total query complexity remains unchanged when we use Theorem 8 instead of Theorem 7 to prepare the probing state of Eq. (1).

3. *Applicability condition for the probing state preparation by Grover-like repetition*

Here, we investigate the threshold of iteration step q in Theorem 8. We rewrite the threshold Eq. (14) as $q^* := \log_2(1/\varepsilon^*)$ by defining ε^* as

$$1/\varepsilon^* := \sqrt{C \ln^{-3/2}(2d/\delta') \left\lceil \sqrt{2(M+1)\ln(2d/\delta')} \right\rceil}, \quad (20)$$

where $C := 2^3 \cdot 33^3/625$. Since the iteration step q runs from 0 to $q_{\max} := \lceil \log_2(1/\varepsilon) \rceil$, we need that the threshold $1/\varepsilon^*$ is smaller than the inverse of the target root MSE $1/\varepsilon$ in order to use the state preparation by the Grover-like repetition.

To clarify this point, we here plot the threshold $1/\varepsilon^*$ for several cases $M = N^1, N^2, N^3, N^4$, and 2^N under target system with the number of qubits $N \equiv \log_2 d$. In Fig. 6, we confirm that the threshold $\log_2(1/\varepsilon^*)$ converges to some constant (~ 5) in the case of $M = N^2$, which is consistent with Eq. (20) because $(1/\varepsilon^*)^2 = \mathcal{O}(\sqrt{M}/N)$ holds. Thus, particularly in this case $M = \mathcal{O}(N^2)$, the method in Theorem 8 is available in a wide range of target precision ε regardless of N. On the other hand, if the number of observables scales as 2^N, the threshold $\log_2(1/\varepsilon^*)$ increases linearly regarding N (note that the horizontal axis in Fig. 6 is logarithmic). This means that in the case of $M = \mathcal{O}(2^N)$, the Grover-based method is applicable only for small-size systems, otherwise the target precision ε is exponentially small with respect to N (the base of the exponential is $2^{-1/4} \approx 0.841$).

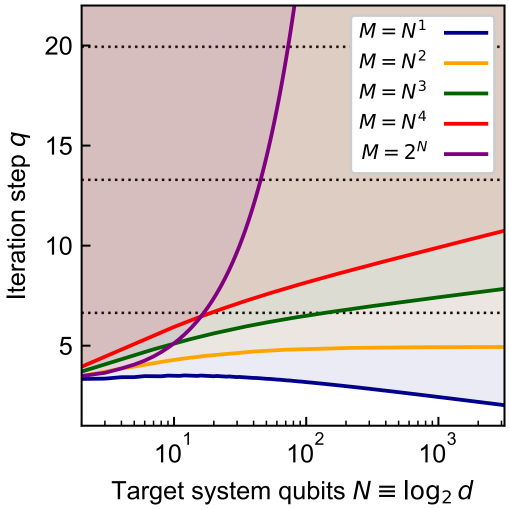

FIG. 6. The condition for the Grover-based state preparation (Theorem 8). The solid lines represent the threshold $q^* := \log_2(1/\varepsilon^*)$ of iteration steps in Eq. (20) (or Eq. (14)). When the iteration step q exceeds the solid lines, we can use the Grover-like repetition to prepare the probing state Eq. (1), instead of using Hamiltonian simulation. The horizontal dotted lines represent $q_{\max} := \lceil \log_2(1/\varepsilon) \rceil$ for $\varepsilon = 10^{-2}$ (bottom), 10^{-4} (middle), and 10^{-6} (top), respectively.

Now, we focus on the case that we require more precise estimates as the number of observables M increases. From the definition of ε^*, if the desired precision ε satisfy $\varepsilon^2 \ll N/(C\sqrt{M})$, then there exists iteration steps q for the Grover-based method. Specifically, considering the desired precision is given by $\varepsilon = c_{\mathrm{mse}}/\sqrt{M} \in (0, 1/\sqrt{M})$ for some $c_{\mathrm{mse}} \in (0,1)$, we can evaluate the difference between the upper bound $q_{\max}$ of iteration steps and the threshold q^* as follows:

$$q_{\max} - q^* \geq \Omega\left(\log\left(N\sqrt{M}\right)\right). \quad (21)$$

Thus, the range of iteration step q such that the Grover-based method is available enlarges in this case, as N or M increases.

V. CONCLUSION

In this work, we proved that multiple quantum observables can be simultaneously estimated with quantum resources at the scaling of Heisenberg limit $1/\varepsilon$ for a root MSE ε. At the same time, the total resource shows a nearly quadratic improvement with respect to the number of observables M, compared to the standard method for this task i.e., the (modified) quantum amplitude estimation [21–23, 37–39]. The resources are quantified by the total number of queries to a state preparation unitary U_ψ whose complexity usually scales as the size of quantum system. We prove these results by explicitly constructing an adaptive quantum algorithm. The key idea of the proposed method is to prepare a quantum state with phases that encode the expectation values of observables, followed by the measurement for quantum gradient estimation [24, 25]. Then, our method determines a single binary digit of the target observables from the measurement outcomes and update the quantum state so that the next measurement has sufficient resolution to determine the next fraction bit. Importantly, our method can be considered as an extension of the iterative or adaptive phase estimation algorithms [3, 29, 31, 45, 46] to the gradient estimation algorithm.

In addition to the Heisenebrg-limited scaling in MSE, the proposed method significantly reduces the requirement of actual implementation, compared to the state-of-the-art algorithms for multiple observables estimation [26, 27]. First, the adaptive nature of the proposed method allows us to reduce an additional space overhead to $\mathcal{O}(M)$ qubits from $\mathcal{O}(M\log(1/\varepsilon))$ qubits in the previous methods. This results in a significant improvement on the space overhead when precise estimates of observables are required. Also, the proposed method can be executed in a parallel way during each iteration step, leading to reduction of the total execution time if we can use several quantum computers.

Next, in constructing quantum circuits of the proposed method, we provide two methods along with their quantum circuit diagrams; one is based on the optimal Hamiltonian simulation protocol and the other is based on Grover-like repetition. While the former can be used in any iteration steps q, in the final step, it requires classical finding of $\mathcal{O}(1/\varepsilon)$ circuit parameters, as well as the previous method, for quantum signal processing (QSP) [48, 49]. As shown in the previous works [42], such a circuit parameter finding requires $\sim 1/\varepsilon^2$ [sec] in classical computation time; the resulting numerical instability is one of the central problems in practical application of QSP or its extension, quantum singular value transformation (QSVT) [13]. The alternative method based on Grover-like repetition can avoid this problem by partially using the QSP for Chebyshev polynomials whose circuit parameters are analytically derived. As a result, the Grover-based method requires only $\mathcal{O}(\mathrm{polylog}(1/\varepsilon))$ classical computation in total, under a specific condition on q. This shows an exponential improvement in classical computation with respect to the target root MSE ε, thereby reducing the barrier of actual implementation significantly. As for the condition of the alternative method, we numerically investigate it in various setups such as $M = \mathcal{O}(N^k)$ for some k and size of target system N.

Appendix A: Quantum gradient estimation

1. Review of Jordan's algorithm

For a given blackbox of a real scalar function $f(\boldsymbol{x})$ on $\boldsymbol{x} \in \mathbb{R}^M$, the quantum algorithm introduced by Stephen P. Jordan [24] can efficiently estimate the M-dimensional gradient of $\nabla f(\mathbf{0})$, with use of less queries to the blackbox compared to classical case. Here, the target point $\boldsymbol{x} = \mathbf{0}$ can be taken as $\boldsymbol{x} \neq \mathbf{0}$ by trivially redefining $f(\boldsymbol{x})$. The quantum algorithm consists of three steps: (i) prepare a superposition state of grid points $\boldsymbol{x}$ around the target point $\boldsymbol{x} = \mathbf{0}$, (ii) apply the blackbox of the target function f to the state and evaluate a phase $e^{if(\boldsymbol{x})}$ at each grid point, and (iii) measure the resulting state by the computational basis labeled by the grid points after the inverse quantum Fourier transformations.

To begin with, we define a set of grid points G_p^M around $\boldsymbol{x} = \mathbf{0}$ to evaluate f, as follows:

$$G_p^M := \left\{ \frac{\mu}{2^p} - \frac{1}{2} + \frac{1}{2^{p+1}} : \mu \in \{0, 1, \cdots, 2^p - 1\} \right\}^M , \tag{A1}$$

where p denotes a positive integer which specifies the estimation precision later. Note that because there is a bijection map

$$\varphi : \mu \mapsto \varphi(\mu) := \frac{\mu}{2^p} - \frac{1}{2} + \frac{1}{2^{p+1}} \in G_p, \tag{A2}$$

we always label the p-qubit computational basis $|\mu\rangle$ by the corresponding element $x \equiv \phi(\mu) \in G_p$. Then, applying the Hadamard gates to initialized pM-qubit registers, we have the superposition state of the grid points $\boldsymbol{x} := (x_1, ..., x_M) \in G_p^M$:

$$\frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x} \in G_p^M} |\boldsymbol{x}\rangle = \frac{1}{\sqrt{2^{pM}}} \sum_{(x_1, \ldots, x_M) \in G_p^M} |x_1\rangle |x_2\rangle \cdots |x_M\rangle . \tag{A3}$$

Here, each $|x_j\rangle$ contains p-qubit registers. Next, we assume access to the *phase oracle* O_f for $f(\boldsymbol{x})$ defined as [25]

$$O_f : |\boldsymbol{x}\rangle \to e^{if(\boldsymbol{x})} |\boldsymbol{x}\rangle \quad \text{for all} \quad \boldsymbol{x} \in G_p^M . \tag{A4}$$

Note that Ref. [25] provides a generic analysis of Jordan's algorithm based on the phase (and probability) oracle, while the original paper [24] assumes another powerful oracle (i.e., η-accurate Binary oracle for f that outputs $f(\boldsymbol{x})$ binarily with accuracy η from an input $\boldsymbol{x}$).

Now, to clarify the basic idea of Jordan's algorithm, we consider a special case where the target function f is an affine linear function, i.e., for a target gradient vector $\boldsymbol{g} \in [-1/3, 1/3]^M$ and some constant $f_0 \in \mathbb{R}$, $f(\boldsymbol{x}) = \boldsymbol{g} \cdot \boldsymbol{x} + f_0$. For such linear functions, the application of the (modified) phase oracle $O_f^{2\pi 2^p}$ to the input state Eq. (A3) yields

$$\frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p f(\boldsymbol{x})}\left|\boldsymbol{x}\right\rangle$$
$$= e^{2\pi i 2^p f_0}\cdot \bigotimes_{j=1}^{M}\left[\frac{1}{\sqrt{2^p}}\sum_{x_j\in G_p} e^{2\pi i 2^p x_j g_j}\left|x_j\right\rangle\right]. \quad \text{(A5)}$$

Then, we apply a slightly modified version of the inverse quantum Fourier transformation $\mathrm{QFT}^\dagger_{G_p}$ over the p-qubit system: for all $x\in G_p$,

$$\mathrm{QFT}_{G_p}: \left|x\right\rangle \mapsto \frac{1}{\sqrt{2^p}}\sum_{k\in G_p} e^{2\pi i 2^p xk}\left|k\right\rangle. \quad \text{(A6)}$$

Note that QFT_{G_p} is the same as the usual p-qubit QFT up to conjugation with a tensor product of p single-qubit gates [25]. The statistics of the computational basis measurement to Eq. (A5) with $\mathrm{QFT}^\dagger_{G_p}$ are similar to that of the output of standard quantum phase estimation algorithm [32]. More precisely, let $(k_1,k_2,...,k_M)\in G_p^M$ be a result of the computational basis measurement, then the following holds [25]:

$$\Pr\left[\left|k_j - g_j\right| > \frac{3}{2^p}\right] \le \frac{1}{4} \quad \text{for every} \quad i = 1,2,\cdots,M. \quad \text{(A7)}$$

In the above description, we assumed that the target function is affine linear. However, if a target function is very close to some affine linear function and thereby the equality of Eq. (A5) approximately holds, we can prove similar results to Eq. (A7), as follows.

Lemma 9 ([25, 26]). *Let $\boldsymbol{g}\in\mathbb{R}^M$ such that $\|\boldsymbol{g}\|_\infty \le 1/3$. Suppose we can prepare the quantum state $\left|\Psi\right\rangle$ that is 1/12-close in the Euclidean distance to the following state*

$$\left(\mathrm{QFT}^\dagger_{G_p}\right)^{\otimes M}\frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p \boldsymbol{g}\cdot\boldsymbol{x}}\left|\boldsymbol{x}\right\rangle. \quad \text{(A8)}$$

Then, measuring the quantum state $\left|\Psi\right\rangle$ in the computational basis, we obtain a coordinate-wise estimate $(k_1,...,k_M)\in G_p^M$ satisfying

$$\Pr\left[\left|k_j - g_j\right| > \frac{3}{2^p}\right] \le \frac{1}{3} \quad \textit{for every} \quad j = 1,2,\cdots,M.$$

Proof. By the closeness assumption, the trace distance between $\left|\Psi\right\rangle$ and Eq. (A8) is upper bounded by 1/12. Since the trace distance provides the upper bound of the total variation distance of two probability measures defined by the two quantum states and an arbitrary common POVM (Theorem 9.1 [32]), the probability (A7) is modified at most 1/12 by measuring $\left|\Psi\right\rangle$ instead of Eq. (A8). □

For more regular functions, Ref. [25] provides an improved version of Jordan's algorithm, using the higher-order finite-difference formulas to enhance the linearity of the target functions in a certain domain.

2. Heisenberg limit

The phase oracle O_f for a smooth real function $f(\boldsymbol{x})$ on $\boldsymbol{x}\in\mathbb{R}^M$ with gradient $\boldsymbol{g} := \nabla f(\boldsymbol{0})$ corresponds to the time evolution operator (with unit time) generated by the following Hamiltonian

$$H(\boldsymbol{g}) + V, \quad H(\boldsymbol{g}) := \sum_{\boldsymbol{x}\in G_p^M} (\boldsymbol{g}\cdot\boldsymbol{x})\left|\boldsymbol{x}\right\rangle\left\langle\boldsymbol{x}\right|, \quad \text{(A9)}$$

where V is a $\boldsymbol{g}$-independent Hermitian operator that commutes with $H(\boldsymbol{g})$. Thus, the estimation of $\boldsymbol{g}$ from O_f with appropriate choice of an input state and a final measurement can be considered as one of the (multi-parameter) unitary estimation problems. Such unitary estimation problems are widely studied in the field of quantum metrology, and one of the major topics in this field is to devise quantum estimation protocols that can achieve the higher precision than any classical protocol [2, 56]. In particular, the Heisenberg limit provides a fundamental bound on the estimation precision (in terms of root mean squared error) under given resources, and it is typically given as $1/t$ where t denotes the total number of resources to be used [2, 57]. Here, we derive the Heisenberg limit in quantum gradient estimation.

To derive the fundamental bound, we here consider a general adaptive estimation protocol [56], which is illustrated in Fig. 7. In the general protocol, we first prepare an arbitrary input state ρ_{in} between the system on which O_f acts and an ancilla system with an arbitrary number of qubits. Then, we apply the following sequence of quantum operations to the input state:

$$U_t(O_f\otimes\mathbf{1})\cdots U_2(O_f\otimes\mathbf{1})U_1(O_f\otimes\mathbf{1}), \quad \text{(A10)}$$

where $\mathbf{1}$ denotes the identity and U_i $(i=1,2,...,t)$ are $\boldsymbol{g}$-independent arbitrary unitary operators acting on the whole system. This sequence contains t uses of the phase oracle in total. Finally, the output state is measured by an arbitrary POVM $\{M_{\boldsymbol{g}}\}$, and we write the corresponding single-shot estimator for g_j as $\hat{g}_j$. Because the interaction U_i to the ancilla systems can extract the information during the estimation process, this protocol also includes adaptive techniques. Obviously, the original method for gradient estimation is captured in this general protocol, by setting ρ_{in} to the uniform superposition state without ancilla qubits, $U_i = \mathbf{1}$ for all i, and $M_{\boldsymbol{g}}$ to the computational basis measurement with the inverse quantum Fourier transformation. Note that the $\boldsymbol{g}$-independent part of O_f can be included in each U_j, and therefore in the following, we consider $O_f = e^{iH(\boldsymbol{g})}$ without loss of generality.

We here remark that $e^{iH(\boldsymbol{g})}$ can be written as a tensor product of time evolutions

$$\bigotimes_{j=1}^{M}\left(\sum_{x_j\in G_p} e^{ig_jx_j}\left|x_j\right\rangle\left\langle x_j\right|\right) \quad \text{(A11)}$$

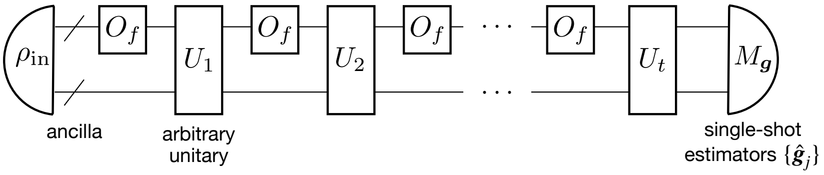

FIG. 7. A general adaptive protocol for estimating $\boldsymbol g$ in O_f.

by the generators $H_j := \sum_{x_j} x_j |x_j\rangle\langle x_j|$ with the bounded spectral norm $\|H_j\| \le 1/2$. Therefore, the estimation of $\boldsymbol g = (g_1, ..., g_M)$ is essentially equal to the estimation of evolving time g_j in each $e^{ig_jH_j}$. Now, we are ready to prove the Heisenberg limit in quantum gradient estimation.

Theorem 10 (Heisenberg limit in quantum gradient estimation)**.** *Suppose we have access to the phase oracle O_f for a smooth real function f on $\mathbb{R}^M$ with gradient $\boldsymbol g := \nabla f(\mathbf 0)$ and g_j belongs to some finite interval $\Theta \subset \mathbb{R}$ for all j. Then, the single-shot estimators $\hat g_j$, obtained from the general adaptive estimation protocol in Fig. 7 with t uses of the phase oracle O_f, satisfy the following inequality:*

$$\min_{j=1,2,\cdots,M} \widehat{\mathrm{MSE}}\left[\hat g_j\right] \ge \frac{\pi^2}{t^2} \quad as \quad t\to\infty, \tag{A12}$$

where $\widehat{\mathrm{MSE}}[\hat g_j]$ denotes the supremum of the mean squared error (MSE) for $\hat g_j$ over the known interval Θ, i.e., the maximum value of MSE over all possible target values $g_j \in \Theta$.

Proof. We prove this theorem by contradiction. Suppose there is a protocol such that for an index $j \in \{1, ..., M\}$, $\widehat{\mathrm{MSE}}\left[\hat g_j\right] < \pi^2/(t^2\Delta G_p^2)$ holds as t goes to ∞, where ΔG_p denotes the difference between extreme eigenvalues of $H_j = \sum_{x_j\in G_p} x_j|x_j\rangle\langle x_j|$ i.e., $\max G_p - \min G_p \le 1$. Now, we recall that the phase oracle O_f can be considered as the product of $e^{ig_jH_j}$ without loss of generality. Then, focusing on the estimation of g_j in the single-parameter unitary $e^{ig_jH_j}$, it can be shown that there is no protocol using the total t uses of $e^{ig_jH_j}$ such that $\widehat{\mathrm{MSE}}[\hat g_j]$ can be less than $\pi^2/t^2\Delta G_p^2$ as t increases [57, 58], which contradicts the above assumption. Therefore, we conclude that

$$\widehat{\mathrm{MSE}}[\hat g_j] \ge \frac{\pi^2}{t^2\Delta G_p^2} \ge \frac{\pi^2}{t^2} \quad \text{as} \quad t\to\infty$$

holds for all j, which completes the proof of Theorem 10. □

As for the achievability of the lower bound, the same methodology as the phase estimation with the minimum phase uncertainty [33–36] can be applied to design an optimal protocol, because the gradient estimation can be considered as separable applications of the phase estimation protocol. Hereafter, we describe an optimal protocol of gradient estimation that is applicable to an affine linear function $f(\boldsymbol x) = \boldsymbol x\cdot\boldsymbol g$ without any adaptive operations. Let us consider M tensor products of an ansatz state $\sum_{x\in G_p} a_x|x\rangle$, where a_x is a real amplitude, as an initial input state instead of the equal superposition state Eq. (A3). Then, applying the phase oracle O_f 2^{p+1} times to the input state and performing the computational basis measurement after $\mathrm{QFT}^\dagger_{G_p}$s, we obtain the measurement result k_j with the probability

$$\Pr\left[k_j\right] = \left|\sum_{x_j=0}^{2^p-1} \frac{a_{x_j}}{\sqrt{2^p}} e^{2\pi i 2^p x_j(g'_j - k_j)}\right|^2, \tag{A13}$$

where $g'_j := g_j/\pi$. For simplicity, we drop the subscript j in the following. Taking the measurement outcome k as an estimator of g', we can approximately evaluate the MSE of k as follows:

$$\mathbb{E}\left[(k-g')^2\right] \simeq \frac{1}{2\pi^2}\left(1 - \mathbb{E}\left[\cos\left(2\pi(k-g')\right)\right]\right), \tag{A14}$$

where we can check the right hand side is close to the MSE when $(k - g')$ is small by the Taylor expansion. As shown in Ref. [59], the expectation of cosine can be analytically calculated:

$$\begin{aligned}&\mathbb{E}\left[\cos\left(2\pi(k-g')\right)\right]\\ &= \sum_{k=1}^{2^p-1} a_{k-1}a_k + a_0a_{2^p-1}\cos\left[2\pi 2^p\left(g' + \frac12 - \frac{1}{2^{p+1}}\right)\right].\end{aligned} \tag{A15}$$

Here, a_k is equivalent to $a_{\varphi(k)}$ for the bijection map defined in Eq. (A2). Therefore, if we take $a_0 = 0$, then the right hand side of Eq. (A14) can be written as a quadratic form $(1/2\pi^2)\sum_{k,l=1}^{2^p-1} A_{kl}a_ka_l$ for the symmetric matrix A:

$$A = \begin{pmatrix} 1 & -1/2 & & \\ -1/2 & 1 & -1/2 & \\ & -1/2 & 1 & \ddots \\ & & \ddots & \ddots \end{pmatrix}. \tag{A16}$$

The minimum eigenvalue and the corresponding eigenvector of A is known as

$$2\sin^2\frac{\pi}{2^{p+1}} \tag{A17}$$

and

$$a_k = \sqrt{\frac{2}{2^p}} \sin \frac{k\pi}{2^p}, \tag{A18}$$

respectively. Consequently, combining Eqs. (A14) and (A17), we can confirm that this protocol achieves the lower bound of Theorem 10 when $t = 2^{p+1}$ is sufficiently large, as

$$\mathbb{E}\left[(\pi k - g)^2\right] \simeq \left(\frac{\pi}{2^{p+1}}\right)^2 . \tag{A19}$$

Finally, we remark that the original implementation of the gradient estimation cannot achieve the quadratic speedup regarding total queries t, i.e., $\varepsilon^2 = \mathcal{O}(1/t^2)$ for a MSE ε^2, even in the target function is an affine linear. This can be checked from Eq. (A14); the uniform superposition state $a_x = 1/\sqrt{2^p}$ for all x gives

$$\min_{g'} \mathbb{E}\left[\cos\left(2\pi(k - g')\right)\right] = 1 - \frac{2}{2^p}, \tag{A20}$$

and thus, $\max_g \mathbb{E}\left[(\pi k - g)^2\right] = \mathcal{O}(1/t)$, which is the same scaling as the shot noise or the standard quantum limit (SQL). Note that this result is consistent with that the quantum phase estimation algorithm fails to achieve the Heisenberg limit when the input ancilla qubits are initialized as the uniform superposition state, unlike the optimal entangled state as in Eq. (A18) [3, 29, 60]. We remark that the proposed adaptive method in this work performs gradient estimation at the same scaling as the Heisenberg limit $\mathcal{O}(1/\varepsilon)$ even when the target function is *approximately* affine linear.

Appendix B: Circuit implementation and theoretical guarantees of the proposed method

In Sec. B 1, we design two methods to prepare the quantum state $|\Upsilon(q)\rangle$ in Eq. (1): one is based on the Hamiltonian simulation protocol, and the other is based on Grover-like repetition. Finally, the performance of the proposed algorithm is analyzed in Sec. B 2. In the following, we often refer to the detailed version Algorithm 1*, instead of Algorithm 1 in Sec. III.

1. Probing state preparation

Here, we provide two quantum algorithms to prepare the probing state $|\Upsilon(q)\rangle$ in Eq. (1), using block encodings of observables $\{O_j\}$ and the state preparation oracle U_ψ. First, we describe a method to construct the block encoding of a linear combination of observables.

a. *Amplified block encoding for observables*

Algorithm 1* Adaptive observables estimation (A detailed version.)

Input: $\log_2 d$-qubit state preparation unitary U_ψ; observables $\{O_j\}_{j=1}^M$ with the spectral norm $\|O_j\| \le 1$ such that

$$M > 2\ln d + 24 = \mathcal{O}(\log d) \tag{B1}$$

holds; confidence parameter $c \in (0, 3/8(1+\pi)^2]$; target precision parameter $\varepsilon \in (0,1)$.

Output: A sample $(\tilde{u}_1, ..., \tilde{u}_M)$ from an estimator $\hat{\boldsymbol{u}} = (\hat{u}_1, ..., \hat{u}_M)$ whose j-th element estimates $\langle O_j \rangle := \langle\psi|O_j|\psi\rangle$ within MSE ε^2 as

$$\max_{j=1,2,...,M} \mathbb{E}\left[(\hat{u}_j - \langle O_j\rangle)^2\right] \le \varepsilon^2$$

```
Set $p := 3$ and $\tilde{u}_j^{(0)} := 0,\ (j = 1, 2, \cdots, M)$
for $q = 0, 1, ..., q_{\max} := \lceil \log_2(1/\varepsilon) \rceil$ do
    Set
        $\tilde{O}_j^{(q)} := \frac{O_j - \tilde{u}_j^{(q)}\mathbf{1}}{2}$ and $\delta^{(q)} := \frac{c}{8^{q_{\max}-q}}$
    Prepare $\mathcal{O}(\log(M/\delta^{(q)}))$ copies of a quantum state that is 1/12-close (in Euclidean distance) to
        $\left(\mathrm{QFT}_{G_p}^\dagger\right)^{\otimes M} |\Upsilon(q)\rangle$, where
        $|\Upsilon(q)\rangle := \frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j 2^{q+1}\pi^{-1}\langle \tilde{O}_j^{(q)}\rangle} |\boldsymbol{x}\rangle$,
    using Lemma 13 or Lemma 14 and perform the computational basis measurement on each of them. Note that each measurement outputs a result in the form of $(x_1, ..., x_M) \in G_p^M$.
    Set coordinate-wise medians of the measurement results as $g_j^{(q)}$
    Set $\tilde{u}_j^{(q+1)} := \tilde{u}_j^{(q)} + \pi 2^{-q} g_j^{(q)}$
    if there are some $j$ such that $\tilde{u}_j^{(q+1)} \ge 1$ (or $\le -1$) then
        Set $\tilde{u}_j^{(q+1)} = 1$ (or $-1$) for such $j$
    end if
end for
return $\tilde{u}_j := \tilde{u}_j^{(q_{\max}+1)}$
```

Let B_j $(j = 1, ..., M)$ be an a-block-encoding of a $d \times d$ observable O_j, and let $\mathbf{p} := (p_1, ..., p_M)$ be a sequence of positive integers. Here, we define a set $G_{\mathbf{p}}$ of grid points as

$$G_{\mathbf{p}} := G_{p_1} \times \cdots \times G_{p_M},$$

where each G_p is defined as in Eq. (A1). For any element $\boldsymbol{x} = (x_1, ..., x_M) \in G_{\mathbf{p}}$, we can construct an $(a + \lceil \log_2 M \rceil + 1)$-block-encoding of $\tilde{H}^{(\boldsymbol{x})} := M^{-1} \sum_{j=1}^M x_j O_j$ by using the LCU method. The corresponding SELECT operation denoted by U_{SEL} is given by

$$U_{\mathrm{SEL}} := \sum_{j=1}^{M} |j\rangle\langle j| \otimes B_j .$$

As for the PREPARE operation, we consider implementation with and without reflecting the signs of coefficients as $P_{\mathrm{R}}^{(\boldsymbol{x})}$ and $P_{\mathrm{L}}^{(\boldsymbol{x})}$, defined as

$$P_{\mathrm{R}}^{(\boldsymbol{x})} : |0\rangle^{\otimes\lceil \log_2 M\rceil} \mapsto \sum_{j=1}^{M} \mathrm{sgn}(x_j)\sqrt{\frac{|x_j|}{\|\boldsymbol{x}\|_1}}\,|j\rangle . \tag{B2}$$

$$P_{\mathrm{L}}^{(\boldsymbol{x})} : |0\rangle^{\otimes\lceil \log_2 M\rceil} \mapsto \sum_{j=1}^{M} \sqrt{\frac{|x_j|}{\|\boldsymbol{x}\|_1}}\,|j\rangle \tag{B3}$$

Then, we can confirm that the unitary $(P_{\mathrm{L}}^{(\boldsymbol{x})} \otimes \mathbf{1})^\dagger U_{\mathrm{SEL}} (P_{\mathrm{R}}^{(\boldsymbol{x})} \otimes \mathbf{1})$ is a block encoding of $\propto \tilde{H}^{(\boldsymbol{x})}$ because for any $|\psi\rangle$,

$$\begin{aligned}
&(P_{\mathrm{L}}^{(\boldsymbol{x})} \otimes \mathbf{1})^\dagger U_{\mathrm{SEL}} (P_{\mathrm{R}}^{(\boldsymbol{x})} \otimes \mathbf{1})\, |0\rangle^{\otimes\lceil \log_2 M\rceil} |\psi\rangle \\
&\quad = \sum_{j=1}^{M} \mathrm{sgn}(x_j)\sqrt{\frac{|x_j|}{\|\boldsymbol{x}\|_1}}\,(P_{\mathrm{L}}^{(\boldsymbol{x})})^\dagger |j\rangle \otimes B_j |\psi\rangle \\
&\quad = |0\rangle^{\otimes\lceil \log_2 M\rceil} \otimes \sum_{j=1}^{M} \frac{x_j}{\|\boldsymbol{x}\|_1} B_j |\psi\rangle + |\tilde{\psi}^{\perp}\rangle ,
\end{aligned} \tag{B4}$$

where $\langle 0|^{\otimes\lceil \log_2 M\rceil} |\tilde{\psi}^{\perp}\rangle = 0$. While the block encoding has the normalization factor $\|\boldsymbol{x}\|_1$ which depends on $\boldsymbol{x}$, it can be modified to M by introducing an additional single ancilla qubit and a single rotation gate $R_y(\theta) = e^{i\theta Y}$. As a result, the following unitary is $(a + \lceil \log_2 M\rceil + 1)$-block-encoding of $\tilde{H}^{(\boldsymbol{x})}$:

$$(I \otimes P_{\mathrm{L}}^{(\boldsymbol{x})} \otimes \mathbf{1})^\dagger\, (I \otimes U_{\mathrm{SEL}})\, (R_y(\theta_{\boldsymbol{x}}) \otimes P_{\mathrm{R}}^{(\boldsymbol{x})} \otimes \mathbf{1}), \tag{B5}$$

where I denotes the 1-qubit identity, and $R_y(\theta_{\boldsymbol{x}}) : |0\rangle \mapsto \frac{\|\boldsymbol{x}\|_1}{M}|0\rangle + \sqrt{1 - \left(\frac{\|\boldsymbol{x}\|_1}{M}\right)^2}\,|1\rangle$.

In this block encoding of $\tilde{H}^{(\boldsymbol{x})}$, only PREPARE operation depends on the grid point $\boldsymbol{x} \in G_{\mathbf{p}}$. Thus, by adding a control to $P_{\mathrm{L}}^{(\boldsymbol{x})}$, $P_{\mathrm{R}}^{(\boldsymbol{x})}$, and R_y, and then sequentially applying them to each $\boldsymbol{x}$, we can implement the following unitary

$$U'_{\mathrm{SEL}} := \sum_{\boldsymbol{x}\in G_{\mathbf{p}}} |\boldsymbol{x}\rangle\langle \boldsymbol{x}| \otimes U^{(\boldsymbol{x})}, \tag{B6}$$

where $U^{(\boldsymbol{x})}$ denotes the block encoding of $\tilde{H}^{(\boldsymbol{x})}$. Because the detailed circuit description of U'_{SEL} is not required in the following, we deal with the unitary U'_{SEL} as an oracle for observables $\{O_j\}_{j=1}^{M}$, instead of U_{SEL}, for a simple expression of gate complexity.

Remark 11. The above straightforward construction of U'_{SEL} results in a very large circuit with $\mathcal{O}(2^{\|\mathbf{p}\|_1})$-depth. Fortunately, we can construct a more efficient circuit by further modifying the PREPARE operation, using a similar way to Ref. [61]. As shown in the Sec. 3 of Ref. [25], we can implement $\sum_{x\in G_p} |x\rangle\langle x| \otimes e^{-ixZ}$ with $\mathcal{O}(p)$-depth circuit using $p+1$ (controlled) single-qubit rotation gates. By sequentially applying the $|j\rangle$-controlled version of this gate (see Fig. 8) over x_j-register, the additional single ancilla qubit, and the $\lceil \log_2 M\rceil$ qubits, we obtain a $\boldsymbol{x}$-controlled block encoding of $e^{i\mathcal{H}^{(\boldsymbol{x})}}$, where $\mathcal{H}^{(\boldsymbol{x})} := \sum_{j=1}^{M} x_j |j\rangle\langle j|$. The corresponding circuit diagram is shown in Fig. 9. Then, we can obtain an ϵ-precise block encoding of $(2/\pi)\mathcal{H}^{(\boldsymbol{x})}$, via the eigenvalue transformation for the logarihm of unitaries: $e^{i\mathcal{H}^{(\boldsymbol{x})}} \mapsto \mathcal{H}^{(\boldsymbol{x})}$ (Corollary 71 in [13]). This implementation consists of $\mathcal{O}(\log(1/\epsilon))$ uses of block-encoding of $e^{i\mathcal{H}^{(\boldsymbol{x})}}$ or its inverse. Now, introducing the SELECT U_{SEL} and Hadamard gates, we have an ϵ-precise block-encoding of $(2M/(\pi 2^{\lceil \log_2 M\rceil}))\tilde{H}^{(\boldsymbol{x})}$ controlled by $\boldsymbol{x}$, using at most $\mathcal{O}(\|\mathbf{p}\|_1 \log(1/\varepsilon))$-depth circuit over $\mathcal{O}(\|\mathbf{p}\|_1 + a + \lceil \log_2 M\rceil + \log_2 d)$ qubits in total:

$$\begin{aligned}
&\langle \mathbf{0}| H^{\otimes\lceil \log_2 M\rceil} \otimes \mathbf{1} \cdot U_{\mathrm{SEL}} \cdot \frac{2}{\pi}\mathcal{H}^{(\boldsymbol{x})} H^{\otimes\lceil \log_2 M\rceil} |\mathbf{0}\rangle \otimes \mathbf{1} \\
&= \frac{2M}{\pi 2^{\lceil \log_2 M\rceil}} \frac{1}{M} \sum_{j=1}^{M} x_j B_j .
\end{aligned} \tag{B7}$$

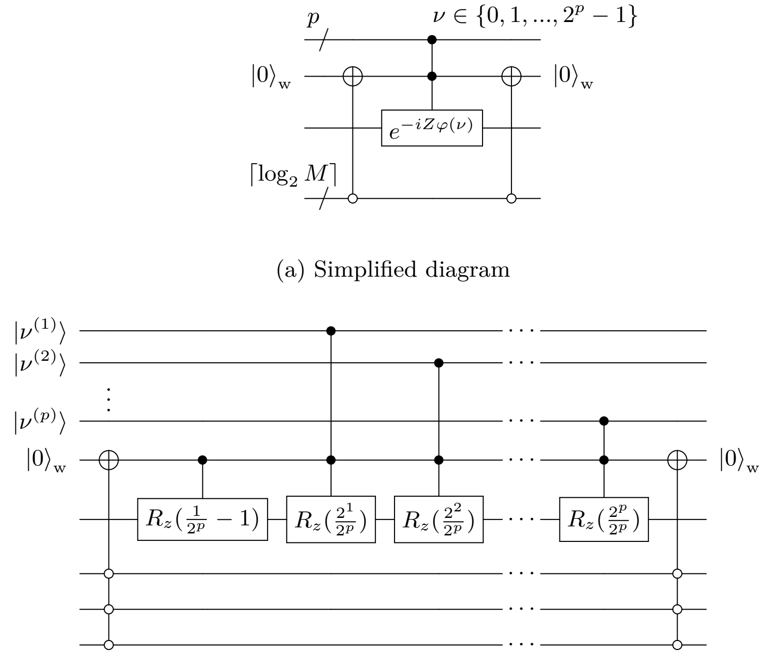
Note that this block encoding has a single use of $U_{\mathrm{SEL}} = \sum_j |j\rangle\langle j| \otimes B_j$ regardless of ϵ.

Using U'_{SEL}, U_ψ, and its conjugation $U_\psi^\dagger$, we obtain a block encoding of the following Hamiltonian:

$$\sum_{\boldsymbol{x}} \langle\psi|\tilde{H}^{(\boldsymbol{x})}|\psi\rangle\, |\boldsymbol{x}\rangle\langle\boldsymbol{x}| = \sum_{\boldsymbol{x}} \left(\sum_j x_j \cdot \frac{\langle O_j\rangle}{M}\right) |\boldsymbol{x}\rangle\langle\boldsymbol{x}| .$$

This allows us to simulate the phase oracle for the affine linear function $\sum_j x_j \langle O_j\rangle/M$ by using the block-Hamiltonian simulation (Lemma 6). However, in estimating the expectation value $\langle O_j\rangle$, we need to amplify the function by the factor M due to the normalization factor $1/M$ in $\tilde{H}^{(\boldsymbol{x})}$, which may result in no speedup for the total queries to U_ψ regarding the number M of observables. To obtain the quadratic speedup regarding M, Ref. [26] (Lemma 36) uses a linear amplification of $\tilde{H}^{(\boldsymbol{x})}$ by Lemma 4, and this amplification can be performed with no use of U_ψ. Here, we provide a slightly modified version of the Lemma 36 in Ref. [26] as follows.

Lemma 12. *Let $\delta' > 0$, $\varepsilon' \in (0, 1/2)$, and let $\mathbf{p} = (p_1, p_2, ..., p_M)$ be any sequence of positive integers. Suppose that for $d \times d$ observables $\{O_j\}_{j=1}^{M}$ with $\|O_j\| \leq 1$ (d is a power of 2), we have access to the oracle $U'_{\mathrm{SEL}} = \sum_{\boldsymbol{x}\in G_{\mathbf{p}}} |\boldsymbol{x}\rangle\langle\boldsymbol{x}| \otimes U^{(\boldsymbol{x})}$, where $U^{(\boldsymbol{x})}$ is an $(a + \lceil \log_2 M\rceil)$-block encoding of observable $\tilde{H}^{(\boldsymbol{x})} := M^{-1}\sum_{j=1}^{M} x_j O_j$ for*



(a) Simplified diagram

(b) Detailed diagram in the case of $\lceil \log_2 M \rceil = 3$

FIG. 8. Quantum circuit for $|0\rangle^{\otimes \lceil \log_2 M \rceil}$-controlled unitary $\sum_\nu |\nu\rangle \langle \nu| \otimes e^{-iZ\varphi(\nu)}$. The qubit $|0\rangle_{\mathrm{w}}$ is an additional work qubit. Here, we recall $\varphi(\mu) := \frac{\mu}{2^p} - \frac{1}{2} + \frac{1}{2^{p+1}} \in G_p$ in Eq. (A2). $R_z(x) := e^{-ixZ/2}$.

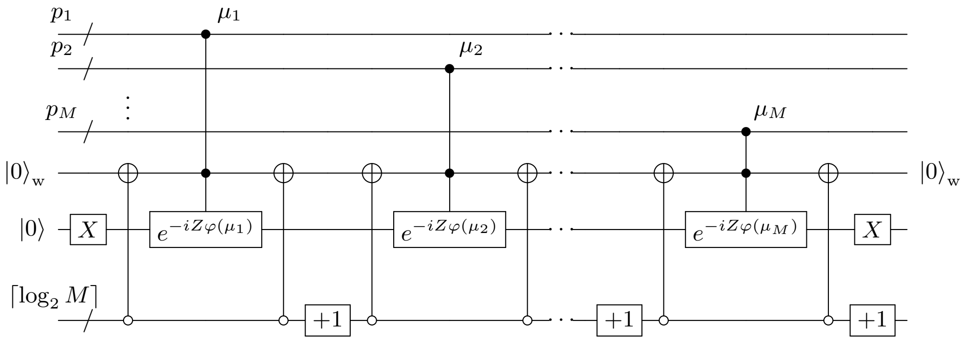


FIG. 9. Quantum circuit for a 2-block-encoding of $\sum_{\boldsymbol{x}} |\boldsymbol{x}\rangle \langle \boldsymbol{x}| \otimes e^{i\mathcal{H}^{(\boldsymbol{x})}}$, where $\mathcal{H}^{(\boldsymbol{x})} := \sum_{j=1}^{M} x_j |j\rangle \langle j|$. The gate $+1$ denotes a bit increment operation such as $|1\rangle \to |2\rangle \to \cdots \to |M\rangle \to |1\rangle$.

some $a \in \mathbb{N}$. If the following inequality holds

$$\sigma := \left\lceil \sqrt{2M \ln(2d/\delta')} \right\rceil < M, \qquad \text{(B8)}$$

then there exists a subset F of $G_{\mathbf{p}}$ with the cardinality $|F| \geq (1-\delta')|G_{\mathbf{p}}|$, and we can implement a unitary (with $\|\mathbf{p}\|_1 + \lceil \log_2 M \rceil + \log_2 d + a + 1$ qubits in total)

$$U_{\mathrm{obs}} := \sum_{\boldsymbol{x} \in G_{\mathbf{p}}} |\boldsymbol{x}\rangle \langle \boldsymbol{x}| \otimes U_{\mathrm{obs}}^{(\boldsymbol{x})} \qquad \text{(B9)}$$

such that $U_{\mathrm{obs}}^{(\boldsymbol{x})}$ is a $(1, a + \lceil \log_2 M \rceil + 1, \varepsilon')$-block-encoding of the Hamiltonian

$$H^{(\boldsymbol{x})} := \frac{1}{\sigma} \sum_{j=1}^{M} x_j O_j \quad \text{if} \quad \boldsymbol{x} \in F \subset G_{\mathbf{p}}. \qquad \text{(B10)}$$

For $m := \mathcal{O}(M\sigma^{-1} \log(M\sigma^{-1}/\varepsilon'))$, this implementation of U_{obs} uses m queries to U'_{SEL} or its inverse, $2m$ NOT gates controlled by $(a + \lceil \log_2 M \rceil)$-qubit, and $\mathcal{O}(m)$ single-qubit gates, with $\mathcal{O}(\mathrm{poly}(m))$ classical precomputation for *finding quantum circuit parameters. The circuit diagram for $U_{\rm obs}$ is shown in Fig. 10.*

Proof of Lemma 12. Let $\gamma := M/\sigma > 1$. To perform the amplification in Lemma 4, it is required that the spectral norm $\|\tilde{H}^{(\boldsymbol{x})}\|$ is upper bounded by $(1-\delta)/\gamma$ for some $\delta \in (0, 1/2)$. To this end, we define a subset $F \subset G_{\mathbf{p}}$ such that

$$F := \left\{ \boldsymbol{x} \in G_{\mathbf{p}} : \|\tilde{H}^{(\boldsymbol{x})}\| < \frac{1}{2\gamma} \right\}.$$

If $\boldsymbol{x} \in F$, we can perform the linear amplification by γ and obtain $(1, a + \lceil \log_2 M \rceil + 1, \varepsilon')$-block-encoding of $\gamma \tilde{H}^{(\boldsymbol{x})}$ from Lemma 4. Next, we show the cardinality of F is equal or more than $(1-\delta') \prod_{j=1}^M 2^{p_j}$. Let us consider independent random variables X_j $(j = 1, ..., M)$ that are uniformly distributed on each G_{p_j}. Because the random variables are also symmetrically distributed on each G_{p_j}, the following matrix series inequality holds (Theorem 35 in [26]):

$$\begin{aligned} &\mathrm{Pr}_{X_1,...,X_M} \left[\left\| \sum_{j=1}^M (2X_j) O_j \right\| \geq t \right] \\ &\leq 2d \cdot \exp\left[-\frac{t^2}{2 \left\| \sum_{j=1}^M O_j^2 \right\|} \right]. \end{aligned} \tag{B11}$$

Thus, inserting M/γ into t, we obtain

$$\mathrm{Pr}_{X_1,...,X_M} \left[\left\| \tilde{H}^{(\boldsymbol{X})} \right\| \geq 1/2\gamma \right] \leq \delta'. \tag{B12}$$

Since the probability of an event $X_j = x_j$ $(j = 1, ..., M)$ is equal to $1/\prod_{j=1}^M 2^{p_j}$ for all x_j, we obtain $|F| \geq (1 - \delta') \prod_{j=1}^M 2^{p_j}$. The gate complexity follows from that of Lemma 4.

□

Here, we make some remarks for Lemma 12. The condition Eq. (B8) for the amplification, $M > \mathcal{O}(\log(d/\delta'))$, is crucial in our algorithm, and for a constant δ', this condition is satisfied when the number of observables is bigger than the number of qubits such as Eq. (B1).

When we use the circuit construction of $U'_{\rm SEL}$ in Remark 11, $U^{(\boldsymbol{x})}$ in the assumption of Lemma 12 should be replaced as the ϵ-precise block encoding of $(2M/(\pi 2^{\lceil \log_2 M \rceil}))\tilde{H}^{(\boldsymbol{x})}$. In this case, the error ε' in the block encoding $U_{\rm obs}^{(\boldsymbol{x})}$ of $H^{(\boldsymbol{x})}$ becomes $\varepsilon' + \mathcal{O}(m\sqrt{\epsilon})$, by the error propagation associated with the uniform amplification Lemma 4 (see; Lemma 22 in Ref. [13]). Thus, replacing ε' and ϵ with $\varepsilon'/2$ and $\mathcal{O}((\varepsilon'/m)^2)$, respectively, we obtain the ε'-precise block encoding $U_{\rm obs}^{(\boldsymbol{x})}$.

b. Approximated state preparation

Now, we are ready to show two quantum algorithms to prepare the probing state $|\Upsilon(q)\rangle$. Note that in the following lemmas, we explicitly construct a quantum circuit in its proof.

Lemma 13 (State preparation by Hamiltonian simulation)**.** *Let O_j $(j = 1, 2, ..., M)$ be $d \times d$ observables O_j (d is a power of 2) with $\|O_j\| \leq 1$, and let p be a positive integer. Also, let U_ψ be a $\log_2 d$-qubit state preparation oracle, and $\langle O_j \rangle := \langle \psi | O_j | \psi \rangle$. Suppose we have access to $U'_{\rm SEL} := \sum_{\boldsymbol{x} \in G_p^M} |\boldsymbol{x}\rangle \langle \boldsymbol{x}| \otimes U^{(\boldsymbol{x})}$, where $U^{(\boldsymbol{x})}$ is an $(a + \lceil \log_2 M \rceil)$-block-encoding of $M^{-1} \sum_{j=1}^M x_j O_j$ for some $a \in \mathbb{N}$. We assume $\sigma := \left\lceil \sqrt{2M \ln(2d/\delta')} \right\rceil < M$ holds for $\delta' = 2^{-10}$. Then, for any non-negative integer q, we can prepare the pM-qubit quantum state*

$$\frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x} \in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j 2^{q+1} \pi^{-1} \langle O_j \rangle} |\boldsymbol{x}\rangle$$

up to 1/12 Euclidean distance error, with $4Q$ uses of U_ψ or $U_\psi^\dagger$, $4mQ$ uses of controlled $U'_{\rm SEL}$ or its inverse, $\mathcal{O}(mQ)$ uses of NOT gates controlled by at most $\mathcal{O}(a + \lceil \log_2 M \rceil + \log_2 d)$ qubits, $\mathcal{O}(mQ + pM)$ uses of single-qubit or two-qubit gates, additional $(\lceil \log_2 M \rceil + \log_2 d + a + 3)$ ancilla qubits, and $\mathcal{O}(\mathrm{poly}(Q) + \mathrm{poly}(m))$ classical precomputation for finding quantum circuit parameters, where

$$Q = \mathcal{O}\left(2^{p+q+2}\sigma\right) \quad and \quad m = \mathcal{O}\left(\frac{M}{\sigma}(p + q + \log M)\right).$$

Note that if we have a block encoding B_j of O_j, then a block encoding of $(O_j - \tilde{u}_j^{(q)} \mathbf{1})/2$ for any $\tilde{u}_j^{(q)} \in [-1, 1]$ is easily constructed by the LCU method; see Fig. 11. Therefore, Lemma 13 provides a method to approximately prepare the probing state $|\Upsilon(q)\rangle$.

Proof of Lemma 13. Let $\varepsilon'' = 2^{-14} \in (0, 1)$ and $\varepsilon' = \sqrt{\delta'}/(2^{p+q+2}\sigma) \in (0, 1/2)$. From the assumption and Lemma 12, we have a unitary

$$U_{\rm obs} := \sum_{\boldsymbol{x} \in G_p^M} |\boldsymbol{x}\rangle \langle \boldsymbol{x}| \otimes U_{\rm obs}^{(\boldsymbol{x})}, \tag{B13}$$

where $U_{\rm obs}^{(\boldsymbol{x})}$ is a $(1, a'' = a + \lceil \log_2 M \rceil + 1, \varepsilon')$-block-encoding of the Hamiltonian $H^{(\boldsymbol{x})} := \sigma^{-1} \sum_{j=1}^M x_j O_j$ if $\boldsymbol{x} \in F$ with $|F| \geq (1 - \delta')|G_p^M|$. Thus, using $U_\psi, U_\psi^\dagger$, and $U_{\rm obs}$, we can implement a $(1, a'' + \log_2 d, 0)$-block-encoding of the following Hamiltonian

$$\sum_{\boldsymbol{x} \in G_p^M} \tilde{f}(\boldsymbol{x}) |\boldsymbol{x}\rangle \langle \boldsymbol{x}|, \tag{B14}$$

where

$$\tilde{f}(\boldsymbol{x}) := \langle 0|^{\otimes a'' + \log_2 d} U_\psi^\dagger \cdot U_{\rm obs}^{(\boldsymbol{x})} \cdot U_\psi |0\rangle^{\otimes a'' + \log_2 d}.$$

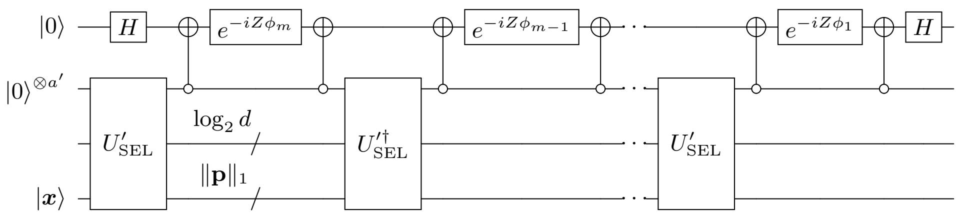

FIG. 10. Quantum circuit for $U_{\rm obs}$ in Eq. (B9). Here, $a' := \lceil \log_2 M \rceil + a$. The circuit parameters $\{\phi_j\}_{j=1}^m$ are adjusted for real QSP based on the degree-m odd polynomial $P(x) \approx \gamma x$, $\gamma = M/\sigma$. Note that $U'_{\rm SEL}$ contains a single use of $U_{\rm SEL} := \sum_{j=1}^M |j\rangle\langle j| \otimes B_j$.

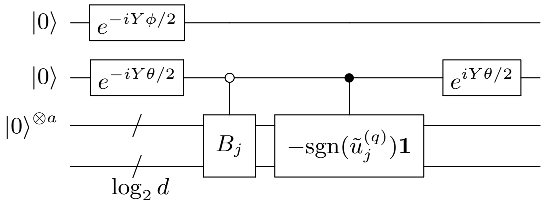

FIG. 11. Quantum circuit for an $(a+2)$-block-encoding of $\tilde{O}_j^{(q)} := (O_j - \tilde{u}_j^{(q)}\mathbf{1})/2$, where $\tilde{u}_j^{(q)} \in [-1,1]$. B_j is an a-block-encoding of O_j. The angles are defined as $\theta := 2\tan^{-1}\sqrt{|\tilde{u}_j^{(q)}|}$ and $\phi := 2\tan^{-1}\sqrt{4-(1+|\tilde{u}_j^{(q)}|)^2/(1+|\tilde{u}_j^{(q)}|)}$.

The corresponding quantum circuit is shown in Fig. 12. Thus, the block-Hamiltonian simulation (Lemma 6) yields the quantum circuit W for a $(1, a''+\log_2 d+2, \varepsilon'')$-block-encoding of time evolution operator

$$\sum_{\boldsymbol{x}\in G_p^M} e^{i\tilde{f}(\boldsymbol{x})t} |\boldsymbol{x}\rangle\langle\boldsymbol{x}| \quad \text{and} \quad t := 2^{p+2+q}\sigma. \tag{B15}$$

Note that a block encoding W' of ε''-precise time evolution operator e^{iHt} for some Hamiltonian H yields $\mathcal{O}(\sqrt{\varepsilon''})$-precise time evolved states, that is, for any state $|\psi\rangle$,

$$\left\| W' |\mathbf{0}\rangle |\psi\rangle - |\mathbf{0}\rangle e^{iHt} |\psi\rangle \right\| \le \varepsilon'' + \sqrt{2\varepsilon''},$$

where $|\mathbf{0}\rangle$ is the signal state for W'. Therefore, for $|\mathbf{0}\rangle = |0\rangle^{\otimes a''+\log_2 d+2}$ and the $+1$ eigenstate $|+\rangle$ of Pauli X , we obtain

$$\begin{aligned}
&\left\| W|\mathbf{0}\rangle|+\rangle^{\otimes pM} - \frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j \pi^{-1} 2^{q+1}\langle O_j\rangle} |\mathbf{0}\rangle|\boldsymbol{x}\rangle \right\| \\
&\le \varepsilon'' + \sqrt{2\varepsilon''} + \frac{1}{\sqrt{2^{pM}}} \left\| \sum_{\boldsymbol{x}\in G_p^M} e^{i\tilde{f}(\boldsymbol{x})t}|\boldsymbol{x}\rangle - \sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j \pi^{-1} 2^{q+1}\langle O_j\rangle} |\boldsymbol{x}\rangle \right\| \\
&\le \varepsilon'' + \sqrt{2\varepsilon''} + \sqrt{5\delta'} < \frac{1}{12}.
\end{aligned} \tag{B16}$$

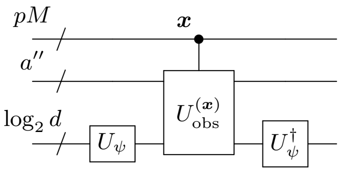

FIG. 12. Quantum circuit for a $(a'' + \log_2 d)$-block-encoding of $\sum_{\boldsymbol{x}\in G_p^M} \tilde{f}(\boldsymbol{x}) |\boldsymbol{x}\rangle \langle\boldsymbol{x}|$ in Eq. (B14).

Here, in the second inequality we used the following evaluation.

$$\begin{aligned}
&\left\| \sum_{\boldsymbol{x}\in G_p^M} e^{i\tilde{f}(\boldsymbol{x})t} |\boldsymbol{x}\rangle - \sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j \pi^{-1} 2^{q+1} \langle O_j\rangle} |\boldsymbol{x}\rangle \right\|^2 \\
&\le \sum_{\boldsymbol{x}\in G_p^M} \left| e^{i\tilde{f}(\boldsymbol{x})t} - e^{2\pi i 2^p \sum_{j=1}^M x_j \pi^{-1} 2^{q+1} \langle O_j\rangle} \right|^2 \\
&\le 4 \times 2^{pM}\delta' + \sum_{\boldsymbol{x}\in F} \left| e^{i\tilde{f}(\boldsymbol{x})t} - e^{2\pi i 2^p \sum_{j=1}^M x_j \pi^{-1} 2^{q+1} \langle O_j\rangle} \right|^2 \qquad (\because |F| \ge (1-\delta')|G_p^M|) \\
&\le 4 \times 2^{pM}\delta' + \sum_{\boldsymbol{x}\in F} \left| \tilde{f}(\boldsymbol{x})t - 2\pi 2^p \sum_{j=1}^M x_j \pi^{-1} 2^{q+1} \langle O_j\rangle \right|^2 \qquad (\because |e^{ia} - e^{ib}| \le |a-b|) \\
&\le 4 \times 2^{pM}\delta' + \sum_{\boldsymbol{x}\in F} (t\varepsilon')^2 \le 2^{pM} \times 5\delta' \quad (\because \varepsilon' := \sqrt{\delta'}/t).
\end{aligned} \tag{B17}$$

The gate complexity follows from that of Lemma 12 and Lemma 6.

□

Lemma 14 (State preparation by Grover-like repetition)**.** *Let O_j $(j = 1, 2, ..., M)$ be $d \times d$ observables O_j (d is a power of 2) with $\|O_j\| \le 1$, and let p be a positive integer. We assume the following two conditions holds for $\delta' := 2^{-14} \in (0,1)$:*

(i) $\sigma := \left\lceil \sqrt{2(M+1)\ln(2d/\delta')} \right\rceil < M+1.$

(ii) For a given $(\log_2 d)$-qubit quantum state $|\psi\rangle$ prepared by U_ψ, $|\langle O_j\rangle| \le 2^{-q-1}$ holds for all $j = 1, 2, ..., M$, where q denotes a non-negative integer satisfying

$$q \ge \log_4 \left[\frac{2^p \cdot 33^3}{625 \ln(2d/\delta')} \frac{\left\lceil \sqrt{2(M+1)\ln(2d/\delta')} \right\rceil}{\sqrt{\ln(2d/\delta')}} \right] \tag{B18}$$

Suppose we have access to $U'_{\mathrm{SEL}} := \sum_{\boldsymbol{x}\in G_p^M \times G_1} |\boldsymbol{x}\rangle \langle\boldsymbol{x}| \otimes U^{(\boldsymbol{x})}$, where $U^{(\boldsymbol{x})}$ is an $(a + \lceil \log_2(M+1) \rceil)$-block-encoding of

$$\frac{1}{M+1} \left(\sum_{j=1}^{M+1} x_j O_j \right)$$

for some $a \in \mathbb{N}$. Here, O_{M+1} denotes a 2×2 observable defined as

$$O_{M+1} := \frac{\pi(1/4 + 4l)}{2^{p+q}} I,$$

where l is an arbitrary integer satisfying $\|2^{q+1} O_{M+1}\| \le 1$ and I denotes the 1-qubit identity. Then, we can successfully prepare the following pM-qubit quantum state with a measurement result of ancilla qubits indicating the success:

$$\frac{1}{\sqrt{2^{pM}}} \sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p \sum_{j=1}^M x_j 2^{q+1} \pi^{-1} \langle O_j\rangle} |\boldsymbol{x}\rangle$$

up to 1/12 Euclidean distance error with the success probability ≥ 0.462. This implementation consists of $2t$ uses of U_ψ or $U_\psi^\dagger$, mt uses of U'_{SEL} or its inverse, $(2m+1)t$ uses of NOT gates controlled by at most $(a + \lceil \log_2(M +$

1)⌉ + $\log_2 d$) qubits, $\mathcal{O}(mt + pM)$ uses of single-qubit or two-qubit gates, additional $(\lceil \log_2(M+1)\rceil + \log_2 d + a + 2)$ ancilla qubits, and $\mathcal{O}(\mathrm{poly}(m))$ classical precomputation for finding quantum circuit parameters, where

$$t = 2^{p+q+2}\sigma \quad \text{and} \quad m = \mathcal{O}\left(\frac{M}{\sigma}\left(p + q + \log M\right)\right).$$

Proof of Lemma 14. Let $\varepsilon' = \sqrt{\delta'}/(2^{p+q+2}\sigma) \in (0, 1/2)$. From the assumption and Lemma 12, we have a unitary

$$U_{\text{obs}} := \sum_{(\boldsymbol{x},y)\in G_p^M \times G_1} |\boldsymbol{x}, y\rangle \langle \boldsymbol{x}, y| \otimes U_{\text{obs}}^{(\boldsymbol{x},y)}, \tag{B19}$$

where $U_{\text{obs}}^{(\boldsymbol{x},y)}$ is a $(1, a'' = a + \lceil \log_2 (M+1) \rceil + 1, \varepsilon')$-block-encoding of the Hamiltonian

$$H^{(\boldsymbol{x},y)} := \frac{1}{\sigma}\left(yO_{M+1} + \sum_{j=1}^{M} x_j O_j\right)$$

if $(\boldsymbol{x}, y) \in F$ with $|F| \geq (1-\delta')2|G_p^M|$. Thus, using $U_\psi, U_\psi^\dagger$, and U_{obs}, we can implement a $(1, a'' + \log_2 d, 0)$-block-encoding of the following Hamiltonian

$$\sum_{(\boldsymbol{x},y)\in G_p^M \times G_1} \tilde{f}(\boldsymbol{x}, y) |\boldsymbol{x}, y\rangle \langle \boldsymbol{x}, y|, \quad \text{where} \quad \tilde{f}(\boldsymbol{x}, y) := \langle 0|^{\otimes a'' + \log_2 d} U_\psi^\dagger \cdot U_{\text{obs}}^{(\boldsymbol{x},y)} \cdot U_\psi |0\rangle^{\otimes a'' + \log_2 d}. \tag{B20}$$

Since $U_{\text{obs}}^{(\boldsymbol{x},y)}$ is the ε'-precise block encoding of $H^{(\boldsymbol{x},y)}$, $\tilde{f}(\boldsymbol{x}, y)$ is close to an affine linear function as

$$\left| \tilde{f}(\boldsymbol{x}, y) - \frac{1}{\sigma}\left(y\langle O_{M+1}\rangle + \sum_{j=1}^{M} x_j \langle O_j \rangle\right)\right| \leq \varepsilon' \quad \text{for all} \quad (\boldsymbol{x}, y) \in F. \tag{B21}$$

Thus, Grover-like repetition on Eq. (B20), that is, Lemma 5 yields the quantum circuit W for an $(a'' + \log_2 d)$-block-encoding of the following operator

$$\sum_{(\boldsymbol{x},y)\in G_p^M \times G_1} T_t\left(\tilde{f}(\boldsymbol{x}, y)\right) |\boldsymbol{x}, y\rangle \langle \boldsymbol{x}, y| \quad \text{and} \quad t := 2^{p+q+2}\sigma.$$

Applying W to the state $|+\rangle^{\otimes pM+1} |\mathbf{0}\rangle$ with $|\mathbf{0}\rangle = |0\rangle^{\otimes a'' + \log_2 d}$, we obtain

$$W |+\rangle^{\otimes pM+1} |\mathbf{0}\rangle = \frac{\mathcal{N}_t}{\sqrt{2}}\left[\frac{1}{\mathcal{N}_t}\frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x},y} T_t\left(\tilde{f}(\boldsymbol{x}, y)\right)|\boldsymbol{x}, y\rangle\right]|\mathbf{0}\rangle + \sqrt{1 - \left(\frac{\mathcal{N}_t}{\sqrt{2}}\right)^2}\,|\Phi^\perp\rangle, \tag{B22}$$

where $|\Phi^\perp\rangle$ denotes a normalized quantum state satifying $(\mathbf{1} \otimes |\mathbf{0}\rangle\langle\mathbf{0}|)\,|\Phi^\perp\rangle = \mathbf{0}$ and $\mathcal{N}_t$ is defined as:

$$\mathcal{N}_t := \left\| \frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x},y} T_t\left(\tilde{f}(\boldsymbol{x}, y)\right)|\boldsymbol{x}, y\rangle \right\|. \tag{B23}$$

Measuring the $(a'' + \log_2 d)$-qubit ancilla registers in (B22), we obtain the outcome $|\mathbf{0}\rangle$ and the following state with the probability $\mathcal{N}_t^2/2$:

$$\frac{1}{\mathcal{N}_t}\frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x},y} T_t\left(\tilde{f}(\boldsymbol{x}, y)\right)|\boldsymbol{x}, y\rangle. \tag{B24}$$

In the following, we show this quantum state is close to the following state

$$\begin{aligned} &\frac{1}{\sqrt{2^{pM}}}\sum_{(\boldsymbol{x},x_{M+1})\in G_p^M \times G_1} \cos\left[t\left(\frac{\pi}{2} - \frac{1}{\sigma}\sum_{j=1}^{M+1} x_j \langle O_j\rangle\right)\right] |\boldsymbol{x}\rangle\,|x_{M+1}\rangle \\ &= \frac{1}{\sqrt{2}}\sum_{s=\pm 1}\sum_{\boldsymbol{x}\in G_p^M} \frac{1}{\sqrt{2^{pM}}} e^{2\pi i 2^p \sum_{j=1}^{M}(s x_j)\pi^{-1}2^{q+1}\langle O_j\rangle} |\boldsymbol{x}\rangle \otimes \mathrm{QFT}_{G_1}|s/4\rangle. \end{aligned} \tag{B25}$$

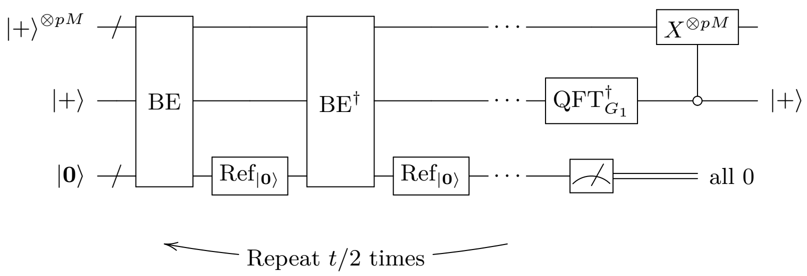

FIG. 13. Quantum circuit for the approximate probing state preparation $|\Upsilon(q)\rangle$ by Grover-like repetition. $|\mathbf{0}\rangle := |0\rangle^{\otimes a'' + \log_2 d}$ and BE denotes the block encoding of Eq. (B20). $\mathrm{Ref}_{|\mathbf{0}\rangle}$ is the reflection on $|\mathbf{0}\rangle$, i.e., $\mathrm{Ref}_{|\mathbf{0}\rangle} := 2\,|\mathbf{0}\rangle\,\langle\mathbf{0}| - \mathbf{1}$. The measurement outcome $|\mathbf{0}\rangle$ is obtained with the probability $\mathcal{N}_t^2/2 \geq 0.462$.

Note that the equality in Eq. (B25) can be shown as follows.

$$\begin{aligned}
&\sum_{(\boldsymbol{x}, x_{M+1}) \in G_p^M \times G_1} \cos\left[t\left(\frac{\pi}{2} - \frac{1}{\sigma}\sum_{j=1}^{M+1} x_j \langle O_j\rangle\right)\right] |\boldsymbol{x}\rangle\,|x_{M+1}\rangle \\
&= \frac{1}{2}\sum_{\boldsymbol{x},y}\sum_{s=\pm1} e^{-is\frac{t}{\sigma}\left(y\langle O_{M+1}\rangle + \sum_{j=1}^M x_j\langle O_j\rangle\right)}\,|\boldsymbol{x}\rangle\,|y\rangle \quad (\because e^{ist\pi/2} = e^{2\pi i s 2^{p+q}\sigma} = 1) \\
&= \frac{1}{\sqrt{2}}\sum_{s=\pm1}\sum_{\boldsymbol{x}\in G_p^M} e^{-ist\frac{1}{\sigma}\sum_{j=1}^M x_j\langle O_j\rangle}\,|\boldsymbol{x}\rangle \otimes \frac{1}{\sqrt{2}}\sum_{y\in G_1} e^{-ist\frac{1}{\sigma}y\langle O_{M+1}\rangle}\,|y\rangle \\
&= \frac{1}{\sqrt{2}}\sum_{s=\pm1}\sum_{\boldsymbol{x}\in G_p^M} e^{-ist\frac{1}{\sigma}\sum_{j=1}^M x_j\langle O_j\rangle}\,|\boldsymbol{x}\rangle \otimes \mathrm{QFT}_{G_1}\,|-s/4\rangle \quad (\because \langle O_{M+1}\rangle = \frac{\pi(1/4+4l)}{2^{p+q}}) \\
&= \frac{1}{\sqrt{2}}\sum_{s=\pm1}\sum_{\boldsymbol{x}\in G_p^M} e^{-is2\pi 2^p\sum_{j=1}^M x_j\pi^{-1}(2^{q+1})\langle O_j\rangle}\,|\boldsymbol{x}\rangle \otimes \mathrm{QFT}_{G_1}\,|-s/4\rangle\,.
\end{aligned} \tag{B26}$$

Thus, by applying $\mathrm{QFT}^\dagger_{G_1}$ and controlled $X^{\otimes pM}$ gate to the state (B22), we can prepare the target state:

$$\frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x}\in G_p^M} e^{2\pi i 2^p\sum_{j=1}^M x_j 2^{q+1}\pi^{-1}\langle O_j\rangle}\,|\boldsymbol{x}\rangle \otimes |+\rangle \tag{B27}$$

up to some Euclidean distance error with the probability $\mathcal{N}_t^2/2$, because $X^{\otimes pM}\,|\boldsymbol{x}\rangle = |-\boldsymbol{x}\rangle$ holds. Note that $\mathrm{QFT}^\dagger_{G_1}$ and controlled $X^{\otimes pM}$ does not change the probability to obtain the success flag $|\mathbf{0}\rangle$. Here, we show the corresponding quantum circuit to prepare Eq. (B27) in Fig. 13.

For subsequent proof, we here show that for any $\delta' \in (0,1)$ and any real weight w_j $(j = 1, 2, ..., M+1)$, a subset F' of $G_p^M \times G_1$ defined as

$$F' := \left\{(\boldsymbol{x}, y) \in G_p^M \times G_1 : \left|\sum_{j=1}^{M+1} w_j x_j\right| < \sqrt{\frac{\ln(2/\delta')}{2}\sum_{j=1}^{M+1}|w_j|^2}\right\} \tag{B28}$$

has the cardinality $|F'| \geq (1-\delta')2^{pM+1}$. This fact can be proved from the Hoeffding's inequality as follows. Let us consider independent random variables X_j $(j = 1, 2, ..., M)$ and Y. Here, X_j are identically and uniformly distributed in G_p and Y is uniformly distributed in G_1. Note that the random variables are upper bounded by $1/2$ from the definition of G_p. Therefore, from the Hoeffding's inequality, we obtain

$$\mathrm{Pr}_{X_1,...,X_M,Y}\left[\left|\sum_{j=1}^{M+1} w_j X_j\right| \geq c\right] \leq 2\mathrm{exp}\left[-\frac{2c^2}{\sum_j |w_j|^2}\right]. \tag{B29}$$

Thus, taking c as $c = \sqrt{\frac{\ln(2/\delta')}{2}\sum_{j=1}^{M+1}|w_j|^2}$, we obtain

$$\mathrm{Pr}_{X_1,\dots,X_M,Y}\left[\left|\sum_{j=1}^{M+1} w_j X_j\right| \geq \sqrt{\frac{\ln(2/\delta')}{2}\sum_{j=1}^{M+1}|w_j|^2}\right] \leq \delta'. \tag{B30}$$

Since the independent random variables $X_1,\dots,X_M,Y$ has uniform distributions, F' has the cardinality $\geq 2^{pM+1}(1-\delta')$.

Now, we are ready to show the closeness between Eq. (B24) and Eq. (B25). Defining F' for $\delta' = 2^{-14}$ and $w_j = \langle O_j\rangle$ as

$$F' := \left\{(\boldsymbol{x},y)\in G_p^M \times G_1 : \left|\sum_{j=1}^{M+1} x_j\langle O_j\rangle\right| < \sqrt{\frac{\ln(2/\delta')}{2}\sum_{j=1}^{M+1}|\langle O_j\rangle|^2}\right\} \tag{B31}$$

and recalling that $|F'|,|F| \geq (1-\delta')2^{pM+1}$, we proceed as follows.

$$\begin{aligned}
&\left\|\sum_{(\boldsymbol{x},y)\in G_p^M\times G_1} T_t(\tilde{f}\,(\boldsymbol{x},y))\,|\boldsymbol{x}\rangle\,|y\rangle - \sum_{(\boldsymbol{x},y)\in G_p^M\times G_1} \cos\left[t\left(\frac{\pi}{2}-\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle\right)\right]|\boldsymbol{x}\rangle\,|y\rangle\right\|^2\\
&= \sum_{(\boldsymbol{x},x_{M+1})\in G_p^M\times G_1}\left|T_t(\tilde{f}(\boldsymbol{x},x_{M+1})) - \cos\left[t\left(\frac{\pi}{2}-\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle\right)\right]\right|^2\\
&\leq 4\times 2\times 2^{pM+1}\delta' + \sum_{(\boldsymbol{x},x_{M+1})\in F\cap F'}\left|t\cos^{-1}\left[\tilde{f}(\boldsymbol{x},x_{M+1})\right] - t\left(\frac{\pi}{2}-\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle\right)\right|^2,
\end{aligned} \tag{B32}$$

where we used $|\cos(a)-\cos(b)| \leq |a-b|$ and $G_p^M\times G_1 = (F\cap F')\cup(F^{\mathrm{c}}\cup(F')^{\mathrm{c}})$ in the third line. Now, we focus on the case $(\boldsymbol{x},x_{M+1})\in F\cap F'$.

$$\begin{aligned}
|\tilde{f}(\boldsymbol{x},x_{M+1})| &\leq \varepsilon' + \left|\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle\right| \qquad (\because \text{Eq. (B21)})\\
&\leq \varepsilon' + \sqrt{\frac{\sum_j|\langle O_j\rangle|^2}{4(M+1)}}\sqrt{\frac{\ln(2/\delta')}{\ln(2d/\delta')}} \qquad (\because \text{Eq. (B31)})\\
&\leq \frac{\sqrt{\delta'}}{2^{p+q+2}\sigma} + \frac{1}{2^{q+2}}\sqrt{\frac{\ln(2/\delta')}{\ln(2d/\delta')}} < \frac{33/10}{2^{q+2}\sqrt{\ln(2d/\delta')}} < 1/4.
\end{aligned} \tag{B33}$$

In the case of $|x|\leq 1/4$, $\left|\cos^{-1}(x)-\pi/2+x\right| \leq \frac{1}{5}|x|^3$ holds, and therefore we obtain

$$\begin{aligned}
&t\left|\cos^{-1}\left[\tilde{f}(\boldsymbol{x},x_{M+1})\right] - \left(\frac{\pi}{2}-\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle\right)\right|\\
&= t\left|\cos^{-1}\left[\tilde{f}(\boldsymbol{x},x_{M+1})\right] - \frac{\pi}{2} + \tilde{f}(\boldsymbol{x},x_{M+1}) + \left(\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle - \tilde{f}(\boldsymbol{x},x_{M+1})\right)\right|\\
&\leq t\varepsilon' + t\left|\cos^{-1}\left[\tilde{f}(\boldsymbol{x},x_{M+1})\right] - \frac{\pi}{2} + \tilde{f}(\boldsymbol{x},x_{M+1})\right|\\
&\leq t\varepsilon' + \frac{t}{5}\left|\frac{33/10}{2^{q+2}\sqrt{\ln(2d/\delta')}}\right|^3.
\end{aligned} \tag{B34}$$

From the assumption, the non-negative integer q satisfies $\frac{t}{5}\left|\frac{33/10}{2^{q+2}\sqrt{\ln(2d/\delta')}}\right|^3 \le \sqrt{\delta'}$, then we conclude that

$$\begin{aligned}&\left\|\sum_{(\boldsymbol{x},y)\in G_p^M\times G_1} T_t(\tilde{f}\,(\boldsymbol{x},y))\,|\boldsymbol{x}\rangle\,|y\rangle - \sum_{(\boldsymbol{x},y)\in G_p^M\times G_1}\cos\left[t\left(\frac{\pi}{2}-\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle\right)\right]|\boldsymbol{x}\rangle\,|y\rangle\right\|\\ &\le \sqrt{4\times 2\times 2^{pM+1}\delta' + \sum_{(\boldsymbol{x},x_{M+1})\in F\cap F'}(2\sqrt{\delta'})^2}\\ &\le 2\sqrt{6\delta'}\times\sqrt{2^{pM}}.\end{aligned} \tag{B35}$$

This leads to

$$1-2\sqrt{6\delta'} \le \mathcal{N}_t = \left\|\frac{1}{\sqrt{2^{pM}}}\sum_{\boldsymbol{x},y} T_t\left(\tilde{f}(\boldsymbol{x},y)\right)|\boldsymbol{x},y\rangle\right\| \le 1+2\sqrt{6\delta'} \tag{B36}$$

and

$$\begin{aligned}&\left\|\frac{1}{\mathcal{N}_t}\sum_{(\boldsymbol{x},y)\in G_p^M\times G_1} T_t(\tilde{f}\,(\boldsymbol{x},y))\,|\boldsymbol{x}\rangle\,|y\rangle - \sum_{(\boldsymbol{x},y)\in G_p^M\times G_1}\cos\left[t\left(\frac{\pi}{2}-\frac{1}{\sigma}\sum_{j=1}^{M+1}x_j\langle O_j\rangle\right)\right]|\boldsymbol{x}\rangle\,|y\rangle\right\|\\ &\le \sqrt{2^{pM}}\times\frac{4\sqrt{6\delta'}}{1-2\sqrt{6\delta'}} < \sqrt{2^{pM}}\times\frac{1}{12}.\end{aligned} \tag{B37}$$

Therefore, we can prepare the target state up to $1/12$ Euclidean distance error with the probability $\mathcal{N}_t^2/2 > 0.462$. Finally, the gate complexity follows from that of Lemma 12 and Lemma 5.

□

Note that we can coherently amplify the success probability in Lemma 14 by quantum amplitude amplification [37], while this requires a quantum circuit with 3-fold depth compared to the quantum circuit (before measurement) in Fig. 13.

2. Maximum mean squared error (MSE) and query complexity

Here, we evaluate the relation between the root mean squared error ε and the total queries to the state preparation in Algorithm 1*.

Proof of Theorem 2. The core idea of this proof is similar to the previous methods [45, 46, 50], but we need carefully to deal with the condition of gradient estimation. In the following, we prove this theorem based on the state preparation by Lemma 13; see remarks after this proof for the case of Lemma 14.

We start by clarifying the statistical property of $g_j^{(q)}$ in the step 5 of Algorithm 1*. The truncation in Step 7 guarantees $\tilde{u}_j^{(q)} \in [-1,1]$ for all q; we can construct a block-encoding U'_{SEL} for $\{\tilde{O}_j^{(q)}\}$, which is assumed to be accessible in Lemma 13, from the block encodings of $\{O_j\}$; see Fig. 11. Therefore, using the Lemma 13, we can prepare the quantum state in Step 4.

Now, we consider the case that the following condition for gradient estimation holds at the beginning of an iteration q: for all j,

$$\left|\langle\tilde{O}_j^{(q)}\rangle\right| = \left|\frac{\langle O_j\rangle - \tilde{u}_j^{(q)}}{2}\right| \le 2^{-q-1}. \tag{B38}$$

Then, a single shot measurement result $\boldsymbol{k} := (k_1,\ldots,k_M)\in G_p^M$ in Step 4 follows

$$\Pr\left[\left|k_j - \frac{2^q(\langle O_j\rangle - \tilde{u}_j^{(q)})}{\pi}\right| > \frac{3}{2^p}\right] \le \frac{1}{3},$$

for every $j = 1,2,\ldots,M$, from the analysis of gradient estimation in Lemma 9. If we take $p=5$, then the additive error $3/2^p$ is smaller than $1/2\pi$, and therefore, the temporal estimate $\tilde{u}_j^{(q)} + \frac{\pi}{2^q}k_j$ becomes a 1-bit more precise estimate of $\langle O_j\rangle$ at least $2/3$ probability. However, the choice of $p=5$ is sufficient but not tight. Here, we employ the following tighter bound that we numerically found [62]: if we take $p=3$,

$$\Pr\left[\left|k_j - \frac{2^q(\langle O_j\rangle - \tilde{u}_j^{(q)})}{\pi}\right| > \frac{1}{2\pi}\right] < 0.18 + \frac{1}{12}, \tag{B39}$$

holds for every j, where the term $1/12$ arises from the Euclidean distance error as well as Lemma 9. Since the

$g_j^{(q)}$ is defined as the coordinate-wise median of independent samples $\boldsymbol{k}^{(1)}, ..., \boldsymbol{k}^{(\#)}$, the Hoeffding's inequality for the independent and bounded random variables $\{\chi[|k_j^{(i)} - 2^q(\langle O_j\rangle - \tilde{u}_j^{(q)})/\pi| > 1/(2\pi)]\}_i$ yields

$$\Pr\left[\left|g_j^{(q)} - \frac{2^q(\langle O_j\rangle - \tilde{u}_j^{(q)})}{\pi}\right| > \frac{1}{2\pi}\right] \leq e^{-\frac{\#}{9}}, \tag{B40}$$

for every j. Here, $\chi[\bullet]$ denotes the indicator function. Therefore, taking $\# := 9\ln(M/\delta^{(q)})$ and using the union bound, we can bound the probability of the event

$$\mathbf{A}^{(q)} : \max_j \left|g_j^{(q)} - 2^q(\langle O_j\rangle - \tilde{u}_j^{(q)})/\pi\right| \leq \frac{1}{2\pi}$$

as $\Pr[\mathbf{A}^{(q)}] \geq 1 - \delta^{(q)}$. In the event $\mathbf{A}^{(q)}$, $|\langle\tilde{O}_j^{(q+1)}\rangle| \leq 2^{-q-2}$ holds even if we truncate $\tilde{u}_j^{(q+1)}$ in Step 7. On the other hand, if the condition Eq. (B38) is false, the gradient estimation does not work, and we only say that the measurement result $g_j^{(q)}$ is bounded as $g_j^{(q)} \in [-1/2, 1/2]$ because of the definition of G_p^M.

In the case of $q = 0$, the condition Eq. (B38) holds, and thus, the event $\mathbf{A}^{(0)}$ occurs with the probability $1 - \delta^{(0)}$. By repeating this, in branches such that all of $\{\mathbf{A}^{(q)}\}_{q=0}^{q'-1}$ occur, the temporal estimate $\tilde{u}_j^{(q')}$ satisfy $|\tilde{u}_j^{(q')} - \langle O_j\rangle| \leq 1/2^{q'}$ for all j. Moreover, considering branches such that all of $\{\mathbf{A}^{(q)}\}_{q=0}^{q'-1}$ occur but the complement of $\mathbf{A}^{(q')}$ occurs at the iteration q', we bound the additive error of the final estimate $\tilde{u}_j$ in such branches as follows:

$$\begin{aligned}|\tilde{u}_j - \langle O_j\rangle| &\leq |\tilde{u}_j - \tilde{u}_j^{(q')}| + |\tilde{u}_j^{(q')} - \langle O_j\rangle| \\ &\leq \pi\left|\sum_{q\geq q'} \frac{g_j^{(q)}}{2^q}\right| + \frac{1}{2^{q'}} \\ &\leq \frac{1+\pi}{2^{q'}}.\end{aligned} \tag{B41}$$

In the third line, we use the fact $|g_j^{(q)}| \leq 1/2$. Thus, we can calculate the mean squared error of $\hat{u}_j$ as

$$\begin{aligned}&\mathbb{E}\left[(\hat{u}_j - \langle O_j\rangle)^2\right] \\ &\leq \frac{1}{2^{2(q_{\max}+1)}} + (1+\pi)^2 \sum_{q=0}^{q_{\max}} \frac{\delta^{(q)}}{4^q} \\ &\leq \frac{1}{2^{2(q_{\max}+1)}} + (1+\pi)^2 c 2^{-2q_{\max}+1} \\ &\leq \varepsilon^2,\end{aligned} \tag{B42}$$

where we defined $q_{\max} := \lceil \log_2(1/\varepsilon)\rceil$. In the final line, we used the fact $c \in (0, 3/(8(1+\pi)^2)]$. The inequality holds for all j, which completes the proof of Eq. (4).

Next, we count the total queries to the state preparation U_ψ. At each iteration q, we prepare $\# := 9\ln(M/\delta^{(q)})$ copies of a quantum state that approximates the probing state $|\Upsilon(q)\rangle$. If we prepare a single copy of this state using the method in Lemma 13, then the $\mathcal{O}(2^{p+q+2}\sigma)$ queries to U_ψ and its inverse are required, and therefore the total queries are calculated as

$$\begin{aligned}&\sum_{q=0}^{q_{\max}} 2^{p+q+2}\sigma \times 9\ln(M/\delta^{(q)}) \\ &= 9\cdot 2^{p+2}\sigma \times \sum_{q=0}^{q_{\max}} 2^q \ln(M/\delta^{(q)}) \\ &= 9\cdot 2^{p+2}\sigma\left[2^{q_{\max}+1}\ln\frac{8M}{c} - (q_{\max}+2)\ln 8 - \ln\frac{M}{c}\right] \\ &= \mathcal{O}(\varepsilon^{-1}\sqrt{M}\log M).\end{aligned}$$

□

Here, we discuss the case that we employ Lemma 14 to the state preparation in Step 4 of Algorithm 1*. This alternative method can prepare the probing state $|\Upsilon(q)\rangle$ under the following conditions: (i) $|\langle\tilde{O}_j^{(q)}\rangle| \leq 2^{-q-1}$ and (ii) the iteration step q satisfies Eq. (B18). In the case that only the condition (i) (or equivalently, Eq. (B38)) is violated, the quantum circuit in Fig. 13 for Lemma 14 yields a pM-qubit quantum state that may be far from the target probing state. However, this does not affect the proof of Theorem 2 because it is only required that the measurement results at the end of Fig. 13 are in the range of $[-1/2, 1/2]$. On the other hand, the condition (ii) restricts the usage of the alternative method, as discussed in Sec. IV B 3.

Variational quantum simulation: a case study for understanding warm starts

Abstract. The barren plateau phenomenon, characterized by loss gradients that vanish exponentially with system size, poses a challenge to scaling of variational quantum algorithms (VQAs). In our work, we explore the potential of warm starts, whereby initializing close to a solution, we hope to enjoy larger gradients. Focusing on an iterative variational method for quantum simulation, we analytically show that a small region around the initialization at each iteration exhibits substantial gradients with convexity guarantees. However, our study highlights scenarios where a good minimum shifts outside the region with guarantees. Our analysis leaves open the question whether such minima jumps necessitate optimization across barren plateau landscapes or whether there exist gradient flows, i.e., fertile valleys away from the plateau with substantial gradients, that allow for training.

Keywords: Variational Quantum Algorithms, Warm Start, Trainability guarantees, Barren Plateaus, Quantum Simulation

1 Summary

Barren plateaus, i.e., loss landscapes that concentrate exponentially in system size towards their mean value with high probability, [1–19] are widely thought to pose a significant barrier to the scaling up of variational quantum algorithms. However, barren plateaus are fundamentally a statement about the landscape on average. Indeed, regions of the landscape with significant gradients must exist around the minima. This has motivated the study of *warm starts* whereby the algorithm is cleverly initialized closer to one. Numerical studies indicate that these methods may be promising [20–23]. In parallel, analytic studies have proven that initializations around identity can exhibit non-exponentially vanishing gradients [24–28]. Nonetheless, a good solution may be far from this identity region.

Here we consider a family of variational quantum algorithms that inherently use warm starts and take this as a case study to better understand their potential and limitations. In particular, we study an approach for learning shorter depth circuits for simulating quantum systems by iteratively compressing real or imaginary time Trotter evolution circuits [29–35]. At each iteration, the previous solution is used to initialize the parameters to learn a new compressed circuit to implement a slightly longer evolution as shown in Fig. 1a).

This case study is an ideal playground for studying warm starts because its inbuilt structure allows one to analytically compute bounds on its trainability. **(I)** We start by proving that as long as the training in one time-step is successful then the algorithm will exhibit substantial gradients in a small region around the next initialization. **(II)** We then establish guarantees on the approximate convexity of the gradients in this region and further argue that for polynomially large time-steps the new optimum (called an adiabatic minimum) will typically remain in this convex region. These results are summarised in Fig. 1b.

However, these positive findings are partially tempered by the observation there is no guarantee that a good minimum remains in this region. **(III)** Namely, there exist cases where a good minimum jumps from the region with trainability guarantees. Our analysis leaves open the question of whether such minima jumps necessitate optimization across barren plateau landscapes or whether there exist gradient flows that allow for training. **(IV)** As numerically observed in our contrived example on a 10-qubit system, such fertile valleys, i.e. small regions away from the plateau with substantial gradients, that allow for successful training are theoretically possible. However, to what extent they arise in practise is an open question. We end by discussing the wider applications of our work to other iterative and/or perturbative variational quantum algorithms.

2 Framework

Iterative Variational Trotter Compression. One standard approach to simulate the time evolution of some initial state $|\psi_0\rangle$ under a Hamiltonian H is by a Trotter evolution where the total time t is broken down into a sequence of N short δt Trotter steps with $t = N\delta t$, such that $e^{-iHt}|\psi_0\rangle \approx \prod_{k=1}^{N} e^{-iH\delta t}|\psi_0\rangle$ where the approximation error is in $\mathcal{O}(N\delta t)$. However, these approaches are fundamentally limited by the linear growth of circuit depths with time simulated. Here we focus on the proposal to use a variational quantum algorithm to compress the depth of the Trotter circuit at each iteration of the algorithm [29–35] as shown in Fig. 1. More concretely, at any iteration of the algorithm, one variationally minimizes the following loss:

$$\mathcal{L}(\boldsymbol{\theta}) = 1 - |\langle\psi_0|U(\boldsymbol{\theta})^\dagger e^{-iH\delta t}U(\boldsymbol{\theta}^*)|\psi_0\rangle|^2 \qquad (1)$$

[*] The first two authors contributed equally to this work.

Figure 1: a) Each iteration of the variational compression scheme consists of four steps. Starting from the top: (i) apply the circuit with the last set of parameters $\boldsymbol{\theta}^*$ to the initial state, (ii) apply $e^{-iH\delta t}$ for a small time-step δt, (iii) train the circuit initialising your parameters around the previous ones, (iv) update the parameters. b) We sketch a typical representation of a loss function $\mathcal{L}(\boldsymbol{\theta})$ with a barren plateau across the full landscape (Region I). In Theorem 1 we prove that in a hypercube of width $2r$ with $r \in \Theta\left(1/\sqrt{M}\right)$ (sketched as Region II) the variance of the loss is only polynomially vanishing in system size n. In Theorem 2 we prove that in a smaller hypercube (highlighted as the blue region) the landscape is approximately convex.

where $U(\boldsymbol{\theta})$ is a parameterized quantum circuit and $\boldsymbol{\theta}^*$ denotes the optimized parameters found at the previous iteration step [29, 31, 33]. At iteration k the loss $\mathcal{L}(\boldsymbol{\theta})$ is optimized using a hybrid quantum classical optimization loop to find the next set of optimal parameters $\boldsymbol{\theta}^*_{\rm new}$. We consider a general ansatz of the form $U(\boldsymbol{\theta}) = \prod_{i=1}^{M} V_i e^{-i\theta_i\sigma_i}$ where $\{\theta_i\}$ is a set of M uncorrelated trainable parameters, $\{V_i\}_{i=1}^{M}$ is a set of fixed unitary matrices and $\{\sigma_i\}_{i=1}^{M}$ is a set of generators on n qubits such that $\sigma_i = \sigma_i^\dagger$ and $\sigma_i^2 = \mathbb{1}$. In the manuscript we also consider the case of imaginary time evolution.

Gradient magnitudes and barren plateaus. For a wide class of problems (including the loss in Eq. (1) with random initialization) [1–19], one can show that the loss variance vanishes exponentially with problem sizes, i.e. $\text{Var}_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})] \in \mathcal{O}(c^{-n})$ with $c > 1$. On such *barren plateau* landscapes exponentially precise loss evaluations are required to navigate the towards the global minimum and hence the resources (shots) required for training also scales exponentially. This has prompted the search for strategies where loss variances vanish at worst polynomially with system size, $\text{Var}_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})] \in \Omega\left(1/\text{poly}(n)\right)$, such that resource requirements may scale polynomially.

3 Main results

Lower-bound on the loss variance. We analytically and rigorously provide guarantees for all iterations of the algorithm that the region around the starting point has substantial gradients for a sufficiently small time-step as sketched in Fig. 1b). Our guarantees are based on the observation that assuming the previous step was sufficiently well optimised, and the time-step δt is small enough, then one can initialize close enough to the new global minimum (or, more modestly, a good new minimum). We use this observation to derive Theorem 1 in our manuscript which analytically provides a loss variance lower bound. More concretely, consider a hypercube region $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r) := \{\boldsymbol{\theta}\}$ such that $\theta_i \in [\theta_i^* - r, \theta_i^* + r]\ \forall\ i$. Theorem 1 indicates that for a small $\delta t \in \mathcal{O}\left(1/\lambda_{\max}\right)$ with $\lambda_{\max}$ being the largest eigenvalue of H and $r \in \Theta\left(1/\sqrt{M}\right)$, the variance over $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$, where each parameter is uniformly sampled, scales at least polynomial in the system's size.

In Fig. 2(a - c), we numerically study the scaling of the variance and further empirically observe that for large r the loss variance vanishes exponentially, hence recovering a common barren plateau result. However, the width of the region of attraction, as indicated by non-exponentially vanishing loss variances, scales as $r \in \Theta\left(1/\sqrt{M}\right)$ (inline with our analytic bounds).

Convexity region and adiabatic minimum. Non-vanishing gradients in the region around the initialisation are a necessary condition to have any hope of successfully training a variational quantum algorithm but they are not sufficient. Of particular importance is the potential to become trapped in spurious local minima. One way to provide guarantees against this concern is to prove that this region is (approximately) convex. Theorem 2 in our manuscript analytically indicates that for each iteration it is possible to choose a polynomially small time-step δt such that the loss region around initialization (within the substantial gradient region) is *approximately* convex.

We then introduce the notion of the adiabatic minima (see Definition 2) as the minima that would be reached by increasing δt infinitely slowly and minimizing $\mathcal{L}(\boldsymbol{\theta})$ by gradient descent with a very small learning rate. Crucially, in Theorem 3, we argue that as long as the time-step is δt is not too large (i.e. decreases polynomially with the number of parameters M) we can ensure that an adiabatic minima is within the convex region with non-vanishing gradients, and thus it should be possible to train to the adiabatic minimum.

Minimum jump and fertile valleys. We explore the limitations of our analytic bounds. Firstly, we highlight that our analysis can not provide convergence guarantees to a good minimum because *minima jumps* are possible. Namely, from one time-step to the other, the adiabatic minimum can become a relatively poor local minimum and a superior minimum can emerge elsewhere in the

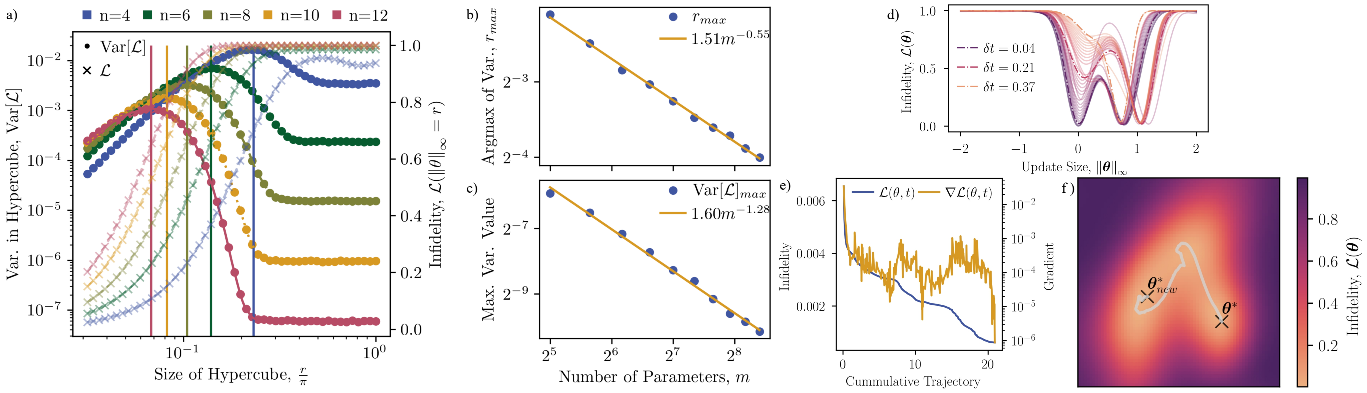

Figure 2: **(a - c) Variance of landscape and width of narrow gorge.** Here we study the landscape of $\mathcal{L}(\boldsymbol{\theta})$, for the first time-step of the variational Trotter compression algorithm, for different system sizes n as a function of the width of the hypercube r. We consider a hardware efficient ansatz with n layers and random initial parameters within the hypercube. a) We plot $\mathcal{L}(\boldsymbol{\theta})$ and its variance $\text{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}[\mathcal{L}(\boldsymbol{\theta})]$ as function of r/π. Since the shape of the landscape depends on the direction of the parameter update, to plot $\mathcal{L}(\boldsymbol{\theta})$ we have taken the average over 500 different directions. For $\text{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}[\mathcal{L}(\boldsymbol{\theta})]$, we keep track of its maximum value (marked with a vertical line) for each system size. b) The value $r_{\max}$ for which the variance peaks as function of the number of parameters in the ansatz. c) Maximum value of the variance for different system sizes. While the results shown here are for the first iteration of the variational compression scheme very similar results are observed at later iterations (in line with Theorem 1). **d) Minimum jump.** Here we show a 1D-cut of the landscape $\mathcal{L}(\boldsymbol{\theta})$ as we increase the time-step δt. The cut includes the initial parameters-with update $\delta t = 0$ and $||\boldsymbol{\theta}||_\infty = 0$. We choose a 10 qubit Ising Hamiltonian $H = \sum X_i X_{i+1} - 0.95 \sum Y_i$ on a 1D-lattice. We use a 2-layered Hamiltonian Variational Ansatz. **(e - f) Fertile valley.** Here we show a 2D plot of the loss landscape at $\delta t = 0.04$ for a 10 qubit Ising Hamiltonian $H = \sum X_i X_{i+1} - 0.95 \sum Y_i$ on a 1D-lattice and use a 2-layered Hamiltonian Variational Ansatz. e) We plot the loss and directional loss gradient along the trajectory from the old to new minimum. f) $\boldsymbol{\theta_0}$ is the initial starting point and $\boldsymbol{\theta^*}$ is the true global minimum. The axes are chosen using principle component analysis to project the multi-dimensional space into a 2D-plane using ORQVIZ [36] and the white line is the projection of the optimization trajectory onto this 2D-plane.

landscape. This has been illustrated in Fig 2d).

We are then faced with the question of whether such minima jumps necessitate optimisation across barren plateau landscapes or whether there exist gradient flows between these minima. We provide numerical evidence in Fig. 2(e - f) for a 10-qubit contrived example of a gradient flow from an initialization to a seemingly jumped minima which suggests such gradient flows can exist. Investigating whether such fertile valleys can exist for larger more complex problems is an important direction for future research on the scalability of VQAs.

4 Wider impact of our results

Our results illustrate the potential of warm starts to train VQA landscapes with barren plateaus. While we have framed our results here in the context of an iterative variational scheme for quantum simulation, most of our results here would carry over to other iterative variational approaches. In the manuscript we show how our results carry over to ground state preparation via imaginary time evolution. More generally, one could imagine starting with a circuit for preparing the ground state of an easier Hamiltonian and then iteratively perturbing the Hamiltonian and applying the variational quantum eigensolver between each perturbation. If the perturbations do not pass through a phase transition then such an iterative scheme is plausible and could potentially be characterised in a similar manner to as we have done here. Thus the impact of our results are by no means confined to variational quantum simulation methods but rather offer hope for the field more widely.

(Dated: April 23, 2024)

The barren plateau phenomenon, characterized by loss gradients that vanish exponentially with system size, poses a challenge to scaling variational quantum algorithms. Here we explore the potential of warm starts, whereby one initializes closer to a solution in the hope of enjoying larger loss variances. Focusing on an iterative variational method for learning shorter-depth circuits for quantum real and imaginary time evolution we conduct a case study to elucidate the potential and limitations of warm starts. We start by proving that the iterative variational algorithm will exhibit substantial (at worst vanishing polynomially in system size) gradients in a small region around the initializations at each time-step. Convexity guarantees for these regions are then established, suggesting trainability for polynomial size time-steps. However, our study highlights scenarios where a good minimum shifts outside the region with trainability guarantees. Our analysis leaves open the question whether such minima jumps necessitate optimization across barren plateau landscapes or whether there exist gradient flows, i.e., fertile valleys away from the plateau with substantial gradients, that allow for training.

I. INTRODUCTION

Variational quantum algorithms are a flexible family of quantum algorithms, whereby a problem-specific cost function is efficiently evaluated on a quantum computer, and a classical optimizer aims to minimize this cost by training a parametrized quantum circuit [1–3]. While a popular paradigm the potential of scaling these algorithms to interesting system sizes attracts much debate [4, 5], in part due to the barren plateau phenomenon [6–24]. Barren plateaus are loss landscapes that concentrate exponentially in system size towards their mean value and thus, with high probability, exhibit exponentially small gradients [10, 25]. As quantum losses are computed via measurement shots, on a barren plateau landscape the resources required for training typically scale exponentially, quickly becoming prohibitive.

However, barren plateaus are fundamentally a statement about the landscape on average. They do not preclude the existence of regions of the landscape with significant gradients and indeed, the region immediately around a good minimum, must have such gradients. This has motivated the study of *warm starts* whereby the algorithm is cleverly initialized closer to a minimum. Numerical studies indicate that these methods may be promising [26–29]. In parallel, analytic studies have proven that small angle initializations, whereby the parameterized quantum circuit is initialized in a small region typically around identity, can exhibit non-exponentially vanishing gradients [30–34]. However, a good solution may be far from this region.

Here we will consider a family of variational quantum algorithms that inherently use warm starts and take this as a case study to better understand their potential and limitations. In particular, we study an approach for learning shorter depth circuits for simulating quantum systems by iteratively compressing real or imaginary time Trotter evolution circuits [35–41]. While not necessarily always framed explicitly from this perspective, these approaches effectively use warm starts in virtue of their iterative constructions. At each iteration, the previous solution is used to initialize the parameters to learn a new compressed circuit to implement a slightly longer evolution.

This case study is an ideal playground for studying warm starts because its inbuilt structure allows one to analytically compute bounds on its trainability. We start by proving that as long as the training in one time-step is successful then the algorithm will exhibit substantial (at worst polynomially vanishing with problem size n) gradients in a small (a hypercube of radius $2r$ with $r \in \Omega(\frac{1}{\mathrm{poly}(n)})$) region around the next initialization. We then establish guarantees on the approximate convexity of the gradients in this region and further argue that for polynomially large time-steps the new optimum will typically remain in this convex region. These results are summarised in Fig. 1

However, these positive findings are partially tempered by the observation there is no guarantee that a good minimum remains in this region. Namely, there exist cases where a good minimum jumps from the region with trainability guarantees. Our analysis leaves open the question of whether such minima jumps necessitate optimization across barren plateau landscapes or whether there exist valleys away from the barren plateau that allow for training. Such fertile valleys, i.e. small regions away from the plateau with substantial gradients, that allow for successful training are theoretically possible but to what extent they arise in practise is an open question.

FIG. 1. a) Each iteration of the variational compression scheme consists of four steps. Starting from the top: (i) apply the circuit with the last set of parameters $\boldsymbol{\theta}^*$ to the initial state, (ii) apply $e^{-iH\delta t}$ for a small time-step δt, (iii) train the circuit initialising your parameters around the previous ones, (iv) update the parameters. b) We sketch a typical representation of a loss function $\mathcal{L}(\boldsymbol{\theta})$ with a barren plateau across the full landscape (Region I). In Theorem 1 we prove that in a hypercube of width $2r$ with $r \in \Theta\left(\frac{1}{\sqrt{M}}\right)$ (sketched as Region II) the variance of the loss is only polynomially vanishing in system size n. In Theorem 2 we prove that in a smaller hypercube (highlighted as the blue region) the landscape is approximately convex.

II. PRELIMINARIES

A. Iterative Variational Trotter Compression

We consider simulating the evolution of some initial state $|\psi_0\rangle$ under a Hamiltonian H up to time t. That is, our aim is to implement a quantum circuit that approximates $e^{-iHt}|\psi_0\rangle$. One standard approach [42] to do so is to use the well known Trotter approximation to break the total evolution t into a sequence of N short δt evolutions, with $t = N\delta t$, such that

$$e^{-iHt}|\psi_0\rangle \approx \prod_{k=1}^{N} e^{-iH\delta t}|\psi_0\rangle \;, \tag{1}$$

where the approximation error is in $\mathcal{O}(N\delta t)$. Similarly, one can simulate imaginary time evolution (for ground or thermal state preparation) by setting $\tau = it$:

$$e^{-H\tau}|\psi_0\rangle \approx \prod_{k=1}^{N} e^{-H\delta\tau}|\psi_0\rangle \;, \tag{2}$$

with the error in $\mathcal{O}(N\delta\tau)$. However, these approaches are fundamentally limited by the linear growth of circuit depths with time simulated. This has prompted ongoing efforts to find alternative approaches that avoid this linear growth [35–38, 43–56].

Here we focus on the proposal to use a variational quantum algorithm to compress the depth of the Trotter circuit at each iteration of the algorithm [35–41] as shown in Fig. 1. More concretely, at any iteration of the algorithm, one variationally minimizes the following loss:

$$\mathcal{L}(\boldsymbol{\theta}) = 1 - |\langle\psi_0|U(\boldsymbol{\theta})^\dagger e^{-iH\delta t}U(\boldsymbol{\theta}^*)|\psi_0\rangle|^2 \tag{3}$$

where $U(\boldsymbol{\theta})$ is a parameterized quantum circuit and $\boldsymbol{\theta}^*$ denotes the optimized parameters found at the previous iteration step [35, 37, 39]. At iteration k the loss $\mathcal{L}(\boldsymbol{\theta})$ is optimized using a hybrid quantum classical optimization loop to find the next set of optimal parameters $\boldsymbol{\theta}^*_{\rm new}$. We note that while we focus on a fidelity loss here other cost functions are possible, e.g. in Ref. [36] they considered the real part of the state overlap and in Ref. [37] a local fidelity measure, and a similar analysis could be performed in those cases. It is also possible to use this approach to learn circuits to prepare approximate ground states and thermal states by replacing it with τ in Eq. (3) and with an appropriate choice in initial state $|\psi_0\rangle$ [36].

The success of this protocol depends on a variety of factors including the choice of *ansatz* for the parameterised circuit. Here we focus on a general ansatz of the form

$$U(\boldsymbol{\theta}) = \prod_{i=1}^{M} V_i U_i(\theta_i) \tag{4}$$

where $\{V_i\}_{i=1}^M$ are a set of fixed unitary matrices, $\{U_i(\theta_i) = e^{-i\theta_i\sigma_i}\}_{i=1}^M$ are parameter-dependent rotations, M is the number of parameters in the circuit, and $\{\sigma_i\}_{i=1}^M$ is a set of generators on n qubits such that $\sigma_i = \sigma_i^\dagger$ and $\sigma_i^2 = \mathbb{1}$. In this work, we assume that all parameters θ_j are uncorrelated.

B. Gradient magnitudes and barren plateaus

In recent years there has been concerted effort to understand when quantum losses are trainable or untrainable. Several factors can lead to untrainable losses including the presence of sub-optimal local minima [4, 57, 58], expressivity limitations [59] and abrupt transitions in layerwise learning [60]. However, much of this research has focused on loss gradients.

To train a variational quantum algorithm successfully, the loss landscape must exhibit sufficiently large loss gradients (or more generally, loss differences). Chebyshev's inequality bounds the probability that the cost value deviates from its average as

$$\mathrm{Pr}_{\boldsymbol{\theta}}(|\mathcal{L}(\boldsymbol{\theta}) - \mathbb{E}_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})]| \geqslant \delta) \leqslant \frac{\mathrm{Var}_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})]}{\delta^2}\,, \tag{5}$$

for some $\delta > 0$ and the variance of the loss defined as

$$\mathrm{Var}_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})] = \mathbb{E}_{\boldsymbol{\theta}}\left[\mathcal{L}^2(\boldsymbol{\theta})\right] - \left(\mathbb{E}_{\boldsymbol{\theta}}\left[\mathcal{L}(\boldsymbol{\theta})\right]\right)^2\,, \tag{6}$$

where the expectation value is taken over the parameters. Hence if the variance is small then the probability of observing non-negligible loss differences for any randomly chosen parameter setting is negligible.

For a wide class of problems [6–24], one can show that the loss variance vanishes exponentially with problem sizes, i.e. $\mathrm{Var}_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})] \in \mathcal{O}(c^{-n})$ with $c > 1$. On such *barren plateau* landscapes exponentially precise loss evaluations are required to navigate the towards the global minimum and hence the resources (shots) required for training also scales exponentially. This has prompted the search for architectures where loss variances vanish at worst polynomially with system size, $\mathrm{Var}_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})] \in \Omega\left(\frac{1}{\mathrm{poly}(n)}\right)$, such that resource requirements may scale polynomially.

III. MAIN RESULTS

In this paper we analyse the trainability of the variational Trotter compression scheme and use this to illustrate the complex interplay between the barren plateau phenomena, local minima and expressivity limitations. We start by presenting an overview of the factors we will consider, and the context provided by prior work, before proceeding to present our main analytic and numerical findings.

A. Overview of analysis

The variance of the loss, Eq. (6), necessarily depends on the parameter region it is computed over. The majority of analyses of quantum loss landscapes have assumed the angles are initialized according to some distribution in the region $[0, 2\pi]$ and hence considered the variance over the entire loss landscape [6–15, 17–23]. However, in practise one is interested in the loss landscape in the region explored during the optimisation process (i.e., in the region around the initialization, the region around the sufficiently 'good' minima and ideally the landscape that connects these regions). An analytic study of these different regions in the general case seems daunting. However, the structure provided by the variational Trotter compression scheme allows us to take steps in this direction.

Prior work has established that small angle initializations, whereby the parameterized quantum circuit is initialized in a small region around identity, provide a means of provably avoiding barren plateaus [30–34]. More concretely, let us define

$$\boldsymbol{\mathcal{V}}(\boldsymbol{\phi}, r) := \{\boldsymbol{\theta}\} \;\text{ such that }\; \theta_i \in [\phi_i - r, \phi_i + r] \;\forall\; i, \tag{7}$$

as the hypercube of parameter space centered around the point $\boldsymbol{\phi}$, and define $\boldsymbol{\mathcal{D}}(\boldsymbol{\phi}, r)$ as a uniform distribution over the hypercube $\boldsymbol{\mathcal{V}}(\boldsymbol{\phi}, r)$. It was shown in Ref. [32], that if the parameters are uniformly sampled in a small hypercube with $r \in \mathcal{O}\left(\frac{1}{\sqrt{L}}\right)$ around $\boldsymbol{\phi} = \mathbf{0}$ for some hardware efficient architecture with L being the number of layers, then the variance $\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}[\mathcal{L}(\boldsymbol{\theta})] \in \Omega\left(\frac{1}{\mathrm{poly}(L)}\right)$ decays only polynomially with the depth of the circuit. Similar conclusions were reached for the Hamiltonian Variational Ansatz in Refs. [31, 33] and for Gaussian initializations in Ref. [30, 34]. Typically in these cases the small angle initialization corresponds to initializing close to identity.

These guarantees can broadly be used to argue that the first iteration of variational Trotter compression scheme will exhibit non-vanishing variances for certain circuits. Moreover, assuming δt is small such that $e^{-iH\delta t}$ is close to identity, and assuming that the ansatz is sufficient expressive to be able to capture a good approximation of $e^{-iH\delta t}$, it is reasonable to expect that the good approximate solution circuit is contained within the region $\boldsymbol{\mathcal{V}}\left(\mathbf{0}, \frac{1}{\sqrt{M}}\right)$ that enjoys polynomial loss variances. However, at later time-steps, when $U(\boldsymbol{\theta})$ is far from identity, the guarantees provided for these small angle initializations are of debatable relevance.

Here we address the task of providing guarantees for all iterations of the algorithm for a very general family of parameterized quantum circuits. Our guarantees are based on the observation that assuming the previous step was sufficiently well optimised, and the time-step δt is small enough, then one can initialize close enough to the new global minimum (or, more modestly, a good new minimum) such that the landscape exhibits substantial gradients as sketched in Fig. 1b). In Section III B we use this observation to derive such analytical variance lower bounds. We note that Ref. [40] provides an approximate lower bound on the variance in the loss for an iterative compression scheme; however, to do so it makes a number of approximations and in effect assumes the convexity of the problem from the outset. We go beyond this by providing exact bounds without prior assumptions.

Non-vanishing gradients in the region around the initialisation are a necessary condition to have any hope of successfully training a variational quantum algorithm but they are far from sufficient. Of particular importance is the potential to become trapped in spurious local minima. One way to provide guarantees against this concern is to prove that this region is convex. We tackle this issue in Section III C by proving convexity guarantees in the region around the initialization provided by the previous iteration.

We then introduce the notion of the adiabatic minima as the minima that would be reached by increasing δt

infinitely slowly and minimizing $\mathcal{L}(\boldsymbol{\theta})$ by gradient descent with a very small learning rate in Section III D. We argue that as long as the time-step is δt is not too large (i.e. decreases polynomially with the number of parameters M) we can ensure that an adiabatic minima is within the convex region with non-vanishing gradients, and thus it should be possible to train to the adiabatic minimum.

Finally, in Section III E we explore the limitations of our analytic bounds. Firstly, we highlight that our analysis can not provide convergence guarantees to a good minimum because *minima jumps* are possible. Namely, from one time-step to the other, the adiabatic minimum can become a relatively poor local minimum and a superior minimum can emerge elsewhere in the landscape. We are then faced with the question of whether such minima jumps necessitate optimisation across barren plateau landscapes or whether there exist gradient flows between these minima. We provide numerical evidence for a 10-qubit contrived example of a gradient flow from an initialization to a seemingly jumped minima which suggests such gradient flows can exist.

B. Lower-bound on the variance

The variance of the loss function at any iteration around the parameters $\boldsymbol{\theta}^*$ obtained for the previous iteration will depend on the length of the time-step δt as well as the volume of the region of the parameter space explored. Here we study the variance of the loss in a uniformly sampled hypercube of sides $2r$ around $\boldsymbol{\theta}^*$ as defined in Eq. (7). As proven in Appendix B, we obtain the following bound.

Theorem 1 (Lower-bound on the loss variance, Informal)**.** *Consider the general ansatz in Eq. (4) and assume that in the first iteration the system is prepared in a product initial state $\rho_0 = \bigotimes_{j=1}^n \rho_j$ with ρ_j and let us choose σ_1 such that $\mathrm{Tr}[\rho_0\sigma_1\rho_0\sigma_1] = 0$. Given that the Trotter time-step is bounded as*

$$\delta t \in \mathcal{O}\left(\frac{1}{\lambda_{\max}}\right) \tag{8}$$

where $\lambda_{\max}$ is the largest eigenvalue of H and we consider uniformly sampling parameters in a hypercube of width $2r$ around the solution from the previous iteration $\boldsymbol{\theta}^*$, i.e. $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$, such that

$$r \in \Theta\left(\frac{1}{\sqrt{M}}\right) . \tag{9}$$

Then the variance at any iteration of the algorithm is lower bounded as

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}(\boldsymbol{\theta})\right] \in \Omega\left(\frac{1}{M}\right) . \tag{10}$$

Thus, for $M \in \mathcal{O}(\mathrm{poly}(n))$ we have

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}(\boldsymbol{\theta})\right] \in \Omega\left(\frac{1}{\mathrm{poly}(n)}\right) . \tag{11}$$

In Appendix E we present a version of Theorem 1 for the imaginary time evolution.

Theorem 1 establishes that within a small, but non-exponentially vanishing ($r \propto 1/\sqrt{M}$), region around the previous optimal solution, the loss landscape will exhibit non-exponentially vanishing gradients so long as $\delta t \in \mathcal{O}(1/\lambda_{\max})$. The constraint on the Trotter time-step is to ensure that a state corresponding to a previous solution has a large overlap with a new target state. If the Trotter step is too large, then the initialization no longer contains enough information about the target state and it is equivalent to initializing on the barren plateau region. The $\delta t \in \mathcal{O}(1/\lambda_{\max})$ scaling comes from a loose bound on the overlap between the old optimised state and the new target state and thus a larger δt is likely viable in practise.

On another related topic, our bound is presented here for simulating the evolution of an initially product state. This assumption is made for ease of presentation. However, as highlighted in the appendices, this assumption is not strictly necessary. Rather one just needs to ensure that a gate in the first layer has a non-trivial effect on the loss.

It is important to stress that Theorem 1 provides a sufficient, not a necessary, condition for observing polynomially vanishing gradients. For a necessary condition one would need to derive an upper bound as a function of r and δt. In general, this seems challenging and is likely to be highly ansatz dependent [61]. Instead we address this question numerically.

In Fig. 2 we study the landscape of $\mathcal{L}(\boldsymbol{\theta})$ for an initial time-step as a function of the width of the hypercube, $2r$. For concreteness, we consider a hardware efficient ansatz with n layers and uniformly sampled parameters within the hypercube. The variance over the full landscape ($r = \pi$) vanishes exponentially in n. However, as r is decreased the variance increases with r and ceases to decay exponentially in n. When r is very small the variance again begins to decrease. This is because for sufficiently small r we are computing the variance over a small region of the loss landscape at the base of the narrow gorge. This account is confirmed by the average behaviour of $\mathcal{L}(\boldsymbol{\theta})$ also shown in Fig. 2a). In particular, when the variance peaks, we have an infidelity of approximately 0.7 for each system size, which indicates that the peak of the variance is a good measure of the width of our gorge.

In Fig. 2 b) and c) we plot the r value for which the variance peaks and the maximum value of the variance as function of the number of parameters in the ansatz M. Both quantities decay polynomially in M. In particular, we find that $r_{\max}$ scales as $\frac{1}{\sqrt{M}}$ implying that the width of the gorge decreases with a $\frac{1}{\sqrt{M}}$ scaling. This is consistent with our theoretical lower bound, Theorem 1, which also suggests that to ensure at worst poly vanishing gradients its necessary to consider a region of width $\frac{1}{\sqrt{M}}$ around the minimum.

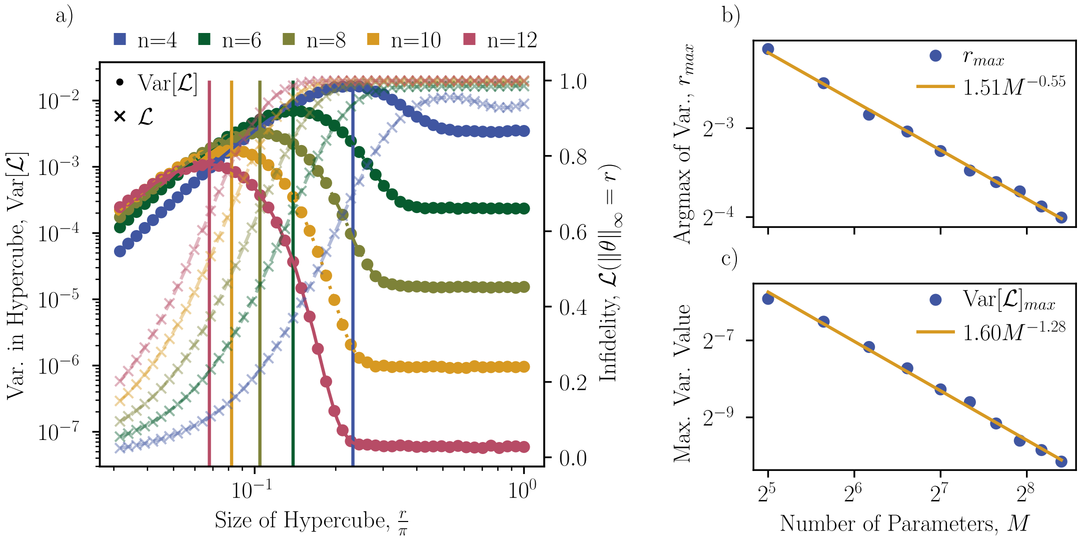

FIG. 2. **Variance of landscape and width of narrow gorge.** Here we study the landscape of $\mathcal{L}(\boldsymbol{\theta})$, for the first time-step of the variational Trotter compression algorithm, for different system sizes n as a function of the width of the hypercube r. We consider a hardware efficient ansatz with n layers and random initial parameters within the hypercube. a) We plot $\mathcal{L}(\boldsymbol{\theta})$ and its variance $\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}[\mathcal{L}(\boldsymbol{\theta})]$ as function of r/π. Since the shape of the landscape depends on the direction of the parameter update, to plot $\mathcal{L}(\boldsymbol{\theta})$ we have taken the average over 500 different directions. For $\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}[\mathcal{L}(\boldsymbol{\theta})]$, we keep track of its maximum value (marked with a vertical line) for each system size. b) The value $r_{\max}$ for which the variance peaks as function of the number of parameters in the ansatz. c) Maximum value of the variance for different system sizes. While the results shown here are for the first iteration of the variational compression scheme very similar results are observed at later iterations (in line with Theorem 1).

C. Convexity region around the starting point

Substantial gradients are a necessary condition but not sufficient condition for trainability. If the substantial gradients are attributable to poor local minima then finding a good solution is likely to be highly challenging. However, if as well as having substantial gradients, we can prove that the landscape is convex, or approximately convex, then training to a minimum looks promising. In this section, we present a theorem which shows that the region around the starting parameters is approximately convex. As expected, our condition depends both on the width of the hypercube region considered and the time-step δt taken.

A function is convex over a parameter range if its second order partial derivatives are all non-negative in that parameter range. In practise, a more convenient means of diagnosing convexity is to study the Hessian, $\nabla^2_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})]$, of a function. If the Hessian is positive semi definite, i.e. $\nabla^2_{\boldsymbol{\theta}}[\mathcal{L}(\boldsymbol{\theta})] \geqslant 0$, in a given parameter region then the function is convex in that region. We will introduce a notion of approximate convexity by relaxing this constraint and saying that a landscape is ϵ convex if the following condition holds:

Definition 1 (ϵ-convexity)**.** *A loss is ϵ-convex in the region $\boldsymbol{\theta} \in \boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$ if*

$$\left[\nabla^2_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta})\right]_{\min} \geqslant -|\epsilon| \tag{12}$$

for all $\boldsymbol{\theta} \in \boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$. Here $\nabla^2_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta})$ denotes the Hessian of $\mathcal{L}(\boldsymbol{\theta})$ and we denote $[A]_{\min}$ as the smallest eigenvalue of the matrix A.

If a loss is ϵ-convex the loss is convex up to ϵ small deviations, as sketched in Fig. 1b), and argued more formally in Appendix A 3. This notion is particularly important in a quantum context where the loss is only ever measured with a finite number of shots making it hard to tell apart ϵ negative curvatures from ϵ positive ones. Thus in practise the relevant ϵ will be determined by the shot noise floor.

Equipped with this definition we now show that a polynomially sized region around the starting point of the previous iteration is approximately convex.

Theorem 2 (Approximate convexity of the landscape, Informal)**.** *For a time-step of size*

$$\delta t \in \mathcal{O}\left(\frac{\mu_{\min} + 2|\epsilon|}{M\lambda_{\max}}\right) , \tag{13}$$

the loss landscape is ϵ-convex in a hypercube of width $2r_c$ around a previous optimum $\boldsymbol{\theta}^*$ i.e., $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$ such that

$$r_c \in \Omega\left(\frac{\mu_{\min} + 2|\epsilon|}{16M^2} - \frac{\lambda_{\max}\delta t}{M}\right) , \tag{14}$$

where $\mu_{\min}$ is the minimal eigenvalue of the Fisher information matrix associated with the loss at $\boldsymbol{\theta}^*$.

In Appendix E we show that an analogous convexity guarantee can be proven for imaginary time evolution.

Theorem 2 tells us that it is always possible to pick a polynomially scaling $\delta t, r_c$ such that the landscape of $\mathcal{L}(\boldsymbol{\theta})$ with respect to the parameters is approximately convex. The constraints on δt and r_c for convexity are pretty stringent in practice. However, convexity is also a lot to demand of a loss landscape. Nonetheless, it is nice to see that approximate convexity can be ensured at 'only' a polynomially scaling cost.

D. Adiabatic minimum

So far we have identified two constraints on our parameters that push in the direction of trainability guarantees. Specifically, we have established a region in our landscape with substantial gradients and approximate convexity. The final condition required for convergence guarantees is to ensure our target circuit, i.e., a good minimum, lies within this region.

To address this point, let us start by introducing the notion of the *adiabatic minima*. Intuitively, these are the minima that would be reached by increasing δt infinitely slowly and minimizing $\mathcal{L}(\boldsymbol{\theta})$ by gradient descent with a very small learning rate. By analogy, one can imagine dropping a marble in the initial minima and then slowly modifying the landscape by infinitesimally increasing δt. The position of the marble would correspond to our adiabatic minima and, in practice, it is where we expect our algorithm to converge for sufficiently small δt. In Fig. 3 a) we plot a cut through the cost landscape around the old minimum $\boldsymbol{\theta}^*$ as a function of δt. We can see that the minimum smoothly moves rightwards and increases with increasing δt. More formally, we define the adiabatic minima as follows.

Definition 2 (Adiabatic Minimum)**.** *For any time δt in the range $[0, T]$, a function*[1] *corresponding to the evolution of the adiabatic minima for some initial minimum $\boldsymbol{\theta}^*$, is a continuous function $\boldsymbol{\theta}_A(\delta t) \in C^\infty(\mathbb{R}, \mathbb{R}^m)$ such that $\boldsymbol{\theta}_A(0) = \boldsymbol{\theta}^*$ and $\nabla_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta}_A(\delta t), \delta t) = \mathbf{0}$. The adiabatic minimum at time δt is $\boldsymbol{\theta}_A(\delta t)$.*

One can ensure that the iterative variational compression scheme will converge to some minimum if the time-step is small enough that an adiabatic minimum is inside of the convex region with non-vanishing gradients. One can question how good this minimum will be but we will set aside this question for the moment. Thus our next step will be to assess how small the time-step needs to be picked in order to guarantee this. In the following theorem we formalize this concept by bounding the δt required to ensure an adiabatic minimum is in the substantial gradient region and in the convex region.

Theorem 3 (Adiabatic minimum is within provably 'nice' training region, Informal)**.** *If the time-step δt is chosen such that*

$$\delta t \in \mathcal{O}\left(\frac{\beta_A}{M\lambda_{\max}}\right) , \tag{15}$$

then the adiabatic minimum $\boldsymbol{\theta}_A(\delta t)$ is guaranteed to be within the non-exponentially-vanishing gradient region (as per Theorem 1), and additionally, if δt is chosen such that

$$\delta t \in \mathcal{O}\left(\frac{\beta_A(\mu_{\min} + 2|\epsilon|)}{M^{5/2}\lambda_{\max}}\right) , \tag{16}$$

then the adiabatic minimum $\boldsymbol{\theta}_A(\delta t)$ is guaranteed to be within the ϵ-convex region (as per Theorem 2) where

$$\beta_A := \frac{\dot{\boldsymbol{\theta}}_A^T(\delta t)\left(\nabla^2_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta})\big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_A(\delta t)}\right)\dot{\boldsymbol{\theta}}_A(\delta t)}{\|\dot{\boldsymbol{\theta}}_A(\delta t)\|_2^2} \tag{17}$$

corresponds to the second derivative of the loss in the direction in which the adiabatic minimum moves.

Theorem 3 tells us that it suffices to consider a time-step that scales as $\delta t \in \Omega\left(\frac{1}{M}\right)$ to ensure that the adiabatic minimum falls in the region with substantial gradients, or more stringently to take $\delta t \in \Omega\left(\frac{1}{\text{poly}(M)}\right)$ to ensure that the adiabatic minimum falls within the $|\epsilon|$-convex region. As in general $M \sim \text{poly}(n)$ it follows that if δt is decreased polynomially with problem size, and the learning rate is chosen appropriately, it should be possible to train to the new adiabatic minimum.

We stress that this interpretation of Theorem 3 is only possible assuming that β_A is not exponentially vanishing. This is a reasonable assumption as $\beta_A \to 0$ corresponds to the curvature of the loss at the minimum being flat in the direction in which the adiabatic minimum moves. While this is conceivably possible it is unlikely in practise (as is supported by our numerics in Fig. 3 and Fig. 4). Moreover, the β_A dependence of Theorem 3 is a genuine feature that affects trainability, rather than a relic of our proof techniques. Namely, if the landscape is very flat in the direction of the new minimum then indeed the adiabatic minimum can move significant distances at short times. More poetically, one might visualise this case as a *barren gorge*. That is, a sub-region of the landscape within the substantial gradient region that nonetheless has vanishing gradients. Such features are possible but perhaps unlikely unless the ansatz is highly degenerate.

Another caveat is that Theorem 3 only holds in the case that there exists a well-defined adiabatic minimum function $\boldsymbol{\theta}_A(\delta t)$ in the time interval of interest. This is not always guaranteed to be the case because a minimum can vanish by evolving into a slope as δt increases. If this

[1] We note that it is in fact possible for a single initial minima to have multiple corresponding adiabatic minima functions if there are multiple directions with zero gradients.

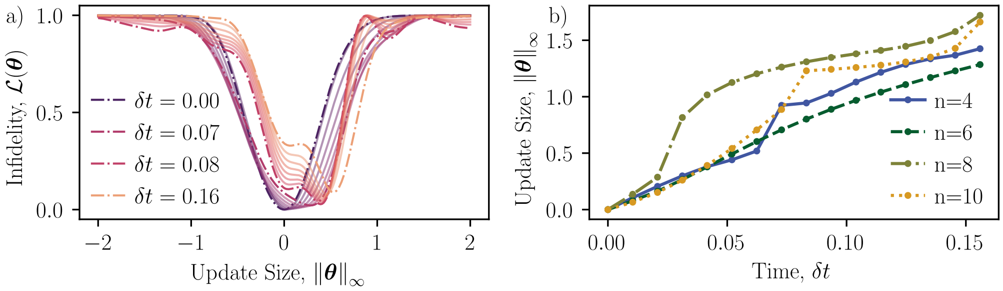

FIG. 3. **Routine evolution of the adiabatic minimum**. Here we study the landscape of $\mathcal{L}(\boldsymbol{\theta})$ as we increase the time-step δt. We study a 10 qubit Hamiltonian with nearest-neighbour interactions on a 1D lattice with $H = \sum X_i Z_{i+1} - 0.95 \sum Y_i$ where X_i, Y_i and Z_i are X-Pauli, Y-Pauli and Z-Pauli operators on the qubit i. a) We plot our landscape for different δt. The cuts in our high dimensional $\mathcal{L}(\boldsymbol{\theta})$ space contain both the initial parameters $\boldsymbol{\theta} = \mathbf{0}$ and the adiabatic minimum $\boldsymbol{\theta}_A(\delta t)$ at δt. b) We plot the size of our parameter update $\|\boldsymbol{\theta}\|_\infty$, i.e. the distance along the cuts between the old minimum and the new minimum, as a function of the time-step for different system sizes.

occurs then the continuity condition in our definition of the adiabatic minima function fails. Nonetheless, this is not a situation that necessarily causes trainability problems (if the minimum turns into a slope then training is possible down that slope), rather it is a situation that makes finding analytic trainability guarantees more challenging. For a more detailed discussion of this caveat and a proof of Theorem 3 see Appendix D.

Relatedly, it is worth mentioning that while Theorem 3 allows for polynomially shrinking step sizes in practise these step sizes are rather small. In particular, for the small problem sizes studied already in the literature practitioners have typically used larger step sizes than those that we have managed to derive guarantees for here. In parallel, we can see from our numerical implementations in Fig. 3 that training would seem viable for larger δt than allowed by our bounds. It is arguably an open question to what extent this can be attributed to looseness of our bounds or the small problem sizes that can be simulated classically. One thing to note in this regard is that optimisation is often much more successful in practise than can be analytically guaranteed or even explained. As such, in practise, larger δt may well be viable. This is specially relevant if one considers using adaptive approaches where δt is modified at each step until a given precision threshold is reached. While heuristic, this method in the worst case enjoys the mathematical guarantees proven here, while in the best case allows for larger time-steps (and so reduces the average number of time-steps required in total).

E. Minima jumps and fertile valleys

A final limitation of our analysis is that the adiabatic minimum (or indeed any minimum within the region with gradient guarantees) need not be a good minimum. The adiabatic minimum is the minimum that evolves away from the old minimum after the application of a time-step δt. However, it is possible that a different better minimum emerges in a different region of the landscape [60]. That is, it is possible for the best minimum (or, more modestly, simply a significantly better minimum) to *jump* from the initialization region to another region of the parameter landscape. As we only have lower bounds on the variance of the loss and convexity guarantees in the region around the initialization if the minimum jumps then we have no trainability guarantees to these superior minima. Moreover, if the full landscape has a barren plateau, which will be the case for most deep ansätze [20, 21], it may be very hard to train to this new minimum.

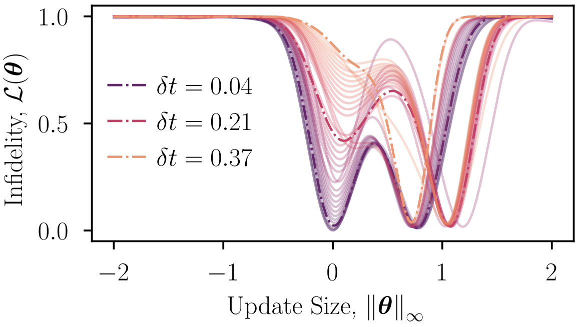

FIG. 4. **Minimum jump.** Here we show a 1D-cut of the landscape $\mathcal{L}(\boldsymbol{\theta})$ as we increase the time-step δt. The cut includes the initial parameters-with update $\delta t = 0$ and $||\boldsymbol{\theta}||_\infty = 0$. We choose a 10 qubit Ising Hamiltonian $H = \sum X_i X_{i+1} - 0.95 \sum Y_i$ on a 1D-lattice. We use a 2-layered Hamiltonian Variational Ansatz.

In Fig. 4 we suggest that such apparent *minimum jumps* can indeed occur. In particular we show a 1D cut of the landscape $\mathcal{L}(\boldsymbol{\theta})$ for different time-steps δt. The 1D cut includes both the ‘old minimum’ at time $\delta t = 0$ and a new minimum that emerges for larger δt. Even after a short time-step $\delta t = 0.04$ the best minimum has jumped

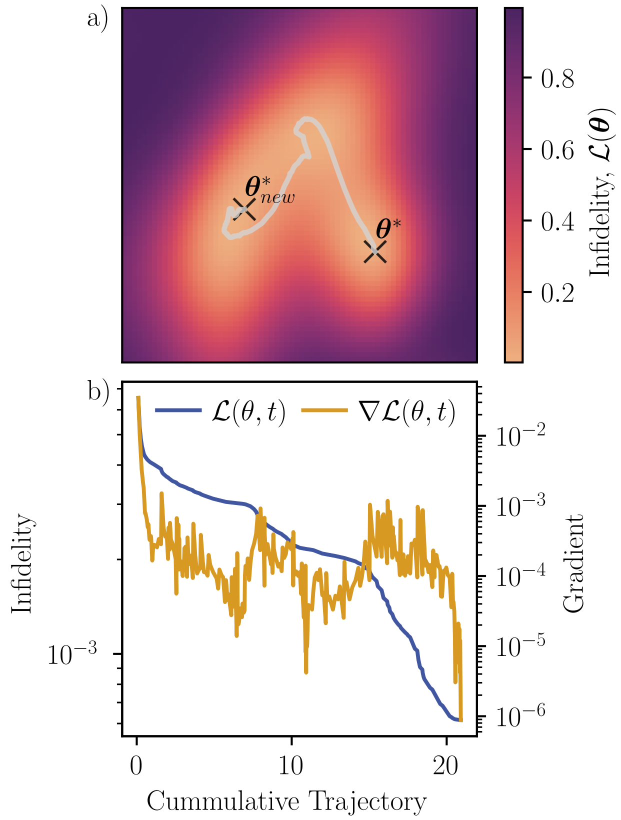

FIG. 5. **Fertile valley.** a) Here we show a 2D plot of the loss landscape at $\delta t = 0.04$ for a 10 qubit Ising Hamiltonian $H = \sum X_i X_{i+1} - 0.95 \sum Y_i$ on a 1D-lattice and use a 2-layered Hamiltonian Variational Ansatz. $\boldsymbol{\theta_0}$ is the initial starting point and $\boldsymbol{\theta^*}$ is the true global minimum. The axes are chosen using principle component analysis to project the multi-dimensional space into a 2D-plane using ORQVIZ [62] and the white line is the projection of the optimization trajectory onto this 2D-plane. b) We plot the loss and directional loss gradient along the trajectory from the old to new minimum.

by a distance $||\boldsymbol{\theta}||_\infty \approx 0.8$. At this short time, the new minimum is only very slightly superior to the adiabatic minimum. However, at longer times the new minimum becomes substantially better.

When a minimum jumps our theoretic guarantees developed in this manuscript lose most of their value. However, this does not mean that it is not possible to train (even in the case where the overall landscape exhibits a barren plateau). For training the 'only thing' we need is a gradient flow, i.e., a path with substantial gradients, from the initialization to the new minimum. Such fertile valleys with nice gradients can theoretically exist on a barren plateau landscape but to what extent they occur in practise is currently unknown.

In Fig. 5 we provide numerical evidence for a toy example of such a case. Specifically, we show a 2D cross-section of the landscape containing both an initialisation minimum and an apparently jumped minimum (marked by black crosses). We managed to successfully train from this initial minimum to the new minimum using the BFGS algorithm. This algorithm is a non-stochastic algorithm and so this indicates that there is indeed a trajectory between the two minima. As shown here in b) the gradients along this trajectory are of the order 10^{-3}, in contrast to of the order of 10^{-6} on average over the landscape for a 10 qubit problem as shown in Fig. 2. Thus, while a significant shot budget ($\sim 10^6$ shots) is likely needed for training it would seem that it is possible to train between these two minima without crossing into the most barren parts of the landscape.

The discussion in this section is necessarily heuristic. In our numerical investigations we found some minima jumps that we could train between (indicating a fertile valley) and other minima jumps where we could not. In the latter case there may or may not be fertile valleys. In both cases this is evidence for toy problems and at a small problem sizes (10 qubits). To what extent these phenomena occur at larger problem sizes, for more interesting problems and for relevant time-step sizes, remains entirely open.

IV. DISCUSSION

Thanks to significant progress in recent years, the barren plateau phenomenon, defined as an average statement for an entire loss landscape, is by now technically well understood [20, 21]. However, prior analyses are consistent with different accounts of the behaviour of the loss landscape in the subregions most important for optimization. In this work we have taken steps to address these open questions by investigating a popular iterative variational circuit compression scheme [35–41]. The iterative nature of this algorithm ensures that variational problem is repeatedly warm started at each iteration of the variational scheme.

Theorem 1 establishes that for short enough time-steps the loss variance is guaranteed to decrease at worst polynomially in the number of parameters M in a hypercube with a width that scales as $1/\sqrt{M}$ around the new initialization. Theorem 2 strengthens this result by arguing that in a region $\sim 1/M^2$ around the initialization the landscape will be approximately convex. Finally, we sew together these results with a bound on the distance the adiabatic minimum (Definition 2) can move after applying a Trotter step of length δt. Thus in Theorem 3 we establish that as long as the time-step is decreased polynomially with the number of trainable parameters in the ansatz the adiabatic minimum remains in the approximately convex region with substantial gradients. Hence we show that by decreasing the time-step appropriately one should be able to train to a new minimum.

Our analysis leaves room for further research opportunities. For one, the analytic bounds provided here are lower bounds. We do not here provide upper bounds.

Thus our analysis leaves open the question of whether the region exhibiting polynomial gradients strictly decreases as $1/\sqrt{M}$ or whether potentially a larger region exhibits substantial gradients. Our numerical implementations (Fig. 2) suggest that for the problems we have looked at this $1/\sqrt{M}$ is reasonable. However, analytic upper bounds to verify this would be more satisfying.

Moreover, whether these bounds are to be viewed positively or negatively remains open. While in 'complexity-theory-land' polynomial guarantees are typically satisfactory, in practise polynomially vanishing gradients, in polynomially shrinking regions, with polynomially shrinking step sizes may not be that appealing. In particular, the δt values that enjoy guarantees via Theorem 3 are typically smaller than those used currently by practitioners for the small problem sizes accessible currently. To what extent these bounds can be tightened versus to what extent they indicate a fundamental limitation remains to be seen. Indeed, there is always the possibility that heuristically the optimization turns out to be more effective than analytic guarantees would suggest (as is typically the case for optimizing classical machine learning models).

Here we have pushed our analysis beyond a conventional average case analyses for the full loss landscape. However, our analysis is still fundamentally an average case analysis within a hypercube around an initialization. The limitations of this are highlighted by our inability to analytically describe the minimum jumps and fertile valleys that we numerically observe in Fig. 4 and Fig. 5. To analytically study such phenomena new theoretical tools will need to be developed to analyse quantum landscapes.

We remark that recent work has highlighted a strong link between provable absence of barren plateaus and the classical simulability and surrogatability of the hybrid optimisation loop of a variational quantum algorithm [5]. The lower bounds obtained here are consistent with these claims. In particular, for classically simulable initial states one could perform early iterations fully classically and then later iterations by collecting data from quantum computer and then training a classical surrogate of the landscape. We leave a discussion of the relative merits of this approach to future work.

Finally, we have framed our results here in the context of an iterative variational scheme for quantum simulation; however, most of our results here would carry over to other iterative variational approaches. For example, one could imagine starting with a circuit for preparing the ground state of an easier Hamiltonian and then iteratively perturbing the Hamiltonian and applying the variational quantum eigensolver between each perturbation. If the perturbations do not pass through a phase transition then such an iterative scheme is plausible and could potentially be characterised in a similar manner to as we have done here.

Appendix A: Preliminaries

In this section, we briefly review some analytical tools and concepts that will be used through out the other sections.

1. Relation between Hessian of the loss function and quantum Fisher information

Given the optimal parameters obtained from the previous iteration $\boldsymbol{\theta}^*$ and a time-step δt of the Hamiltonian H, the loss function at the current iteration is of the form

$$\mathcal{L}(\boldsymbol{\theta}) = 1 - \left|\langle\psi_0|U^\dagger(\boldsymbol{\theta})e^{-iH\delta t}U(\boldsymbol{\theta}^*)|\psi_0\rangle\right|^2 \tag{A1}$$

$$= 1 - F\left(U(\boldsymbol{\theta})|\psi_0\rangle, e^{-iH\delta t}U(\boldsymbol{\theta}^*)|\psi_0\rangle\right) \tag{A2}$$

where $F\left(|\psi\rangle, |\phi\rangle\right)$ is a fidelity between two pure states $|\psi\rangle$ and $|\phi\rangle$. We remark that although δt is often taken as fixed and not optimised during the training process, the loss function also implicitly depends on δt.

The warm-start strategy is to initialise the training of the current iteration around $\boldsymbol{\theta}^*$. To analyse the trainability of this strategy, we often consider the expansion of the loss around $\boldsymbol{\theta}^*$ and $\delta t = 0$. In this context, it is convenient to write $\boldsymbol{x} = (\boldsymbol{\theta} - \boldsymbol{\theta}^*, \delta t)$ and $F(\boldsymbol{x}) := F\left(U(\boldsymbol{\theta})|\psi_0\rangle, e^{-iH\delta t}U(\boldsymbol{\theta}^*)|\psi_0\rangle\right)$. Upon expanding the loss around $\boldsymbol{x} = \boldsymbol{0}$, the connection between the Hessian of the loss function and the quantum fisher information is

$$\nabla^2_{\boldsymbol{x}}\mathcal{L}(\boldsymbol{x})\Big|_{\boldsymbol{x}=\boldsymbol{0}} = -\nabla^2 F(\boldsymbol{x})\Big|_{\boldsymbol{x}=\boldsymbol{0}} = \frac{1}{2}\mathcal{F}(\boldsymbol{0}) , \tag{A3}$$

where $\mathcal{F}(\boldsymbol{0})$ is the quantum fisher information evaluated at $\boldsymbol{x} = \boldsymbol{0}$ and measures how the quantum state $U(\boldsymbol{\theta}^*)|\psi_0\rangle$ is sensitive to local perturbations around $\boldsymbol{\theta}^*$ and $\delta t = 0$ [63–65].

2. Taylor remainder theorem

We present the Taylor remainder theorem which expresses a multivariate differentiable function as a series expansion. We refer the reader to Ref. [66] for further details.

Theorem 4 (Taylor reminder theorem). *Consider a multivariate differentiable function $f(\boldsymbol{x})$ such that $f : \mathbb{R}^N \to \mathbb{R}$ and some positive integer K. The function $f(\boldsymbol{x})$ can be expanded around some fixed point $\boldsymbol{a}$ as*

$$f(\boldsymbol{x}) = \sum_{k=0}^{K}\sum_{i_1,i_2,\ldots,i_k}^{N} \frac{1}{k!}\left(\frac{\partial^k f(\boldsymbol{x})}{\partial x_{i_1}\partial x_{i_2}\ldots\partial x_{i_k}}\right)\Bigg|_{\boldsymbol{x}=\boldsymbol{a}} (x_{i_1} - a_{i_1})(x_{i_2} - a_{i_2})\ldots(x_{i_k} - a_{i_k}) + R_{K,\boldsymbol{a}}(\boldsymbol{x}) , \tag{A4}$$

where the remainder is of the form

$$R_{K,\boldsymbol{a}}(\boldsymbol{x}) = \sum_{i_1,i_2,\ldots,i_{K+1}}^{N} \frac{1}{(K+1)!}\left(\frac{\partial^{K+1} f(\boldsymbol{x})}{\partial x_{i_1}\partial x_{i_2}\ldots\partial x_{i_{K+1}}}\right)\Bigg|_{\boldsymbol{x}=\boldsymbol{\nu}} (x_{i_1} - a_{i_1})(x_{i_2} - a_{i_2})\ldots(x_{i_{K+1}} - a_{i_{K+1}}) , \tag{A5}$$

with $\boldsymbol{\nu} = c\boldsymbol{x} + (1-c)\boldsymbol{a}$ for some $c \in [0,1]$.

As an example, we apply the Taylor remainder theorem to prove the following statement.

Lemma 5. *The fidelity between two pure states ρ and $e^{-iHt}\rho e^{iHt}$ (with the Hamiltonian H) can be upper bounded as*

$$F\left(\rho, e^{-itH}\rho e^{itH}\right) \geqslant 1 - 2\lambda^2_{\max}t^2 \tag{A6}$$

where $\lambda_{\max}$ is the largest eigenvalue of H.

Proof. First, we denote $F(t) := F\left(\rho, e^{-itH}\rho e^{itH}\right)$. By using Theorem 4 (expanding around $t = 0$ up to the second order), the fidelity is of the form

$$F(t) = 1 + \frac{t^2}{2}\left(\frac{d^2F(t)}{dt^2}\right)\Bigg|_{t=\tau} , \tag{A7}$$

where the zero order term is 1, the first order term is zero by a direct computation and the second order term is evaluated at some $\tau \in [0, t]$. We can then bound the second derivative as the following

$$\left(\frac{d^2F(t)}{dt^2}\right)\bigg|_{t=\tau} = \mathrm{Tr}\left(\rho e^{-iH\tau} i\left[i\left[\rho, H\right], H\right] e^{iH\tau}\right) \tag{A8}$$

$$\leqslant \|\rho\|_1 \|e^{-iH\tau} i\left[i\left[\rho, H\right], H\right] e^{iH\tau}\|_\infty \tag{A9}$$

$$\leqslant 4\lambda_{\text{max}}^2 \ , \tag{A10}$$

where the first inequality is due to Hölder's inequality. In the second inequality, we rely on the following identities: (i) $\|\rho\|_1 = 1$ for a pure state, (ii) the unitary invariance of the Schatten p-norm i.e., $\|UA\|_p = \|A\|_p$ for any unitary U, (iii) $\|i[A, B]\|_p \leqslant 2\|A\|_p\|B\|_p$ and lastly (iv) $\|AB\|_p \leqslant \|A\|_p\|B\|_p$. Thus, the fidelity can be lower bounded as

$$F(t) \geqslant 1 - 2\lambda_{\text{max}}^2 t^2 \ . \tag{A11}$$

This completes the proof. □

3. Approximate convexity

In this section, we provide a formal explanation of our definition of an ϵ-convex function. We start by defining what convexity is (see for example Ref. [67]) and we relate it to our notion of ϵ-convexity.

Definition 3 (Convexity)**.** *A differentiable function of several variables $f : \mathbb{R}^N \to \mathbb{R}$ is convex in a region $\mathcal{R}$, if and only if for all $\boldsymbol{x}, \boldsymbol{y} \in \mathcal{R}$ the function fulfils*

$$f(\boldsymbol{x}) \geqslant f(\boldsymbol{y}) + \nabla f(\boldsymbol{y}) \cdot (\boldsymbol{x} - \boldsymbol{y}) \ . \tag{A12}$$

or equivalently, $\nabla^2 f(\boldsymbol{x})$ is positive semi-definite. Here $\nabla^2 f(\boldsymbol{x})$ denotes the Hessian of $f(\boldsymbol{x})$. Notice that we use $\nabla f(\boldsymbol{y}) = \nabla_{\tilde{\boldsymbol{y}}} f(\tilde{\boldsymbol{y}})|_{\tilde{\boldsymbol{y}}=\boldsymbol{y}}$, $\nabla^2 f(\boldsymbol{y}) = \nabla^2_{\tilde{\boldsymbol{y}}} f(\tilde{\boldsymbol{y}})|_{\tilde{\boldsymbol{y}}=\boldsymbol{y}}$

Informally this means that all the tangent planes to f are below f in the region $\mathcal{R}$. This is shown for one variable in Fig. 6 a).

Definition 1 (ϵ-approximate convexity.)**.** *A differentiable function of several variables $f : \mathbb{R}^N \to \mathbb{R}$ is ϵ-convex in a region $\mathcal{R}$ if*

$$\left[\nabla^2 f(\boldsymbol{x})\right]_{\text{min}} \geqslant -|\epsilon| \tag{A13}$$

for all $\boldsymbol{x} \in \mathcal{R}$. Here $\nabla^2 f(\boldsymbol{x})$ denotes the Hessian of $f(\boldsymbol{x})$ and we denote $[A]_{\text{min}}$ as the smallest eigenvalue of the matrix A.

If a function is ϵ-convex in a finite region $\mathcal{R}$, then we can show an equivalent intuition to the one for convexity. Indeed, if a function f is ϵ-convex in a finite region $\mathcal{R}$, then we can say that an "ϵ-displacement" in every tangent line is enough to make it below f in $\mathcal{R}$ as shown in Fig. 6 b).

Proposition 1. *If a differentiable function of several variables $f : \mathbb{R}^n \to \mathbb{R}$ is ϵ-convex in finite a region $\mathcal{R}$, then for all $\boldsymbol{x}, \boldsymbol{y} \in \mathcal{R}$ the function fulfils*

$$f(\boldsymbol{x}) \geqslant f(\boldsymbol{y}) + \nabla f(\boldsymbol{y}) \cdot (\boldsymbol{x} - \boldsymbol{y}) - |\epsilon|\alpha \ , \tag{A14}$$

where $\alpha = \frac{1}{2}\max_{\boldsymbol{a},\boldsymbol{b}\in\mathcal{R}} ||\boldsymbol{a} - \boldsymbol{b}||_2^2$.

Proof. First we recall the Taylor reminder theorem in A 2. Then we can expand the function f around the point $\boldsymbol{y}$ as

$$f(\boldsymbol{x}) = f(\boldsymbol{y}) + \sum_i^n \frac{\partial f(\boldsymbol{q})}{\partial q_i}\bigg|_{\boldsymbol{q}=\boldsymbol{y}} (x_i - y_i) + \frac{1}{2}\sum_{i,j}^n \frac{\partial^2 f(\boldsymbol{q})}{\partial q_i \partial q_j}\bigg|_{\boldsymbol{q}=\boldsymbol{z}} (x_j - y_j)(x_i - y_i) \tag{A15}$$

$$= f(\boldsymbol{y}) + \nabla f(\boldsymbol{y}) \cdot (\boldsymbol{x} - \boldsymbol{y}) + \frac{1}{2}(\boldsymbol{x} - \boldsymbol{y})^T \nabla^2 f(\boldsymbol{z})(\boldsymbol{x} - \boldsymbol{y}) \ , \tag{A16}$$

for some $\boldsymbol{z} = c\boldsymbol{x} + (1 - c)\boldsymbol{y}$ with some $c \in [0, 1]$. In the last equality we wrote the expression in its vector form for simplicity.

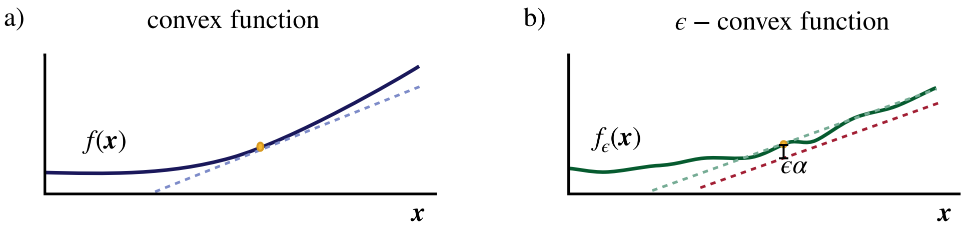

FIG. 6. **Convexity and ϵ-convexity.** Here we show two schematics for one variable functions. a) Represents a convex function and the tangent (dashed line). The tangent is always below f. b) Represents a ϵ-convex function and the tangent (dashed line). The light-green dashed line represents the tangent to the function. The red line represents the tangent displaced $\alpha\epsilon$ with respect to the green one. A "displacement of $\alpha\epsilon$" on the tangent makes it such that is always below the function.

Now if we apply the notion of ϵ-convexity we can lower-bound the right-hand side of the previous equality to find

$$f(\boldsymbol{x}) \geqslant f(\boldsymbol{y}) + \nabla f(\boldsymbol{y}) \cdot (\boldsymbol{x}-\boldsymbol{y}) - \frac{1}{2}|\epsilon|(\boldsymbol{x}-\boldsymbol{y})^T(\boldsymbol{x}-\boldsymbol{y}) \ , \tag{A17}$$

which can be further bounded by using that $(\boldsymbol{x}-\boldsymbol{y})^T(\boldsymbol{x}-\boldsymbol{y}) \leqslant \alpha$. Recall that $\alpha = \frac{1}{2}\max_{\boldsymbol{a},\boldsymbol{b}\in\mathcal{R}} ||\boldsymbol{a}-\boldsymbol{b}||_2^2$. With this we find

$$f(\boldsymbol{x}) \geqslant f(\boldsymbol{y}) + \nabla f(\boldsymbol{y}) \cdot (\boldsymbol{x}-\boldsymbol{y}) - |\epsilon|\alpha \ , \tag{A18}$$

□

Notice that in general α can increase with the dimension of the input $\boldsymbol{x}$ (for the loss function in Eq (3) this is equivalent to the number of parameters M) as well as with the size of the region that we demand ϵ-convexity over. That is, for a region of size r, α approximately scales as Mr^2. In the regime that is relevant to our work (particularly, Theorem 2), the region in which we require ϵ-convexity is of order $r \in \Omega\left(1/M^2\right)$ (for appropriately chosen δt). Hence, α decays with the number of parameters as $1/M^2$.

4. Upper bound on the eigenvalues

We present a simplified version of Gershgorin's circle theorem [68] which can be used to upper bound the eigenvalues of a real squared matrix.

Proposition 2. *Consider a real $M \times M$ matrix A and denote $\lambda_{\max}$ as the largest eigenvalue of A. Given that the sum of elements in any row is upper bounded by some value T_0, that is $\sum_j |A_{ij}| \leqslant T_0$ for any $i \in \{1, ..., M\}$, the largest eigenvalue of A can be bounded as*

$$\lambda_{\max} \leqslant T_0 \ \ . \tag{A19}$$

Proof. Let $\boldsymbol{v}$ be an eigenvector corresponding the largest eigenvalue of A. There exists the largest component in the eigenvector denoted as v_i. Then, we consider this eigenvector component in the eigenvalue equation

$$\sum_j A_{ij} v_j = \lambda_{\max} v_i \ . \tag{A20}$$

The bound of the largest eigenvalue follows as

$$\begin{aligned} \lambda_{\max} &\leqslant \sum_j \frac{|A_{i,j}| \cdot |v_j|}{|v_i|} && \text{(A21)}\\ &\leqslant \sum_j |A_{i,j}| && \text{(A22)}\\ &\leqslant T_0 \ , && \text{(A23)} \end{aligned}$$

where the first inequality is due to triangle inequality, the second inequality is from $\frac{|v_j|}{|v_i|} \leqslant 1$ and in the last inequality we use the assumption that $\sum_j |A_{i,j}| \leqslant T_0$. □

Appendix B: Lower bound of the variance of the loss function

In this section, we provide the exact formula for the lower bound of the loss function for the variational Trotter compression algorithm.

1. Exact formula for the lower bound

Proposition 3. *Consider the loss function $\mathcal{L}(\boldsymbol{\theta})$ as defined in Eq. (3) and with an ansatz of the general form defined in Eq. (4) with M parameters. The variance of $\mathcal{L}(\boldsymbol{\theta})$ over the hypercube parameter region $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$ around an optimal solution of the previous iteration $\boldsymbol{\theta}^*$ can be bounded as*

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}[\mathcal{L}(\boldsymbol{\theta})] \geqslant (c_+ - k_+^2) \min_{\tilde{\xi}\in[-1,1]} \left(k_+^{M-1}\Delta_{\boldsymbol{\theta}^*} + (1-k_+^{M-1})\tilde{\xi}\right)^2 , \tag{B1}$$

where we have

$$c_+ := \mathbb{E}_{\alpha\sim\boldsymbol{\mathcal{D}}(0,r)}[\cos^4 \alpha] , \tag{B2}$$

$$k_+ := \mathbb{E}_{\alpha\sim\boldsymbol{\mathcal{D}}(0,r)}[\cos^2 \alpha] , \tag{B3}$$

$$\Delta_{\boldsymbol{\theta}^*} := \mathrm{Tr}\left[(\rho_0 - \sigma_1\rho_0\sigma_1)U^\dagger\left(\boldsymbol{\theta^*}\right)\rho_{(\boldsymbol{\theta}^*,\delta t)}U\left(\boldsymbol{\theta^*}\right)\right] . \tag{B4}$$

Here σ_1 is the Pauli string associated with the first gate in the circuit $U(\boldsymbol{\theta})$ as defined in Eq. (4), $\rho_0 = |\psi_0\rangle\langle\psi_0|$ is an initial state before the time evolution and $\rho_{(\boldsymbol{\theta}^*,\delta t)} = e^{-iH\delta t}U(\boldsymbol{\theta^*})\rho_0 U^\dagger(\boldsymbol{\theta^*})e^{iH\delta t}$ with H being the underlying Hamiltonian of the quantum dynamics.

Proof. First, we recall that the loss function at each iteration (as defined in Eq. (3)) is of the form

$$\mathcal{L}(\boldsymbol{\theta}) = 1 - \left|\langle\psi_0|U^\dagger(\boldsymbol{\theta})|\psi(\boldsymbol{\theta}^*,\delta t)\rangle\right|^2 \tag{B5}$$

$$= 1 - \langle\psi_0|U^\dagger(\boldsymbol{\theta})\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta})|\psi_0\rangle \tag{B6}$$

for some initial state $|\psi_0\rangle$ and

$$\rho_{(\boldsymbol{\theta}^*,\delta t)} := |\psi(\boldsymbol{\theta}^*,\delta t)\rangle\langle\psi(\boldsymbol{\theta}^*,\delta t)| = e^{-iH\delta t}U(\boldsymbol{\theta}^*)|\psi_0\rangle\langle\psi_0|U^\dagger(\boldsymbol{\theta}^*)e^{iH\delta t} , \tag{B7}$$

where $\boldsymbol{\theta}^*$ is an optimal solution of the previous iteration. The parameterised quantum circuit $U(\boldsymbol{\theta})$ with M parameters takes the following general form

$$U\left(\boldsymbol{\theta}\right) = \prod_{i=1}^{M} V_i U_i(\theta_i) , \tag{B8}$$

where $\{V_i\}_{i=1}^M$ are some fixed unitaries and $\{U_i(\theta_i) = e^{-i\theta_i\sigma_i}\}_{i=1}^M$ are a set of parameterised rotation gates with σ_i being a Pauli string associated with the i^{th} gate. Crucially, the rotation gates can be re-expressed as perturbations $\boldsymbol{\alpha}$ around the previous optimal solution i.e., $\theta_i = \theta_i^* + \alpha_i$ for all i

$$U\left(\boldsymbol{\theta}\right) = \prod_{i=1}^{M} V_i U_i(\theta_i^*)U_i(\alpha_i) \tag{B9}$$

$$= \prod_{i=1}^{M} \widetilde{V}_i(\theta_i^*)U_i(\alpha_i) , \tag{B10}$$

where the first equality holds due to $e^{-i\theta_i\sigma_i} = e^{-i\theta_i^*\sigma_i}e^{-i\alpha_i\sigma_i}$ and in the second equality we denote $\widetilde{V}_i := \widetilde{V}_i(\theta_i^*) = V_i e^{-i\theta_i^*\sigma_i}$.

We consider the region of parameters around the previous optimum which can also be expressed in terms of $\boldsymbol{\alpha}$

$$\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r) = \{\boldsymbol{\theta} = \boldsymbol{\theta}^* + \boldsymbol{\alpha} \mid \ \alpha_i \in [-r, r]\} \ , \tag{B11}$$

where r is a characteristic length of the region. Now, we are interested in the variance of the loss function over $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$ such that each parameter is uniformly sampled

$$\begin{aligned}
\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}(\boldsymbol{\theta})\right] &= \mathrm{Var}_{\boldsymbol{\alpha}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}\left[\mathcal{L}(\boldsymbol{\theta} = \boldsymbol{\theta}^* + \boldsymbol{\alpha})\right] & \text{(B12)}\\
&= \mathrm{Var}_{\boldsymbol{\alpha}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}\left[1 - \mathcal{L}(\boldsymbol{\theta})\right] & \text{(B13)}\\
&= \mathbb{E}_{\boldsymbol{\alpha}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))^2\right] - \left(\mathbb{E}_{\boldsymbol{\alpha}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}[1 - \mathcal{L}(\boldsymbol{\theta})]\right)^2 \ , & \text{(B14)}
\end{aligned}$$

where the second equality is due to $\mathrm{Var}_{\boldsymbol{\alpha}}[b_1 X(\boldsymbol{\alpha}) + b_2] = (b_1)^2 \mathrm{Var}_{\boldsymbol{\alpha}} X(\boldsymbol{\alpha})$ for some constants b_1 and b_2.

Importantly, since all parameters are assumed to be uncorrelated, this allows us to compute the variance over each individual parameter one-by-one from the outermost parameter α_M towards the first parameter α_1. That is, each term in Eq. (B14) can be expressed as

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{\alpha}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))^2\right] &= \mathbb{E}_{\alpha_1,\alpha_2,\ldots,\alpha_M}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))^2\right] & \text{(B15)}\\
&= \mathbb{E}_{\alpha_1,\alpha_2,\ldots,\alpha_{M-1}}\mathbb{E}_{\alpha_M}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))^2\right] & \text{(B16)}\\
&:= \mathbb{E}_{\overline{\alpha_M}}\mathbb{E}_{\alpha_M}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))^2\right] \ , & \text{(B17)}
\end{aligned}$$

with $\overline{\alpha_M} := \alpha_1, \alpha_2, ..., \alpha_{M-1}$ and, similarly,

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{\alpha}\sim\boldsymbol{\mathcal{D}}(\mathbf{0},r)}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))\right] &= \mathbb{E}_{\alpha_1,\alpha_2,\ldots,\alpha_{M-1}}\mathbb{E}_{\alpha_M}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))\right] & \text{(B18)}\\
&:= \mathbb{E}_{\overline{\alpha_M}}\mathbb{E}_{\alpha_M}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))\right] \ . & \text{(B19)}
\end{aligned}$$

Before delving into computing these terms, we first stress the α_M dependence of the loss by writing

$$\begin{aligned}
1 - \mathcal{L}(\boldsymbol{\theta}) =& \ \left|\langle\psi_0|U^\dagger(\boldsymbol{\theta})|\psi(\boldsymbol{\theta}^*, \delta t)\rangle\right|^2 & \text{(B20)}\\
=& \ \langle\psi_{M-1}|U_M^\dagger(\alpha_M)\rho_M U_M(\alpha_M)|\psi_{M-1}\rangle \ , & \text{(B21)}
\end{aligned}$$

where we have defined

$$\begin{aligned}
|\psi_{M-1}\rangle &:= \prod_{i=1}^{M-1} \widetilde{V}_i(\theta_i^*) U_i(\alpha_i)|\psi_0\rangle \ , & \text{(B22)}\\
\rho_M &:= \widetilde{V}_M^\dagger(\theta_M^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}\widetilde{V}_M(\theta_M^*) \ . & \text{(B23)}
\end{aligned}$$

Remark that $|\psi_{M-1}\rangle$ depends on the other parameters $\{\alpha_i\}_{i=1}^{M-1}$ while ρ_M is independent of $\boldsymbol{\alpha}$. Next we use the identity

$$U_i(\alpha_i) = \cos(\alpha_i)\mathbb{1} - i\sin(\alpha_i)\sigma_i \ , \tag{B24}$$

to rewrite the loss as

$$\begin{aligned}
1 - \mathcal{L}(\boldsymbol{\theta}) =& \ \cos^2(\alpha_M)\langle\psi_{M-1}|\rho_M|\psi_{M-1}\rangle + \sin^2(\alpha_M)\langle\psi_{M-1}|\sigma_M\rho_M\sigma_M|\psi_{M-1}\rangle \\
& - \cos(\alpha_M)\sin(\alpha_M)\langle\psi_{M-1}|i[\rho_M, \sigma_M]|\psi_{M-1}\rangle & \text{(B25)}\\
=& \ \cos^2(\alpha_M)\langle\rho_M\rangle_{\psi_{M-1}} + \sin^2(\alpha_M)\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}} - \cos(\alpha_M)\sin(\alpha_M)\langle i[\rho_M, \sigma_M]\rangle_{\psi_{M-1}} \ , & \text{(B26)}
\end{aligned}$$

where in the final line we use the shorthand

$$\langle O\rangle_\psi := \langle\psi|O|\psi\rangle \ , \tag{B27}$$

for some observable O and some state $|\psi\rangle$.

We are now ready to proceed with the averaging over α_M in Eq. (B17) which results in

$$\begin{aligned}
\mathbb{E}_{\alpha_M}\left[(1 - \mathcal{L}(\boldsymbol{\theta}))^2\right] &= c_+\langle\rho_M\rangle_{\psi_{M-1}}^2 + c_-\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}^2 + c_0\langle i[\rho_M, \sigma_M]\rangle_{\psi_{M-1}}^2 & \text{(B28)}\\
&\quad + 2c_0\langle\rho_M\rangle_{\psi_{M-1}}\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}} \\
&\geqslant c_+\langle\rho_M\rangle_{\psi_{M-1}}^2 + c_-\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}^2 + 2c_0\langle\rho_M\rangle_{\psi_{M-1}}\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}} \ , & \text{(B29)}
\end{aligned}$$

where we have

$$c_+ = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \cos^4(\alpha_M)\ , \tag{B30}$$

$$c_- = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \sin^4(\alpha_M)\ , \tag{B31}$$

$$c_0 = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \cos^2(\alpha_M)\sin^2(\alpha_M)\ , \tag{B32}$$

$$0 = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \cos^3(\alpha_M)\sin(\alpha_M) = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \cos(\alpha_M)\sin^3(\alpha_M)\ . \tag{B33}$$

Similarly, by considering Eq. (B19), we have

$$\mathbb{E}_{\alpha_M}\left[1-\mathcal{L}(\boldsymbol{\theta})\right] = k_+\langle\rho_M\rangle_{\psi_{M-1}} + k_-\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\ , \tag{B34}$$

with

$$k_+ = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \cos^2(\alpha_M)\ , \tag{B35}$$

$$k_- = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \sin^2(\alpha_M)\ , \tag{B36}$$

$$0 = \frac{1}{2r}\int_{-r}^{r} d\alpha_M \cos(\alpha_M)\sin(\alpha_M)\ . \tag{B37}$$

From the above expressions, we can see that $\mathrm{Var}_\alpha[\cos^2(\alpha)] = c_+ - k_+^2$, $\mathrm{Var}_\alpha[\sin^2(\alpha)] = c_- - k_-^2$ and $\mathrm{Cov}_\alpha[\cos^2(\alpha), \sin^2(\alpha)] = c_0 - k_+k_-$. In addition, it can be verified by a direct computation that

$$c_+ - k_+^2 = c_- - k_-^2 = -(c_0 - k_+k_-) = \frac{-1+4r^2+\cos(4r)+r\sin(4r)}{32r^2}\ . \tag{B38}$$

Together, the variance in Eq. (B14) can be bounded as

$$\begin{aligned}
\mathrm{Var}_{\boldsymbol{\theta}}\left[\mathcal{L}(\boldsymbol{\theta})\right] &= \mathbb{E}_{\alpha_1,\dots,\alpha_{M-1}}\mathbb{E}_{\alpha_M}\left[(1-\mathcal{L}(\boldsymbol{\theta}))^2\right] - \left(\mathbb{E}_{\alpha_1,\dots,\alpha_{M-1}}\mathbb{E}_{\alpha_M}\left[1-\mathcal{L}(\boldsymbol{\theta})\right]\right)^2 && \text{(B39)}\\
&\geqslant \mathbb{E}_{\overline{\alpha_M}}\left[c_+\langle\rho_M\rangle^2_{\psi_{M-1}} + c_-\langle\sigma_M\rho_M\sigma_M\rangle^2_{\psi_{M-1}} + 2c_0\langle\rho_M\rangle_{\psi_{M-1}}\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right]\\
&\quad - \left(\mathbb{E}_{\overline{\alpha_M}}\left[k_+\langle\rho_M\rangle_{\psi_{M-1}} + k_-\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right]\right)^2 && \text{(B40)}\\
&= c_+\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle^2_{\psi_{M-1}}\right] - k_+^2\left(\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}\right]\right)^2\\
&\quad + c_-\mathbb{E}_{\overline{\alpha_M}}\left[\langle\sigma_M\rho_M\sigma_M\rangle^2_{\psi_{M-1}}\right] - k_-^2\left(\mathbb{E}_{\overline{\alpha_M}}\left[\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right]\right)^2\\
&\quad + 2c_0\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] - 2k_+k_-\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}\right]\mathbb{E}_{\overline{\alpha_M}}\left[\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] && \text{(B41)}\\
&= (c_+ - k_+^2)\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle^2_{\psi_{M-1}}\right] + k_+^2\mathrm{Var}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}\right]\\
&\quad + (c_- - k_-^2)\mathbb{E}_{\overline{\alpha_M}}\left[\langle\sigma_M\rho_M\sigma_M\rangle^2_{\psi_{M-1}}\right] + k_-^2\mathrm{Var}_{\overline{\alpha_M}}\left[\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right]\\
&\quad + 2(c_0 - k_+k_-)\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] + 2k_+k_-\mathrm{Cov}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}, \langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] && \text{(B42)}\\
&= (c_+ - k_+^2)\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle^2_{\psi_{M-1}} + \langle\sigma_M\rho_M\sigma_M\rangle^2_{\psi_{M-1}} - 2\langle\rho_M\rangle_{\psi_{M-1}}\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right]\\
&\quad + k_+^2\mathrm{Var}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}\right] + k_-^2\mathrm{Var}_{\overline{\alpha_M}}\left[\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] + 2k_+k_-\mathrm{Cov}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}}, \langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] && \text{(B43)}\\
&= (c_+ - k_+^2)\mathbb{E}_{\overline{\alpha_M}}\left[\langle\rho_M\rangle_{\psi_{M-1}} - \langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right]^2 + \mathrm{Var}_{\overline{\alpha_M}}\left[k_+\langle\rho_M\rangle_{\psi_{M-1}} + k_-\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] && \text{(B44)}\\
&\geqslant \mathrm{Var}_{\overline{\alpha_M}}\left[k_+\langle\rho_M\rangle_{\psi_{M-1}} + k_-\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] && \text{(B45)}
\end{aligned}$$

where the first inequality is due to Eq. (B29), we then reach Eq. (B42) by using the fact that $\mathrm{Var}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha})] = \mathbb{E}_{\boldsymbol{\alpha}}[X^2(\boldsymbol{\alpha})] - (\mathbb{E}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha})])^2$ and $\mathrm{Cov}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha}), Y(\boldsymbol{\alpha})] = \mathbb{E}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha})Y[\boldsymbol{\alpha}]] - \mathbb{E}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha})]\mathbb{E}_{\boldsymbol{\alpha}}[Y(\boldsymbol{\alpha})]$, Eq. (B43) is from the relation presented in Eq. (B38). Next, in Eq. (B44) we use the identity $\mathrm{Var}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha})+Y(\boldsymbol{\alpha})] = \mathrm{Var}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha})] + \mathrm{Var}_{\boldsymbol{\alpha}}[Y(\boldsymbol{\alpha})] + 2\mathrm{Cov}_{\boldsymbol{\alpha}}[X(\boldsymbol{\alpha}), Y(\boldsymbol{\alpha})]$ and to reach the next inequality we throw away the first positive term in the sum.

Notably, the variance of the term in Eq. (B45) is no longer taken over α_M (i.e., the contribution to the variance from α_M is already taken into account). In addition, by denoting $|\psi_{M-2}\rangle = \prod_{i=1}^{M-2} \widetilde{V}_i(\theta_i^*)U_i(\alpha_i)|\psi_0\rangle$ as well as

$$\widetilde{\rho}_{M-1} = k_+ \widetilde{V}^\dagger_{M-1}(\theta^*_{M-1})\rho_M \widetilde{V}_{M-1}(\theta_{M-1}) + k_- \widetilde{V}^\dagger_{M-1}(\theta^*_{M-1})\sigma_M \rho_M \sigma_M \widetilde{V}_{M-1}(\theta^*_{M-1}) \,, \tag{B46}$$

the lower bound in Eq. (B45) can be expressed as

$$\begin{aligned} \mathrm{Var}_{\boldsymbol{\theta}}\left[\mathcal{L}(\boldsymbol{\theta})\right] &\geqslant \mathrm{Var}_{\overline{\alpha_M}}\left[k_+\langle\rho_M\rangle_{\psi_{M-1}} + k_-\langle\sigma_M\rho_M\sigma_M\rangle_{\psi_{M-1}}\right] && \text{(B47)}\\ &= \mathrm{Var}_{\alpha_1,\alpha_2,\ldots,\alpha_{M-1}}\left[\langle\psi_{M-2}|U^\dagger_{M-1}(\alpha_{M-1})\widetilde{\rho}_{M-1}U_{M-1}(\alpha_{M-1})|\psi_{M-2}\rangle\right] && \text{(B48)} \end{aligned}$$

Crucially, the derivation steps from Eq. (B28) to Eq. (B48), which are used to get rid of α_M dependence, can be repeated to recursively integrate over other parameters. To be more precise, let us first define

$$|\psi_{M-l-1}\rangle = \prod_{i=1}^{M-l-1} \widetilde{V}_i(\theta_i^*)U_i(\alpha_i)|\psi_0\rangle \,, \tag{B49}$$

as well as a general recursive form of Eq. (B46)

$$\widetilde{\rho}_{M-l} = k_+ \widetilde{V}^\dagger_{M-l}(\theta^*_{M-l})\widetilde{\rho}_{M-l+1} \widetilde{V}_{M-l}(\theta^*_{M-l}) + k_- \widetilde{V}^\dagger_{M-l}(\theta^*_{M-l})\sigma_{M-l+1} \widetilde{\rho}_{M-l+1} \sigma_{M-l+1} \widetilde{V}_{M-l}(\theta^*_{M-l}) \,, \tag{B50}$$

where $l \in \{1, 2, ..., M-1\}$ and we have $\widetilde{\rho}_M = \rho_M$ which gives back Eq. (B46) for $l = 1$. We note that $\widetilde{\rho}_{M-l}$ can be seen as a mixed state between $\widetilde{V}^\dagger_{M-l}(\theta^*_{M-l})\widetilde{\rho}_{M-l+1}\widetilde{V}_{M-l}(\theta^*_{M-l})$ and $\widetilde{V}^\dagger_{M-l}(\theta^*_{M-l})\sigma_{M-l+1}\widetilde{\rho}_{M-l+1}\sigma_{M-l+1}\widetilde{V}_{M-l}(\theta^*_{M-l})$ for all l. This is since $k_+ + k_- = 1$ and ρ_M is a valid quantum state.

The variance then can be recursively lower bounded, leading to

$$\begin{aligned} \mathrm{Var}_{\boldsymbol{\theta}}\left[\mathcal{L}(\boldsymbol{\theta})\right] &\geqslant \mathrm{Var}_{\alpha_1,\alpha_2,\ldots,\alpha_{M-1}}\left[\langle\psi_{M-2}|U^\dagger_{M-1}(\alpha_{M-1})\widetilde{\rho}_{M-1}U_{M-1}(\alpha_{M-1})|\psi_{M-2}\rangle\right] && \text{(B51)}\\ &\geqslant \mathrm{Var}_{\alpha_1,\alpha_2,\ldots,\alpha_{M-l}}\left[\langle\psi_{M-l-1}|U^\dagger_{M-l}(\alpha_{M-l})\widetilde{\rho}_{M-l}U_{M-l}(\alpha_{M-l})|\psi_{M-l-1}\rangle\right] && \text{(B52)}\\ &\geqslant \mathrm{Var}_{\alpha_1}\left[\langle\psi_1|U^\dagger_1(\theta_1)\widetilde{\rho}_1U_1(\theta_1)|\psi_1\rangle\right] \,, && \text{(B53)} \end{aligned}$$

where in the second inequality we have recursively integrated out parameters $\alpha_{M-l+1}, ..., \alpha_M$ and in the last equality we have integrated out all the parameters except α_1.

All that remains is to explicitly bound the variance with respect to α_1

$$\begin{aligned} \mathrm{Var}_{\boldsymbol{\theta}}\left[\mathcal{L}(\boldsymbol{\theta})\right] &\geqslant \mathrm{Var}_{\alpha_1}\left[\langle\psi_1|U^\dagger_1(\theta_1)\widetilde{\rho}_1U_1(\theta_1)|\psi_1\rangle\right] && \text{(B54)}\\ &\geqslant \left(c_+\langle\widetilde{\rho}_1\rangle^2_{\psi_0} + c_-\langle\sigma_1\widetilde{\rho}_1\sigma_1\rangle^2_{\psi_0} + 2c_0\langle\widetilde{\rho}_1\rangle_{\psi_0}\langle\sigma_1\widetilde{\rho}_1\sigma_1\rangle_{\psi_0}\right) - \left(k_+\langle\widetilde{\rho}_1\rangle_{\psi_0} + k_-\langle\sigma_1\widetilde{\rho}_1\sigma_1\rangle_{\psi_0}\right)^2 && \text{(B55)}\\ &= (c_+ - k_+^2)\left(\langle\widetilde{\rho}_1\rangle_{\psi_0} - \langle\sigma_1\widetilde{\rho}_1\sigma_1\rangle_{\psi_0}\right)^2 && \text{(B56)}\\ &= (c_+ - k_+^2)\left(\mathrm{Tr}\left[\left(|\psi_0\rangle\langle\psi_0| - \sigma_1|\psi_0\rangle\langle\psi_0|\sigma_1\right)\widetilde{\rho}_1\right]\right)^2 && \text{(B57)} \end{aligned}$$

where Eq. (B55) to Eq. (B57) follows in the same manner as Eq. (B40) to Eq. (B45). From recursively expanding $\widetilde{\rho}_1$ (according to Eq. (B50)), we can write:

$$\begin{aligned} \widetilde{\rho}_1 &= k_+^{M-1}\left(\prod_{i=1}^{M}\widetilde{V}_i(\theta_i^*)\right)^\dagger \rho_{(\boldsymbol{\theta}^*,\delta t)} \left(\prod_{i=1}^{M}\widetilde{V}_i(\theta_i^*)\right) + (1-k_+^{M-1})\xi && \text{(B58)}\\ &= k_+^{M-1}U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*) + (1-k_+^{M-1})\xi && \text{(B59)}\\ & && \text{(B60)} \end{aligned}$$

where ξ is some complicated mixed state and, for clarification, we note that $k_+^{M-1} = (k_+)^{M-1}$ with k_+ defined in Eq B35 [2]. Thus we can write

$$\begin{aligned} \mathrm{Var}_{\boldsymbol{\theta}}\left[\mathcal{L}(\boldsymbol{\theta})\right] &\geqslant (c_+ - k_+^2)\left(\mathrm{Tr}\left[\left(|\psi_0\rangle\langle\psi_0| - \sigma_1|\psi_0\rangle\langle\psi_0|\sigma_1\right)\left(k_+^{M-1}U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*) + (1-k_+^{M-1})\xi\right)\right]\right)^2 && \text{(B61)}\\ &\geqslant (c_+ - k_+^2)\min_{\tilde{\xi}\in[-1,1]}\left(k_+^{M-1}\,\mathrm{Tr}\left[\left(|\psi_0\rangle\langle\psi_0| - \sigma_1|\psi_0\rangle\langle\psi_0|\sigma_1\right)U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*)\right] + (1-k_+^{M-1})\tilde{\xi}\right)^2 && \text{(B62)} \end{aligned}$$

[2] This clarification on k_+^M is included at the request of one of the authors.

where in the final line we minimize over the free parameter $\tilde{\xi} = \mathrm{Tr}\left[(|\psi_0\rangle\langle\psi_0| - \sigma_1|\psi_0\rangle\langle\psi_0|\sigma_1)\,\xi\right] \in [-1,1]$ by noting that $\mathrm{Tr}\left[(|\psi_0\rangle\langle\psi_0| - \sigma_1|\psi_0\rangle\langle\psi_0|\sigma_1)\,\xi\right]$ is bounded between -1 and 1. This completes the proof of the proposition. □

2. Proof of Theorem 1

In this subsection, we analytically show that the lower bound of the variance scales polynomially with the number of parameters M when the perturbation is within $1/\sqrt{M}$ region.

Theorem 1 (Lower-bound on the loss variance, Formal)**.** *Assume a product initial state $\rho_0 = \bigotimes_{j=1}^{n}\rho_j$ with ρ_j and let us choose σ_1 such that $\mathrm{Tr}[\rho_0\sigma_1\rho_0\sigma_1] = 0$. Given that the Trotter time-step δt respects*

$$\frac{1}{2\lambda_{\max}} \geqslant \delta t\ , \tag{B63}$$

where $\lambda_{\max}$ is the largest eigenvalue of H, and the perturbation r obeys

$$\frac{3r_0^2\left(1-4\lambda_{\max}^2\delta t^2\right)}{2(M-1)\left(1-2\lambda_{\max}^2\delta t^2\right)} \geqslant r^2\ , \tag{B64}$$

with some r_0 such that $0<r_0<1$, then the variance of the loss function within the region $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$ is lower bounded as

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}(\boldsymbol{\theta})\right] \geqslant \frac{4r^4}{45}\left(1-\frac{4r^2}{7}\right)\left[(1-r_0)(1-4\lambda_{\max}^2\delta t^2)\right]^2\ . \tag{B65}$$

In addition, by choosing r such that $r \in \Theta\left(\frac{1}{\sqrt{M}}\right)$, we have

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}(\boldsymbol{\theta})\right] \in \Omega\left(\frac{1}{M^2}\right)\ . \tag{B66}$$

Proof. From Proposition 3, we first recall the variance bound in Eq. (B1) is of the form

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}[\mathcal{L}(\boldsymbol{\theta})] \geqslant\ (c_+ - k_+^2)\min_{\tilde{\xi}\in[-1,1]}\left(k_+^{M-1}\Delta_{\boldsymbol{\theta}^*} + (1-k_+^{M-1})\tilde{\xi}\right)^2\ , \tag{B67}$$

where we have

$$c_+ := \mathbb{E}_{\alpha\sim\boldsymbol{\mathcal{D}}(0,r)}[\cos^4\alpha]\ , \tag{B68}$$

$$k_+ := \mathbb{E}_{\alpha\sim\boldsymbol{\mathcal{D}}(0,r)}[\cos^2\alpha]\ , \tag{B69}$$

$$\Delta_{\boldsymbol{\theta}^*} := \mathrm{Tr}\big[(\rho_0 - \sigma_1\rho_0\sigma_1)U^\dagger\left(\boldsymbol{\theta}^*\right)\rho_{(\boldsymbol{\theta}^*,\delta t)}U\left(\boldsymbol{\theta}^*\right)\big]\ . \tag{B70}$$

Here σ_1 is the Pauli string associated with the first gate in the circuit $U(\boldsymbol{\theta})$ as defined in Eq. (4), $\rho_0 = |\psi_0\rangle\langle\psi_0|$ is an initial state before the time evolution and $\rho_{(\boldsymbol{\theta}^*,\delta t)} = e^{-iH\delta t}U(\boldsymbol{\theta}^*)\rho_0 U^\dagger(\boldsymbol{\theta}^*)e^{iH\delta t}$ with H being the underlying Hamiltonian of the quantum dynamics.

We now notice that if the perturbation r is chosen such that the following condition is satisfied

$$k_+^{M-1}\Delta_{\boldsymbol{\theta}^*} \geqslant 1 - k_+^{M-1}\ , \tag{B71}$$

then $\tilde{\xi} = -1$ minimises the lower bound which leads to

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}(\boldsymbol{\theta})\right] \geqslant (c_+ - k_+^2)\left(k_+^{M-1}\Delta_{\boldsymbol{\theta}^*} - (1-k_+^{M-1})\right)^2 \tag{B72}$$

$$= (c_+ - k_+^2)\left(k_+^{M-1}\,\mathrm{Tr}\left[(\rho_0 - \sigma_1\rho_0\sigma_1)\,U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*)\right] - (1-k_+^{M-1})\right)^2 \tag{B73}$$

$$= (c_+ - k_+^2)\left(k_+^{M-1}\left(F\left(\rho_{(\boldsymbol{\theta}^*,0)},\rho_{(\boldsymbol{\theta}^*,\delta t)}\right) - \mathrm{Tr}\left[U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}\right]+1\right)-1\right)^2\ , \tag{B74}$$

where $F(\rho,\rho') = \mathrm{Tr}[\rho\rho']$ is the fidelity between two pure states ρ and ρ', and

$$\rho_{(\boldsymbol{\theta}^*,\delta t)} = |\psi(\boldsymbol{\theta}^*,\delta t)\rangle\langle\psi(\boldsymbol{\theta}^*,\delta t)| = e^{-iH\delta t}U(\boldsymbol{\theta}^*)\rho_0U^\dagger(\boldsymbol{\theta}^*)e^{iH\delta t}\ . \tag{B75}$$

We note that the condition in Eq. (B71) can be equivalently expressed as

$$k_+^{M-1} \geqslant \frac{1}{1+\Delta_{\boldsymbol{\theta}^*}} = \frac{1}{1+\mathrm{Tr}\left[\left(\rho_0 - \sigma_1\rho_0\sigma_1\right)U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*)\ \right]}\ , \tag{B76}$$

where we explicitly expand $\Delta_{\boldsymbol{\theta}^*}$.

Crucially, for the majority of the rest of the proof, we aim to show that the condition in Eq. (B76) is satisfied if the perturbation is chosen such that

$$\frac{3r_0^2\left(1-4\lambda_{\max}^2\delta t^2\right)}{2(M-1)\left(1-2\lambda_{\max}^2\delta t^2\right)} \geqslant r^2\ , \tag{B77}$$

where r_0 is some constant within the range $0 < r_0 < 1$. In order to prove this, we first note the following bound of k_+^{M-1} which follows as

$$k_+^{M-1} = \left(\frac{1}{2r}\int_{-r}^{r} d\alpha\cos^2(\alpha)\right)^{M-1} \tag{B78}$$

$$= \left(\frac{1}{2}+\frac{\sin(2r)}{4r}\right)^{M-1} \tag{B79}$$

$$\geqslant \left(1-\frac{r^2}{3}\right)^{M-1} \tag{B80}$$

$$\geqslant 1-\frac{(M-1)r^2}{3} \tag{B81}$$

$$> 1-\frac{(M-1)r^2}{3r_0^2}\ , \tag{B82}$$

where the first inequality is by directly expanding the base and keeping only the second order term, the second inequality is due to Bernoulli's inequality and finally the last inequality holds because $0 < r_0 < 1$. We will come back to this inequality soon.

Now, the term $\mathrm{Tr}\left[\left(\rho_0 - \sigma_1\rho_0\sigma_1\right)U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*)\ \right]$ can be bounded as follows. Since $\rho_0 = \bigotimes_{j=1}^n \rho_j$ is a product state, we can choose σ_1 to be a single rotation around the axis such that $\mathrm{Tr}[\rho_0\sigma_1\rho_0\sigma_1] = 0$ [3], which leads to

$$\mathrm{Tr}\left[\rho_{(\boldsymbol{\theta}^*,0)}U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*)\right] = \mathrm{Tr}\left[\rho_0\sigma_1\rho_0\sigma_1\right] = 0\ . \tag{B83}$$

Then, we construct an orthonormal basis $\{|\phi_i\rangle\langle\phi_i|\}_{i=1}^{2^n}$ such that

$$|\phi_1\rangle\langle\phi_1| = \rho_{(\boldsymbol{\theta}^*,0)}\ , \tag{B84}$$

$$|\phi_2\rangle\langle\phi_2| = U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*)\ , \tag{B85}$$

and the rest are some other orthornormal states necessary to complete the basis. With this basis, we have the following bound

$$\mathrm{Tr}\left[\left(\rho_0 - \sigma_1\rho_0\sigma_1\right)U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*)\ \right] = F\left(\rho_{(\boldsymbol{\theta}^*,0)},\rho_{(\boldsymbol{\theta}^*,\delta t)}\right) - \mathrm{Tr}\left[|\phi_2\rangle\langle\phi_2|\rho_{(\boldsymbol{\theta}^*,\delta t)}\right] \tag{B86}$$

$$\geqslant F\left(\rho_{(\boldsymbol{\theta}^*,0)},\rho_{(\boldsymbol{\theta}^*,\delta t)}\right) - \sum_{i=2}^{2^n}\mathrm{Tr}\left[|\phi_i\rangle\langle\phi_i|\rho(\boldsymbol{\theta}^*,\delta t)\right] \tag{B87}$$

$$= 2F\left(\rho_{(\boldsymbol{\theta}^*,0)},\rho_{(\boldsymbol{\theta}^*,\delta t)}\right) - 1 \tag{B88}$$

$$\geqslant 1-4\lambda_{\max}^2\delta t^2\ , \tag{B89}$$

where the first equality is by writing the first term in the fidelity form and writing the second term in $|\phi_2\rangle\langle\phi_2|$ in Eq. (B85), in the first inequality we include terms corresponding to other basis (which holds since $\mathrm{Tr}[\rho|\phi_i\rangle\langle\phi_i|] \geqslant 0$

[3] For example, consider the all-zero basis state as an initial state $\rho_0 = |00...0\rangle\langle 00...0|$. We can pick the first generator as $\sigma_1 = X_1$.

for any ρ and $|\phi_i\rangle\langle\phi_i|$). Next, the second equality is from the completeness of the basis $\sum_{i=1}^{2^n}|\phi_i\rangle\langle\phi_i| = \mathbb{1}$, the last inequality is due to Lemma 5 with $\lambda_{\max}$ being the largest eigenvalue of H.

We note that in order for the lower bound in Eq. (B89) to be informative it is required that $1 \geqslant 4\lambda_{\max}^2\delta t^2$. Up on rearranging, this leads to the constraint on the time-step as

$$\frac{1}{2\lambda_{\max}} \geqslant \delta t \ , \tag{B90}$$

which is the condition specified in Eq. (B63). By assuming that the time-step satisfying the aforementioned constrain, we now proceed from Eq. (B89) by adding 1 to both sides and rearranging the terms which leads to

$$\frac{1}{2-4\lambda_{\max}^2\delta t^2} \geqslant \frac{1}{1+\mathrm{Tr}\left[\left(\rho_0-\sigma_1\rho_0\sigma_1\right)U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*)\ \right]} \ . \tag{B91}$$

We remark that the right-hand side of Eq. (B91) appears in the condition in Eq. (B76).

We are now ready to put everything together. Importantly, the condition in Eq. (B76) is satisfied if we enforce the left-hand side of Eq. (B82) to be larger than the right-hand side of Eq. (B91). That is, we have $k_+^{M-1} \geqslant \frac{1}{1+\mathrm{Tr}\left[\left(\rho_0-\sigma_1\rho_0\sigma_1\right)U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}U(\boldsymbol{\theta}^*)\ \right]}$ to be true if the following holds

$$1-\frac{(M-1)r^2}{3r_0^2} \geqslant \frac{1}{2-4\lambda_{\max}^2\delta t^2} \ . \tag{B92}$$

By rearranging the inequality in Eq. (B92), we have the perturbation regime of r to be Eq. (B77) as previously stated.

The last step is to bound the variance when r satisfies Eq. (B77). the variance of the loss in Eq. (B74) can be bounded as

$$\begin{aligned}
\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}(\boldsymbol{\theta})\right] &\geqslant (c_+-k_+^2)\left[k_+^{M-1}\left(F\left(\rho_{(\boldsymbol{\theta}^*,0)},\rho_{(\boldsymbol{\theta}^*,\delta t)}\right)-\mathrm{Tr}\left[U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}\right]+1\right)-1\right]^2 && \text{(B93)}\\
&\geqslant (c_+-k_+^2)\left[k_+^{M-1}\left(2-4\lambda_{\max}^2\delta t^2\right)-1\right]^2 && \text{(B94)}\\
&\geqslant (c_+-k_+^2)\left[\left(1-\frac{(M-1)r^2}{3}\right)\left(2-4\lambda_{\max}^2\delta t^2\right)-1\right]^2 && \text{(B95)}\\
&\geqslant (c_+-k_+^2)\left[(1-r_0^2)(1-4\lambda_{\max}^2\delta t^2)\right]^2 && \text{(B96)}\\
&\geqslant \frac{4r^4}{45}\left(1-\frac{4r^2}{7}\right)\left[(1-r_0^2)(1-4\lambda_{\max}^2\delta t^2)\right]^2 \ , && \text{(B97)}
\end{aligned}$$

where the second inequality is due to Eq. (B89), the third inequality is by bounding k_+^{M-1} with Eq. (B81) and in the next inequality we explicitly use the perturbation regime of r in Eq. (B77). To reach the last inequality, we directly bound $c_+-k_+^2 = \frac{1}{2r}\int_{-r}^{r}d\alpha\cos^4(\alpha)-\left(\frac{1}{2r}\int_{-r}^{r}d\alpha\cos^2(\alpha)\right)^2 \geqslant \frac{4r^4}{45}-\frac{16r^6}{315}$ by expanding it in the series and keeping the terms which result in the lower bound.

□

We now comment on the assumption that an initial state ρ_0 is a product state and discuss a possible extension to an arbitrary initial state. In essence, the product state assumption is used in the proof above to ensure that the term $\Delta_{\boldsymbol{\theta}^*}$ in Eq. (B4) is non-vanishing (see Eq. (B83) to Eq. (B89)). However, we argue here that our results should hold more generally for arbitrary initial states as long as the first gate interacts non-trivially with the loss. In particular, this happens for a small enough Trotter time-step δt as long as the first gate does not rotate ρ_0 into a subspace that is fully parallel to itself.

To illustrate this, we can expand $e^{-iH\delta t}$ and keep only the leading order in δt with an arbitrary non-product initial state. Since ρ_0 is no longer limited to be a product state, the orthornormal basis construction where $U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*)$ is chosen to be orthonormal to $\rho_{(\boldsymbol{\theta}^*,0)}$ (see Eq. (B83)) is no longer guaranteed. However, we can modify the steps slightly and decompose $U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*)$ into a parellel and a perpendicular component i.e.,

$$U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*) = \left(a\left|\phi_1\right\rangle+b\left|\phi_2\right\rangle\right)\left(\left\langle\phi_1\right|a^*+\left\langle\phi_2\right|b^*\right) \ , \tag{B98}$$

where $|\phi_1\rangle\langle\phi_1| = \rho_{(\boldsymbol{\theta}^*,0)}$, $|\phi_2\rangle\langle\phi_2|$ is orthonormal to $\rho_{(\boldsymbol{\theta}^*,0)}$, a and b are coefficients in the parallel and orthogonal directions such that $|a|, |b| \leqslant 1$. Then we can use Taylor's series to expand

$$\begin{aligned}\mathrm{Tr}\left[U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1 U^\dagger(\boldsymbol{\theta}^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}\right] &= \mathrm{Tr}\left[(a|\phi_1\rangle + b|\phi_2\rangle)(\langle\phi_1| a^* + \langle\phi_2| b^*)\rho_{(\boldsymbol{\theta}^*,\delta t)}\right] && \text{(B99)}\\ &= \mathrm{Tr}\left[(a|\phi_1\rangle + b|\phi_2\rangle)(\langle\phi_1| a^* + \langle\phi_2| b^*) e^{-iH\delta t}|\phi_1\rangle\langle\phi_1| e^{iH\delta t}\right] && \text{(B100)}\\ &= |a|^2 + \delta t\left(iab^*\langle\phi_1| H|\phi_2\rangle - ia^*b\langle\phi_2| H|\phi_1\rangle\right) + \mathcal{O}\big(\delta t^2\big)\ , && \text{(B101)}\end{aligned}$$

where, for the purpose of demonstration, we are only interested in the leading order in δt. Therefore with this we have that the term $\Delta_{\boldsymbol{\theta}^*}$ is

$$\Delta_{\boldsymbol{\theta}^*} = (1-|a|^2) + \delta t\left(iab^*\langle\phi_1| H|\phi_2\rangle - ia^*b\langle\phi_2| H|\phi_1\rangle\right) + \mathcal{O}\big(\delta t^2\big)\ . \tag{B102}$$

Hence, for $|a| \in \Omega(1/\operatorname{poly}(n))$ (which is expected to hold when the first gate does not commute with ρ_0) and small Trotter time-step $\delta t \ll 1$, one can follow the same proof steps which then results in the polynomial scaling of the loss variance in the hypercube with r scaling polynomially.

Appendix C: Proof convexity

Theorem 2 (Approximate convexity of the landscape, Formal)**.** *For a time-step of size*

$$\delta t \leqslant \frac{\mu_{\min} + 2|\epsilon|}{16M\lambda_{\max}}\ , \tag{C1}$$

the loss landscape is ϵ-convex in a hypercube of width $2r_c$ around a previous optimum $\boldsymbol{\theta}^*$ i.e., $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$ such that

$$r_c \geqslant \frac{1}{M}\left(\frac{\mu_{\min} + 2|\epsilon|}{16M} - \lambda_{\max}\delta t\right)\ , \tag{C2}$$

where $\mu_{\min}$ is the minimal eigenvalue of the Fisher information matrix associated with the loss.

Proof. We first recall that the region of the loss function is ϵ-convex (i.e., Definition 1) if all eigenvalues of the Hessian matrix of the loss function i.e., $\mathcal{L}(\boldsymbol{\theta}) = 1 - F\left[U(\boldsymbol{\theta})\rho_0 U^\dagger(\boldsymbol{\theta}), \rho(\boldsymbol{\theta}^*, \delta t)\right]$ within the region are larger than $-|\epsilon|$, which can be re-expressed in terms of the fidelity as

$$\left[\nabla^2_{\boldsymbol{\theta}} F\left(U(\boldsymbol{\theta})\rho_0 U^\dagger(\boldsymbol{\theta}), \rho(\boldsymbol{\theta}^*, \delta t)\right)\right]_{\max} \leqslant |\epsilon|\ , \tag{C3}$$

for all $\boldsymbol{\theta} \in \boldsymbol{\mathcal{V}}(\theta^*, r)$ with $[A]_{\max}$ being the largest eigenvalue of the matrix A.

By using Taylor's expansion around $\boldsymbol{\theta}^*$ (see Theorem 4), the fidelity can be written in the form of

$$F(\boldsymbol{x}) = 1 - \sum_{i,j}\frac{x_i x_j}{4}\mathcal{F}_{ij}(\boldsymbol{0}) + \sum_{i,j,k}\frac{x_i x_j x_k}{6}\left(\frac{\partial^3 F(\boldsymbol{x})}{\partial x_i\partial x_j\partial x_k}\right)\bigg|_{\boldsymbol{x}=\boldsymbol{\nu}}\ , \tag{C4}$$

where we introduce the shorthand notation of the fidelity around this region as $F(\boldsymbol{x})$ with $\boldsymbol{x} = (\boldsymbol{\theta} - \boldsymbol{\theta}^*, \delta t)$, $\mathcal{F}_{ij}(\boldsymbol{0})$ are elements of the quantum fisher information at $\boldsymbol{x} = \boldsymbol{0}$, and the last term is the result of the Taylor's remainder theorem with $\boldsymbol{\nu} = c\boldsymbol{x}$ for some $c \in [0,1]$.

For convenience, we denote $\mathcal{A}_{ijk}(\boldsymbol{x}) = \frac{\partial^3 F(\boldsymbol{x})}{\partial x_i\partial x_j\partial x_k}$. This third derivative can be expressed as a nested commutator of the form (for $k > j > i$)

$$\mathcal{A}_{ijk}(\boldsymbol{x}) := \frac{\partial^3 F(\boldsymbol{x})}{\partial x_i\partial x_j\partial x_k} = \mathrm{Tr}\left[U^{(M+1,k)}i\left[U^{(k,j)}i\left[U^{(j,i)}i\left[U^{(i,0)}\rho_0 U^{(i,0)\dagger}, \sigma_i\right]U^{(j,i)\dagger}, \sigma_j\right]U^{(k,j)\dagger}, \sigma_k\right]U^{(M+1,k)\dagger}\rho_{(\boldsymbol{\theta}^*,0)}\right]\ , \tag{C5}$$

where $U(\boldsymbol{x}) = U^{(M+1,k)}U^{(k,j)}U^{(j,i)}U^{(i,0)}$ with $U^{(a,b)} = \prod_{l=a+1}^{b} e^{-ix_l\sigma_l}\widetilde{V}_l$ such that $\sigma_{M+1} := H$ and $\widetilde{V}_{M+1} = \mathbb{1}$. For clarification we emphasise that the notation $\sigma_{M+1} := H$ does *not* imply that $H^2 = \mathbb{1}$, H is still a general Hamiltonian, but rather this is just a way of simplifying the notation. That is, $U(\boldsymbol{x})$ is decomposed into 4 sections e.g., $U^{(i,0)}$ contains the part of $U(\boldsymbol{\theta})$ from the first gate to the i^{th} gate.

Now, we consider an element of $\nabla^2_{\boldsymbol{\theta}} F\left(\boldsymbol{x}\right)$ which can be obtained by explicitly differentiating $F(\boldsymbol{x})$ in Eq. (C4) with respect to the variational parameters (i.e., x_l and x_m cannot be δt)

$$\frac{\partial^2 F(\boldsymbol{x})}{\partial x_l \partial x_m} = -\frac{1}{2}\mathcal{F}_{lm}(\boldsymbol{0}) + \frac{1}{6}\widetilde{\mathcal{A}}_{lm}(\boldsymbol{\nu}) \ , \tag{C6}$$

with

$$\widetilde{\mathcal{A}}_{lm}(\boldsymbol{\nu}) = \sum_{i=1}^{M+1} x_i \left(\mathcal{A}_{lmi}(\boldsymbol{\nu}) + \mathcal{A}_{lim}(\boldsymbol{\nu}) + \mathcal{A}_{ilm}(\boldsymbol{\nu}) + \mathcal{A}_{mli}(\boldsymbol{\nu}) + \mathcal{A}_{mil}(\boldsymbol{\nu}) + \mathcal{A}_{iml}(\boldsymbol{\nu})\right) \ , \tag{C7}$$

where we remark that here the sum includes the time component δt.

Now, the largest eigenvalue of $\nabla^2_{\boldsymbol{\theta}} F\left(\boldsymbol{x}\right)$ can be bounded as

$$\left[\nabla^2_{\boldsymbol{\theta}} F\left(\boldsymbol{x}\right)\right]_{\max} \leqslant -\frac{1}{2}\left[\mathcal{F}(\boldsymbol{0})\right]_{\min} + \frac{1}{6}[\widetilde{\mathcal{A}}(\boldsymbol{\nu})]_{\max} \ , \tag{C8}$$

where we denote $[A]_{\min}$ as the smallest eigenvalue of the matrix A.

In order to bound $[\widetilde{\mathcal{A}}(\boldsymbol{\nu})]_{\max}$, we first consider the bound on $\mathcal{A}_{ilm}(\boldsymbol{\nu})$

$$\mathcal{A}_{ilm}(\boldsymbol{\nu}) \leqslant |\mathcal{A}_{ilm}(\boldsymbol{\nu})| \tag{C9}$$

$$\leqslant \left\| U^{(M+1,m)} i \left[U^{(m,l)} i \left[U^{(l,i)} i \left[U^{(i,0)} \rho_0 U^{(i,0)^\dagger}, \sigma_i \right] U^{(l,i)^\dagger}, \sigma_l \right] U^{(m,l)^\dagger}, \sigma_m \right] U^{(M+1,m)^\dagger} \right\|_\infty \left\| \rho_{(\boldsymbol{\theta}^*,0)} \right\|_1 \tag{C10}$$

$$\leqslant 2^3 \|\sigma_i\|_\infty \|\sigma_l\|_\infty \|\sigma_m\|_\infty \tag{C11}$$

$$= 8\|\sigma_i\|_\infty \ . \tag{C12}$$

Here the second inequality is due to Hölder's inequality. In the third inequality we use a few identities including (i) the one-norm of a pure state is 1, (ii) $\|UA\|_p = \|A\|_p$ for any unitary U, (iii) $\|i[A,B]\|_p = 2\|A\|_p\|B\|_p$ and lastly (iv) $\|AB\|_p \leqslant \|A\|_p\|B\|_p$. To reach the final equality, we recall that since x_l and x_m cannot be a time component δt, σ_l and σ_m are generators of the circuit which have $\|\sigma_l\|_\infty = \|\sigma_m\|_\infty = 1$.

We now bound the sum of the absolute of elements in a row of $\widetilde{\mathcal{A}}(\boldsymbol{\nu})$ as

$$\sum_{m=1}^{M} \left|\widetilde{\mathcal{A}}_{lm}(\boldsymbol{\nu})\right| \leqslant \sum_{m=1}^{M}\sum_{i=1}^{M+1} |x_i| \left(|\mathcal{A}_{lmi}(\boldsymbol{\nu})| + |\mathcal{A}_{lim}(\boldsymbol{\nu})| + |\mathcal{A}_{ilm}(\boldsymbol{\nu})| + |\mathcal{A}_{mli}(\boldsymbol{\nu})| + |\mathcal{A}_{mil}(\boldsymbol{\nu})| + |\mathcal{A}_{iml}(\boldsymbol{\nu})|\right) \tag{C13}$$

$$\leqslant 48 \sum_{m=1}^{M}\sum_{i=1}^{M+1} |x_i| \|\sigma_i\|_\infty \tag{C14}$$

$$\leqslant 48M\left(\lambda_{\max}\delta t + Mr\right) \tag{C15}$$

By invoking Proposition 2, the largest eigenvalue of the matrix can then be bounded as

$$[\widetilde{\mathcal{A}}(\boldsymbol{\nu})]_{\max} \leqslant 48M\left(\lambda_{\max}\delta t + Mr\right) \ . \tag{C16}$$

Finally, we can guarantee the region of ϵ-convexity (i.e., Eq. (C3)) by enforcing the following condition

$$-\frac{1}{2}\left[\mathcal{F}(\boldsymbol{0})\right]_{\min} + 8M\left(\lambda_{\max}\delta t + Mr\right) \leqslant |\epsilon| \ . \tag{C17}$$

Upon rearranging the terms, we have

$$r \leqslant \frac{1}{M}\left(\frac{\mu_{\min} + 2|\epsilon|}{16M} - \lambda_{\max}\delta t\right) \ . \tag{C18}$$

Indeed, this implies that *any* hypercube $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$ such that r satisfies Eq. (C18) is guaranteed to be approximately convex. Hence, we know that the total ϵ-convex region has to be at least of size $\frac{1}{M}\left(\frac{\mu_{\min}+2|\epsilon|}{16M} - \lambda_{\max}\delta t\right)$. More explicitly, by denoting r_c to be the length of the total ϵ-approximate convex region $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$, we have

$$r_c \geqslant \frac{1}{M}\left(\frac{\mu_{\min} + 2|\epsilon|}{16M} - \lambda_{\max}\delta t\right) \ . \tag{C19}$$

We note that the bound is only informative if the Trotter time-step respects

$$\delta t \leqslant \frac{\mu_{\min} + 2|\epsilon|}{16M\lambda_{\max}} \ . \tag{C20}$$

This completes the proof of the theorem. □

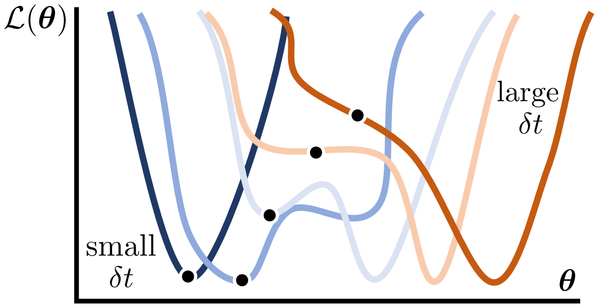

FIG. 7. **Adiabatic minima.** Here we show the adiabatic minima (highlighted in the black dots) as a function of the Trotter time-step δt. From dark blue to orange, we highlight how the loss function evolves with increasing δt. Indeed, when the time-step increases the adiabatic minima stops being the global minima. Then it turns into a saddle point and finally disappears to become a slope. As mentioned in the main text, when the adiabatic minima disappears it turns into a slope.

Appendix D: Adiabatic Moving Minima

In this section, we provide further analysis on the adiabatic moving minimum, including the proof of Theorem 3 and some some technical subtleties. We first recall the definition of the adiabatic minimum and also introduce a definition of the adiabatic shift.

Definition 2 (Adiabatic Minima)**.** *For any time δt in the range $[0, T]$, the function corresponding to the evolution of the adiabatic minima for some initial minimum $\boldsymbol{\theta}^*$, is a continuous function $\boldsymbol{\theta}_A(\delta t) \in C^\infty(\mathbb{R}, \mathbb{R}^m)$ such that $\boldsymbol{\theta}_A(0) = \boldsymbol{\theta}^*$ and*

$$\nabla_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta}_A(\delta t), \delta t) = \mathbf{0} \ . \tag{D1}$$

The adiabatic minimum at time δt is $\boldsymbol{\theta}_A(\delta t)$

Definition 4 (Adiabatic shift of the previous minima)**.** *The shift of the adiabatic minimum with respect to the previous optimal point is defined as*

$$\boldsymbol{\alpha}_A(\delta t) = \boldsymbol{\theta}_A(\delta t) - \boldsymbol{\theta}^* \ , \tag{D2}$$

and also respects

$$\nabla_{\boldsymbol{\alpha}} \mathcal{L}(\boldsymbol{\alpha}, \delta t)\big|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(\delta t)} = \mathbf{0} \ , \tag{D3}$$

for any time δt.

Intuitively, the adiabatic function corresponds to the minima one would converge to by increasing δt infinitely slowly and minimizing $\mathcal{L}(\boldsymbol{\theta}, \delta t)$ by gradient descent with a very small learning rate. By analogy, one can imagine dropping a marble in the initial minima and then slowly modifying the landscape by increasing δt. The position of the marble would correspond to our adiabatic minima and in practice it is where we expect our algorithm to converge.

Up to this point, there are two caveats that we would like to highlight. First, this adiabatic minimum is not necessarily the global minimum (as discussed in Section III E - there could potentially be a jump in the global minimum). The other subtlety is that the existence of the adiabatic minimum is not always guaranteed for increasing δt. This is highlighted in Figure 7. While for a small Trotter time-step one intuitively expects to have the adiabatic minimum, it is not certain whether we have this for large Trotter time-steps. That is, the adiabatic function can cease to be continuous beyond T (and in practice we do not in general know what T is). Crucially, the discontinuity in the adiabatic minimum path implies that zero gradients now turn into some slopes. Hence, the lack of a continuous adiabatic minimum does not necessarily imply untrainability.

With these caveats in mind, we proceed under the assumption that the adiabatic minimum exists within the Trotter time-step of our interest. We first present Proposition 4 which shows that the shift in the adiabatic minimum can be bounded with the Trotter time-step.

Proposition 4. *Given a Trotter time-step of the current iteration δt and assuming that the adiabatic minimum exists within this time frame, the shift of the adiabatic minimum $\boldsymbol{\alpha}_A(\delta t)$ as defined in Definition 4 can be bounded as*

$$\|\boldsymbol{\alpha}_A(\delta t)\|_2 \leqslant \frac{2\sqrt{M}\lambda_{\max}\delta t}{\beta_A} \ , \tag{D4}$$

where M is the number of parameters, $\lambda_{\max}$ is the largest eigenvalue of the dynamic Hamiltonian H and $\beta_A = \frac{\dot{\boldsymbol{\alpha}}_A^T(\delta t)\left(\nabla^2_{\boldsymbol{\alpha}}\mathcal{L}(\boldsymbol{\alpha},\delta t)\big|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(\delta t)}\right)\dot{\boldsymbol{\alpha}}_A(\delta t)}{\|\dot{\boldsymbol{\alpha}}_A(\delta t)\|_2^2}$.

Proof. We note that to improve readability of the proof it is more convenient here to use t to refer as a Trotter time-step (instead of δt as in other sections). We recall from Definition 4 that the adiabatic shift can be expressed as

$$\nabla_{\boldsymbol{\alpha}}\mathcal{L}(\boldsymbol{\alpha},t)\big|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(t)} = \mathbf{0}\ , \tag{D5}$$

which holds for *any* t. For convenience, we denote $\nabla_{\boldsymbol{\alpha}_A}\mathcal{L} := \nabla_{\boldsymbol{\alpha}}\mathcal{L}(\boldsymbol{\alpha},t)\big|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(t)}$. By a direct differentiation with respect to t, this leads to

$$\frac{d}{dt}\left(\nabla_{\boldsymbol{\alpha}_A}\mathcal{L}\right) = \partial_t\nabla_{\boldsymbol{\alpha}_A}\mathcal{L} + \left(\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}\right)\dot{\boldsymbol{\alpha}}_A = \mathbf{0}\ , \tag{D6}$$

where we denote $\partial_t = \partial/\partial t$ and $\dot{\boldsymbol{\alpha}}_A = d\boldsymbol{\alpha}_A(t)/dt$. We remark that $\left(\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}\right)\dot{\boldsymbol{\alpha}}_A$ is a matrix vector multiplication with $\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}$ a Hessian matrix evaluated at $\boldsymbol{\alpha}_A(t)$. By multiplying with $\frac{\dot{\boldsymbol{\alpha}}_A^T}{\|\dot{\boldsymbol{\alpha}}_A\|_2}$ from the left, we have

$$\frac{\dot{\boldsymbol{\alpha}}_A^T}{\|\dot{\boldsymbol{\alpha}}_A\|_2}\partial_t\nabla_{\boldsymbol{\alpha}_A}\mathcal{L} + \frac{\dot{\boldsymbol{\alpha}}_A^T\left(\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}\right)\dot{\boldsymbol{\alpha}}_A}{\|\dot{\boldsymbol{\alpha}}_A\|_2^2}\|\dot{\boldsymbol{\alpha}}_A\|_2 = 0\ . \tag{D7}$$

For convenience, we denote $\beta_A := \dot{\boldsymbol{\alpha}}_A^T\left(\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}\right)\dot{\boldsymbol{\alpha}}_A/\|\dot{\boldsymbol{\alpha}}_A\|_2^2$. By rearranging the terms, we can bound the norm of $\dot{\boldsymbol{\alpha}}_A(t)$ as

$$\begin{aligned}
\|\dot{\boldsymbol{\alpha}}_A(t)\|_2 &= \left\|-\frac{\dot{\boldsymbol{\alpha}}_A^T\partial_t\nabla_{\boldsymbol{\alpha}_A}\mathcal{L}}{\|\dot{\boldsymbol{\alpha}}_A\|_2\beta_A}\right\|_2 && \text{(D8)}\\
&\leqslant \frac{\|\partial_t\nabla_{\boldsymbol{\alpha}_A}\mathcal{L}\|_2}{\beta_A} && \text{(D9)}\\
&\leqslant \frac{\sqrt{M}\left|\partial_t\partial_{\alpha_A^{(i)}}\mathcal{L}\right|_{\max}}{\beta_A} && \text{(D10)}\\
&\leqslant \frac{2\sqrt{M}\lambda_{\max}}{\beta_A}\ , && \text{(D11)}
\end{aligned}$$

where the first inequality is due to Cauchy-Schwarz inequality, in the second inequality we expand the 2-norm out explicitly and take the largest value in the sum i.e., $\|\boldsymbol{a}\|_2 = \sqrt{\sum_{i=1}^M a_i^2} \leqslant \sqrt{M}|a_i|_{\max}$ with $\alpha_A^{(i)}$ being the i^{th} component of $\boldsymbol{\alpha}_A$. To reach the last inequality, we recall that the loss function is of the form $\mathcal{L}(\boldsymbol{\alpha},t) = 1 - \text{Tr}\left(e^{-iHt}\rho_{\boldsymbol{\theta}^*}e^{iHt}\rho_{\boldsymbol{\theta}}\right)$ where H is the dynamic Hamiltonian, $\rho_{\boldsymbol{\theta}^*}$ is the state corresponding to the solution of the previous iteration and $\rho_{\boldsymbol{\theta}}$ is the parametrized state that depends on $\boldsymbol{\alpha}$ and respects a parameter shift's rule. We can then bound the quantity of interest as

$$\begin{aligned}
\partial_t\partial_{\alpha_A^{(i)}}\mathcal{L} &= \frac{\partial}{\partial t}\left(\frac{\partial}{\partial\alpha^{(i)}}\mathcal{L}(\boldsymbol{\alpha},t)\right)\Bigg|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(t)} && \text{(D12)}\\
&= \frac{1}{2}\left(\frac{\partial}{\partial t}\mathcal{L}\left(\boldsymbol{\alpha}_A + \frac{\pi}{2}\hat{\alpha}_i\right) - \frac{\partial}{\partial t}\mathcal{L}\left(\boldsymbol{\alpha}_A - \frac{\pi}{2}\hat{\alpha}_i\right)\right) && \text{(D13)}\\
&= \frac{1}{2}\left(\text{Tr}\left(i[H, e^{-iHt}\rho_{\boldsymbol{\theta}^*}e^{iHt}]\rho_{\boldsymbol{\alpha}_{A,+}}\right) - \text{Tr}\left(i[H, e^{-iHt}\rho_{\boldsymbol{\theta}^*}e^{iHt}]\rho_{\boldsymbol{\alpha}_{A,-}}\right)\right) && \text{(D14)}\\
&\leqslant \left\|[H, e^{-iHt}\rho_{\boldsymbol{\theta}^*}e^{iHt}]\right\|_\infty && \text{(D15)}\\
&\leqslant 2\lambda_{\max}\ , && \text{(D16)}
\end{aligned}$$

where the second equality is due to a parameter shift's rule, in the third equality we perform the direct differentiation with t and denote $\boldsymbol{\alpha}_{A,+} = \boldsymbol{\alpha}_A + \frac{\pi}{2}\hat{\alpha}_i$ as well as $\boldsymbol{\alpha}_{A,-} = \boldsymbol{\alpha}_A - \frac{\pi}{2}\hat{\alpha}_i$. The first inequality is due to the triangle inequality followed by the Hölder's inequality with the fact that $\|\rho\|_1 = 1$ for any pure quantum state ρ. In the last inequality, we use $\|i[A,B]\|_p = 2\|A\|_p\|B\|_p$ and the unitary invariance of the p-norm $\|UA\|_p = \|A\|_p$ as well as $\|\rho\|_\infty = 1$ for any pure quantum state ρ.

Lastly, we can bound the shift of the adiabatic minimum as

$$\|\boldsymbol{\alpha}_A(t)\|_2 = \left\| \int_0^t \dot{\boldsymbol{\alpha}}_A(\tau) d\tau \right\|_2 \tag{D17}$$

$$\leqslant \int_0^t \|\dot{\boldsymbol{\alpha}}_A(\tau)\|_2 d\tau \tag{D18}$$

$$\leqslant \frac{2\sqrt{M}\lambda_{\max} t}{\beta_A} \,, \tag{D19}$$

which completes the proof.

□

Note that for the bound in Eq. D4 to be informative about the asymptotic scaling we require β_A to be at least polynomially small.

In order for the training to have convergence guarantees to the adiabatic minimum, we need to ensure that our time-step is small enough so that our *adiabatic minima* is inside of the trainable and convex regions. This is formalized in Theorem 3 which is presented in the main text and proved here.

Theorem 3 (Adiabatic minimum is within provably 'nice' region, Formal)**.** *If the time-step δt is chosen such that*

$$\delta t \leqslant \frac{\eta_0 \beta_A}{2M\lambda_{\max}} \,, \tag{D20}$$

with some small constant η_0, then the adiabatic minimum $\boldsymbol{\theta}_A(\delta t)$ is guaranteed to be within the non-vanishing gradient region (as per Theorem 1), and additionally, if δt is chosen such that

$$\delta t \leqslant \frac{\beta_A(\mu_{\min} + 2|\epsilon|)}{32\lambda_{\max} M^{5/2}\left(1 + \frac{\beta_A}{2M^{3/2}}\right)} \,. \tag{D21}$$

then the adiabatic minimum $\boldsymbol{\theta}_A(\delta t)$ is guaranteed to be within the ϵ-convex region (as per Theorem 2) where

$$\beta_A := \frac{\dot{\boldsymbol{\theta}}_A^T(\delta t)\left(\nabla^2_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta})\big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_A(\delta t)}\right)\dot{\boldsymbol{\theta}}_A(\delta t)}{\|\dot{\boldsymbol{\theta}}_A(\delta t)\|_2^2} \tag{D22}$$

corresponds to the second derivative of the loss in the direction in which the adiabatic minimum moves.

Proof. From Proposition 4 and the norm inequality, the adiabatic minimum follows

$$\|\boldsymbol{\alpha}_A(\delta t)\|_\infty \leqslant \|\boldsymbol{\alpha}_A(\delta t)\|_2 \leqslant \frac{2\sqrt{M}\lambda_{\max}\delta t}{\beta_A} \,. \tag{D23}$$

What we want now is to incorporate the conditions of the regions of interest. That is, by fine-tuning δt, we want a guarantee that the new minimum is within (i) the non-vanishing gradient region and (ii) the convex region.

For (i) the non-vanishing gradient region, we recall from the formal version of Theorem 1 that given the Trotter time-step bounded as $\delta t \leqslant 1/2\lambda_{\max}$, the hypercube of width $2r$ has the substantial non-vanishing gradients when r follows

$$r = \frac{\eta_0}{\sqrt{M}} \,, \tag{D24}$$

with some constant η_0. Then, it is sufficient to have the guarantee that the adiabatic minimum is inside this region by imposing

$$\|\boldsymbol{\alpha}_A(\delta t)\|_\infty \leqslant \frac{2\sqrt{M}\lambda_{\max}\delta t}{\beta_A} \leqslant \frac{\eta_0}{\sqrt{M}} \,, \tag{D25}$$

which leads to

$$\delta t \leqslant \frac{\eta_0 \beta_A}{2M\lambda_{\max}} \,. \tag{D26}$$

For (ii) the convex region, from Theorem 2, recall that given $\delta t \leqslant \frac{\mu_{\min}+2|\epsilon|}{16M\lambda_{\max}}$, we have an ϵ-convex hypercube region of width $2r_c$ such that

$$r_c \geqslant \frac{1}{M}\left(\frac{\mu_{\min}+2|\epsilon|}{16M} - \lambda_{\max}\delta t\right) \, . \tag{D27}$$

Therefore, it is sufficient to guarantee that the adiabatic minimum is inside this convex region by imposing

$$\|\boldsymbol{\alpha}_A(\delta t)\|_\infty \leqslant \frac{2\sqrt{M}\lambda_{\max}\delta t}{\beta_A} \leqslant \frac{1}{M}\left(\frac{\mu_{\min}+2|\epsilon|}{16M} - \lambda_{\max}\delta t\right) \leqslant r_c \, . \tag{D28}$$

Upon rearranging the terms, the time-step is bounded as

$$\delta t \leqslant \frac{\beta_A(\mu_{\min}+2|\epsilon|)}{32\lambda_{\max}M^{5/2}\left(1+\frac{\beta_A}{2M^{3/2}}\right)} \, . \tag{D29}$$

We remark that this bound in Eq. (D29) is much tighter than the bound in Theorem 2 (specified above). That is, to have such a guarantee, δt is relatively shorter.

□

Appendix E: Imaginary Time Evolution

1. Framework

The variational imaginary time evolution can be used to prepare ground states and thermal states [69–72]. In this section, we focus on a variational Trotter compression version of imaginary time evolution [36]. Most steps of the algorithm are identical to the real-time version described in the main text except we substitute $\delta t \to i\delta\tau$. This leads to $U = e^{i\delta t H} \to \mathcal{U} = e^{-\delta\tau H}$. One key technicality is to add a constraint such that the state after the evolution is forced to be normalised. That is, we have

$$|\psi_{\delta\tau}\rangle = \frac{1}{\sqrt{Z}} e^{-\delta\tau H}|\psi\rangle \tag{E1}$$

where $Z = \langle\psi| e^{-2\tau H}|\psi\rangle$. We remark that $|\psi_{\delta\tau}\rangle$ is now a valid *pure* quantum state and thus there is a unitary that prepares it. To have any chance of preparing the ground state via imaginary time evolution the initial state $|\psi\rangle$ must have a non-vanishing overlap with the ground state. If the initial state is instead a maximally entangled state, and imaginary time evolution is applied to only half the Bell state, then this approach can be used to prepare a thermal double field state (and thereby a thermal state). However, in what follows we will focus on ground state preparation.

In the variational Trotter compression approach for imaginary time evolution, one aims to iteratively learn $|\psi_{\delta\tau}\rangle$ with a parametrized quantum circuit $U(\boldsymbol{\theta})$ (with parameters initialized around the optimal parameter values obtained from the previous iteration). More explicitly, the loss function at each iteration is of the form

$$\mathcal{L}_{\text{ITE}}(\boldsymbol{\theta}) = \text{Tr}\left[U(\boldsymbol{\theta})\rho U^\dagger(\boldsymbol{\theta})\frac{1}{Z}e^{-\delta\tau}U(\boldsymbol{\theta}^*)\rho U^\dagger(\boldsymbol{\theta}^*)e^{-\delta\tau}\right] \, , \tag{E2}$$

where $\boldsymbol{\theta}^*$ are the optimal parameters from the previous iteration. For details on how to compute this loss in practise see Ref. [36]. We further suppose that the parametrised quantum circuit is of the same form used in the real-time case i.e.,

$$U(\boldsymbol{\theta}) = \prod_{i=1}^{M} V_i U_i(\theta_i) \tag{E3}$$

where $\{V_i\}_{i=1}^M$ are a set of fixed unitary matrices, $\left\{U_i(\theta_i) = e^{-i\theta_i\sigma_i}\right\}_{i=1}^M$, are the parameter-dependant rotations, and $\{\sigma_i\}_{i=1}^M$ is a set of gate generators such that $\sigma_i^2 = \mathbb{1}$ e.g., Pauli strings on n qubits. Crucially, it is natural to consider the parameter initialization around $\boldsymbol{\theta}^*$ i.e.,

$$\boldsymbol{\theta} \sim \boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*, r) \, , \tag{E4}$$

with r being some small perturbation.

2. Summary of analytical results for imaginary time evolution

Here we summarize analytical results similar to those obtained for the real time evolution scenario. These include the existence of the non-vanishing gradient region with the warm-start initialization, the guarantee of the approximate convex region as well as the analysis on the adiabatic minimum. We note that the derivations of these results follow the same steps as in the case of the real-time evolution and are provided in Appendix E 3 for the completeness.

First, we show that the region around the optimal solution of the previous iteration exhibits substantial gradients. More precisely, the following theorem demonstrates the polynomial large variance of the loss function within in a small hypercube around the starting point. This theorem is similar to Theorem 1 (as discussed in Section III B of the main text).

Theorem 4 (Lower-bound on the loss variance for imaginary time evolution, Informal)**.** *Assume a product initial state $\rho_0 = \bigotimes_{j=1}^{n} \rho_j$ with ρ_j and let us choose σ_1 such that $\mathrm{Tr}[\rho_0\sigma_1\rho_0\sigma_1] = 0$. Given that the imaginary Trotter time-step scales as $\delta\tau \leqslant \frac{1}{\sqrt{24}\lambda_{\max}}$ where $\lambda_{\max}$ is the largest eigenvalue of H and we consider a hypercube of width $2r$ such that*

$$r = \Theta\left(\frac{1}{\sqrt{M}}\right) , \tag{E5}$$

the variance at any iteration of the variational compression algorithm is lower bounded as

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})\right] \in \Omega\left(\frac{1}{M}\right) . \tag{E6}$$

Thus, for $M \in \mathcal{O}(\mathrm{poly}(n))$, then we have

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})\right] \in \Omega\left(\frac{1}{\mathrm{poly}(n)}\right) . \tag{E7}$$

Next, we can ensure that for a sufficiently small time-step the loss landscape around the optimal solution of the previous iteration is $|\epsilon|$-convex. We refer the readers to Appendix A 3 for the definition of the $|\epsilon|$-convexity. This result is an imaginary time evolution version of Theorem 2 discussed in Section III C.

Theorem 5 (Approximate convexity of the landscape for imaginary time evolution, Informal.)**.** *For a time-step of size*

$$\delta\tau \in \mathcal{O}\left(\frac{\mu_{\min} + 2|\epsilon|}{M\lambda_{\max}}\right) \tag{E8}$$

the loss landscape is ϵ-convex in a hypercube of width $2r_c$ around a previous optimum $\boldsymbol{\theta}^*$ i.e., $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$ such that

$$r_c \in \Omega\left(\frac{\mu_{\min} + 2|\epsilon|}{16M^2} - 3\lambda_{\max}\delta\tau\right) \tag{E9}$$

where $\mu_{\min}$ is the minimal eigenvalue of the Fisher information matrix associated with the loss at $\boldsymbol{\theta}^*$.

A similar result on the adiabatic minimum in Theorem 3 can also be analytically obtained. Assuming the adiabatic minimum exists within our time interval of interest, we present below the scaling of imaginary time-step such that the adiabatic minimum is in the region with substantial gradients and in the convex region. We refer the readers to Section III D and Appendix D for the refresher of the adiabatic minimum.

Theorem 6 (Adiabatic minimum is within provably 'nice' region for imaginary time evolution, Informal)**.** *If the imaginary time-step $\delta\tau$ is chosen such that*

$$\delta\tau \in \mathcal{O}\left(\frac{\beta_A}{M\lambda_{\max}}\right) , \tag{E10}$$

then the adiabatic minimum $\boldsymbol{\theta}_A(\delta\tau)$ is guaranteed to be within the non-vanishing gradient region (as per Theorem 4), and additionally, if $\delta\tau$ is chosen such that

$$\delta\tau \in \mathcal{O}\left(\frac{\beta_A(\mu_{\min} + 2|\epsilon|)}{M^{5/2}\lambda_{\max}}\right) \tag{E11}$$

then the adiabatic minimum $\boldsymbol{\theta}_A(\delta\tau)$ is guaranteed to be within the ϵ-convex region (as per Theorem 5) where

$$\beta_A := \frac{\dot{\boldsymbol{\theta}}_A^T(\delta\tau)\left(\nabla^2_{\boldsymbol{\theta}}\mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})\big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_A(\delta\tau)}\right)\dot{\boldsymbol{\theta}}_A(\delta\tau)}{\|\dot{\boldsymbol{\theta}}_A(\delta\tau)\|_2^2} \tag{E12}$$

corresponds to the second derivative of the loss in the direction in which the adiabatic minimum moves.

Finally, it is crucial to note that the discussion about the minimum jumps and the potential existence of the fertile valley in Section III E is also applicable to imaginary time evolution.

3. Proof of analytical results

In this section, we analytically derive the analytical results presented in the previous sub-section. Again, these derivations are identical to the ones presented in Appendix B, Appendix C and Appendix D. We present them again here for completeness and the readers are also encouraged to look at those relevant appendices.

a. Bound on the variance of the landscape: Proof of Theorem 4

First, we introduce the equivalent version of Lemma 5 for imaginary time evolution.

Lemma 7. *The fidelity between two pure states ρ and $\rho_\tau = \frac{1}{Z}e^{-H\tau}\rho e^{-H\tau}$ with $Z = \mathrm{Tr}\left(e^{-H\tau}\rho e^{-H\tau}\right)$ can be upper bounded as*

$$F\left[\rho, \rho_\tau\right] \geqslant 1 - 12\lambda_{\max}^2\tau^2 \tag{E13}$$

where $\lambda_{\max}$ is the largest eigenvalue of H.

Proof. First, the derivative of the loss function with respect to time can be written as

$$\frac{d\rho_\tau}{dt} = -\{\rho_\tau, H\} + 2\,\mathrm{Tr}(H\rho_\tau)\rho_\tau\ , \tag{E14}$$

where $\{\cdot,\cdot\}$ is an anti-commutator.

Now we can use a Taylor's expansion around $\tau = 0$, and then the fidelity is of the form

$$F\left[\rho, \rho_\tau\right] = 1 + \frac{\tau^2}{2}\left(\frac{d^2F\left[\rho,\rho_\tau\right]}{d\tau^2}\right)\Bigg|_{\tau=\tau'} \tag{E15}$$

where the zero order term is 1, the first order term is zero by a direct computation and the second order term is evaluated at $\tau' \in [0,\tau]$ by Taylor's remainder (see Theorem 4). Thus we can bound the second derivative as follows.

$$\begin{aligned}\left(\frac{d^2F\left[\rho,\rho_\tau\right]}{d\tau^2}\right)\Bigg|_{\tau=\tau'} &= 2\mathrm{Re}\left[\mathrm{Tr}\left(\rho\rho_\tau H^2\right)\right] + 2\,\mathrm{Tr}(\rho H\rho_\tau H) - 8\,\mathrm{Tr}(H\rho_\tau)\mathrm{Re}[\mathrm{Tr}(\rho\rho_\tau H)] - 4\,\mathrm{Tr}\left(H^2\rho_\tau\right)\mathrm{Tr}(\rho\rho_\tau) \quad \text{(E16)}\\ &\quad + 8\,\mathrm{Tr}(\rho_\tau H)^2\,\mathrm{Tr}(\rho_\tau\rho)\\ &\leqslant 24\lambda_{\max}^2 \quad \text{(E17)}\end{aligned}$$

where in the inequality is due to (i) Hölder's inequality, (ii) $\|\rho\|_1 = 1$ for any pure quantum state ρ, (iii) $\|AB\|_p \leqslant \|A\|_p\|B\|_p$. More precisely, we used the following bounds to reach Eq. (E17)

$$\mathrm{Tr}\left(\rho\rho_\tau H^2\right) \leqslant ||\rho||_1||\rho_\tau H^2||_\infty \leqslant \lambda_{\max}^2 \tag{E18}$$

$$\mathrm{Tr}(\rho H\rho_\tau H) \leqslant ||\rho||_1||\rho_\tau H^2||_\infty \leqslant \lambda_{\max}^2 \tag{E19}$$

$$\mathrm{Tr}(\rho\rho_\tau H) \leqslant ||\rho||_1||\rho_\tau H||_\infty \leqslant \lambda_{\max} \tag{E20}$$

$$\mathrm{Tr}(H\rho_\tau) \leqslant \lambda_{\max} \tag{E21}$$

$$\mathrm{Tr}\left(H^2\rho_\tau\right) \leqslant \lambda_{\max}^2 \tag{E22}$$

$$\mathrm{Tr}(\rho_\tau\rho) \leqslant 1 \tag{E23}$$

Lastly, we can just substitute Eq. (E17) back to Eq. (E15) and obtain

$$F\left[\rho, \rho_\tau\right] \geqslant 1 - 12\tau^2\lambda_{\max}^2 \, , \tag{E24}$$

which completes the proof. □

We now present the formal version of Theorem 4 and provide a detailed proof.

Theorem 4 (Lower-bound on the loss variance for imaginary time evolution, Formal)**.** *Assume a product initial state $\rho_0 = \bigotimes_{j=1}^n \rho_j$ with ρ_j and let us choose σ_1 such that $\mathrm{Tr}[\rho_0\sigma_1\rho_0\sigma_1] = 0$. Given that the Trotter time-step $\delta\tau$ respects*

$$\frac{1}{\sqrt{24}\lambda_{\max}} \geqslant \delta\tau \, , \tag{E25}$$

where $\lambda_{\max}$ is the largest eigenvalue of H as well as the perturbation r follows

$$r^2 \leqslant \frac{3r_0^2(1 - 24\lambda_{\max}^2\delta\tau^2)}{2(M-1)(1 - 12\lambda_{\max}^2\delta\tau^2)} \, , \tag{E26}$$

with some r_0 such that $0 < r_0 < 1$, then the variance of the loss function within the region $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$ is lower bounded as

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})\right] \geqslant \frac{4r^2}{45}\left[(1 - r_0)(1 - 24\lambda_{\max}^2\delta\tau^2)\right]^2 \, . \tag{E27}$$

In addition, by choosing r such that $r \in \Theta\left(\frac{1}{\sqrt{M}}\right)$, then we have

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}\left[\mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})\right] \in \Omega\left(\frac{1}{M}\right) \, . \tag{E28}$$

Proof. First, we note that Proposition 1 in Appendix B also applies for the imaginary time evolution. This is since all the proof steps in Proposition 1 hold when replacing $i\delta t \to \delta\tau$ and $\mathcal{L}(\boldsymbol{\theta}) \to \mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})$. Hence, this proof starts by recalling Proposition 1

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}[\mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})] \geqslant \; (c_+ - k_+^2) \min_{\tilde{\xi}\in[-1,1]} \left(k_+^{M-1}\Delta_{\boldsymbol{\theta}^*} + (1 - k_+^{M-1})\tilde{\xi}\right)^2 , \tag{E29}$$

where the quantities in the bound above are

$$c_+ := \mathbb{E}_{\alpha\sim\boldsymbol{\mathcal{D}}(0,r)}[\cos^4\alpha] \, , \tag{E30}$$

$$k_+ := \mathbb{E}_{\alpha\sim\boldsymbol{\mathcal{D}}(0,r)}[\cos^2\alpha] \, , \tag{E31}$$

$$\Delta_{\boldsymbol{\theta}^*} := \mathrm{Tr}\big[(\rho_0 - \sigma_1\rho_0\sigma_1)U^\dagger\left(\boldsymbol{\theta^*}\right)\rho_{(\boldsymbol{\theta}^*,\delta\tau)}U\left(\boldsymbol{\theta^*}\right)\big] \, , \tag{E32}$$

$$\rho_{(\boldsymbol{\theta}^*,\delta\tau)} = \frac{1}{Z}e^{-H\delta\tau}U\left(\boldsymbol{\theta}^*\right)\rho_0 U^\dagger\left(\boldsymbol{\theta}^*\right)e^{-H\delta\tau} \, , \tag{E33}$$

$$Z = \mathrm{Tr}\left[e^{-H\delta\tau}U\left(\boldsymbol{\theta}^*\right)\rho_0 U^\dagger\left(\boldsymbol{\theta}^*\right)e^{-H\delta\tau}\right] \, . \tag{E34}$$

with σ_1 being the first (non commuting) gate of the ansatz and ρ_0 is the initial state.

Importantly, we notice that if the perturbation r is chosen such that the following condition is satisfied

$$k_+^{M-1}\Delta_{\boldsymbol{\theta}^*} \geqslant (1 - k_+^{M-1}) \tag{E35}$$

then $\hat{\xi} = -1$ minimises the variance lower bound in Eq. (E29) which leads to

$$\mathrm{Var}_{\boldsymbol{\theta}\sim\boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*,r)}[\mathcal{L}(\boldsymbol{\theta})] \geqslant \; (c_+ - k_+^2)\left(k_+^{M-1}(\Delta_{\boldsymbol{\theta}^*} + 1) - 1\right)^2 , \tag{E36}$$

Now, we focus now on $\Delta_{\boldsymbol{\theta}^*}$ which can be expressed as

$$\begin{aligned}\Delta_{\boldsymbol{\theta}^*} :=& \,\mathrm{Tr}\big[(\rho_0 - \sigma_1\rho_0\sigma_1)U^\dagger\left(\boldsymbol{\theta^*}\right)\rho_{(\boldsymbol{\theta}^*,\delta\tau)}U\left(\boldsymbol{\theta^*}\right)\big] & \text{(E37)}\\ =& F(\rho_{(\boldsymbol{\theta}^*,0)}, \rho_{(\boldsymbol{\theta}^*,\delta\tau)}) - \mathrm{Tr}\left[\sigma_1\rho_0\sigma_1 U^\dagger\left(\boldsymbol{\theta^*}\right)\rho_{(\boldsymbol{\theta}^*,\delta\tau)}U\left(\boldsymbol{\theta^*}\right)\right] & \text{(E38)}\end{aligned}$$

where we have the fidelity $F(\rho_{(\boldsymbol{\theta}^*,0)}, \rho_{(\boldsymbol{\theta}^*,\delta\tau)}) = \mathrm{Tr}\big(\rho_{(\boldsymbol{\theta}^*,0)}\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\big)$. Since $\rho_0 = \bigotimes_{j=1}^n \rho_j$ is a product state, we can choose σ_1 to be a single rotation around the axis such that $\mathrm{Tr}[\rho_0\sigma_1\rho_0\sigma_1] = 0$ which also implies

$$\mathrm{Tr}\left[\rho_{(\boldsymbol{\theta}^*,0)}U(\boldsymbol{\theta}^*)\sigma_1\rho_0\sigma_1U^\dagger(\boldsymbol{\theta}^*)\right] = \mathrm{Tr}\left[\rho_0\sigma_1\rho_0\sigma_1\right] = 0\,. \tag{E39}$$

Then, we define an orthonormal $\{\phi_i := |\phi_i\rangle\langle\phi_i|\}_{i=1}^{2^n}$ basis as

$$\phi_1 = \rho_{(\boldsymbol{\theta}^*,0)}\ , \tag{E40}$$

$$\phi_2 = U\left(\boldsymbol{\theta}^*\right)\sigma_1\rho_0\sigma_1U^\dagger\left(\boldsymbol{\theta}^*\right)\ , \tag{E41}$$

and other $\{\phi_i\}$ are necessary orthornormal states to complete the basis. We can upper bound the second term on the right hand side of Eq. (E37) as

$$\mathrm{Tr}\left[\sigma_1\rho_0\sigma_1U^\dagger\left(\boldsymbol{\theta}^*\right)\rho_{(\boldsymbol{\theta}^*,\delta\tau)}U\left(\boldsymbol{\theta}^*\right)\right] = \mathrm{Tr}\left(\phi_2\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\right) \tag{E42}$$

$$\leqslant \sum_{i=2}^{2^n}\mathrm{Tr}\left(\phi_i\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\right) \tag{E43}$$

$$= \mathrm{Tr}\left[(\mathbb{1}-\phi_1)\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\right] \tag{E44}$$

$$= F(\rho_{(\boldsymbol{\theta}^*,0)}, \rho_{(\boldsymbol{\theta}^*,\delta\tau)}) - 1 \tag{E45}$$

where in the inequality we add terms corresponding to other basis which holds because the trace of positive matrices is positive and in Eq. (E44) we use the fact that $\sum_i \phi_i = \mathbb{1}$.

With this we can lower-bound $\Delta_{\boldsymbol{\theta}^*}$ as follows

$$\Delta_{\boldsymbol{\theta}^*} \geqslant 2F(\rho_{(\boldsymbol{\theta}^*,0)}, \rho_{(\boldsymbol{\theta}^*,\delta\tau)}) - 1 \tag{E46}$$

$$\geqslant 1 - 24\lambda_{\mathrm{max}}^2\delta\tau^2 \tag{E47}$$

where we have used Lemma 7 in the last inequality. We remark that the bound in Eq. (E47) can be equivalently expressed as

$$\frac{1}{2-24\lambda_{\mathrm{max}}^2\delta\tau^2} \geqslant \frac{1}{1+\Delta_{\boldsymbol{\theta}^*}}\,. \tag{E48}$$

Importantly, for this bound to be informative (i.e., non-negative), we require the constrain on $\delta\tau$ as

$$\frac{1}{\sqrt{24}\lambda_{\mathrm{max}}} \geqslant \delta\tau\,. \tag{E49}$$

In this next step, we show how the condition in Eq. (E35) can be fulfilled. We note that the condition can be equivalently expressed as

$$k_+^{M-1} \geqslant \frac{1}{1+\Delta_{\boldsymbol{\theta}^*}} \tag{E50}$$

We consider the bound of k_+^{M-1} which follows as

$$k_+^{M-1} = \left(\frac{1}{2r}\int_{-r}^{r} d\alpha\cos^2(\alpha)\right)^{M-1} \tag{E51}$$

$$= \left(\frac{1}{2}+\frac{\sin(2r)}{4r}\right)^{M-1} \tag{E52}$$

$$\geqslant \left(1-\frac{r^2}{3}\right)^{M-1} \tag{E53}$$

$$\geqslant 1-\frac{(M-1)r^2}{3} \tag{E54}$$

$$> 1-\frac{(M-1)r^2}{3r_0^2}\ , \tag{E55}$$

where the first inequality is by directly expanding the base and keeping only the second order term, the second inequality is due to Bernoulli's inequality and finally the last inequality holds because $0 < r_0 < 1$.

With this we can see that the condition in Eq. (E50) holds if the right hand side of Eq. (E55) is larger then the left hand side of Eq. (E48) i.e.,

$$1 - \frac{(M-1)r^2}{3r_0^2} > \frac{1}{2 - 24\lambda_{\max}^2 \delta\tau^2} \quad \Rightarrow \quad k_+^{M-1} \geqslant \frac{1}{1 + \Delta_{\boldsymbol{\theta}^*}} \ . \tag{E56}$$

By rearranging Eq. (E56), we find the bound on the perturbation r as

$$r^2 \leqslant \frac{3r_0^2(1 - 24\lambda_{\max}^2\delta\tau^2)}{2(M-1)(1 - 12\lambda_{\max}^2\delta\tau^2)} \tag{E57}$$

.

By enforcing the condition of the perturbation in Eq. (E57), the variance can be lower-bounded further from Eq. (E36) as

$$\begin{aligned}
\mathrm{Var}_{\boldsymbol{\theta} \sim \boldsymbol{\mathcal{D}}(\boldsymbol{\theta}^*, r)}[\mathcal{L}(\boldsymbol{\theta})] \geqslant & \, (c_+ - k_+^2)\left[k_+^{M-1}(\Delta_{\boldsymbol{\theta}^*} + 1) - 1\right]^2 & \text{(E58)} \\
\geqslant & (c_+ - k_+^2)\left[\left(1 - \frac{(M-1)r^2}{3}\right)(2 - 24\lambda_{\max}^2\delta\tau^2) - 1\right]^2 & \text{(E59)} \\
\geqslant & \, (c_+ - k_+^2)\left[(1 - r_0^2)(1 - 24\lambda_{\max}^2\delta\tau^2)\right]^2 & \text{(E60)} \\
\geqslant & \frac{4r^4}{45}\left[(1 - r_0^2)(1 - 24\lambda_{\max}^2\delta\tau^2)\right]^2 \ , & \text{(E61)}
\end{aligned}$$

where the second inequality is due to Eq. (E47) and Eq. (E54), the third inequality is by the condition on r in Eq. (E57). To reach the last inequality, we directly bound $c_+ - k_+^2 = \frac{1}{2r}\int_{-r}^{r} d\alpha \cos^4(\alpha) - \left(\frac{1}{2r}\int_{-r}^{r} d\alpha \cos^2(\alpha)\right)^2 \geqslant \frac{4r^4}{45} - \frac{16r^6}{315}$ by expanding it in the series and keeping the terms which result in the lower bound. This completes the proof.

□

b. Convexity guarantee: Proof of Theorem 5

We devote this subsection to prove Theorem 5 which shows the convexity of the loss landscape for imaginary time evolution.

Theorem 5 (Approximate convexity of the landscape for imaginary time evolution, Formal)**.** *Given that the dynamic imaginary time follows*

$$\delta\tau \leqslant \frac{\mu_{\min} + 2|\epsilon|}{48M\lambda_{\max}} \ , \tag{E62}$$

the loss landscape is ϵ-convex in a hypercube of width $2r_c$ around a previous optimum $\boldsymbol{\theta}^*$ i.e., $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$ such that

$$r_c \geqslant \frac{1}{M}\left(\frac{\mu_{\min} + 2|\epsilon|}{16M} - 3\lambda_{\max}\delta\tau\right) \tag{E63}$$

where $\mu_{\min}$ is the minimal eigenvalue of the Fisher information matrix associated with the loss.

Proof. We first recall that the region of the loss function is ϵ-convex (i.e., Definition 1) if all eigenvalues of the Hessian matrix within the region are larger than $-|\epsilon|$, which can be re-expressed in terms of the fidelity as

$$\left[\nabla_{\boldsymbol{\theta}}^2 F\left(U(\boldsymbol{\theta})\rho_0 U^\dagger(\boldsymbol{\theta}), \rho_{(\boldsymbol{\theta}^*, \delta\tau)}\right)\right]_{\max} \leqslant |\epsilon| \ , \tag{E64}$$

for all $\boldsymbol{\theta} \in \boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$.

By using Taylor's expansion around $\boldsymbol{\theta}^*$ and Taylor reminder theorem (explained in Appendix A 2), we can write the fidelity like

$$F(\boldsymbol{x}) = 1 - \sum_{i,j} \frac{x_i x_j}{4}\mathcal{F}_{ij}(\boldsymbol{0}) + \sum_{i,j,k} \frac{x_i x_j x_k}{6}\left(\frac{\partial^3 F(\boldsymbol{x})}{\partial x_i \partial x_j \partial x_k}\right)\Bigg|_{\boldsymbol{x} = \boldsymbol{\nu}} \ , \tag{E65}$$

where we introduce the shorthand notation of the fidelity around this region as $F(\boldsymbol{x})$ with $\boldsymbol{x} = (\boldsymbol{\theta} - \boldsymbol{\theta}^*, \delta\tau)$, $\mathcal{F}_{ij}(\mathbf{0})$ are elements of the Quantum Fisher Information matrix at $\boldsymbol{x} = \mathbf{0}$, and the last term is the result of the Taylor's remainder theorem with $\boldsymbol{\nu} = c\boldsymbol{x}$ such that $c \in [0, 1]$. We remark that by this notation of $\boldsymbol{x}$ the imaginary time component is the last component of $\boldsymbol{x}$ i.e., $x_{M+1} = \delta\tau$.

A third order derivative in the last term when taken only with respect to the parameters $\boldsymbol{\theta}$ (i.e., no $\delta\tau$ component) can be expressed as (which is the same fashion as in Eq. (E14) for the real time dynamic case)

$$\frac{\partial^3 F(\boldsymbol{x})}{\partial\theta_i\partial\theta_j\partial\theta_k} = \frac{1}{Z}\operatorname{Tr}\left\{e^{-\delta\tau H}U^{(M,k)}i\left[U^{(k,j)}i\left[U^{(j,i)}i\left[U^{(i,0)}\rho_0 U^{(i,0)\dagger}, \sigma_i\right]U^{(j,i)\dagger}, \sigma_j\right]U^{(k,j)\dagger}, \sigma_k\right]U^{(M,k)\dagger}e^{-\delta\tau H}\rho_{(\boldsymbol{\theta}^*,0)}\right\}, \tag{E66}$$

where $U(\boldsymbol{\theta}) = U^{(M,k)}U^{(k,j)}U^{(j,i)}U^{(i,0)}$ with $U^{(a,b)} = \prod_{l=a+1}^{b} e^{-ix_l\sigma_l}\widetilde{V}_l$ (for $b < M+1$).

When the third derivative is taken with respect to the imaginary time in of the components, by direct calculation we have

$$\frac{\partial^3 F(\boldsymbol{x})}{\partial\theta_i\partial\theta_j\partial\tau} = \operatorname{Tr}\left[-\rho_{(\boldsymbol{\theta}^*,0)}\{\mathcal{B}_{i,j}, H\} + 2\operatorname{Tr}[H\mathcal{B}_{i,j}]\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\rho_{(\boldsymbol{\theta}^*,0)} + 2\operatorname{Tr}\left[\rho_{(\boldsymbol{\theta}^*,\delta\tau)}H\right]\mathcal{B}_{i,j}\rho_{(\boldsymbol{\theta}^*,0)}\right] \tag{E67}$$

where we defined $\mathcal{B}_{i,j} = \frac{\partial^2\rho_{(\boldsymbol{\theta}^*,\delta\tau)}}{\partial\theta_i\partial\theta_j}$ which can be written as a nested commutator as

$$\mathcal{B}_{i,j} = \frac{1}{Z}\operatorname{Tr}\left\{e^{-\tau H}U^{(M,k)}i\left[U^{(k,i)}i\left[U^{(i,0)}\rho_0 U^{(i,0)\dagger}, \sigma_i\right]U^{(j,i)\dagger}, \sigma_j\right]U^{(M,j)\dagger}e^{-\tau H}\rho_{(\boldsymbol{\theta}^*,0)}\right\}. \tag{E68}$$

We note that the other third derivative terms with respect to the imaginary time in more than one components can be also be expressed in a similar way. However, since they are not important in our analysis, we do not write them explicitly. Indeed, if we now compute the Hessian matrix of $F(\boldsymbol{x})$ with respect to the variational parameters $\boldsymbol{\theta}$, all the terms with higher derivatives in time will be 0.

We now focus on one element of this hessian matrix $\nabla^2_{\boldsymbol{\theta}}F(\boldsymbol{x})$ (recall that $\boldsymbol{x} = (\boldsymbol{\theta} - \boldsymbol{\theta}^*, \tau)$). For convenience, we denote $\mathcal{A}_{i,j,k}(\boldsymbol{x}) = \frac{\partial^3 F(\boldsymbol{x})}{\partial x_i\partial x_j\partial x_k}$. By direct compuation, we see that

$$\frac{\partial^2 F(x)}{\partial\theta_i\partial\theta_j} = -\frac{1}{2}\mathcal{F}_{j,k}(\mathbf{0}) + \frac{1}{6}\widetilde{\mathcal{A}}_{j,k}(\nu) \tag{E69}$$

with

$$\widetilde{\mathcal{A}}_{j,k}(\boldsymbol{\nu}) = \sum_{i=1}^{M+1} x_i\left(\mathcal{A}_{j,k,i}(\boldsymbol{\nu}) + \mathcal{A}_{j,i,k}(\boldsymbol{\nu}) + \mathcal{A}_{i,j,k}(\boldsymbol{\nu}) + \mathcal{A}_{k,j,i}(\boldsymbol{\nu}) + \mathcal{A}_{k,i,j}(\boldsymbol{\nu}) + \mathcal{A}_{i,k,j}(\boldsymbol{\nu})\right), \tag{E70}$$

where we remark that the sum up to $M+1$ is because $\delta\tau$ is included in this sum.

Thus, the largest eigenvalue of $\nabla^2_{\boldsymbol{\theta}}F(\boldsymbol{x})$ can be bounded as follows

$$\left[\nabla^2_{\boldsymbol{\theta}}F(\boldsymbol{x})\right]_{\max} \leqslant -\frac{1}{2}\left[\mathcal{F}(\mathbf{0})\right]_{\min} + \frac{1}{6}[\widetilde{\mathcal{A}}(\boldsymbol{\nu})]_{\max}, \tag{E71}$$

where we define $[A]_{\max}$ as the largest eigenvalue of the matrix A and similarly $[A]_{\min}$ is used for the smallest eigenvalue.

Our strategy is to bound $[\widetilde{\mathcal{A}}(\boldsymbol{\nu})]_{\max}$ with Proposition 2. To do this, we first consider a bound on $\mathcal{A}_{i,j,k}(\boldsymbol{x})$. We consider two cases when (i) the index k represents the parameter component or (ii) the index k represents the time component. For the first case, we can do the same steps as in the real time dynamics presented in Eq. (C9) to Eq. (C12), which is repeated here for completeness.

$$\begin{aligned}
\mathcal{A}_{i,j,k}(\boldsymbol{\nu}) &\leqslant |\mathcal{A}_{i,j,k}(\boldsymbol{\nu})| && \text{(E72)}\\
&\leqslant \left\|e^{-\delta\tau H}U^{(M,k)}i\left[U^{(k,j)}i\left[U^{(j,i)}i\left[U^{(i,0)}\rho_0 U^{(i,0)\dagger}, \sigma_i\right]U^{(j,i)\dagger}, \sigma_j\right]U^{(k,l)\dagger}, \sigma_k\right]U^{(M,k)\dagger}e^{-\delta\tau H}\right\|_\infty \left\|\rho_{(\boldsymbol{\theta}^*,0)}\right\|_1 && \text{(E73)}\\
&\leqslant 2^3\|\sigma_i\|_\infty\|\sigma_j\|_\infty\|\sigma_k\|_\infty && \text{(E74)}\\
&= 8 && \text{(E75)}
\end{aligned}$$

Here the second inequality is due to Hölder's inequality. In the third inequality we use a few identities including (i) the one-norm of a pure state is 1, (ii) $\|UA\|_p = \|A\|_p$ for any unitary U, (iii) $\|i[A,B]\|_p = 2\|A\|_p\|B\|_p$, (iv)

$\|AB\|_p \leqslant \|A\|_p \|B\|_p$ and lastly (v) $\|e^{-\delta\tau H}\|_\infty < 1$. To reach the final equality, we recall that since x_l and x_m cannot be a time component δt, σ_l and σ_m are generators of the circuit which have $\|\sigma_i\|_\infty = \|\sigma_j\|_\infty = \|\sigma_k\|_\infty = 1$.

For the second case with the index k representing th time component, we have the following

$$\begin{aligned}
\mathcal{A}_{i,j,M+1}(\boldsymbol{x}) &= \operatorname{Tr}\left[-\rho_{(\boldsymbol{\theta}^*,0)}\left\{\mathcal{B}_{i,j}, H\right\} + 2\operatorname{Tr}[H\mathcal{B}_{i,j}]\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\rho_{(\boldsymbol{\theta}^*,0)} + 2\operatorname{Tr}\big[\rho_{(\boldsymbol{\theta}^*,\delta\tau)}H\big]\mathcal{B}_{i,j}\rho_{(\boldsymbol{\theta}^*,0)}\right] && \text{(E76)}\\
&\leqslant \left|\operatorname{Tr}\left[-\rho_{(\boldsymbol{\theta}^*,0)}\left\{\mathcal{B}_{i,j}, H\right\} + 2\operatorname{Tr}[H\mathcal{B}_{i,j}]\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\rho_{(\boldsymbol{\theta}^*,0)} + 2\operatorname{Tr}\big[\rho_{(\boldsymbol{\theta}^*,\delta\tau)}H\big]\mathcal{B}_{i,j}\rho_{(\boldsymbol{\theta}^*,0)}\right]\right| && \text{(E77)}\\
&\leqslant \left|\operatorname{Tr}\left[-\rho_{(\boldsymbol{\theta}^*,0)}\left\{\mathcal{B}_{i,j}, H\right\}\right]\right| + \left|\operatorname{Tr}\left[2\operatorname{Tr}[H\mathcal{B}_{i,j}]\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\rho_{(\boldsymbol{\theta}^*,0)}\right]\right| + \left|\operatorname{Tr}\left[2\operatorname{Tr}\big[\rho_{(\boldsymbol{\theta}^*,\delta\tau)}H\big]\mathcal{B}_{i,j}\rho_{(\boldsymbol{\theta}^*,0)}\right]\right| && \text{(E78)}
\end{aligned}$$

Now we can bound each individual term in Eq. (E78) with

$$\begin{aligned}
&\left|\operatorname{Tr}\left[-\rho_{(\boldsymbol{\theta}^*,0)}\left\{\mathcal{B}_{i,j}, H\right\}\right]\right| \leqslant 2\left|\operatorname{Tr}\left[\rho_{(\boldsymbol{\theta}^*,0)}\mathcal{B}_{i,j}H\right]\right| && \text{(E79)}\\
&\left|\operatorname{Tr}\left[2\operatorname{Tr}[H\mathcal{B}_{i,j}]\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\rho_{(\boldsymbol{\theta}^*,0)}\right]\right| \leqslant 2\left|\operatorname{Tr}[H\mathcal{B}_{i,j}]\right| && \text{(E80)}\\
&\left|\operatorname{Tr}\left[2\operatorname{Tr}\big[\rho_{(\boldsymbol{\theta}^*,\delta\tau)}H\big]\mathcal{B}_{i,j}\rho_{(\boldsymbol{\theta}^*,0)}\right]\right| = 2||H||_\infty\left|\operatorname{Tr}\left[\mathcal{B}_{i,j}\rho_{(\boldsymbol{\theta}^*,0)}\right]\right| && \text{(E81)}
\end{aligned}$$

where we are using $|\operatorname{Tr}\big[\rho_{(\boldsymbol{\theta}^*,\delta\tau)}\rho_{(\boldsymbol{\theta}^*,0)}\big]| \leqslant 1$ in Eq. (E80) and Hölder's inequality in Eq. (E81). Now, all of the remaining terms can be bounded using Eq. (C9). Thus we obtain

$$\mathcal{A}_{i,j,M+1} \leqslant 24||H||_\infty \,. \tag{E82}$$

Now, we can bound the sum of the absolute of elements in a row of $\widetilde{\mathcal{A}}(\boldsymbol{\nu})$ as

$$\begin{aligned}
\sum_{j=1}^{M}\left|\widetilde{\mathcal{A}}_{ij}(\boldsymbol{\nu})\right| &\leqslant \sum_{j=1}^{M}\sum_{k=1}^{M+1}|x_k|\left(|\mathcal{A}_{i,j,k}(\boldsymbol{\nu})| + |\mathcal{A}_{i,k,j}(\boldsymbol{\nu})| + |\mathcal{A}_{k,i,j}(\boldsymbol{\nu})| + |\mathcal{A}_{j,i,k}(\boldsymbol{\nu})| + |\mathcal{A}_{j,k,i}(\boldsymbol{\nu})| + |\mathcal{A}_{k,j,i}(\boldsymbol{\nu})|\right) && \text{(E83)}\\
&\leqslant 48M(3\lambda_{\max}\delta\tau + Mr)\,. && \text{(E84)}
\end{aligned}$$

Finally we invoke Proposition 2. Thus, the largest eigenvalue of the matrix $\widetilde{\mathcal{A}}$, $[\widetilde{\mathcal{A}}_{j,k}]_{\max}$ can be bounded by

$$[\widetilde{\mathcal{A}}_{j,k}]_{\max} \leqslant 48M(3\lambda_{\max}\delta\tau + Mr_c)\,. \tag{E85}$$

With this result we can guarantee the legion of ϵ-convexity (i.e. Eq. (E64)) by enforcing the following condition

$$-\frac{1}{2}\left[\mathcal{F}(\mathbf{0})\right]_{\min} + 8M\left(3\lambda_{\max}\delta\tau + Mr\right) \leqslant |\epsilon|\,. \tag{E86}$$

Upon rearranging the terms, we find

$$r \leqslant \frac{1}{M}\left(\frac{\mu_{\min} + 2|\epsilon|}{16M} - 3\lambda_{\max}\delta\tau\right)\,. \tag{E87}$$

Indeed, this implies that *any* hypercube $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r)$ such that r satisfies Eq. (E87) is guaranteed to be approximately convex. Hence, we know that the total ϵ-convex region has to be at least of size $\frac{1}{M}\left(\frac{\mu_{\min}+2|\epsilon|}{16M} - 3\lambda_{\max}\delta\tau\right)$. More explicitly, by denoting r_c to be the length of the total ϵ-approximate convex region $\boldsymbol{\mathcal{V}}(\boldsymbol{\theta}^*, r_c)$, we have

$$r_c \geqslant \frac{1}{M}\left(\frac{\mu_{\min} + 2|\epsilon|}{16M} - \lambda_{\max}\delta\tau\right)\,. \tag{E88}$$

Finally, we note that the bound is only informative if the Trotter time-step respects

$$\delta\tau \leqslant \frac{\mu_{\min} + 2|\epsilon|}{48M\lambda_{\max}}\,. \tag{E89}$$

This completes the proof of the theorem.

□

c. *Adiabatic moving minima: Proof of Theorem 6*

In this subsection, we analytically prove Theorem 6. We first show an equivalent result to Proposition 4 for imaginary time evolution. We refer the readers to Appendix D for definitions of adiabatic minimum (Definition 2) and adiabatic shift (Definition 4).

Proposition 5. *Given a Trotter time-step of the current iteration $\delta\tau$ and assuming that the adiabatic minimum exists within this time frame, the shift of the adiabatic minimum $\boldsymbol{\alpha}_A(\delta\tau)$ as defined in Definition 4 can be bounded as*

$$\|\boldsymbol{\alpha}_A(\delta\tau)\|_2 \leqslant \frac{4\sqrt{M}\lambda_{\max}\delta\tau}{\beta_A} \,, \tag{E90}$$

where M is the number of parameters, $\lambda_{\max}$ is the largest eigenvalue of the dynamic Hamiltonian H and $\beta_A = \frac{\dot{\boldsymbol{\alpha}}_A^T(\delta\tau)\left(\nabla^2_{\boldsymbol{\alpha}}\mathcal{L}(\boldsymbol{\alpha},\delta\tau)\big|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(\delta\tau)}\right)\dot{\boldsymbol{\alpha}}_A(\delta\tau)}{\|\dot{\boldsymbol{\alpha}}_A(\delta\tau)\|_2^2}$

Proof. The proof here is very similar to the equivalent version for Real Time Evolution. Through out this proof, it is more convenient to use τ as an imaginary Trotter time-step (instead of $\delta\tau$). We start by recalling that by Definition 4, the adiabatic shift follows

$$\nabla_{\boldsymbol{\alpha}}\mathcal{L}(\boldsymbol{\alpha},\tau)\big|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(\tau)} = \mathbf{0} \,, \tag{E91}$$

which holds for any τ. Similarly to the previous case, we use this notation $\nabla_{\boldsymbol{\alpha}_A}\mathcal{L} := \nabla_{\boldsymbol{\alpha}}\mathcal{L}(\boldsymbol{\alpha},\tau)\big|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(\tau)}$.

We can derivative with respect to τ to find

$$\frac{d}{d\tau}\left(\nabla_{\boldsymbol{\alpha}_A}\mathcal{L}\right) = \partial_\tau\nabla_{\boldsymbol{\alpha}_A}\mathcal{L} + \left(\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}\right)\dot{\boldsymbol{\alpha}}_A = \mathbf{0} \,, \tag{E92}$$

where we denote $\partial_\tau = \partial/\partial\tau$ and $\dot{\boldsymbol{\alpha}}_A(\tau) = d\boldsymbol{\alpha}_A(\tau)/d\tau$.

Recall that $\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}$ is a matrix vector multiplication with the $\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}$ is the Hessian Matrix evaluated at the adiabatic minima $\boldsymbol{\alpha}_A(\tau)$. We multiply from the left with $\dot{\boldsymbol{\alpha}}_A^T(\tau)/\|\dot{\boldsymbol{\alpha}}_A(\tau)\|_2$ to find

$$\frac{\dot{\boldsymbol{\alpha}}_A^T}{\|\dot{\boldsymbol{\alpha}}_A\|_2}\partial_\tau\nabla_{\boldsymbol{\alpha}_A}\mathcal{L} + \frac{\dot{\boldsymbol{\alpha}}_A^T\left(\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}\right)\dot{\boldsymbol{\alpha}}_A}{\|\dot{\boldsymbol{\alpha}}_A\|_2^2}\|\dot{\boldsymbol{\alpha}}_A\|_2 = 0 \,. \tag{E93}$$

For convenience, we denote $\beta_A := \dot{\boldsymbol{\alpha}}_A^T\left(\nabla^2_{\boldsymbol{\alpha}_A}\mathcal{L}\right)\dot{\boldsymbol{\alpha}}_A/\|\dot{\boldsymbol{\alpha}}_A\|_2^2$. We then rearrange the terms to find a bound on the norm of $\dot{\boldsymbol{\alpha}}_A(\tau)$:

$$\begin{aligned} \|\dot{\boldsymbol{\alpha}}_A(\tau)\|_2 &= \left\| -\frac{\dot{\boldsymbol{\alpha}}_A^T\partial_\tau\nabla_{\boldsymbol{\alpha}_A}\mathcal{L}}{\|\dot{\boldsymbol{\alpha}}_A\|_2\beta_A} \right\|_2 && \text{(E94)} \\ &\leqslant \frac{\|\partial_\tau\nabla_{\boldsymbol{\alpha}_A}\mathcal{L}\|_2}{\beta_A} && \text{(E95)} \\ &\leqslant \frac{\sqrt{M}\left|\partial_\tau\partial_{\alpha_A^{(i)}}\mathcal{L}\right|_{\max}}{\beta_A} && \text{(E96)} \\ &\leqslant \frac{4\sqrt{M}\lambda_{\max}}{\beta_A} \,, && \text{(E97)} \end{aligned}$$

where in the first inequality we use Cauchy-Schwartz. In the second we expand the 2-norm explicitly and take the largest value of the sum (i.e. $\|\boldsymbol{a}\|_2 = \sqrt{\sum_{i=1}^M a_i^2} \leqslant \sqrt{M}|a_i|_{\max}$ with $\alpha_A^{(i)}$ being the i^{th} component of $\boldsymbol{\alpha}_A$).

To reach the last inequality we use the explicit form of the loss function $\mathcal{L}(\boldsymbol{\alpha},\tau) = 1 - \operatorname{Tr}\left(e^{-H\tau}\rho_{\boldsymbol{\theta}^*}e^{H\tau}\rho_{\boldsymbol{\theta}}\right)$ where H is the dynamical Hamiltonian, $\rho_{\boldsymbol{\theta}^*}$ is the state corresponding to the solution of the previous iteration and $\rho_{\boldsymbol{\theta}}$ is the parameterised state that depends on $\boldsymbol{\alpha}$ and respect a parameter shift rule. With this, we can bound the term

$\left|\partial_\tau \partial_{\alpha_A^{(i)}} \mathcal{L}\right|_{\max}$ as follows

$$\begin{aligned}
\left|\partial_\tau \partial_{\alpha_A^{(i)}} \mathcal{L}\right|_{\max} &= \left|\frac{\partial}{\partial\tau}\left(\frac{\partial}{\partial\alpha^{(i)}}\mathcal{L}(\boldsymbol{\alpha},\tau)\right)\bigg|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_A(\tau)}\right|_{\max} && \text{(E98)}\\
&= \left|\frac{1}{2}\left(\frac{\partial}{\partial\tau}\mathcal{L}\left(\boldsymbol{\alpha}_A+\frac{\pi}{2}\hat{\alpha}_i\right)-\frac{\partial}{\partial\tau}\mathcal{L}\left(\boldsymbol{\alpha}_A-\frac{\pi}{2}\hat{\alpha}_i\right)\right)\right|_{\max} && \text{(E99)}\\
&\leqslant \max_i\left|\frac{\partial}{\partial\tau}\mathcal{L}\left(\boldsymbol{\alpha}_A\pm\frac{\pi}{2}\hat{\alpha}_i\right)\right| && \text{(E100)}\\
&= \left\|e^{-H\tau}\left(-\{\rho_{\boldsymbol{\theta}^*},H\}+2\,\mathrm{Tr}[\rho_{\boldsymbol{\theta}^*}H]\rho_{\boldsymbol{\theta}^*}\right)e^{-\tau H}\right\|_\infty && \text{(E101)}\\
&\leqslant 4\lambda_{\max}\ , && \text{(E102)}
\end{aligned}$$

where we use the parameter shift rule in the second equality. In the first inequality we we maximise on all the possible terms of this parameter shift rule, and in the third equality we apply the derivative of imaginary time shown in E14, apply Hölder's inequality and use that $\|\rho\|_1 = 1$ for any pure quantum state ρ. In the last inequality we simply use the triangle inequality to bound the $\|A+B\|_p \leqslant \|A\|_p + \|B\|_p$.

Lastly, we can bound shift in the adiabatic minima as follows

$$\begin{aligned}
\|\boldsymbol{\alpha}_A(\tau)\|_2 &= \left\|\int_0^\tau \dot{\boldsymbol{\alpha}}_A(\tau')d\tau'\right\|_2 && \text{(E103)}\\
&\leqslant \int_0^\tau \|\dot{\boldsymbol{\alpha}}_A(\tau')\|_2 d\tau' && \text{(E104)}\\
&\leqslant \frac{4\sqrt{M}\lambda_{\max}\tau}{\beta_A}\ , && \text{(E105)}
\end{aligned}$$

which completes the proof.

□

We are now ready to prove Theorem 6 which is detailed in the following.

Theorem 6 (Adiabatic minimum is within provably 'nice' region for imaginary time evolution, Formal)**.** *If the imaginary time-step $\delta\tau$ is chosen such that*

$$\delta\tau \leqslant \frac{\eta_0\beta_A}{4M\lambda_{\max}}\ , \tag{E106}$$

for some small constant $\eth_0$. then the adiabatic minimum $\boldsymbol{\theta}_A(\delta\tau)$ is guaranteed to be within the non-vanishing gradient region (as per Theorem 4), and additionally, if $\delta\tau$ is chosen such that

$$\delta\tau leq\frac{\beta_A(\mu_{\min}+2|\epsilon|)}{64M^{5/2}\lambda_{\max}\left(1+\frac{3\beta_A}{4M^{3/2}}\right)}\ , \tag{E107}$$

then the adiabatic minimum $\boldsymbol{\theta}_A(\delta\tau)$ is guaranteed to be within the $|\epsilon|$-convex region (as per Theorem 5) where

$$\beta_A := \frac{\dot{\boldsymbol{\theta}}_A^T(\delta\tau)\left(\nabla^2_{\boldsymbol{\theta}}\mathcal{L}_{\mathrm{ITE}}(\boldsymbol{\theta})\big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_A(\delta\tau)}\right)\dot{\boldsymbol{\theta}}_A(\delta\tau)}{\|\dot{\boldsymbol{\theta}}_A(\delta\tau)\|_2^2} \tag{E108}$$

corresponds to the second derivative of the loss in the direction in which the adiabatic minimum moves.

Proof. From Proposition 5 and the norm inequality, the adiabatic minimum follows

$$\|\boldsymbol{\alpha}_A(\delta\tau)\|_\infty \leqslant \|\boldsymbol{\alpha}_A(\delta\tau)\|_2 \leqslant \frac{4\sqrt{M}\lambda_{\max}\delta\tau}{\beta_A}\ . \tag{E109}$$

Now we want to incorporate the conditions of the region that we are interested. Indeed, by tuning $\delta\tau$, we want a guarantee that the adiabatic minimum is within (i) the region with substantial gradients and/or (ii) the convex region.

For (i) the region with substantial gradients, we recall from Theorem 4 that for the imaginary time scaling as $\delta\tau \leqslant 1/12\lambda_{\max}$, the hypercube of width $2r$ has polynomial large variance within the region where r scales as

$$r = \frac{\eta_0}{\sqrt{M}} \,, \tag{E110}$$

for some constant η_0. Hence, the sufficient condition to have the adiabatic minimum to be within this substantial gradient region is that

$$\|\boldsymbol{\alpha}_A(\delta\tau)\|_\infty \leqslant \frac{4\sqrt{M}\lambda_{\max}\delta\tau}{\beta_A} \leqslant \frac{\eta_0}{\sqrt{M}} \,, \tag{E111}$$

which, upon rearranging leads to

$$\delta\tau \leqslant \frac{\eta_0\beta_A}{4M\lambda_{\max}} \,. \tag{E112}$$

For (ii) the convex region, from Theorem 5, if we have the dynamic time bounded as $\delta\tau \leqslant \frac{\mu_{\min}+2|\epsilon|}{48M\lambda_{\max}}$, we have ϵ-convexity in the hypercube of with $2r_c$ for

$$r_c \geqslant \frac{1}{M}\left(\frac{\mu_{\min}+2|\epsilon|}{16M} - 3\lambda_{\max}\delta\tau\right) \tag{E113}$$

Therefore it is sufficient to have the guarantee that the adiabatic minima is inside this convex region by imposing

$$\|\boldsymbol{\alpha}_A(t)\|_\infty \leqslant \frac{4\sqrt{M}\lambda_{\max}\delta\tau}{\beta_A} \leqslant \frac{1}{M}\left(\frac{\mu_{\min}+2|\epsilon|}{16M} - 3\lambda_{\max}\delta\tau\right) \leqslant r_c \tag{E114}$$

which after rearranging terms the imaginary time-step is bounded by

$$\delta\tau \leqslant \frac{\beta_A(\mu_{\min}+2|\epsilon|)}{64M^{5/2}\lambda_{\max}\left(1+\frac{3\beta_A}{4M^{3/2}}\right)} \,. \tag{E115}$$

This completes the proof. □

Extending Classically Simulatable Bounds of Clifford Circuits with Nonstabilizer States via Framed Wigner Functions

Guedong Park[1] * Hyukjoon Kwon[2] † Hyunseok Jeong[1] ‡

[1] *Department of Physics and Astronomy, Seoul National University, Seoul, 08826, Korea*
[2] *School of Computational Sciences, Korea Institute for Advanced Study, Seoul, 02455, Korea*

Abstract. Application of Wigner function to classically simulate the quantum circuit out of Clifford circuit regime has a limitation in qubit system due to negativity occurence by Clifford gates. We present a novel classical simulation method for qubit Clifford circuits based on the framed Wigner function. Here, a wide class of non-stabilizer states can be positively represented. Also, we prevent the negativity occurence after the Clifford operation by switching the frame defining the structure of Wigner function. From this formalism, we set a systematic algorithm to find the efficiently simulatable marginal measurements, hence extending the classically simulatable region of circuits in qubit system.

Keywords: Classical simulation of quantum circuit, Clifford circuit and stabilizer states, Gottesmann-Knill theorem, Discrete Wigner function, Vertex cover problem.

1 Introduction

Quantum algorithms, which are algorithms based on quantum mechanical principles, have been shown to outperform the classical algorithms for many computational tasks [1, 2]. However, not all quantum algorithms show such computational speed up over its classical counterparts. One typical example is Clifford circuits [3]: circuits consist of an input state in the computational basis and Clifford gates, resulting in a stabilizer state as an ouput. By the Gottesmann-Knill theorem [3], we can classically simulate an n-qubit Clifford circuit in $\mathcal{O}(n^3)$-time. The theorem necessitates [4] the usage of non-stabilizer states to achieve effective speed up over classical computer. However, classifying simulatable circuits even out of Clifford circuit regime has been important task to demonstrate the classical hardness of near-term quantum computing [5, 6, 7, 8].

In odd-prime dimensional system, one of the representative methods to extend the classical simulability of non-Clifford circuits is to utilize the Wigner function [9, 10]. Here, we use the Wigner function of discretized structure of phase space operator, alternative to original version of inifinite dimensional system. It enables some non-stabilizer mixed states to be positively represented and positivity of Wigner function of given state is not harmed under Clifford operations and Pauli measurements. Then we can make a classical simulation scheme based on such a stochastic representation of dynamics in the circuit. Therefore, the Wigner formalism extends the region of simulatable circuits over the realm of Gottesmann-Knill theorem.

These interesting facts lead us to apply such formalism to qubit (even dimensional) system. Furthermore, there exist non-stabilizer pure states with positive Wigner function [12]. However, similar classical simulation scheme is no longer valid due to its another exotic features. That is, Clifford operations can induce negativity in the Wigner function which prohibits the classical simulation of most qubit Clifford circuits. Although there have been many efforts to circumvent such problems [13, 14, 15, 16], these approaches have their own limitations. For example, the positive representation of non-stabilizer is unknown [13, 14, 15] or phase point of given state cannot be sampled or updated efficiently under Clifford operations and Pauli measurements [16, 15, 17]. Therefore, finding suitable structure of qubit Wigner formalism which includes from the simulability of Clifford circuits to non-Clifford cases is still under open questions.

In this paper [18], we propose a new efficient classical simulation algorithm for unitary Clifford circuits with non-stabilizer inputs based on the qubit Wigner function. To do so, we introduce a generalized notion of the Wigner function, parametrized by a family of *frame functions*. Our strategy is that under the following Clifford operation, we properly switch the frame defining the Wigner function to make an enacted state with positive Wigner function still preserve the positivity. From this, given that we efficiently sample the phase point from the Wigner function of an initial state, we have a deterministic update rule of phase point under Clifford operation. Negativity which was circumvented during the intermediate Clifford operation will be transferred to the measurement parts. Even if so, efficiently measurable qubits can be found by the solving vertex cover problem to the graph representation of the final frame. For log-depth random Clifford circuits with nonstabilizer inputs, we find that the number of simulatable qubits scales linearly with n for a 1D architecture, while observing a phase transition in its scaling for a completely connected architecture.

2 Main results

We consider n-qubit system. First, we define the *framed Wigner function*,

$$W_\rho^F(\mathbf{u}) \equiv \frac{1}{2^n}\mathrm{Tr}\left[\rho A^F(\mathbf{u})\right]. \quad (1)$$

Here $\mathbf{u} \in \mathbb{Z}_2^{2n}$, and the phase space operator $A^F(\mathbf{u})$ is defined as

$$A^F(\mathbf{u}) \equiv \frac{1}{2^n} \sum_{\mathbf{a}\in\mathbb{Z}_2^{2n}} (-1)^{[\mathbf{u},\mathbf{a}]+F(\mathbf{a})} T_{\mathbf{a}}, \tag{2}$$

where $\mathbf{a} = (\mathbf{a}_x, \mathbf{a}_z)$ and $T_{\mathbf{a}} \equiv \bigotimes_{j=1}^n i^{a_{jx}a_{jz}} X_j^{a_{jx}} Z_j^{a_{jz}}$ Also, $[\mathbf{u}, \mathbf{a}] = \mathbf{u}_x \cdot \mathbf{a}_z + \mathbf{u}_z \cdot \mathbf{a}_x$ is a $2n$-dimensional symplectic inner product. The structure of the Wigner function is parametrized as a *frame function* $F(\mathbf{a}) : \mathbb{Z}_2^{2n} \to \mathbb{Z}_2$ satisfying $F(\mathbf{0}) = 0$. From the completeness relation $\text{Tr}\big[A^F(\mathbf{u})A^F(\mathbf{v})\big] = 2^n\delta_{\mathbf{u},\mathbf{v}}$, a quantum state can be expressed as

$$\rho = \sum_{\mathbf{u}\in\mathbb{Z}_2^{2n}} W_\rho^F(\mathbf{u})A^F(\mathbf{u}). \tag{3}$$

If $W_\rho^F(\mathbf{u}) \geq 0$ for $\forall \mathbf{u} \in \mathbb{Z}_2^{2n}$, we say ρ is *positively represented under the frame F*.

Given that ρ is positively represented under the frame F_{in}, let us enact the Clifford unitary $U \in \text{Cl}_n$. If we fix the frame after the operation, the Wigner function $W_{U\rho U^\dagger}^{F_{\text{in}}}(\mathbf{u})$ may have negativity. However, there exists a frame changing rule depending on U such that if we change the frame F_{in} to F, then we can preserve the positivity of evolved state. Then the update of Wigner function has a similar form with odd-prime dimensional case, i.e. there exists $\mathbf{k} \in \mathbb{Z}_2^{2n}$ and $2n$ by $2n$ binary symplectic matrix S corresponding to U such that

$$W_{U\rho U^\dagger}^F(S(\mathbf{u}+\mathbf{k})) = W_\rho^{F_{in}}(\mathbf{u}), \tag{4}$$

except that the frame is changed. Both S and $\mathbf{k}$ can be found efficiently. Furthermore, we can change the frame under the each of the Clifford bases $\{H, S, CNOT\}$ (see Fig. 1). From the fact that all Clifford operation can be decomposed with this basis, we can find up to 3rd-degree resulting frame, which positively represent $U\rho U^\dagger$, in poly(n)-time and $\mathcal{O}(n^3)$-memory. For example, it is well known that 2-qubit computational basis $|00\rangle\langle 00|$ is positively represented under the zero frame $F_{\text{in}} = 0$ and that if we enact Hadamard gate and CNOT gate to make a Bell state $|\Phi\rangle\langle\Phi|$ with $|\Phi\rangle = 1/\sqrt{2}\,|00\rangle + 1/\sqrt{2}\,|11\rangle$, then it has negativity with respect to zero frame. However, the Bell state can be positively represented under the non-local frame $F(\mathbf{a}) = a_{1x}a_{1z} + a_{1z}a_{2z}a_{1x} + a_{2z}a_{1x}a_{2x}$ (mod 2). From now on, we assume the final frame F has zero linear term since we can show that non-zero linear term can always be absorbed into $\mathbf{k}$.

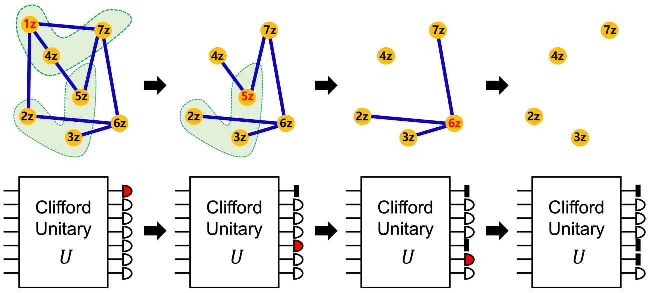

Figure 2: Identifying efficiently simulatable qubits by solving the vertex cover problem using a greedy algorithm. Lines and shaded regions represent the quadratic and cubic terms in the final frame function $F(\mathbf{0}, \mathbf{a}_z) = a_{1z}a_{4z}a_{7z} + a_{2z}a_{3z}a_{5z} + a_{1z}a_{4z} + a_{4z}a_{5z} + a_{5z}a_{7z} + a_{1z}a_{2z} + a_{2z}a_{6z} + a_{3z}a_{6z} + a_{6z}a_{7z}$. A qubit with the largest number of connected hyperedges is traced out at each step until all the edges vanishes. The outcomes of the remaining qubits are efficiently simulatable.

Another point is that there exists set of non-stabilizer states which can be positively represented under the specified frame functions. For example, n-copies of *F-state*, $|A\rangle \equiv \cos(\theta/2)\,|0\rangle + e^{i(\pi/4)}\sin(\theta/2)\,|1\rangle$ with $\theta = \cos^{-1}(1/\sqrt{3})$ is positively represented under the zero frame. Also, non-stabilizer state which can be formed by arbitrary Clifford operation to such F-copies can be positively represented under the another frame, which can be found by the frame chaning rule.

Moreover, from the final frame after the Clifford operation, we can select the marginal qubits whose Z-basis Pauli measurements can be exactly and efficiently simulated. We summarize aforementioned arguments as a following theorem.

Theorem 1. *Suppose an n-qubit quantum circuit composed of a product state input $\rho = \bigotimes_{i=1}^n \rho_i$ and a Clifford unitary U. If each ρ_i is positively represented in either zero or dual frame ($F = a_{ix}a_{iz}$), the final state $U\rho U^\dagger$ is positively represented within $\mathcal{O}(n^3)$-memory and $\mathcal{O}(\text{poly}(n))$-time costs. From this, one can sample the measurement outcomes of some marginal qubits in the computational basis within $\mathcal{O}(n^2)$-time cost, where these marginal qubits are determined by the frame F.*

The simulatable marginal qubits can be found from the graph representation of the final frame with $\mathbf{a}_x = \mathbf{0}$, i.e. $F(\mathbf{0}, \mathbf{a}_z)$. Since the final frame has at most 3rd-degree, we can represent $F(\mathbf{0}, \mathbf{a}_z)$ as 3rd-ordered hypergraph where vertices and lines indicate each variable and quadratic

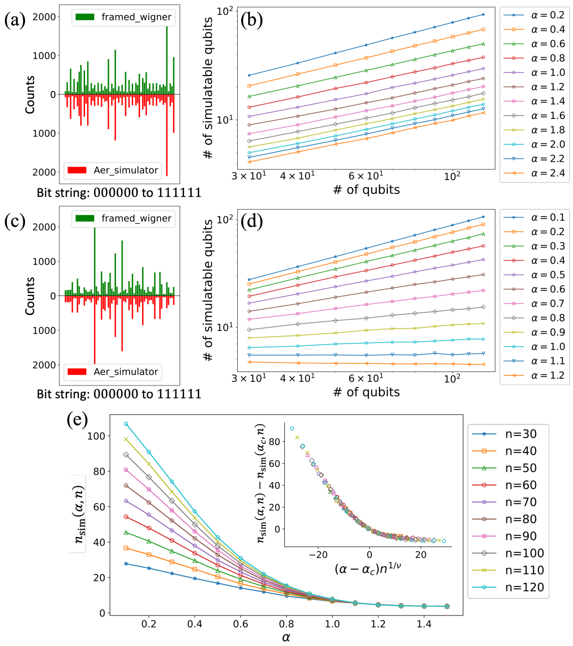

Figure 3: (a), (c): Comparison between sampling results using the framed Wigner function and Qiskit Aer simulator for a randomly chosen 10-qubit log-depth Clifford circuit with (a) 1D-neighboring and (c) completely connected architecture. For both cases, nonstabilizer input state $|A\rangle\langle A|^{\otimes 10}$ is taken, and 6 marginal qubits are selected after solving the vertex cover problem. The y-axis shows the number of counts of binary string that simulators sampled by taking a total of 20000 samples. (b), (d): The averaged number of simulatable qubits ($n_{\rm sim}$) by increasing the gate count $L = \alpha(n \ln n)$ of 1000 random Clifford circuits with (b) 1D-neighboring and (d) completely connected architectures. (e) Scaling behavior of $n_{\rm sim}$ by increasing α and data collapse after finite-size scaling.

term of frame function respectively, also 3rd-hyperedges describe cubic terms. If we trace the i-th ($i \in [n]$) qubit, then we eliminate all edges containing a_{iz} vertex. Repeating several times, when the resulting graph exhausts all hyperedges (including lines), then remaining qubits can be measured efficiently. *Vertex cover problem* is the problem to find the minimal vertices to trace out so that after above elimination routine, no edges are left. Such problem is directly related to finding the largest simulatable qubits, but is known to be NP-Hard [19]. However, we can approximately solve it by using the *greedy algorithm* [20] where for each repetition, we select the vertex which has the largest number of connecting edges. See the Fig. 2 for the schematic illustration of finding the simulatable marginals via the greedy algorithm.

3 Numerical simulations

We apply the proposed simulation algorithm to two different types of random n-qubit log-depth Clifford circuits, with 1D-neighboring and arbitrary long-range interactions (completely connected) between two qubits, where gate count is $L = \alpha n \ln(n)$. In both cases, we take the input state $\rho = |A\rangle\langle A|^{\otimes n}$, and adopt the greedy algorithm to find efficiently simulatable marginal qubits. Figure 3(a,c) shows that our simulation method successfully samples the measurement outcomes.

Figure 3(b) shows that for 1D architecture, the average number of classically simulatable qubits ($n_{\rm sim}$) increases linearly by n. This result can be compared to the tensor network simulation, where all the n-qubit outcomes of these circuits can be efficiently simulated with $e^{\mathcal{O}(\alpha \ln n)} \sim n^{\mathcal{O}(\alpha)}$ time cost [21, 22]. In contrast, our algorithm simulates a linear portion of qubits with $\mathcal{O}(\alpha \mathrm{poly}(n))$ time cost, including both finding the final frame F and solving its vertex cover problem. Therefore, our approach offers faster simulation when the α becomes large. We also observed remarkable improvement compared to the matrix product state simulator of the IBM Qiskit [23]. For the completely connected architecture, see Fig. 3 (d) and (e), we observed a sharp transition of $n_{\rm sim}$ depending on the gate count. From the finite sized scaling analysis, we checked such a transition occurred at the critical point $\alpha_c \simeq 0.81$. Even in this case, our simulator shows effective extension of simulatable region, given that efficient and exact classical simulability of even the constant-depth 2-D circuit is still not known [21].

The Wigner function formalism has played a pivotal role in examining the non-classical aspects of quantum states and their classical simulatability. Nevertheless, its application in qubit systems faces limitations due to negativity induced by Clifford gates. In this work, we propose a novel classical simulation method for qubit Clifford circuits based on the framed Wigner function, an extended form of the Wigner function with an additional phase degree of freedom. In our framework, Clifford gates do not induce negativity by switching to a suitable frame; thereby, a wide class of nonstabilizer states can be represented positively. By leveraging this technique, we show that some marginal outcomes of Clifford circuits with nonstabilizer state inputs can be efficiently sampled at polynomial time and memory costs. We develop a graph-theoretical approach to identify classically simulatable marginal outcomes and apply it to log-depth random Clifford circuits. We also present the outcome probability estimation scheme using the framed Wigner function and discuss its precision. Our approach opens new avenues for utilizing quasi-probabilities to explore classically simulatable quantum circuits.

Applying quantum mechanical principles to computer science has led to the discovery of quantum algorithms [1, 2]. However, not every quantum algorithm manifests exponential speedup over classical algorithms as some quantum circuits can be efficiently simulated classically [3–5]. The best-known class of such quantum circuits is defined by the Gottesman-Knill theorem [3, 6]; circuits consist of an input state in the computational basis and Clifford gates, resulting in a stabilizer state as an output. While the theorem identifies necessary elements for universal quantum computation [7, 8], understanding the hardness of a more restrictive family of experimentally feasible quantum circuits, such as instantaneous quantum polynomial circuits [9], quantum random circuits [10], and unitary Clifford circuits with nonstabilizer inputs [5, 11, 12], also plays an important role in the near-term demonstration of quantum computational advantage.

Meanwhile, in a physics-oriented direction, the classical simulatability of quantum circuits has been studied based on the Wigner function [13], which describes quantum phase space. In quantum optics, Gaussian states are the only pure states with a positive Wigner function [14], and Gaussian operations preserve the positivity of the Wigner function. A remarkable similarity can be found in discrete variable quantum phase space with odd-prime dimensions [15], where stabilizer states and Clifford operations correspond to Gaussian states and Gaussian operations, respectively. This common feature enables the unified construction [16] of a classical simulation method for both discrete [17] and continuous [18, 19] variable quantum circuits with positive Wigner functions. Moreover, these approaches open up the possibility to simulate nonstabilizer mixed states with positive Wigner functions [17].

For a qubit system, however, classical simulation based on the Wigner function formalism is no longer applicable due to its exotic features [20–22]. A crucial problem arises as Clifford operations can induce negativity in the Wigner function [20, 23], which prohibits the classical simulation of most qubit Clifford circuits. Despite considerable efforts to address this problem [20, 22, 24, 25], these approaches have their own limitations. For example, the positive representation of the nonstabilizer state may not be fully identified [20, 24] or phase space points may not be efficiently sampled and tracked [22, 24, 25]. Thus, constructing a qubit Wigner function formalism that behaves well under Clifford operations and developing classical simulation algorithms based on it remain open problems.

In this Letter, we propose an efficient classical simulation algorithm for unitary Clifford circuits with nonstabilizer inputs based on the qubit Wigner function formalism. To this end, we adopt a generalized notion of the Wigner function parameterized by a family of frame functions [21–23], while actively utilizing its non-local form. Our key observation is that phase space points transform covariantly under qubit Clifford gates without inducing negativity when the frame is appropriately switched. This leads to the qubit Wigner function formalism consistent with the Gottesman-Knill theorem for simulating stabilizer states and significantly extends the classically simulatable regime of Clifford circuits with nonstabilizer inputs, allowing for efficient sampling of their marginal outcomes. We show that the efficiently simulatable marginal outcomes can be identified by solving the vertex cover problem [26] in graph theory. For log-depth random Clifford circuits, we find that the number of simulatable qubits scales linearly with n for a 1D architecture, while observing a phase transition in its scaling for a completely connected architecture. We also discuss the precision of probability estimation [23, 27] using our approach.

Simulating quantum circuits in phase space.—Suppose

$P^F(\mathbf{x}|\mathbf{u}) \geq 0$

FIG. 1: Condition for efficient classical simulation of a Clifford circuit with a nonstabilizer input using the framed Wigner function.

a quantum circuit, consisting of initial state ρ, unitary evolution U, and measurement operators $\{\Pi_{\mathbf{x}}\}$ with outcomes $\mathbf{x}$. One way to classically simulate the outcomes $\mathbf{x}$ following the probabilities $p(\mathbf{x}) = \mathrm{Tr}[U\rho U^\dagger \Pi_{\mathbf{x}}]$ is by representing quantum states in phase space [16, 17, 27]. This can be done by mapping a quantum state to a distribution in phase space V as $\rho = \sum_{\mathbf{u}\in V} W_\rho(\mathbf{u}) A(\mathbf{u})$, where $A(\mathbf{u})$ are phase space operators composing an operator basis. The outcome probability is then represented as

$$p(\mathbf{x}) = \sum_{\mathbf{u}\in V} W_{U\rho U^\dagger}(\mathbf{u}) P(\mathbf{x}|\mathbf{u}), \tag{1}$$

where $P(\mathbf{x}|\mathbf{u}) \equiv \mathrm{Tr}[A(\mathbf{u})\Pi_{\mathbf{x}}]$. The phase space distribution $W_\rho(\mathbf{u})$ is well-normalized but can have negative values, in general, often referred to as *quasi-probability* [13]. Nevertheless, some quantum circuits may have both positive $W_{U\rho U^\dagger}(\mathbf{u})$ and $P(\mathbf{x}|\mathbf{u})$. In this case, the outcomes $\mathbf{x}$ can be classically simulated by sampling the phase space point $\mathbf{u}$ from $W_{U\rho U^\dagger}(\mathbf{u})$, followed by sampling $\mathbf{x}$ from the conditional probability distribution $P(\mathbf{x}|\mathbf{u})$ [16].

The canonical form of phase space for an n-qubit system is given by a $2^n \times 2^n$ lattice, $\mathbf{u} = (\mathbf{u}_x, \mathbf{u}_z) = (u_{1x}, u_{2x}, \cdots, u_{nx}, u_{1z}, u_{2z}, \cdots, u_{nz}) \in V_n = \mathbb{Z}_2^n \times \mathbb{Z}_2^n$, where the phase space operator $A(\mathbf{u}) \equiv \frac{1}{2^n}\sum_{\mathbf{a}\in V_n}(-1)^{[\mathbf{u},\mathbf{a}]} T_{\mathbf{a}}$ is constructed from the Weyl operator $T_{\mathbf{a}} \equiv \bigotimes_{i=1}^{n} i^{a_{ix}a_{iz}} X^{a_{ix}} Z^{a_{iz}}$. Here, $[\mathbf{u},\mathbf{a}] \equiv \mathbf{u}_x \cdot \mathbf{a}_z + \mathbf{u}_z \cdot \mathbf{a}_x$ is a symplectic inner product and X and Z are Pauli operators corresponding to shift and boost operations in phase space, respectively. This leads to the *discrete Wigner function* defined as $W_\rho(\mathbf{u}) \equiv \frac{1}{2^n}\mathrm{Tr}(\rho A(\mathbf{u}))$ [21, 23, 27], which shares common properties with the continuous-variable Wigner function [13, 21]: (i) it is real-valued and well-normalized, $\sum_{\mathbf{u}\in V_n} W_\rho(\mathbf{u}) = 1$; (ii) it is covariant under translation, $W_{T_{\mathbf{a}}\rho T_{\mathbf{a}}^\dagger}(\mathbf{u}) = W_\rho(\mathbf{u}+\mathbf{a})$; and (iii) its marginals indicate correct outcome probabilities.

On the other hand, the qubit Wigner function has exotic properties compared with the odd prime dimensional or continuous variable Wigner function [16, 17] that Clifford operations can induce negativity [21]. For example, a two-qubit state $|00\rangle$ in the computational basis state has a positive Wigner function, but after applying the Hadamard and CNOT gates, the resulting Bell state $|\Phi\rangle = \frac{|00\rangle+|11\rangle}{\sqrt{2}}$ has a negative Wigner function. This strongly limits the range of classically simulatable quantum circuits using qubit Wigner functions [28].

Efficient classical simulation via framed Wigner functions— To circumvent this problem, we introduce an additional degree of freedom to the qubit Wigner function [21–23]. We define a *framed Wigner function*

$$W_\rho^F(\mathbf{u}) \equiv \frac{1}{2^n}\mathrm{Tr}\left[\rho A^F(\mathbf{u})\right], \tag{2}$$

using a *frame function* F that characterizes an additional phase factor of phase space operators,

$$A^F(\mathbf{u}) \equiv \frac{1}{2^n}\sum_{\mathbf{a}\in V_n}(-1)^{[\mathbf{u},\mathbf{a}]+F(\mathbf{a})} T_{\mathbf{a}}. \tag{3}$$

The frame function maps a phase space point to a binary value, i.e., $F(\mathbf{a}) \in \{0,1\}$ for $\mathbf{a} \in V_n$, and satisfies the condition $F(\mathbf{0}) = 0$ to ensure that W_ρ^F is well-normalized. For example, a single qubit has two choices of frames, $F(a_x, a_z) = 0$ (zero frame) or $F(a_x, a_z) = a_x a_x$ (dual frame), up to translation symmetry under $T_{(a_x,a_z)}$ [21]. The framed Wigner function also respects some other properties of the conventional Wigner function, a special case with $F(\mathbf{a}) = 0$, such as covariance under translation and having a proper notion of marginals [15, 21, 29].

In terms of the framed Wigner function, the probability in Eq. (1) can be rewritten as

$$p(\mathbf{x}) = \sum_{\mathbf{u}\in V_n} W_{U\rho U^\dagger}^F(\mathbf{u}) P^F(\mathbf{x}|\mathbf{u}), \tag{4}$$

where $P^F(\mathbf{x}|\mathbf{u}) \equiv \mathrm{Tr}[A^F(\mathbf{u})\Pi_{\mathbf{x}}]$. Consequently, the circuit is classically simulatable when both $W_{U\rho U^\dagger}^F(\mathbf{u})$ and $P^F(\mathbf{x}|\mathbf{u})$ are positively represented. Our main result states that the additional degree of freedom given by the frame function (or simply frame) leads to a wider class of efficiently simulatable quantum circuits (see also Fig. 1):

Theorem 1. *Suppose an n-qubit quantum circuit composed of a product state input $\rho = \bigotimes_{i=1}^{n}\rho_i$ and a Clifford unitary U. If each ρ_i is positively represented in either zero or dual frame, the final state $U\rho U^\dagger$ is positively represented in a frame F, which can be evaluated from the initial frame with $\mathcal{O}(n^3)$-memory and $\mathcal{O}(\mathrm{poly}(n))$-time costs. From this, one can sample the measurement outcomes of some marginal qubits in the computational basis within $\mathcal{O}(n^2)$-time cost, where these marginal qubits are determined by the frame F.*

We highlight that pure nonstabilizer input states, such as $|A\rangle = \cos(\theta/2)|0\rangle + e^{i(\pi/4)}\sin(\theta/2)|1\rangle$ with $\theta = \cos^{-1}(1/\sqrt{3})$ [30], as well as their multiple copies

$|A\rangle^{\otimes m}$ can be positively represented by the framed Wigner function [21]. This can be compared to Ref. [22] utilizing a different phase space structure, wherein multi-copy nonstabilizer states are not always positively represented. While any quantum circuit can have a positive representation [24], it does not necessarily imply efficient classical simulation. In contrast, we explicitly construct a classical simulation algorithm that is efficient in both time and memory costs.

Compared to the classical simulation algorithm in Ref. [11], our algorithm covers some high Pauli-rank input states, such as $|A\rangle$. Moreover, our method provides an exact simulation, whereas Ref. [11] focuses on approximate simulation whose time cost depends on the accuracy. Hence, our results significantly extend a family of classically simulatable quantum circuits, despite their general hardness [5, 12].

The key idea of our algorithm is to defer the negativity induced by Clifford gates, enabling the phase point update until the measurement, summarized as follows:

Observation 1 (Clifford covariance under frame switching)**.** *For any Clifford gate U and input frame F_{in}, one can always find a frame F, a symplectic transform S, and $\mathbf{v} \in V_n$ such that $W^F_{U\rho U^\dagger}(S(\mathbf{u}) + \mathbf{v}) = W^{F_{\text{in}}}_\rho(\mathbf{u})$. Consequently, when an input state ρ is positively represented, i.e., $W^{F_{\text{in}}}_\rho(\mathbf{u}) \geq 0$, the output state can also be positively represented, i.e., $W^F_{U\rho U^\dagger}(\mathbf{u}) \geq 0$.*

While this stems from the fact that a Clifford gate transforms any Pauli operator to another Pauli operator up to the phase factor [6], a detailed form of F and S can be found in the Supplementary Material [31]. For example, the Bell state $|\Phi\rangle$, which exhibits negativity in the conventional Wigner function, can be positively represented under the frame $F(\mathbf{a}) = a_{1x}a_{1z} + a_{1z}a_{2z}a_{1x} + a_{2z}a_{1x}a_{2x} \pmod 2$. This observation can be applied to all stabilizer states and a wide class of nonstabilizer states generated from Clifford circuits. Compared to the case of a fixed framed function with adaptive Pauli measurements, where single-qubit operations are the only operations that preserve the positivity of the Wigner function [21], our result shows that positivity is preserved for any unitary, i.e., non-adaptive, Clifford operations by switching the frame.

We sketch the classical simulation algorithm described in Theorem 1, starting from the phase space point sampling. The framed Wigner function of a product input state $\rho = \bigotimes_{i=1}^n \rho_i$ is written as $W^{F_{\text{in}}}_\rho(\mathbf{u}) = \prod_{i=1}^n W^{F_i}_{\rho_i}(u_{ix}, u_{iz})$ with $F_{\text{in}}(\mathbf{a}) = \sum_{i=1}^n F_i(a_{ix}, a_{iz})$, where F_i can be either zero or dual frame. Hence, when $W^{F_i}_{\rho_i}$ is positive for every $i = 1, \cdots, n$, the phase space point of the final state following the distribution $W^F_{U\rho U^\dagger}(\mathbf{u}) = W^{F_{\text{in}}}_\rho(S^{-1}(\mathbf{u}))$ can be sampled by i) sampling (u_{ix}, u_{iz}) from each $W^{F_i}_{\rho_i}(u_{ix}, u_{iz})$, and then ii) applying the symplectic transform S to $(u_{1x}, \cdots, u_{nx}, u_{1z}, \cdots, u_{nz})$ followed by adding $\mathbf{v}$ from Observation 1, which overall takes $\mathcal{O}(n^2)$-time.

On the other hand, the positive Wigner function does not suffice for efficient classical simulation of the quantum circuit. One issue is that a frame function $F(\mathbf{a})$ may contain the high-degree monomials in $\mathbf{a}$, such as $\prod_{i=1}^n a_{ix}a_{iz}$. This gives rise to an exploding number of possible frame choices $(2^{(2^{2n}-2n-1)})$ [32], requiring exponential memory cost. For Clifford circuits with product state inputs, however, we show that the frame functions with polynomials of degree 3, i.e., cubic, are sufficient to run the proposed protocol. In other words, the frame can be written in the form, $F(\mathbf{a}) = \sum_{\mu,\nu} c_{\mu\nu} a_\mu a_\nu + \sum_{\mu,\nu,\omega} c_{\mu\nu\omega} a_\mu a_\nu a_\omega \pmod 2$, where $\mu, \nu, \omega \in \{1x, \ldots, nx, 1z, \ldots, nz\}$ and $c_{\mu\nu}, c_{\mu\nu\omega} \in \{0, 1\}$. This is because any frame function for each ith input qubit is either 0 or $a_{ix}a_{iz}$, and every frame transformation under a Clifford gate adds up to cubic terms [31]. We also note that linear terms can always be absorbed in the translation under $T_{\mathbf{a}}$ [21]. Thus, the possible number of frames is reduced into $2^{\mathcal{O}(n^3)}$, which can be efficiently manipulated with a $\mathcal{O}(n^3)$ bit memory.

For a given phase space point $\mathbf{u}$, the outcomes $\mathbf{x}$ can be classically sampled under the condition $P^F(\mathbf{x}|\mathbf{u}) \geq 0$. A sufficient condition for efficient sampling of the n-qubit computational basis measurement $\Pi_{\mathbf{x}} = |\mathbf{x}\rangle\langle\mathbf{x}|$ with $\mathbf{x} = (x_1, \cdots, x_n) \in \mathbb{Z}_2^n$ can be found as $F(\mathbf{0}_x, \mathbf{a}_z) = 0$, which leads to $P^F(\mathbf{x}|\mathbf{u}) = \langle\mathbf{x}| A^F(\mathbf{u}) |\mathbf{x}\rangle = (1/2^n) \sum_{\mathbf{a}_z \in \mathbb{Z}_2^n} (-1)^{(\mathbf{u}_x + \mathbf{x})\cdot\mathbf{a}_z + F(\mathbf{0}_x, \mathbf{a}_z)} = \delta_{\mathbf{x},\mathbf{u}_x}$ by noting that $\langle\mathbf{x}| T_{\mathbf{a}} |\mathbf{x}\rangle = \delta_{\mathbf{a}_x,\mathbf{0}_\mathbf{x}}(-1)^{\mathbf{x}\cdot\mathbf{a}_z}$. This directly leads to the outcome sampling of $\mathbf{x} = \mathbf{u}_x$ from the given phase space point $\mathbf{u}$. Remarkably, any Clifford circuit with a stabilizer input always has positive representation in a frame F obeying this condition so that *all the n-qubit outcomes can be efficiently simulated for stabilizer states*, reproducing the result of the Gottesman-Knill theorem [31].

For nonstabilizer inputs, however, it is uncommon to obtain a frame F with the condition $F(\mathbf{0}_x, \mathbf{a}_z) = 0$. Nevertheless, an efficient classical simulation of some marginal outcomes is still possible. We note that after tracing out the jth qubit, the phase space operator of the remaining qubits is given by $\text{Tr}_j[A^F(\mathbf{u})] = A^{F'}(\mathbf{u}')$ with $\mathbf{u}' = (\mathbf{u}'_x, \mathbf{u}'_z) \in V_{n-1}$ with $\mathbf{u}'_\lambda = (u_{1\lambda}, \cdots, u_{(j-1)\lambda}, u_{(j+1)\lambda}, \cdots, u_{n\lambda})$ for $\lambda = x, z$ and $F'(\mathbf{a}') = F(\mathbf{a})|_{a_{jx}=a_{jz}=0}$ with $\mathbf{a}' \in V_{n-1}$ similarly defined as $\mathbf{u}'$. Hence, all the monomials containing a_{jx} or a_{jz} are removed in the reduced frame F'. We repeat this step for $(n-k)$ times until the reduced frame of the remaining k-qubits satisfies $F'(\mathbf{0}'_x, \mathbf{a}'_z) = 0$. Therefore, the measurement outcomes $\mathbf{x}' = (x'_1, \cdots, x'_k) \in \mathbb{Z}_2^k$ on the remaining k-marginal qubits $\Pi_{\mathbf{x}'} = |\mathbf{x}'\rangle_M \langle\mathbf{x}'| \otimes \mathbb{1}_T$ can be efficiently sampled from $\mathbf{u}$ as $P^F(\mathbf{x}'|\mathbf{u}) = \text{Tr}[A^F(\mathbf{u})\Pi_{\mathbf{x}'}] = \langle\mathbf{x}'|A^{F'}(\mathbf{u}')|\mathbf{x}'\rangle = \delta_{\mathbf{x}',\mathbf{u}'_x}$, where M and T represent the Hilbert space of the measured and traced-

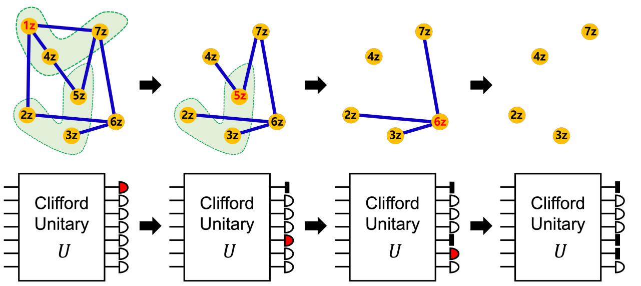

FIG. 2: Identifying efficiently simulatable qubits by solving the vertex cover problem using a greedy algorithm. Lines and shaded regions represent the hyperedges of $\mathcal{E}_2$, and $\mathcal{E}_3$, respectively. A qubit with the largest number of connected hyperedges is traced out at each step until all the hyperedges vanishes. The outcomes of the remaining qubits are efficiently simulatable.

out qubits, respectively.

Furthermore, finding efficiently simulatable marginal qubits can be translated into a graph problem by taking $\mathcal{V} = \{a_{1z}, \cdots, a_{nz}\}$ as vertices and by expressing $F(\mathbf{0}_x, \mathbf{a}_z) = \sum_{(i,j)\in\mathcal{E}_2} a_{iz}a_{jz} + \sum_{(i,j,k)\in\mathcal{E}_3} a_{iz}a_{jz}a_{kz}$ (mod 2) as hyperedges $\mathcal{E}_2$ and $\mathcal{E}_3$ connecting two and three vertices, respectively. We note that tracing out the jth qubit (taking $a_{jz} = 0$) corresponds to removing the vertex a_{jz} along with all hyperedges connected to it. Hence, removing vertices that fully cover the hyperedges leads to the remaining k-qubits satisfying $F'(\mathbf{0}'_x, \mathbf{a}'_z) = 0$. While finding the minimum number of such vertices, so-called the vertex cover problem, is an NP-hard problem [33], there exists a sub-optimal algorithm, for example, a *greedy algorithm* [26] running in poly-time (see Fig. 2).

Examples.—We apply the proposed simulation algorithm to two different types of random n-qubit log-depth Clifford circuits with 1D-neighboring and arbitrary long-range (completely connected) interactions between two qubits, where gate count is $L = \alpha n \ln(n)$ (see Refs. [31, 34] for more details). In both cases, we take the input state $\rho = |A\rangle\langle A|^{\otimes n}$ and adopt the greedy algorithm to find efficiently simulatable marginal qubits. As the circuit depth increases, the hypergraph of the final frame becomes more complicated, requiring a larger number of vertices (qubits) to be removed (traced out) [31]. Figure 3(a,c) shows that our simulation method successfully samples the measurement outcomes.

Figure 3(b) shows that for 1D architecture, the average number of classically simulatable qubits (n_{sim}) increases linearly by n. This result can be compared to the tensor network simulation, where all the n-qubit outcomes of these circuits can be efficiently simulated with $e^{\mathcal{O}(\alpha \ln n)} \sim n^{\mathcal{O}(\alpha)}$ time cost [35, 36]. In contrast, our algorithm simulates a linear portion of qubits with $\mathcal{O}(\alpha\text{poly}(n))$ time cost, including both evaluating the final frame F and solving its vertex cover problem [31].

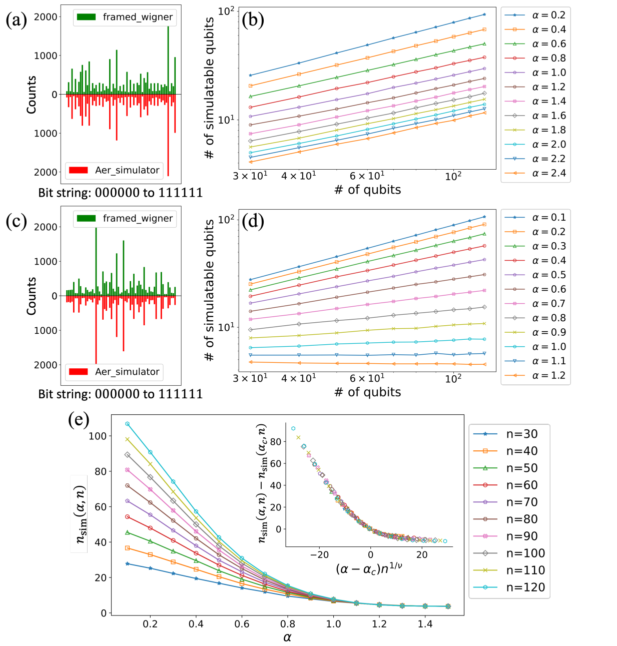

FIG. 3: (a), (c): Comparison between sampling results using the framed Wigner function and Qiskit Aer simulator for a randomly chosen 10-qubit log-depth Clifford circuit with (a) 1D-neighboring and (c) completely connected architecture. For both cases, nonstabilizer input state $|A\rangle\langle A|^{\otimes 10}$ is taken, and 6 marginal qubits are selected after solving the vertex cover problem. The y-axis shows the number of counts of binary string that simulators sampled by taking a total of 20000 samples. (b), (d): The averaged number of simulatable qubits (n_{sim}) by increasing the gate count $L = \alpha(n \ln n)$ of 1000 random Clifford circuits with (b) 1D-neighboring and (d) completely connected architectures. (e) Scaling behavior of n_{sim} by increasing α and data collapse after finite-size scaling.

Therefore, for the selected marginal outcomes, our approach offers a faster simulation than the tensor network method when the circuit depth α becomes large. From the numerical simulation, we observe remarkable improvement compared to the matrix product state simulator of the IBM Qiskit [31].

For the completely connected architecture, we observe a sharp transition of n_{sim} depending on the gate count. For $\alpha \leq \alpha_c$, n_{sim} scales linearly by increasing the number of qubits. In contrast, if the gate count exceeds a certain value $\alpha \geq \alpha_c$, we observe the sub-linear scaling of the n_{sim} (see Fig. 3(d)). From the finite-size scaling analysis by taking a general scaling form $n_{\text{sim}}(\alpha, n) - n_{\text{sim}}(\alpha_c, n) = f((\alpha - \alpha_c)n^{1/\nu})$ [37], we numerically estimate the critical value $\alpha_c \approx 0.81$ and $\nu \approx 1.28$ (see Fig. 3(e)). We conjecture that this critical phenomenon is closely related to the anti-concentration properties of the completely connected random circuit [34] as their critical points closely align, $\alpha = 5/6$.

Born probability estimation.— The framed Wigner function can also be utilized for estimating the Born probability in Eq. (4) under less restrictive conditions than outcome sampling. When the final phase space point $\mathbf{u}$ can be efficiently sampled from $W^F_{U\rho U^\dagger}(\mathbf{u}) \geq 0$, one can take an estimator $\hat{p}^F_{\mathbf{u}}(\mathbf{x}) = P^F(\mathbf{x}|\mathbf{u})$ for each $\mathbf{u}$. This leads to an unbiased estimation of the probability $p(\mathbf{x}) = \mathbb{E}_{\mathbf{u}}[\hat{p}^F_{\mathbf{u}}(\mathbf{x})]$, where $\mathbb{E}_{\mathbf{u}}[\cdot]$ denotes averaging over phase space points $\mathbf{u}$ from the distribution $W^F_{U\rho U^\dagger}(\mathbf{u})$ [27]. The estimator $\hat{p}^F_{\mathbf{u}}(\mathbf{x})$ is not necessarily positive and can be efficiently calculated for every $\mathbf{u}$ when $F(\mathbf{0}_x, \mathbf{a}_z)$ is quadratic [38–40]. One can also apply a procedure similar to the sampling scheme by tracing out $(n-k)$ qubits until $F'(\mathbf{0}'_x, \mathbf{u}'_z)$ becomes quadratic, resulting in an efficient estimation of the k-marginal outcome probability. The proposed protocol can be generalized for an arbitrary product state by mixing two different frames without affecting the degree of the reduced frame of the final state [31].

We analyze the precision of the proposed estimator using the mean squared error (MSE), $\mathrm{Var}_{\mathrm{Wig}}(\mathbf{x}') \equiv \mathbb{E}_{\mathbf{u}}[|\hat{p}^F_{\mathbf{u}}(\mathbf{x}') - p(\mathbf{x}')|^2]$ [41, 42]. The average MSE over all possible outcomes becomes $\overline{\mathrm{Var}}_{\mathrm{Wig}} \equiv 1/2^k \sum_{\mathbf{x}' \in \mathbb{Z}_2^k} \mathrm{Var}_{\mathrm{Wig}}(\mathbf{x}') = (1 - Z^{(k)}_{\mathrm{col}})/2^k$, where $Z^{(k)}_{\mathrm{col}} \equiv \sum_{\mathbf{x}' \in \mathbb{Z}_2^k} p(\mathbf{x}')^2 \geq 1/2^k$ is the collision probability of the k-marginal outcomes [10, 34]. This improves the previous result using the estimator in terms of the Pauli operator [43] with the average MSE of $\overline{\mathrm{Var}}_{\mathrm{Pauli}} = (1 - 1/2^k) Z^{(k)}_{\mathrm{col}} \geq \overline{\mathrm{Var}}_{\mathrm{Wig}}$ [31].

Remarks.— We have constructed a classical simulation algorithm for a Clifford circuit with nonstabilizer inputs based on the framed Wigner function. Our key observation is that the phase space point can be covariantly transformed under any Clifford gate by switching the frame of the Wigner function, which significantly extends the regime of positively represented states. Our protocol offers a classically efficient sampling of marginal outcomes with efficient time and memory cost, where these outcomes can be identified by solving the vertex cover problem. As examples, we have explored log-depth Clifford circuits and observed that the number of simulatable qubits behaves differently between locally and completely connected circuits.

While our approach of introducing a family of frame functions establishes a clear connection between Clifford operations and positive Wigner functions, even for a qubit system, it also leaves potential extensions and further exploration. A crucial question would be whether the proposed methods can be further extended to classically simulate non-Clifford circuits or adaptive Clifford circuits in the presence of noise.

CONTENTS

I. PROOF OF THEOREM 1

In this section, we prove Theorem 1 in the main text. Let us first restate Theorem 1 and clarify each step of the proof.

Theorem 1. *Suppose an n-qubit quantum circuit composed of a product state input $\rho = \bigotimes_{i=1}^{n} \rho_i$ and a Clifford unitary U. If each ρ_i is positively represented in either zero or dual frame, the final state $U\rho U^\dagger$ is positively represented within $\mathcal{O}(n^3)$-memory and $\mathcal{O}(\mathrm{poly}(n))$-time costs. From this, one can sample the measurement outcomes of some marginal qubits in the computational basis within $\mathcal{O}(n^2)$-time cost, where these marginal qubits are determined by the frame F.*

To complete the proof, we separately show the following four main parts of Theorem 1.

1. The Wigner representation of a product state input via zero or dual frame.
2. Changing the positively representing frame by the Clifford operation and how the Wigner function transforms as a result. This proves Observation 1.
3. Time and memory complexities of task 2.
4. The capability of classical simulation with a reduced frame after marginalization.

Additionally, we will prove that all stabilizer states can be positively represented under a specific frame so that single-qubit Pauli measurements on all qubits can be efficiently carried out via our method, hence reproducing the result of the Gottesmann-Knill theorem [1]. Finally, we will discuss the accessibility of information on sampled outcomes when the final frame has relaxed conditions of its degree.

A. Wigner representation of a product state

We discuss how a product state can be positively represented under a quadratic frame function. When we consider only a single qubit system, the frame function can have up to a second degree. Therefore, there are two frame $F = 0$ (*zero frame*) and $F = a_{1x}a_{1z}$ (*dual frame*). Now, suppose that for $i \in [n]$, each single qubit state ρ_i is positively represented under $F_i = b_i a_{ix} a_{iz}$ with $b_i = 0$ (zero frame) or $b_i = 1$ (dual frame). Also, we define the Pauli operator acting on the i-th qubit, $T_{\mathbf{a}_i} \equiv i^{a_{ix}a_{iz}} X^{a_{ix}} Z^{a_{iz}}$. Then, we can rewrite ρ_i as

$$\rho_i = \frac{1}{2} \sum_{\mathbf{u}_i, \mathbf{a}_i \in \mathbb{Z}_2^2} W_{\rho_i}(\mathbf{u}_i)(-1)^{[\mathbf{u}_i, \mathbf{a}_i] + b_i a_{ix} a_{iz}} T_{\mathbf{a}_i}. \tag{1}$$

Consequently, we obtain the Wigner representation of a product state input as follows:

$$\rho = \bigotimes_i^n \rho_i = \frac{1}{2^n} \sum_{\mathbf{u}, \mathbf{a} \in V_n} \left(\prod_{i=1}^n W_{\rho_i}(\mathbf{u}_i) \right) (-1)^{[\mathbf{u}, \mathbf{a}] + \sum_{i=1}^n b_i a_{ix} a_{iz}} T_{\mathbf{a}}, \tag{2}$$

where $\mathbf{u} = (\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n)$, $\mathbf{a} = (\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_n)$, and $T_{\mathbf{a}} = \bigotimes_{i=1}^n T_{\mathbf{a}_i}$. Note that ρ is positively represented under the frame $\sum_{i=1}^n b_i a_{ix} a_{iz}$. Hence, the Wigner function of a product state can be represented as a product of single-qubit Wigner functions.

B. Frame changing rules (Observation 1)

We explain the frame-changing rules under the Clifford operations and the corresponding transformation of the Wigner function. Suppose an n-qubit quantum state ρ is positively represented under the frame F_{in}. As we discussed in the main text, after applying a Clifford unitary U, $U\rho U^\dagger$ may have negativity [2] when the frame is fixed. However, we note that the transformation of $T_{\mathbf{a}}$ under any Clifford unitary U has the following form [1]:

$$U T_{\mathbf{a}} U^\dagger = (-1)^{P(\mathbf{a})} T_{S(\mathbf{a})}, \tag{3}$$

where symplectic matrices S and phase functions $P(\mathbf{a})$ for each Clifford gate are given in Table I. This leads to

$$\begin{aligned}
U\rho U^\dagger &= \frac{1}{2^n} \sum_{\mathbf{u}, \mathbf{a} \in V_n} W_\rho^{F_{\text{in}}}(\mathbf{u})\, (-1)^{[\mathbf{u}, \mathbf{a}] + F_{\text{in}}(\mathbf{a})}\, U T_{\mathbf{a}} U^\dagger &(4)\\
&= \frac{1}{2^n} \sum_{\mathbf{u}, \mathbf{a}} W_\rho^{F_{\text{in}}}(\mathbf{u})\, (-1)^{[\mathbf{u}, \mathbf{a}] + F_{\text{in}}(\mathbf{a}) + P(\mathbf{a})}\, T_{S(\mathbf{a})} &(5)\\
&= \frac{1}{2^n} \sum_{\mathbf{u}, \mathbf{a}} W_\rho^{F_{\text{in}}}(\mathbf{u})\, (-1)^{[S(\mathbf{u}), \mathbf{a}] + F_{\text{in}}(S^{-1}(\mathbf{a})) + P(S^{-1}(\mathbf{a}))}\, T_{\mathbf{a}} &(6)\\
&= \frac{1}{2^n} \sum_{\mathbf{u}, \mathbf{a}} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}))\, (-1)^{[\mathbf{u}, \mathbf{a}] + F_{\text{in}}(S^{-1}(\mathbf{a})) + P(S^{-1}(\mathbf{a}))}\, T_{\mathbf{a}} &(7)\\
&= \frac{1}{2^n} \sum_{\mathbf{u}, \mathbf{a}} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}))\, (-1)^{[\mathbf{u}, \mathbf{a}] + F(\mathbf{a})}\, T_{\mathbf{a}} &(8)\\
&= \frac{1}{2^n} \sum_{\mathbf{u}} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u})) A^F(\mathbf{u}). &(9)
\end{aligned}$$

By noting that $U\rho U^\dagger = \frac{1}{2^n} \sum_{\mathbf{u}} W_{U\rho U^\dagger}^F(\mathbf{u}) A^F(\mathbf{u})$ in the new frame $F(\mathbf{a}) = F_{\text{in}}(S^{-1}\mathbf{a}) + P(S^{-1}\mathbf{a})$, we obtain $W_{U\rho U^\dagger}^{F_{\text{in}}}(\mathbf{u}) = W_\rho^F(S^{-1}(\mathbf{u}))$. This proves Observation 1.

Clifford gate	S	$P(\mathbf{a})$
$CNOT_{i\to j}$-gate	$a_{iz}\longleftarrow a_{iz}+a_{jz}$ $a_{jx}\longleftarrow a_{ix}+a_{jx}$	$a_{jz}a_{ix}(a_{iz}+a_{jx}+1)$
H_i-gate	$a_{ix}\longleftarrow a_{iz}$ $a_{iz}\longleftarrow a_{ix}$	$a_{iz}a_{ix}$
S_i-gate	$a_{iz} \longleftarrow a_{ix}+a_{iz}$	$a_{iz}a_{ix}$

TABLE I. A table that shows the symplectic transformation (S) of elementary Clifford gates and corresponding phase function ($P(\mathbf{a})$). $A \leftarrow B$ means A is transformed to B.

We further note that all linear terms within the frame $F(\mathbf{a})$ can be replaced by a translation in the Wigner function. By noting that linear terms can be expressed as $[\mathbf{v},\mathbf{a}]$ for some $\mathbf{v}\in V_n$, we obtain

$$W_\rho^F(\mathbf{u}) = \frac{1}{2^n}\sum_{\mathbf{a}\in V_n}(-1)^{[\mathbf{u},\mathbf{a}]+F(\mathbf{a})}\mathrm{Tr}[\rho T_{\mathbf{a}}] \tag{10}$$

$$= \frac{1}{2^n}\sum_{\mathbf{a}\in V_n}(-1)^{[\mathbf{u}+\mathbf{v},\mathbf{a}]+(F(\mathbf{a})+[\mathbf{v},\mathbf{a}])}\mathrm{Tr}[\rho T_{\mathbf{a}}] \tag{11}$$

$$= \frac{1}{2^n}\sum_{\mathbf{a}\in V_n}(-1)^{[\mathbf{u}+\mathbf{v},\mathbf{a}]+F'(\mathbf{a})}\mathrm{Tr}[\rho T_{\mathbf{a}}] \tag{12}$$

$$= W_\rho^{F'}(\mathbf{u}+\mathbf{v}), \tag{13}$$

where $F'(\mathbf{a}) = F(\mathbf{a}) + [\mathbf{v},\mathbf{a}]$. In other words, if a frame F has a linear term, then its Wigner function of σ follows by translating the arguments of the original Wigner function.

C. Time and memory complexities of frame changing

We discuss the time and memory complexities of the proposed simulation algorithm. We first discuss the memory cost for storing the frame functions. Suppose we have a product state input ρ which is positively represented under the frame $F_{\mathrm{in}} = \sum_{i=1}^n b_i a_{ix} a_{iz}$ with $b_i \in \{0,1\}$. We recall that the final frame after the Clifford operation has the following transformation rule, $F(\mathbf{a}) = F_{\mathrm{in}}(S^{-1}\mathbf{a}) + P(S^{-1}\mathbf{a})$. Since all Clifford operations can be generated by gates in the set $\{CNOT, H, S\}$ shown in Table. I with phase functions of degree up to 3 and linear transformation S^{-1} does not raise the degree of frame function, the resulting frame must have up to the third degree. In light of those facts, we can formalize the final frame as the following cubic binary valued polynomial,

$$F(\mathbf{a}) = \sum_\mu c_\mu a_\mu + \sum_{\mu,\nu} c_{\mu\nu} a_\mu a_\nu + \sum_{\mu,\nu,\omega} c_{\mu\nu\omega} a_\mu a_\nu a_\omega \pmod 2, \tag{14}$$

where $\mu,\nu,\omega \in \{1x,\dots,nx,1z,\dots,nz\}$. To store that information of the frame, we need $\mathcal{O}(n^3)$-memory to contain all coefficients of possible monomials.

We then discuss the time and memory costs for updating the frames for each Clifford gate acting on at most two qubits. With $\mathcal{O}(1)$-time and memory complexity, we can find the symplectic matrix S and phase function P for this gate. Given a frame F to be changed, we collect all monomials having variables in $\{a_{ix}, a_{iz}, a_{jx}, a_{jz}\}$. As we collect each monomial, we linearly transform it via S^{-1} and obtain the set of newly generated monomials. Then we add this set of monomials to F, and we add constant-sized monomials of $P(S^{-1}(\mathbf{a}))$. Since we need at most $\mathcal{O}(n^3)$ memory to record arbitrary cubic frame functions and the above steps do not raise the degree of the output frame, newly generated monomials can be recorded in another $\mathcal{O}(n^3)$-memory. Moreover, we can obtain the set of generated monomials in at most $\mathcal{O}(n^3)$-time by putting or deleting the generated monomial in the new memory, as we transform the selected monomial in F with constant time. The union with the generated set can be done in time complexity with the same scaling of memory. Therefore, the total time complexity is at most $\mathcal{O}(\mathrm{poly}(n))$ given that we have poly(n)-number of 2-qubit Clifford gates.

After getting through all the Clifford gates, by the last argument of Section I B, we can always choose $\mathbf{v}_F \in V_n$ for the final frame without linear terms by applying an additional translation to the Wigner function to be $W_\rho^{F_{\mathrm{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))$, i.e., $W_{U\rho U^\dagger}^F(S(\mathbf{u})+\mathbf{v}_F) = W_\rho^{F_{\mathrm{in}}}(\mathbf{u})$. Also, this translation does not affect the scale of total time complexity. From now on, for convenience, we will always assume that the final frame has no linear terms.

D. Weak simulation

Now, we discuss sufficient conditions of weak simulation via the framed Wigner function. Suppose the frame F satisfies $F(\mathbf{0}_x, \mathbf{a}_z) = 0$. We then note that $P^F(\mathbf{x}|\mathbf{u})$ with $\mathbf{x} \in \mathbb{Z}_2^n$ can be expressed as

$$\begin{aligned} P^F(\mathbf{x}|\mathbf{u}) &= \langle \mathbf{x}|A^F(\mathbf{u})|\mathbf{x}\rangle && (15)\\ &= \frac{1}{2^n} \sum_{\mathbf{a}\in V_n} (-1)^{[\mathbf{u},\mathbf{a}]+F(\mathbf{a})} \langle \mathbf{x}|T_{\mathbf{a}}|\mathbf{x}\rangle && (16)\\ &= \frac{1}{2^n} \sum_{\mathbf{a}\in V_n} (-1)^{[\mathbf{u},\mathbf{a}]+F(\mathbf{a})} \delta_{\mathbf{a}_x,0} (-1)^{\mathbf{a}_z\cdot\mathbf{x}} && (17)\\ &= \frac{1}{2^n} \sum_{\mathbf{a}_z\in\mathbb{Z}_2^n} (-1)^{\mathbf{a}_z\cdot(\mathbf{x}+\mathbf{u}_x)} && (18)\\ &= \delta_{\mathbf{x},\mathbf{u}_x}. && (19) \end{aligned}$$

Next, we express the Born probability $p(\mathbf{x}) = \mathrm{Tr}(U\rho U^\dagger |\mathbf{x}\rangle\langle\mathbf{x}|)$ in terms of the framed Wigner function. When the output state $U\rho U^\dagger$ is positively represented as $W^F_{U\rho U^\dagger}(\mathbf{u}) = W_\rho^{F_{\mathrm{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))$, we observe that

$$\begin{aligned} \mathrm{Tr}(U\rho U^\dagger |\mathbf{x}\rangle\langle\mathbf{x}|) &= \sum_{\mathbf{u},\mathbf{a}\in V_n} W_\rho^{F_{\mathrm{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F)) \langle \mathbf{x}|A^F(\mathbf{u})|\mathbf{x}\rangle && (20)\\ &= \sum_{\mathbf{u},\mathbf{a}} W_\rho^{F_{\mathrm{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))\delta_{\mathbf{x},\mathbf{u}_x} && (21)\\ &= \sum_{\mathbf{u}_z\in\mathbb{Z}_2^n,\mathbf{a}\in V_n} W_\rho^{F_{in}}(S^{-1}((\mathbf{x}+(\mathbf{v}_F)_x, \mathbf{u}_z+(\mathbf{v}_F)_z)). && (22) \end{aligned}$$

By the above result, we can make a weak simulation scheme, which samples outcomes $\mathbf{x}$ following the probability distribution $p(\mathbf{x})$, as follows:

1. Sample the phase point $\mathbf{u} \in V_n$ from $W_\rho^{F_{\mathrm{in}}}(\mathbf{u})$ with the initial frame F_{in}.
2. Update $\mathbf{u} \leftarrow S(\mathbf{u})$
3. Update $\mathbf{u} \leftarrow \mathbf{u} + \mathbf{v}_F$
4. Output $\mathbf{u}_x$.

Even if the resulting frame does not satisfy the condition $F(\mathbf{0}_x, \mathbf{a}_z) = 0$, we could find marginal measurements in which the reduced frame satisfies that condition. We explain this in more detail here. Without losing the generality, assume that we measure only the first to $k(\leq n)$-th qubits and then trace out the others. The marginal measurement probability to obtain $\mathbf{x}' \in \mathbb{Z}_2^k$ then becomes

$$\begin{aligned} p(\mathbf{x}') &= \sum_{\mathbf{x}''\in\mathbb{Z}_2^{n-k}} \mathrm{Tr} U\rho U^\dagger |\mathbf{x}'\oplus\mathbf{x}''\rangle\langle\mathbf{x}'\oplus\mathbf{x}''| && (23)\\ &= \sum_{\mathbf{x}''\in\mathbb{Z}_2^{n-k}} \sum_{\mathbf{u},\mathbf{a}\in V_n} W_\rho^{F_{\mathrm{in}}}(S^{-1}(\mathbf{u}+\mathbf{v})) \langle \mathbf{x}'\oplus\mathbf{x}''|A^F(\mathbf{u})|\mathbf{x}'\oplus\mathbf{x}''\rangle && (24)\\ &= \frac{1}{2^k} \sum_{\mathbf{u}} W_\rho^{F_{\mathrm{in}}}(S^{-1}(\mathbf{u}+\mathbf{v})) \sum_{\mathbf{a}'_z\in\mathbb{Z}_2^k} (-1)^{\mathbf{u}_x\cdot(\mathbf{a}'_z\oplus\mathbf{0}'')+\mathbf{a}'_z\cdot\mathbf{x}'+F(\mathbf{0},\mathbf{a}'_{\mathbf{z}}\oplus\mathbf{0}'')}. && (25) \end{aligned}$$

Hence, if the $F'(\mathbf{0}_x, \mathbf{a}'_z) = F(\mathbf{0}_x, \mathbf{a}'_{\mathbf{z}} \oplus \mathbf{0}'') = 0$, the last equation becomes $\frac{1}{2^k}\sum_{\mathbf{u}} W_\rho^{F_{\mathrm{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))\delta_{\mathbf{x}',\mathbf{u}'_x}$. Then, we can efficiently measure the outcome $\mathbf{x}'$ by similar steps to the main algorithm. We just need to replace $\mathbf{u}_x$ with $(u_{1x}, \ldots, u_{kx}, 0, \ldots, 0)$. In the same way, if the resulting frame after marginalizing arbitrary k-qubits satisfies $F'(\mathbf{0}'_x, \mathbf{a}'_z) = 0$, we can efficiently measure the marginal outcome. We note that after marginalizing $n-1$ qubits, the reduced frame must become zero.

Now, let us recollect the results obtained through this section to encapsulate the proof. We assume that a input state is a product state $\rho = \bigotimes_{i=1}^n \rho_i$ and each ρ_i is positively represented under a single qubit frame $F_i = 0$ or $F_i = a_{ix}a_{iz}$. Then ρ can be positively represented under $F_{\mathrm{in}} = \sum_{i=1}^n b_i a_{ix} a_{iz}$ $(\forall b_i \in \{0,1\})$. As we discussed in the previous section, the time complexity of frame changing is up to poly(n) as well as obtaining S [1] with at most $\mathcal{O}(n^3)$ memory cost. Marginalizing the resulting frame until it becomes linear takes at most $\mathcal{O}(n^4)$-time. This is because checking if a given frame has non-linear terms takes $\mathcal{O}(n^3)$-time, and the reduced frame must be zero after the marginalization of $n-1$ qubits. Also, updating $\mathbf{u}$ to $\mathbf{u}'$ is a simple matrix multiplication which takes $\mathcal{O}(n^2)$ time. This completes the proof of Theorem 1. In Section II, we provide a systematic program to solve this problem by solving the graph theoretical problem.

E. Efficient simulation of Pauli measurements to stabilizer states

If the depth of the circuit becomes high, the resulting frame may contain many quadratic and cubic terms. Hence, only a small number of qubits might be efficiently simulatable. However, we show that if the input is a stabilizer state, any non-adaptive Clifford circuit can be transformed to the *CH-form* [3], which satisfies the efficient sampling condition. This can be shown by the following Lemma:

Lemma 1. *[Bruhat Decomposition [4, 5]] (i) An arbitrary n-qubit Clifford circuit can be rewritten by layers* $\mathrm{hF'}-\mathrm{SW}-\mathrm{H}-\mathrm{hF}$*, where* H *is a layer of Hadamard gates,* SW *is a layer of SWAP gates (hence of CNOT gates) and* $\mathrm{hF},\mathrm{hF'}$ *are CNOT-CZ-S-Pauli layered circuits. This decomposition can be done with poly(n)-time.*

(ii) Starting from the zero frame $F_{\text{in}}=0$, the changed frame F after $\mathrm{Pauli}-\mathrm{H}-\mathrm{hF}$ *section satisfies $F(\mathbf{0}_x,\mathbf{a}_z)=0$.*

Proof. The proof of (i) can be found in Refs. [4, 5]. We show (ii) by noting that the phase functions (see Table. I) of $H, S, CNOT$ gates do not have quadratic or cubic monomials with only a_{iz} terms, and the symplectic transforms of S and $CNOT$ gates do not change a_{ix} to a_{jz}. Furthermore, we can easily note that the phase function of the Pauli operator is linear, and the symplectic operation is identity. Hence, the final frame $F(\mathbf{0},\mathbf{a}_z)$ must be linear, and those linear terms can be converted into translation following the last arguments of Section I C. □

We can represent stabilizer states as zero state input rotated by a Clifford operation. Also, by Lemma 1, this operation can be transformed to $\mathrm{hF'}-\mathrm{S}-\mathrm{H}-\mathrm{hF}$ form. However, the first CNOT-CZ-S part of hF' section does not affect to zero state. Hence, we have a zero state followed by $\mathrm{Pauli}-\mathrm{H}-\mathrm{hF}$ sections. Note the zero states can be positively represented under zero frame, and the resulting frame satisfies $F(\mathbf{0}_x,\mathbf{a}_z)=0$. Therefore, all the n-qubit measurement outcomes $\mathbf{x}$ can be efficiently simulated via the framed Wigner function.

F. Simulation for a resulting frame of second degree

When the resulting frame $F'(\mathbf{0}_x,\mathbf{a}_z)$ is quadratic, we cannot directly measure the outcome. However, we can still obtain some information about those outcomes.

Proposition 1. *Let ρ be positively represented under a single frame F_{in}, and the final frame is F. We take I_F such that $F(\mathbf{a}_x=\mathbf{0},\mathbf{a}_z)\big|_{a_{iz}=0\text{ for }i\notin I_F}$ is a quadratic Boolean function. Then we can simulate to obtain at least $\lfloor\frac{|I_F|+1}{2}\rfloor$ number of Boolean function values with the arguments of $|I_F|$-marginal measurement outcome.*

Proof. We first assume that $F(\mathbf{a}_x=\mathbf{0},a_z)\big|_{a_{iz}=0\text{ for }i\notin I_F}$ only has quadratic terms. We choose one element from $i_1\in[n]\backslash I$ and rewrite $F(\mathbf{a}_x=\mathbf{0},a_z)\big|_{a_{iz}=0\text{ for }i\notin I_F}$ as $a_{i_1z}(L_{\{i_1\}}(\mathbf{a}_z))+Q_{\{i_1\}}(\mathbf{a}_z)$, where $L_{\{j_1,j_2,\dots\}}$ denotes a linear Boolean function that does not have variables $\{a_{j_1z},a_{j_2z},\dots\}$ and $Q_{\{j_1,j_2,\dots\}}$ denotes a quadratic Boolean function not having variables $\{a_{j_1z},a_{j_2z},\dots\}$. Now, we choose one another variable $i_2\neq i_1$ in $L_{\{i_1\}}$ and find an invertible linear transform S_1 that transforms $a_{i_1z}L_{\{i_1\}}$ to $a_{i_1z}a_{i_2z}$ $(i_1\neq i_2)$ and $Q_{\{i_1\}}$ to another quadratic polynomial $Q^{(1)}_{\{i_1\}}$ still not having variable a_{i_1z}. This is possible by taking S_1 which transforms a_{i_2} to $L_{\{i_1\}}(\mathbf{a}_z)$ and leaves the other variables unchanged. Then, S_1 is linear and invertible.

After that, $a_{i_1z}(L_{\{i_1\}}(\mathbf{a}_z))+Q_{\{i_1\}}(\mathbf{a}_z)$ is transformed to $a_{i_1z}a_{i_2z}+Q^{(1)}_{\{i_1\}}(\mathbf{a}_z)$. Next, we decompose $Q^{(1)}_{\{i_1\}}$ so that $a_{i_1z}a_{i_2z}+Q^{(1)}_{\{i_1\}}(\mathbf{a}_z)$ is transformed to $a_{i_1z}a_{i_2z}+a_{i_2z}L_{\{i_1,i_2\}}+Q^{(1)}_{\{i_1,i_2\}}(\mathbf{a}_z)$. If $Q^{(1)}_{\{i_1\}}$ does not have a_{i_2z} hence $L_{\{i_1,i_2\}}=0$, we set S_2 as $n\times n$ identity and choose $i_3\in[n]\backslash\{i_1,i_2\}$ and decompose $Q^{(1)}_{\{i_1\}}$ starting with i_3 as we do with i_1. Otherwise, if $L_{\{i_1,i_2\}}$ is non-zero, then we again take a linear transform S_2 that converts the above equation to $a_{i_1z}a_{i_2z}+a_{i_2z}a_{i_3z}+Q^{(2)}_{\{i_1,i_2\}}(\mathbf{a}_z)$. After repeating this, we obtain the final resulting polynomial $a_{i_1z}a_{i_2z}+c_2a_{i_2z}a_{i_3z}+\dots+c_pa_{i_pz}a_{i_{p+1}z}$ $(p\in\mathbb{N}$ and, $c_2,\dots c_p\in\{0,1\})$.

From these arguments, the marginal outcome probabilities $p(\mathbf{x}')$ on the subset of qubits I_F under U(with symplectic transform S) is

$$p(\mathbf{x}') = \sum_{\mathbf{x}''} \mathrm{Tr}(\left|\mathbf{x}' \oplus \mathbf{x}''\right\rangle \left\langle \mathbf{x}' \oplus \mathbf{x}''\right| U\rho U^{\dagger}) \tag{26}$$

$$= \sum_{\mathbf{u}} \left(\sum_{\substack{\mathbf{a}_z \in \mathbb{Z}_2^n, \\ a_{iz}=0 \text{ for } i\in[n]\setminus I_F}} \frac{1}{2^{|I_F|}} W_{\rho}^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))\,(-1)^{\left((\mathbf{u}_x+(\mathbf{x}'\oplus 0))\cdot \mathbf{a}_z + F'(\mathbf{a}_x=\mathbf{0},\mathbf{a}_z)\right)} \right) \tag{27}$$

$$= \sum_{\mathbf{u}} \left(\sum_{\substack{\mathbf{a}_z \in \mathbb{Z}_2^n, \\ a_{iz}=0 \text{ for } i\in[n]\setminus I_F}} \frac{1}{2^{|I_F|}} W_{\rho}^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))\,(-1)^{((\mathbf{u}_x+(\mathbf{x}'\oplus 0))\cdot(S_1S_2\ldots S_p)(\mathbf{a}_z)+a_{i_1z}a_{i_2z}+c_2a_{i_2z}a_{i_3z}+\ldots+c_pa_{i_pz}a_{i_{p+1}z})} \right) \tag{28}$$

$$= \sum_{\mathbf{u}} \left(\sum_{\substack{\mathbf{a}_z \in \mathbb{Z}_2^n, \\ a_{iz}=0 \text{ for } i\in[n]\setminus I_F}} \frac{1}{2^{|I_F|}} W_{\rho}^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))(-1)^{(S_1S_2\ldots S_p)^T(\mathbf{u}_x+(\mathbf{x}'\oplus 0))\cdot\mathbf{a}_z+a_{i_1z}a_{i_2z}+c_2a_{i_2z}a_{i_3z}+\ldots+c_pa_{i_pz}a_{i_{p+1}z}} \right). \tag{29}$$

Therefore, we conclude that (note that $S_1S_2\ldots S_p$ acts as an identity on the subset of qubits $[n]\setminus I_F$)

$$\sum_{\mathbf{x}''} p\left(\left((S_1S_2\ldots S_p)^T\right)^{-1}(\mathbf{x}'\oplus\mathbf{x}'')\right) \tag{30}$$

$$= \sum_{\mathbf{u}} \left(\sum_{\substack{\mathbf{a}_z \in \mathbb{Z}_2^n, \\ a_{iz}=0 \text{ for } i\in[n]\setminus I_F}} \frac{1}{2^{|I_F|}} W_{\rho}^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))(-1)^{\left((S_1S_2\ldots S_p)^T(\mathbf{u}_x)+(\mathbf{x}'\oplus 0)\right)\cdot\mathbf{a}_z+a_{i_1z}a_{i_2z}+c_2a_{i_2z}a_{i_3z}+\ldots+c_pa_{i_pz}a_{i_{p+1}z}} \right). \tag{31}$$

Now, we further trace out qubits in $\{i_2, i_4, \ldots, i_p\}$ if p is even and $\{i_2, i_4, \ldots, i_{p+1}\}$ if p is odd until the remaining frame becomes linear, then use the simulation algorithm of Section I D. However, after the step 3, we must take $\mathbf{u}_x$ to $(S_1S_2\ldots S_p)^T(\mathbf{u}_x)$. Consequently, given that p is even (routine is similar for odd p), the outcome string is $\left(\left((S_1S_2\ldots S_p)^T(\mathbf{u}_x)\right)_i\right)_{i\in I_F\setminus\{i_2,i_4,\ldots,i_p\}}$. The worst case happens when all c_k $(k\in[n])$ is 1 and $p = |I_F - 1|$ so that the number of measurable qubits is $\lfloor\frac{|I_F|+1}{2}\rfloor$. Time to obtain $(S_1S_2\ldots S_p)^T$ is at most poly(n)-time, and then measuring outcome takes $\mathcal{O}(n^2)$-time. Since we rotate $\mathbf{u}_x$ once more by $(S_1S_2\ldots S_p)^T$, the measured outcome is partial elements of $(S_1S_2\ldots S_p)^T\left((S_1S_2\ldots S_p)^T\right)^{-1}(\mathbf{x}')$ that are the linear Boolean function values of direct measurement outcome $\left((S_1S_2\ldots S_p)^T\right)^{-1}(\mathbf{x}')$ (see Eq. (30)). □

II. FINDING EFFICIENTLY SIMULATABLE QUBITS BY SOLVING THE VERTEX COVER PROBLEM

In the main text, we discuss that the k-marginal qubits are efficiently simulatable when tracing out the $(n-k)$ qubits until the reduced frame meets the condition $F'(\mathbf{0}_x, \mathbf{a}_z') = 0$. In this section, we discuss how this can be translated into a graph theoretical problem, known as *the vertex cover problem* in more detail.

A. Basic notation of graph theory

Here, we introduce a formal definition of hypergraph and the vertex cover problem.

Definition 1 (Hypergraph). *(i) Let V be a non-empty set. We say a tuple $G(V,E)$ is a* hypergraph *if and only if E is a set of subsets $e \in V$ of V. We call each element in E an* edge*. From now on, we always assume $\forall e \in E, |e| > 1$.*

Let $G(V, E)$ be a hypergraph.
(ii) We say G is of kth-degree ($k \in \mathbb{N}$) if all edges in G contain at most k vertices.
*(iii) If all elements of E have ($k \in \mathbb{N}$)-number of elements in V, then we call $G(V, E)$ as a k-*uniform hypergraph *or simply a k-*graph*. Also, a 2-graph is just called a* graph*.*

Next, we define several properties of a hypergraph.

Definition 2. *Let $G(V, E)$ be a hypergraph.*
i) $V' \subset V$ is a vertex cover *if all edges in E contain some elements in V'. $A \subset V$ is the* minimal vertex cover *if every vertex cover $V' \subset V$ satisfies $|V'| \geq |A|$.*
ii) $S' \subset V$ is an independent set *if any two elements in S' are not contained in same edge in E. $B \subset V$ is the* maximal independent set *if every independent set $S' \subset V$ satisfies $|S'| \leq |B|$.*
iii) Let A be a minimal vertex cover of G and B be a maximal independent set in G. Then we denote $\nu(G) \equiv |A|$ and $\triangle(G) \equiv |B|$. We note that minimal(maximal resp.) vertex cover(independent set) could not be unique, but $\nu(G)$ and $\triangle(G)$ are unique.
iv) For $v \in V$, order *of v, $d(v)$ is the number of edges containing v.*
v) Maximal order *of the graph, $d(G)$ is* $\max_{v \in V} \{d(v)\}$.

The *vertex cover problem* is to find the minimal vertex cover of a given hypergraph. Now, we obtain the following result.

Corollary 1. *For any hypergraph $G(V, E)$, $\nu(G) + \triangle(G) \leq |V|$.*

Proof. Consider a maximal independent set $S \subset V$ ($|S| = \triangle(G)$) and suppose $|V \backslash S| = |V| - \triangle(G) < \nu(G)$. Then $V \backslash S$ must not be the vertex cover. Hence, there exists $e \in E$ such that e does not have any elements in $V \backslash S$. Since e is non-zero, without loss of generality, say $e = \{v_1^e, v_2^e, \ldots, v_k^e\} \subset S$ ($k \geq 2$). Since S is independent, $|e| = 1$, which contradicts that $k \geq 2$. In conclusion, $|V \backslash S| = |V| - \triangle(G) \geq \nu(G) \Rightarrow \nu(G) + \triangle(G) \leq |V|$. □

If the graph representation is 2-graph (resulting frame is quadratic), then it is known that $\triangle G = |V| - \nu(G)$.

The vertex cover problem is an NP-hard problem [6], but several efficient and approximative algorithms are valid [7]. These algorithms may obtain vertex covers such that the size is larger than the minimal cover but is within a reasonable scale factor. The typical example we use throughout this paper is a *greedy algorithm.* The detailed procedure of the algorithm is as follows. Suppose we have a hypergraph $G(V, E)$.

1. For each vertex $v \in V$ of G, count $d(v)$ (*order of* v), the number of edges containing v.
2. Take $v' = \text{argmax}_{v \in V} \{d(v)\}$.
3. Remove v' from G and also remove all edges containing v'.
4. Repeat the above sequences with at most $|V|$ times until no edges are left.

Step 1 takes at most $\mathcal{O}(|V||E|)$-time, and Step 2 takes $\mathcal{O}(|V|)$-time. Step 3 takes at most $\mathcal{O}(|E|)$-time, which is the time complexity of set subtraction. Since we repeat these steps at most $|V|$-time, the total time complexity of the greedy algorithm is at most $\mathcal{O}(|V|^2|E|)$.

B. Graph representation of the frame function and marginalization

Now, we show how to connect finding simulatable marginal qubits and the vertex cover problem of the hypergraph. We recall the brief explanation of the graph representation of the frame function in the main text. We shall call this a *frame graph.*

Definition 3. *Suppose we have a frame function F of at most 3rd-degree such that $F(\mathbf{0}_x, \mathbf{a}_z) = \sum_{(i,j) \in \mathcal{E}_2} a_{iz} a_{jz} + \sum_{(i,j,k) \in \mathcal{E}_3} a_{iz} a_{jz} a_{kz}$ (mod 2) for proper index set $\mathcal{E}_2 \subset [n]^{\otimes 2}, \mathcal{E}_3 \subset [n]^{\otimes 3}$. Frame graph G_F of F is a hypergraph $G(V, E)$ where V is a set of vertex $\{a_{1z}, a_{2z}, \ldots, a_{nz}\}$ and $E = \mathcal{E}_2 \bigcup \mathcal{E}_3$.*

From the Section I D, we know that whenever we marginalize the i-th qubit, we substitute $a_{iz} = 0$ to the representing frame $F'(\mathbf{0}_x, \mathbf{a}_z)$. In other words, all monomials containing a_{iz} vanish. In a graphical notation, this means that starting from the frame graph of $F'(\mathbf{0}, \mathbf{a}_z)$, we eliminate both the i-th vertex and all connecting hyperedges. Therefore, tracing the qubits to make the resulting frame function zero is equivalent to finding vertex cover: eliminating vertices and connecting edges until all edges vanish. We can do this using the greedy algorithm and note that $|V|$ is at most n and $|S|$ is within $\mathcal{O}(n^3)$. From the arguments in Section II A, the total time complexity is at most $\mathcal{O}(n^4)$.

Solving the vertex cover problem of the final frame enables us to search simulatable qubits from a given highly entangled circuit that is hard to pick by hand. Also, we can use various modern approximation techniques to find more qubits over the greedy algorithm [6].

We can find the largest number of simulatable qubits if we find the minimal vertex cover. Also, we note that the independent set of the frame graph is also a set of simulatable qubits. However, Corollary 1 says that finding minimum vertex cover and tracing out the qubits corresponding to the vertices produces a larger set of simulatable qubits than finding the maximal independence set.

III. SIMULATIONS ON LOG-DEPTH CLIFFORD CIRCUITS

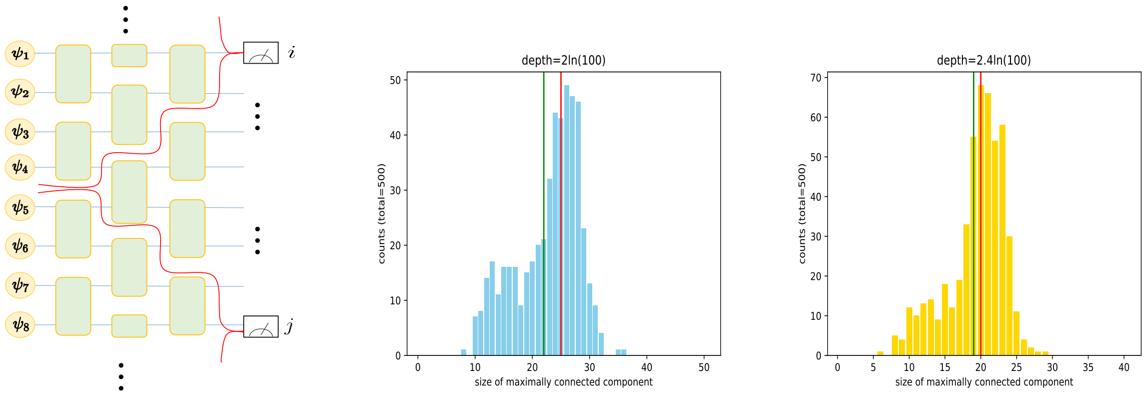
A. Circuit architecture

We first briefly explain the definitions of several n-qubit Clifford circuit architectures [8]. One is the *1D* architecture, which consists of alternating layers with 2-qubit random Clifford gates between neighboring qubits (see Fig. 1(a)). We also regard the Clifford gates connecting the first and the last qubits as a neighboring gate. The other is the *complete graph* architecture, where we put a random single qubit gate to each qubit, and then random Clifford gates are applied between randomly chosen two qubits, regardless of their locations. *Gate count* is the total number of 2-qubit random Clifford gates. In both architectures, random Clifford gates are uniformly chosen [8], and we enact each gate until the gate count reaches the designated value. The *depth* of the circuit is defined as the minimum value of the number of layers in which a set of 2-qubit gates can be applied in parallel (also, see Ref. [8] for more detail). Furthermore, the authors in Ref. [8] showed that in both cases, there exists sufficient and necessary scaling of gate count $\mathcal{O}(n\log(n))$ such that outcome probability distribution of random circuit sampling (including random unitary gates) satisfies the anti-concentration condition [9].

B. On the inseparability of efficiently measurable qubits found from the greedy algorithm for 1D circuits

For the log-depth 1D architecture, even if we do not use the framed Wigner formalism, we can always find many qubits on which measurements are simulatable via brute-forced matrix calculation. We briefly explain how to do this and numerically show that simulatable qubits found by our method do not fall to this case. Suppose we have a d-depth 1D circuit. Now, we pick $i \in [n]$ and choose one group of locations of qubits, $\left\{i - \lfloor\frac{\beta}{2}\log_2(n)\rfloor, i - (\lfloor\frac{\beta}{2}\log_2(n)\rfloor - 1), \ldots, i, \ldots, i + (\lceil\frac{\beta}{2}\log_2(n)\rceil - 1), i + \lceil\frac{\beta}{2}\log_2(n)\rceil\right\}$. Then if we only measure this subset of qubits, we can efficiently simulate it with rotating Pauli operators via Clifford operations [10] with at most $\mathcal{O}(n^{\beta+1}\log_2(n))$-time. Because one method is to calculate the Born probability exactly. To do so, we expand the target binary state by $2^{\beta\log_2(n)} = n^\beta$ number of coherent Z operators and then obtain all traces between the input product state and Pauli operators, which is backward-evolved by Clifford circuit starting from those Z operators. We note that each expectation is obtained in $\mathcal{O}((\log_2(n))^2)$-time [1, 10]. Furthermore, if we choose another $i' \in [n]$ such that $\left\{j - \lfloor\frac{\beta}{2}\log(n)\rfloor, j - (\lfloor\frac{\beta}{2}\log(n)\rfloor - 1), \ldots, j, \ldots, j + (\lceil\frac{\beta}{2}\log(n)\rceil - 1), j + \lceil\frac{\beta}{2}\log(n)\rceil\right\}$ is $2d$-far away from has a distance of $2d$ between the previous group (see Fig. 1 for 3-depth case), then we can also efficiently simulate these measurements by same time complexity because gates involved in two simulations are totally separated. By repeating the same procedure, we find the $\frac{n}{2d+\beta\log_2(n)}$-number of groups of simulatable qubits. Hence, given $d = \alpha\log_2(n)$, the total number of simulatable qubits is $\frac{\beta n}{2\alpha+\beta}$ with total simulation time $\mathcal{O}(n^{\beta+1}(\log_2(n))^2)$.

However, this trivial method only finds distant groups with neighboring qubits. This means that the simulatable qubits should be picked from each group, which always has a distance larger than $2d$ each other. In contrast, our methods also find simulatable qubits that are not far from each other, which can be numerically checked. More precisely, given a non-adaptive Clifford circuit with the Clifford unitary U, let $A_U \equiv \left\{i_1, i_2, \ldots, i_{|A_U|}\right\} \subset [n]$ be a set of locations of simulatable qubits. Now, let Z_i be an n-qubit Paul operator, which affects the Z-operation to the i-th qubit and identity to the other qubits. We calculate the set of Pauli operators $P_{A_U} \equiv \left\{U^\dagger Z_i U | i \in A_U\right\}$ which can be obtained efficiently [10]. We then define the 2-graph $G(A_U, E_{A_U})$ where the set of vertex is A_U, and E_{A_U} is a set of edges which connects $i, j \in A_U$ if and only if two Pauli strings $U^\dagger Z_i U$ and $U^\dagger Z_j U$ have non-trivial (not identity, not need to be same) Pauli operation on the same qubit locations. Now, we denote $\mathcal{C}(G(A_U, E_{A_U})) \subset A_U$ as a set of connected components of G, i.e., vertices consisting of connected subgraphs such that each subgraph is not connected with the others. We note that measurement on the set of qubits with location $C' \in \mathcal{C}(G(A_U, E_{A_U}))$ is independent



(a) (b) (c)

FIG. 1. (a) Schematic illustration of a 3-depth 1D circuit. Measurement on the i-th qubit does not influence the measurement outcome of the j (6-far away from i). If we only simulate these two measurements, we can separate this circuit into two portions sided by the red line. (b,c) The population of the size of maximally connected components for 500 numbers of 100-qubit 1D shallow Clifford samples. The green line represents the average size of maximally connected components, and the red line indicates the average value of total simulatable qubits of each sample. (b): Results of depth $= 2\ln(100)$ 1D circuits (green line:22, red line:25). (c): Results of depth $= 2.4\ln(100)$ 1D circuits (green line:19, red line:20).

of the measurement outcome on the set of other locations in $\mathcal{C}(G(A_U, E_{A_U}))$. Hence, the time complexity of weak simulation is upper bounded by $\mathcal{O}\left(\exp\left(\max_{C\in\mathcal{C}(G(A_U,E_{A_U}))}(|C|)\right)\right)$, which can be achieved by the similar method with the first paragraph. Now we see Fig. 1 (b) and (c). We randomly sample 500 numbers of 100-qubit 1D Clifford circuit U with zero frame input and find $\max_{C\in\mathcal{C}(G(A_U,E_{A_U}))}(|C|)$ efficiently via Python NetworkX packages, and we observed that most of the samples have many connected Pauli operators $U^\dagger Z_i U$ ($i \in A_U$) and hence such a trivial decomposition (in the first paragraph) is not applied to them.

C. Simulation time comparison with Qiskit

In this section, we show two graphs of the simulation speed of shallow non-adaptive Clifford circuits (see Fig. 2). We compare the simulation time between our simulator and the Qiskit Aer_simulators. For the Wigner function method, simulation time includes the frame changing and finding simulatable qubits, as well as sampling and rotating the phase point. In both simulators, Wigner and Qiskit, we measure the marginal outcome only once. The time complexity $\mathcal{O}(\alpha\text{poly}(n))$ in the main text is obtained by changing the frame for each Clifford gate, and hence total time complexity is $\mathcal{O}(n^3)$ multiplied by the gate count $\alpha n\ln n$. For 1D case, by Sec. II A, time complexity for solving vertex cover problem is $\mathcal{O}\left(\alpha^3 n^3(\ln(n))^3\right)$ ($\because |E| = \mathcal{O}(\alpha^3 n(\ln(n))^3)$), lower than frame changing time complexity for large n.

In Fig. 2 (a,b), we observe that our simulator executes the marginal sampling with the polynomial scaling of the time costs by increasing the number of qubits, which can be compared to the Aer_simulators whose time complexity, except for Aer_matrix_product_state (Aer_mps), increases exponentially by increasing the number of qubits. From Fig. 2 (b,c,d), the Aer_mps performs better than framed Wigner when the circuit is low-entangled or has few qubits. Because the Aer_mps employs the tensor network method and is efficient for circuits with large n but with low-entanglement [11]. However, we note that for $n \geq 30$, the simulation time of Aer_mps increases exponentially by increasing the scale factor of gate count, α, hence by increasing the depth. Hence, our method outperforms Aer_mps for this region.

When the number of simulatable qubits is not sufficiently large, there could be other methods, for example, by directly calculating the Born probability to simulate Clifford circuits [1]. However, we expect that the low time scaling of the Wigner function simulator, while keeping a sufficient portion of simulatable qubits, leads to more efficient simulation for larger n compared to the previous methods. In Section III E, we demonstrate that the time complexity can be further improved by utilizing the property of the circuits' shallow depth, at the cost of additional polynomial-sized memory.

FIG. 2. Comparison of simulation time for the log-depth random Clifford circuits between framed Wigner function method and Qiskit Aer simulators. (a,b) Average time (over 200 random samples) for simulating the log-depth Clifford circuits. Here, Aer_density_matrix and Aer_stabilizer simulators are not functioning. We fixed the gate count scaling factor α, while increasing the number of qubits. (c,d) Average time (over 100 random samples) for simulating the 1D Clifford circuits by using the framed Wigner function method and Qiskit Aer simulators. We took the n-copies of $|A\rangle$ state as an input for both (a) and (b)

D. Finite-sized scaling for log-depth completely connected circuits

Here, we explain the finite-sized scaling (FSS) analysis of Fig. 3 (e) in the main text. For the completely connected random Clifford circuits, the average number of measurable qubits ($n_{\rm sim}$) has two different scaling on n for $\alpha > \alpha_c$ and $\alpha < \alpha_c$ with some critical point α_c. In order to explore the critical point, we model the scaling function of $n_{\rm sim}$ in terms of α and n as,

$$n_{\rm sim}(\alpha, n) - n_{\rm sim}(\alpha_c, n) = f((\alpha - \alpha_c), n), \tag{32}$$

for some function f with two different scalings at $\alpha < \alpha_c$ and $\alpha > \alpha_c$. It naturally follows that $f(0, n) = 0$ for all n at the critical point. In order to estimate the critical values, we apply the FSS method to the data set with various α and n values. We take the ansatz $f((\alpha - \alpha_c)n^{\frac{1}{\nu}})$ for some $\nu \in \mathbb{R}$ which is commonly found in the FSS literature [12]. By numerically optimizing the parameter of α_c and ν from the data set, we obtain a good collapse of data as in Fig. 3 (e) in the main text with the optimal parameter $\alpha_c = 0.81$ and $\nu = 1.28$. After we find the (α_c, ν), we observe $n_{\rm sim}(\alpha, n) - n_{\rm sim}(\alpha_c, n) \sim C(\alpha - \alpha_c)n^{\frac{1}{\nu}}$ $(C \in \mathbb{R}^+)$ when $\alpha < \alpha_c$. On the other hand, for $\alpha > \alpha_c$, $n_{\rm sim}(\alpha, n)$ shows almost flat behavior when increasing n (see Fig. 3(d) in the main text).

E. Faster frame changing and finding the vertex cover in shallow depth circuits

We already know that frame changing and finding the vertex cover of the final frame can be done in poly(n)-time. In this subsection, we show that the time complexity can be further reduced for shallow circuits with depth $\mathcal{O}(\alpha \ln(n))$. We also realize that frame changing of uniformly sampled Clifford circuit has time complexity within $\mathcal{O}(n^4)$.

To do so, we further define the equivalent expression of the hypergraph.

Definition 4 (Pivoted graph)**.** *(i) Given a graph $G(V,E)$,* Pivoted graph *of G is a set* $\mathrm{Piv}_G \equiv \left\{(\mathrm{Piv}_1, |\mathrm{Piv}_1|), (\mathrm{Piv}_2, |\mathrm{Piv}_2|), \ldots, (\mathrm{Piv}_{|V|}, |\mathrm{Piv}_{|V|}|)\right\}$ *where for $i \in [|V|]$, the* pivoted set Piv_i *is an indexed set* $\left\{e_j^{(i)}\right\}_{j\in[|\mathrm{Piv}_i|]}$*, which is a subset of E whose edges contain the i-th vertex.*
(ii) A pivoted frame graph *of a frame F is* Piv_{G_F}*.*

Indexing is necessary to search for a specific edge in constant time. Since each pivoted set has a maximal size upper-bounded by $\mathcal{O}(n^2)$, it needs $\mathcal{O}(n^3)$ to represent the frame as its pivoted frame graph.

Next, we review one simple lemma.

Lemma 2. *The time complexity to multiply arbitrary $n \times n$ matrix X and $A \oplus I$ where A is 2×2 matrix and I is $(n-2)\times(n-2)$ identity is $\mathcal{O}(n)$.*

Proof. We can rewrite those two matrices as block matrix forms,

$$X = \begin{pmatrix} C_1 & C_2 \\ C_3 & C_4 \end{pmatrix}, A \oplus I = \begin{pmatrix} A & O \\ O & I \end{pmatrix}. \tag{33}$$

Therefore,

$$X(A\oplus I) = \begin{pmatrix} C_1 A & C_2 \\ C_3 A & C_4 \end{pmatrix}. \tag{34}$$

Hence, we only need to calculate C_1A and C_3A, which takes only $\mathcal{O}(n)$ time complexity, given that A has a constant size and $C_{1(3)}$ has $\mathcal{O}(n)$ size. □

Now, we elaborate on this faster frame-changing algorithm below.

Proposition 2. *Suppose we start from the frame $F_{\mathrm{in}} = \sum_{i=1}^n b_i a_{ix} a_{iz}$, where $\forall i,\ b_i \in \{0,1\}$.*

(i) If the given circuit has 1D architecture and depth d, then obtaining a resulting frame function (and its pivoted frame graph) takes at most $\min\left\{\mathcal{O}(dn^3), \mathcal{O}(d^4 n + dn^2)\right\}$. For a complete graph architecture with depth d, it takes at most $\min\left\{\mathcal{O}(dn^3), \mathcal{O}(8^d \cdot dn + dn^2)\right\}$. To do so, we need $\mathcal{O}(dn^2 + n^3)$-memory.

(ii) There exists a method to uniformly randomly choose a Clifford circuit such that obtaining a resulting pivoted frame graph takes at most $\mathcal{O}(n^4)$.

Proof. (i) Suppose we transform the frame F_0 under a 2-qubit Clifford gate which acts on the i-th and j-th qubits. If we know the pivoted frame graph of F_0, then we just search newly generated monomials from Piv_i, Piv_j, and phase functions. Updating its pivoted frame graph takes $\mathcal{O}(n^2)$-time because the size of the pivoted set is upper bounded by $\mathcal{O}(n^2)$ and updating by generated monomials which come from a single monomial takes constant-time. Then frame changing after a single depth operation takes $\mathcal{O}(n^3)$-time because each depth has $\lfloor \frac{n}{2} \rfloor$ number of neighboring two-qubit gates and changing the pivoted frame graph for each gate takes $\mathcal{O}(n^2)$-time. Hence, the total changing time is at most $\mathcal{O}(dn^3)$, which holds for both 1D and complete graph architecture. Next, let us assume that for each stage $1 \le i \le d$, we act the Clifford operation $U_i \equiv \bigotimes_{j=1}^{k_i} U_{ij}$ where $k_i \in \mathbb{N}, k_i \le \lfloor \frac{n}{2} \rfloor$ and U_{ij} is 2-qubit Clifford operation. We can obtain the symplectic matrix S_i and phase function P_i in $\mathcal{O}(n)$-time because, for each j, the symplectic transform of 2-qubit operation does not affect other qubit pairs. Now, from the arguments in Eq. (9) and Eq. (3), we easily note that resulted symplectic transform S and phase function P is,

$$S = S_d S_{d-1} \ldots S_1, \tag{35}$$

$$P(\mathbf{a}) = P_1(\mathbf{a}) + P_2(S_1(\mathbf{a})) + P_3(S_2(S_1(\mathbf{a}))) + \cdots + P_d(S_{d-1}(S_{d-2}\cdots(S_2(S_1(\mathbf{a})))\cdots)). \tag{36}$$

Hence, the resulting frame function K becomes,

$$\begin{aligned} K(\mathbf{a}) &= F_{\text{in}}(S^{-1}(\mathbf{a})) + P(S^{-1}(\mathbf{a})) && (37)\\ &= P_1(S_1^{-1}(S_2^{-1}\cdots(S_{d-1}^{-1}(S_d^{-1}(\mathbf{a})))\cdots)) + P_2(S_2^{-1}(S_3^{-1}\cdots(S_{d-1}^{-1}(S_d^{-1}(\mathbf{a})))\cdots)) && (38)\\ &\qquad + \cdots + P_{d-1}(S_{d-1}^{-1}((S_d^{-1}(\mathbf{a})))) + P_d(S_d^{-1}(\mathbf{a})) + F(S_1^{-1}(S_2^{-1}\cdots(S_{d-1}^{-1}(S_d^{-1}(\mathbf{a})))\cdots)). && (39) \end{aligned}$$

Each S_i can be expressed as a tensor product $\bigotimes_{j=1}^{k_i} S_{ij}$ of 4×4 matrices, which leads to $S_i^{-1} = \bigotimes_{j=1}^{k_i} S_{ij}^{-1}$. The time complexity to multiply arbitrary $2n\times 2n$ matrix and $A\oplus I_3\oplus\cdots\oplus I_n$, where A is a 4×4 matrix and $I_3,\ldots,I_n$ are 2×2 identities, is $\mathcal{O}(n)$ by the Lem. 2. Therefore, starting from S_d^{-1} and calculating up to $S_1^{-1}(S_2^{-1}\cdots(S_{d-1}^{-1}(S_d^{-1}(\mathbf{a})))\cdots)$ takes $\mathcal{O}(dn^2)$-time. By multiplying each S_i^{-1}'s, we record all $d-1$ output matrices. Storing each output matrix takes $\mathcal{O}(n^2)$-time and therefore we need $\mathcal{O}(dn^2)$-memory and additional $\mathcal{O}(dn^2)$-time.

Now, we prepare another $\mathcal{O}(n^3)$-memory (say M) to represent the pivoted frame graph of zero frame. We will update the graph in a way that the resulting pivoted frame graph is the desired final pivoted frame graph.

For the 1D case, for $m\in[n]$, we easily note that $S^{-1}(\mathbf{a})_{mx(or\ mz)}$ does not have variable $a_{qx(or\ qz)}$ where $|m-q|\ (mod\ n) > d$. If $S^{-1}(\mathbf{a})_{mx(or\ mz)}$ has such variables, two-qubit operation blocks must have propagated from the q-th qubit to the m-th qubit, but this is not the case for the 1D case. Since each P_i is at most of 3rd-degree and has at most $\mathcal{O}(n)$ monomials, expanding $P_i(S_i^{-1}(S_{i+1}^{-1}\cdots(S_2^{-1}(S_1^{-1}(\mathbf{a})))\cdots))$ takes at most $\mathcal{O}((2d)^3 n)$-time. This time complexity is possible because during the expansion, for each obtained single term, we must update the pivoted graph by adding (subtracting resp.) the corresponding edge and adding (subtracting) the order of each pivoted set of target vertices. This step takes constant time. We repeat these steps for d times so that the total time cost is at most $\mathcal{O}(d^4 n)$. Also, in the same manner, adding $F_{\text{in}}(S_1^{-1}(S_2^{-1}\cdots(S_{d-1}^{-1}(S_d^{-1}(\mathbf{a})))\cdots))$ takes $\mathcal{O}((2d)^3 n)$-time.

For a complete graph case, the problem becomes more complicated. Each Clifford gate may entangle two qubits far from each other, and then each qubit can be further affected by different long-ranged Clifford gates. As a results, $S^{-1}(\mathbf{a})_{mx(or\ mz)}$ have the number of variable $a_{qx(or\ qz)}$ upper bounded by 2^{d+1}, so expanding $P_i(S_i^{-1}(S_{i+1}^{-1}\cdots(S_2^{-1}(S_1^{-1}(\mathbf{a})))\cdots))$ takes at most $\mathcal{O}(2^{3d+3}n)$-time. Then we update M in the same way with 1D-case.

(ii) From Ref. [5], we can efficiently sample random Clifford operation in $\mathcal{O}(n^2)$-time. This form always has the layers $F'-S-H-F$, where H is a layer of Hadamard gates, S is a layer of SWAP gates (hence of CNOT gates), and F, F' are CNOT-CZ-S-Pauli layered circuits. CNOT circuit can be decomposed as Clifford bases with depth at most $\mathcal{O}(\frac{n}{\log(n)})$ with at most $\mathcal{O}(n^3)$-time [1, 13]. Also, the depth of the CZ-layer can be upper bounded by $\mathcal{O}(n)$, with $\mathcal{O}(n^3)$-time [14]. Therefore, randomly chosen Clifford circuits can be decomposed to have a depth at most $\mathcal{O}(n)$ (in long-range form). Hence, the total time complexity of frame changing is at most $\mathcal{O}(n^4)$. □

Proposition 2 states that for the complete graph with $\alpha\log(n)$-depth or 1D with n^α-depth where $\alpha < \frac{2}{3}$, we can find another changing algorithm with a reduced order of n. Since the above frame changing is only given by rotations of phase and the argument of the Pauli operator, the application of those algorithms is wider than the scope of the main text.

Next, we discuss solving the vertex cover problem on the pivoted graph Piv_{G_F} of the frame graph G_F. We recall the algorithm of the Section II A. From the pivoted graph, we already know the information on the order of each vertex. Hence step 1 and step 2 takes $\mathcal{O}(|V|)$-time. Now, suppose we eliminate one edge having the vertex v'. Note that this edge has at most another 2 vertices, so when we delete this edge, we also subtract this edge from each pivoted set of those two vertices and adjust the order. We note that this can be done in $\mathcal{O}(1)$-time; hence, getting an updated pivoted graph takes at most $\mathcal{O}(d(G))$-time. Since we repeat these steps for at most $|V|$-time, the total time complexity is at most $\mathcal{O}(|V|d(G)+|V|^2)$.

We summarize these arguments as the following corollary.

Corollary 2. *Suppose we have hypergraph $G(V,E)$ and its pivoted graph* Piv_G. *Then the time complexity of the greedy algorithm is $\mathcal{O}(|V|^2+|V|d(G))$.*

Given an d-depth Clifford circuit, the total time complexity of sampling the initial phase point and obtaining the resulting point after matrix multiplication takes $\mathcal{O}(dn)$-time because the transform of the single qubit part of the phase point under the corresponding two-qubit Clifford block takes constant time. Consider a $\alpha\log(n)$-depth 1D circuit. We note that the total time for the sampling algorithm is at most $\mathcal{O}(\alpha n\log(n))$ because we sample the phase point from the initial framed Wigner function in $\mathcal{O}(n)$-time. Before that, we need to change the frame and solve the vertex cover problem. However, we do not need to do those things over once. Furthermore, by Proposition 2, frame changes (and obtaining its pivoted frame graph) in at most $\min\left\{\mathcal{O}(dn^3), \mathcal{O}(\alpha^4 n(\log(n))^4)+\alpha n^2\log(n)\right\}$-time, and the greedy algorithm can be done in $\mathcal{O}(\alpha^2 n(\log(n))^2+n^2)$-time which is easily derived by Corollary 2 and locality of edges of resulting frame graph. Therefore, even the first trial has a shorter time than a method in the first paragraph of Section III B given that $n^\beta \gg n$.

For each Clifford operation at a specific depth, $\mathcal{O}(n)$ number of new hyperedges are attached. Also, existing edges undergo symplectic transform hence yielding other hyperedges. For the complete graph case, with the worst case, the rate of the number of hyperedges is at most proportional to the number of existing hyperedges. Therefore, the number of hyperedges increases exponentially and the vertex cover size to trace out also increases by the depth. However, if the depth sufficiently increases such that all qubits are interleaved by some edges, then some existing edges rather vanish by the newly generated edges. We expect that this phenomenon will loosen the decreasing rate of vertex cover size and explain the transition of $n_{\rm sim}$ (see Fig. 3 (d) of the main text) by the depth. Whereas, for the 1D case, symplectic transform and hyperedge generation occur locally. Hence the decrease of $n_{\rm sim}$ is much weaker than the complete-graph case, and $\Omega(\frac{n}{\log(n)})$ number of vertex cover is guaranteed.

IV. MORE GENERAL FRAME FORMALISM AND BORN PROBABILITY ESTIMATION

A. Wigner representation using multiple frames

In this section, we further generalize the framed Wigner function formalism by taking multiple frame functions to represent a quantum state. In particular, we show that an arbitrary product state can be positively represented by using multiple quadratic frame functions.

We recall that a single qubit state can be expressed by either zero frame ($F = 0$) or dual frame ($F = a_{1x}a_{1z}$). By combining the phase space operators corresponding to these two frames, one can express any single qubit states by the convex sum of these operators. Hence, if ρ is a product state, it is positively represented under a set of frames $\mathcal{F} \equiv \{\mathbf{b}\cdot(a_{1x}a_{1z}, a_{2x}a_{2z}, \ldots, a_{nx}a_{nz}) | \mathbf{b} \in \mathbb{Z}_2^n\}$. More precisely, for $\rho = \bigotimes_{i=1}^n \rho_i$, we express each ρ_i as

$$\rho_i = \sum_{\mathbf{u}_i \in \mathbb{Z}_2^2} \left(w^0_{\rho_i}(\mathbf{u}_i) A^0(\mathbf{u}_i) + w^{a_{ix}a_{iz}}_{\rho_i}(\mathbf{u}_i) A^{a_{ix}a_{iz}}(\mathbf{u}_i) \right), \tag{40}$$

using eight phase space operators $\{A^0(\mathbf{u}_i), A^{a_{ix}a_{iz}}(\mathbf{u}_i)\}$, where $\mathbf{u}_i \equiv (u_{ix}, u_{iz}) \in \mathbb{Z}_2^2$. Here, w^0 and $w^{a_{ix}a_{iz}}$ are non-negative functions and are different from the Wigner functions $W^F_\rho(\mathbf{u})$ in the main text. We note that summation over phase point of $w^0_{\rho_i}(\mathbf{u}_i)$, or $w^{a_{ix}a_{iz}}_{\rho_i}(\mathbf{u}_i)$ solely does not give unity, but $\sum_{\mathbf{u}_i} \left(w^0_{\rho_i}(\mathbf{u}_i) + w^{a_{ix}a_{iz}}_{\rho_i}(\mathbf{u}_i) \right) = 1$. We also note that these two functions cannot be obtained by inversion in Eq. (2) of the main text because we now have eight phase point operators, which are overcomplete, and hence, their coefficients are not unique. However, we can still efficiently find these two functions because the convex polytope by 8-phase point operators as extreme points contain the Bloch sphere (see Ref. [2]). Hence, solving the constant-sized system of linear equations leads to the following expression of ρ,

$$\rho = \bigotimes_{i=1}^n \rho_i = \sum_{\mathbf{b} \in \mathbb{Z}_2^n} \sum_{\mathbf{u} \in V_n} \left(\prod_{i=1}^n w^{b_i a_{ix} a_{iz}}_{\rho_i}(\mathbf{u}_i) \right) \left(\bigotimes_{i=1}^n A^{b_i a_{ix} a_{iz}}(\mathbf{u}_i) \right), \tag{41}$$

where $\mathbf{u} = \bigoplus_{i=1}^n(\mathbf{u}_i)$. From the definition, $\bigotimes_{i=1}^n A^{b_i a_{ix} a_{iz}}(\mathbf{u}_i)$ is an n-qubit phase point operators with a frame function $F = \mathbf{b}\cdot(a_{1x}a_{1z}, a_{2x}a_{2z}, \ldots, a_{nx}a_{nz})$. Hence, we can rewrite Eq. (41) as

$$\rho = \sum_{F \in \mathcal{F}} \sum_{\mathbf{u} \in V_n} \left(\prod_{i=1}^n w^{b_i a_{ix} a_{iz}}_{\rho_i}(\mathbf{u}_i) \right) (A^F(\mathbf{u})). \tag{42}$$

Therefore, the desired Wigner function is

$$W^F_\rho(\mathbf{u}) = \prod_{i=1}^n w^{b_i a_{ix} a_{iz}}_i(\mathbf{u}_i). \tag{43}$$

Although there could not be a unique expression, the same phase point sampling protocol can be applied to the generalized Wigner functions with multiple frames whenever they are non-negative. This is because the non-negative function W^F_ρ is a probability distribution with random variables of not only $\mathbf{u}$ but also F, so that we can sample both $\mathbf{u}$ and F from $W^F_\rho(\mathbf{u})$. For this case, we say ρ is positively represented under a *frame set* $\mathcal{F}$. Since the Wigner function has a product form and for each $i \in [n]$, we sample $\mathbf{u}_i$ and b_i from $W^{b_i a_{ix} a_{iz}}_i(\mathbf{u}_i)$. The resulting sampling outcome then becomes $\mathbf{u} = \bigoplus_i^n(\mathbf{u}_i)$ and $F = \mathbf{b}\cdot(a_{1x}a_{1z}, a_{2x}a_{2z}, \ldots, a_{nx}a_{nz})$.

B. Generalization of weak simulation results

With the above generalization of using multiple frames representation, we can also obtain a more general statement on the weak simulation. We will discuss this in detail in the next theorem.

Theorem 2. *Suppose that we have a product state $\rho = \bigotimes_{i=1}^{n} \rho_i$ as an input and a non-adaptive Clifford operation U and Z-measurements. Then ρ is positively represented under a frame set $\mathcal{F} \equiv \{\mathbf{b} \cdot (a_{1x}a_{1z}, a_{2x}a_{2z}, \ldots, a_{nx}a_{nz}) | \mathbf{b} \in \mathbb{Z}_2^n\}$. We denote a resulting frame function via the Clifford circuit starting from $F_{\text{in}} \in \mathcal{F}$ as F. Also, let the $I \subset [n]$ satisfies that for all $F_{\text{in}} \in \mathcal{F}$, $F(\mathbf{a}_x = \mathbf{0}, \mathbf{a}_z)\big|_{a_{iz}=0 \text{ for } i \notin I_F}$ is zero. We then can classically simulate $|I|$-number of measurements.*

Proof. We start from Eq. (9). Probability to measure $\mathbf{x} \in \mathbb{Z}_2^n$ is

$$\mathrm{Tr}(|\mathbf{x}\rangle \langle \mathbf{x}| U\rho U^\dagger) = \sum_{\mathbf{u}, F_{\text{in}} \in \mathcal{F}, \mathbf{a}_z \in \mathbb{Z}_2^n} \frac{1}{2^n} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}))\,(-1)^{(\mathbf{u}+\mathbf{x})\cdot \mathbf{a}_z + F_{\text{in}}(S^{-1}(\mathbf{0}_x, \mathbf{a}_z)) + P(S^{-1}(\mathbf{0}_x, \mathbf{a}_z))} \tag{44}$$

$$= \sum_{\mathbf{u}, F_{\text{in}} \in \mathcal{F}, \mathbf{a}_z \in \mathbb{Z}_2^n} \frac{1}{2^n} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}))\,(-1)^{((\mathbf{u}+\mathbf{x})\cdot \mathbf{a}_z + F(\mathbf{0}_x, \mathbf{a}_z))}\,. \tag{45}$$

Now, consider measuring a subset I of qubits. The probability of measuring a marginal string $\mathbf{x}'$ (with arbitrary qubit locations) is as follows. There exists a set of $\mathbf{v}_F \in V_n$ $(F_{\text{in}} \in \mathcal{F})$ such that

$$p(\mathbf{x}') = \sum_{\mathbf{x}''} \mathrm{Tr}(|\mathbf{x}' \oplus \mathbf{x}''\rangle \langle \mathbf{x}' \oplus \mathbf{x}''| U\rho U^\dagger) \tag{46}$$

$$= \sum_{\mathbf{u}, F_{\text{in}} \in \mathcal{F}} \left(\sum_{\substack{\mathbf{a}_z \in \mathbb{Z}_2^n \\ a_{iz}=0 \text{ for } i \in ([n]\setminus I)}} \frac{1}{2^{|I|}} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))\,(-1)^{((\mathbf{u}_x + (\mathbf{x}'\oplus 0))\cdot \mathbf{a}_z)} \right) \tag{47}$$

$$= \sum_{\mathbf{u}, F \in \mathcal{F}} W_\rho^{F_{\text{in}}}(S^{-1}((\mathbf{u}+\mathbf{v}_F))) \prod_{i \in I} \delta_{x_i u_{ix}}\,. \tag{48}$$

Therefore, we obtain the following simulation scheme given that the conditions in Theorem 2 for the final frame hold.

1. Sample a phase space point $\mathbf{u} \in V_n$ and $F_{\text{in}} \in \mathcal{F}$ from $W_\rho^{F_{\text{in}}}(\mathbf{u})$.

2. Change the input frame under the given Clifford operation and obtain both final frame F and $\mathbf{v}_F$

3. Update $\mathbf{u} \leftarrow \mathbf{u}' \equiv S(\mathbf{u})$.

4. Update $\mathbf{u} \leftarrow \mathbf{u} + \mathbf{v}_F$

5. Desired outcome is a marginal string $\mathbf{u}'_x$.

□

We can see that by Theorem 2 (i), the larger the frame set for quantum state input we represent, the fewer the number of measurable qubits. For example, n-copies of *equatorial state*, $|E_\phi\rangle \equiv \frac{1}{\sqrt{2}}\left(|0\rangle + e^{i\phi}|1\rangle\right)$, can have non-negative representation by 2^n-numbers of frame [2]. Whereas, the n-copies of $|A\rangle = \cos(\theta/2)|0\rangle + e^{i(\pi/4)}\sin(\theta/2)|1\rangle$ with $\theta = \cos^{-1}(1/\sqrt{3})$ [15] need only zero frame [2] for non-negative representation. Hence, when we take equatorial states as an input, we have, in general, fewer simulatable qubits than that for $|A\rangle$. In other words, we can expect that equatorial states have more computational power in non-adaptive Clifford circuits. We can see a similar conjecture in universal computing [16]. Here, we can always make a (non-Clifford) T-gate by acting Clifford gates and measurements to $|E_{\frac{\pi}{4}}\rangle$ and we post-process depending on measurement outcome. However, given a quantum state $|A\rangle$ to make a similar non-Clifford gate, we need two copies of $|A\rangle$ and might fail to implement depending on coherent measurement outcome, with fairly high probability. Interestingly, for approximate simulation, there exists an algorithm that marginally simulates a large fraction of circuits with $|E_{\frac{\pi}{4}}\rangle^{\otimes n}$ as an input efficiently but not for $|A\rangle$ state input [17], which has Pauli rank 4.

C. Born probability estimation

We consider the Born probability estimation of a quantum circuit with outcome $\mathbf{x} \in \mathbb{Z}_2^n$ within additive error ϵ. Suppose a given quantum state ρ is positively represented under the frame F_{in}. From Eq. (13), we have

$$\mathrm{Tr}(U\rho U^\dagger |\mathbf{x}\rangle\langle\mathbf{x}|) = \frac{1}{2^n} \sum_{\mathbf{u}\in V_n, F\in\mathcal{F}} \sum_{\mathbf{a}_z\in\mathbb{Z}_2^n} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))(-1)^{(\mathbf{u}_x+\mathbf{x})\cdot\mathbf{a}_z+F(\mathbf{0}_x,\mathbf{a}_z)}, \tag{49}$$

for some $\mathbf{v}_F \in V_n$. The first method is to uniformly choose $\mathbf{a}_z$ and take an estimator,

$$\hat{p}(\mathbf{x}) = \sum_{\mathbf{u}\in V_n, F\in\mathcal{F}} W_\rho^{F_{\text{in}}}(\mathbf{u})(-1)^{(S(\mathbf{u})_x+(\mathbf{v}_F)_x+\mathbf{x})\cdot\mathbf{a}_z+F(\mathbf{0}_x,\mathbf{a}_z)} = \sum_{\mathbf{a}_z\in\mathbb{Z}_2^n} (-1)^{\mathbf{a}_z\cdot\mathbf{x}} \left(\mathrm{Tr}\left(U\rho U^\dagger T_{(\mathbf{0},\mathbf{a}_z)}\right)\right). \tag{50}$$

This estimator can be simulated classically if $W_\rho^{F_{\text{in}}}(\mathbf{u})$ has a product form. However, we also have another expression,

$$\mathrm{Tr}(U\rho U^\dagger |\mathbf{x}\rangle\langle\mathbf{x}|) = \frac{1}{2^n} \sum_{\mathbf{a}_z\in\mathbb{Z}_2^n} (-1)^{\mathbf{a}_z\cdot\mathbf{x}} \left(\mathrm{Tr}\left(U\rho U^\dagger T_{(\mathbf{0},\mathbf{a}_z)}\right)\right) = \frac{1}{2^n} \sum_{\mathbf{a}_z\in\mathbb{Z}_2^n} (-1)^{\mathbf{a}_z\cdot\mathbf{x}} \left(\mathrm{Tr}\left(\rho U^\dagger T_{(\mathbf{0},\mathbf{a}_z)} U\right)\right). \tag{51}$$

Hence, we may just uniformly randomly choose $\mathbf{a}_z$ and find $T'_{(\mathbf{0}_x,\mathbf{a}_z)} \equiv U^\dagger T_{(\mathbf{0},\mathbf{a}_z)} U$ by using the stabilizer tableau [10], and then take an estimator $\hat{p}_s(\mathbf{x}) = (-1)^{\mathbf{a}_z\cdot\mathbf{x}}\mathrm{Tr}(T'_{(\mathbf{0}_x,\mathbf{a}_z)}\rho)$. Therefore, the estimators $\hat{p}(\mathbf{x})$ and $\hat{p}_s(\mathbf{x})$ have same value for given sampled variable $\mathbf{a}_z$. Hence, both estimators have the same mean squared error, which is,

$$\begin{aligned}
\mathrm{Var}_{\mathrm{Pauli}}(\mathbf{x}) &= \frac{1}{2^n} \sum_{\mathbf{a}_z\in\mathbb{Z}_2^n} \left(\mathrm{Tr}\left(\rho U^\dagger T_{(\mathbf{0},\mathbf{a}_z)} U\right)\right)^2 - p(\mathbf{x})^2 && (52)\\
&= \frac{1}{4^n} \sum_{\mathbf{x}\in\mathbb{Z}_2^n} \sum_{\mathbf{a}_z,\mathbf{b}_z\in\mathbb{Z}_2^n} (-1)^{(\mathbf{a}_z+\mathbf{b}_z)\cdot\mathbf{x}} \left(\mathrm{Tr}\left(\rho U^\dagger T_{(\mathbf{0},\mathbf{a}_z)} U\right)\right)\left(\mathrm{Tr}\left(\rho U^\dagger T_{(\mathbf{0},\mathbf{b}_z)} U\right)\right) - p(\mathbf{x})^2. && (53)\\
&= \left(\sum_{\mathbf{x}\in\mathbb{Z}_2^n} p(\mathbf{x})^2\right) - p(\mathbf{x})^2 = Z_{U,\rho} - p(\mathbf{x})^2, && (54)
\end{aligned}$$

where $Z_{U,\rho} \equiv \sum_{\mathbf{x}\in\mathbb{Z}_2^n} p(\mathbf{x})^2$ is the so-called collision probability [8].

The above schemes do not use the probabilistic property of the Wigner function. We introduce another estimation method by sampling phase points from the Wigner function. We enclose it in the following result.

Theorem 3. *Assume $\rho = \bigotimes_{i=1}^n \rho_i$ is a product state, which is positively represented under a frame set $\mathcal{F} \equiv \{\mathbf{b}\cdot(a_{1x}a_{1z}, a_{2x}a_{2z}, \dots, a_{nx}a_{nz}) | \mathbf{b} \in \mathbb{Z}_2^n\}$. Also, let F_0 be the resulting frame via a given circuit starting from a zero frame. Now, we assume that $I_{F_0} \subset [n]$ satisfies that $F_0(\mathbf{a}_x = \mathbf{0}, \mathbf{a}_z)\big|_{a_{iz}=0 \text{ for } i\notin I_{F_0}}$ is a quadratic polynomial, or has $\mathcal{O}(\log(n))$-sized vertex cover of subgraph of G_{F_0} having only third-degree terms. Then there exists an efficient algorithm for estimation of marginal measurement probability $p(\mathbf{x}')$, where $\mathbf{x}'$ is a target string on qubits located on $I_{F'_0}$. Also, averaged variance over uniform outcomes is $(1-Z_{U,\rho}^{(k)})/2^k$. Hence if we uniformly randomly choose a binary string $\mathbf{x}'$, $\mathrm{Var}(\mathbf{x}') \le \frac{a(k)}{2^k} - p(\mathbf{x}')^2$ with probability at least $\left(1 - \frac{1}{a(k)}\right)$, where $a(k)$ is a non-negative function of k.*

Proof. We first consider the Born probability estimation of full string $\mathbf{x} \in \mathbb{Z}_2^n$. In the same manner as Eq.(13), we obtain that

$$\mathrm{Tr}(U\rho U^\dagger |\mathbf{x}\rangle\langle\mathbf{x}|) = \frac{1}{2^n} \sum_{\mathbf{u}\in V_n, F_{\text{in}}\in\mathcal{F}} \sum_{\mathbf{a}_z\in\mathbb{Z}_2^n} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))(-1)^{(\mathbf{u}_x+\mathbf{x})\cdot\mathbf{a}_z+F(\mathbf{0}_x,\mathbf{a}_z)}. \tag{55}$$

Now, we set the Born probability estimation algorithm of $P(\mathbf{x}) \equiv \mathrm{Tr}(U\rho U^\dagger |\mathbf{x}\rangle\langle\mathbf{x}|)$. Here's the scheme.

1. Sample a phase space point $\mathbf{u} \in V_n$ and $F_{\text{in}} \in \mathcal{F}$ from $W_\rho^{F_{\text{in}}}(\mathbf{u})$.
2. Change the input frame under the given Clifford operation and obtain both final frame F and $\mathbf{v}_{F_{\text{in}}}$
3. Update $\mathbf{u} \leftarrow S(\mathbf{u})$ and then update $\mathbf{u} \leftarrow \mathbf{u} + \mathbf{v}_F$

4. Desired estimation value for each trial is $\hat{p}(\mathbf{x}) \equiv \frac{1}{2^n} \sum_{\mathbf{a}_z} (-1)^{(\mathbf{u}_x+\mathbf{x})\cdot\mathbf{a}_z + F(\mathbf{0}_x,\mathbf{a}_z)}$, where F is a final frame starting from F_{in}.

5. Repeat step 2 $\sim$ step 4 to obtain many $\hat{p}(\mathbf{x})$'s. The final estimation will be the sample mean of those $\hat{p}(\mathbf{x})$'s.

Unfortunately, this is not an efficient algorithm. Because at the third stage, $F(\mathbf{0}_x, \mathbf{a}_z)$ is in general of third-order. The exact calculation is #P-Hard problem [18]. However, in the cases where the size of the vertex cover of a hypergraph with terms of third-degree in $F(\mathbf{0}_x, \mathbf{a}_z)$ is $\mathcal{O}(\log(n))$, we can do this efficiently [19]. Therefore, if we do not estimate the probability of all measurements, we can trace some qubits until the resulting frame is such a form. This is a more relaxed condition than one of weak simulation in Section I D. If the final frames (after tracing) become quadratic, then $\hat{p}(\mathbf{x})$ becomes an exponential sum of quadratic binary polynomials, which is efficiently calculated in $\mathcal{O}(k^3)$-time [3].

For every initial second-ordered frame we sampled from, all resulting frames (after we take $\mathbf{a}_x = 0$) have the same third-ordered terms. Because third-ordered terms are obtained only from phase functions of Clifford gates and symplectic transforms, which do not raise the order of the polynomial, therefore the vertex cover problem may be solved only once for the resulting frame starting from $F_{\text{in}} = 0$.

Now, we only see the marginal outcome string $\mathbf{x}'$. The mean squared error $\text{Var}(\mathbf{x}')$ is given as,

$$\text{Var}(\mathbf{x}') = \frac{1}{4^k} \sum_{\mathbf{u}\in V_n, F_{\text{in}}\in\mathcal{F}} \sum_{\mathbf{a}'_z,\mathbf{b}'_z} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F))(-1)^{(\mathbf{u}'_x+\mathbf{x}')\cdot(\mathbf{a}'_z+\mathbf{b}'_z)+F(\mathbf{0}_x,\mathbf{a}'_z\oplus 0)+F(\mathbf{0}_x,\mathbf{b}'_z\oplus 0)} - p(\mathbf{x}')^2, \tag{56}$$

where $\sum_{\mathbf{a}'_z,\mathbf{b}'_z}$ is the sum over strings at which the same marginalization is applied as $\mathbf{x}'$. Let us denote the first term of the right side as $\mathbb{E}(\hat{p}(\mathbf{x}')^2)$. When we take the uniform average to this over binary strings $\mathbf{x}'$,

$$\overline{\mathbb{E}(\hat{p}(\mathbf{x}')^2)}^{\mathbf{x}'} = \frac{1}{2^k} \sum_{\mathbf{u},F_{\text{in}}} W_\rho^{F_{\text{in}}}(S^{-1}(\mathbf{u}+\mathbf{v}_F)) = \frac{1}{2^k}. \tag{57}$$

(Note that $\overline{\text{Var}(\mathbf{x}')}^{\mathbf{x}'} = 1/2^k - Z_{U,\rho}^{(k)}/2^k$, where $Z_{U,\rho}^{(k)} \equiv \sum_{\mathbf{x}'\in\mathbb{Z}_2^k} p(\mathbf{x}')^2$.) Hence, by Markov's inequality, when we uniformly randomly sample $\mathbf{x}'$, the probability of $\mathbb{E}(\hat{p}(\mathbf{x}')^2)$ being larger than $\frac{a(k)}{2^k}$ is,

$$\Pr\left(\mathbb{E}(\hat{p}(\mathbf{x}')^2) \geq \frac{a(k)}{2^k}\right) \leq \frac{2^k\overline{\mathbb{E}(\hat{p}(\mathbf{x}')^2)}^{\mathbf{x}'}}{a(k)} = \frac{1}{a(k)}. \tag{58}$$

We note that $\text{Var}(\mathbf{x}') = \mathbb{E}(\hat{p}(\mathbf{x}')^2) - p(\mathbf{x}')^2$. Hence if we uniformly randomly choose $\mathbf{x}'$, the probability of $\text{Var}(\mathbf{x}') \leq \frac{a(k)}{2^k} - p(\mathbf{x}')^2$ is at least $\left(1 - \frac{1}{a(k)}\right)$. □

Suppose that we use product state input. We need to find the final (and marginal) frame from each initial frame, which can be sampled in $\mathcal{O}(n)$-time. Moreover, all $\mathcal{O}(k^2)$ number of coefficients of second-ordered terms in a final (and marginal) frame can be rewritten by a boolean linear function with the argument $\mathbf{b} \in \mathbb{Z}_2^n$ which represents the input frame sample $F_{\text{in}} = \sum_{\mathbf{b}\in\mathbb{Z}_2^n} b_i a_{ix} a_{iz}$. These functions can be found before the sampling. Therefore, the total time for each trial is $\mathcal{O}(nk^2)$.

Whereas, we can easily derive that from Eq. (51), $\text{Var}_{\text{Pauli}}(\mathbf{x}') = Z_{U,\rho}^{(k)} - p(\mathbf{x}')^2$ and calculation of $\hat{p}_s(\mathbf{x}')$ takes $\mathcal{O}(n)$-time given that $T'_{(\mathbf{0}_x,\mathbf{a}'_z)} \equiv U^\dagger T_{(\mathbf{0},\mathbf{a}'_z)} U$ is known.

The mean squared error is connected to the required number of samples to achieve additive estimation error ϵ with probability larger than $1-\delta$, given by $\mathcal{O}\left(\frac{\text{Var}(\mathbf{x})}{\epsilon^2}\log\left(\frac{1}{\delta}\right)\right)$ [20, 21]. Suppose that the input state is a product state. Using Theorem 3, we note that for any choice of a non-negative function $a(k) \geq 1$ at least $2^k(1-\frac{1}{a(k)})$-number of binary strings $\mathbf{x}'$ can be estimated with $\mathcal{O}\left(\frac{a(k)/2^k - p(\mathbf{x}')^2}{\epsilon^2}\log\left(\frac{1}{\delta}\right)\right)$ samples using the Wigner function approach. In contrast, Ref. [22] requires $\mathcal{O}\left(\frac{Z_{U,\rho}^{(k)} - p(\mathbf{x}')^2}{\epsilon^2}\log\left(\frac{1}{\delta}\right)\right)$ samples for any string $\mathbf{x}'$. The total time to simulate is the product of the sample number and the time taken to run the estimator once. From the above arguments, if the input state is a product (by ignoring the time for the first trial) we have a time improvement for $2^k(1-\frac{1}{a(k)})$-number of strings when the collision probability $Z_{U,\rho}^{(k)} \geq \mathcal{O}(\frac{a(k)k^2}{2^k})$. The one of such cases is when $k \sim \beta n$ ($\beta \in (0,1)$, n is large) and the k-marginal probability distribution is far from *anti-concentration*, $Z_{U,\rho}^{(k)} \sim \frac{1}{2^{\alpha k}}$ ($\alpha \in (0,1)$) in which we take improvements for $2^k(1-\frac{1}{poly(k)})$ number of strings.

Keywords: bosonic randomized benchmarking, passive Gaussian transformations, LOP.

Bosonic quantum systems play a major role for the design of quantum computing platforms. Most prominently, this includes photonic quantum computing as a popular proposal for real world implementations of quantum computers [1–4]. The biggest advantages of this model rely on the implementation of particle sources, detectors, and linear optical circuits on the same integrated chips [5–8], and access to mixed schemes for quantum error correction [9]. Bosonic systems also offer interesting non-universal models of computation to test quantum supremacy, such as boson sampling [10] and Gaussian boson sampling [11, 12].

The characterization of quantum devices, and, in particular, of the involved unitary gates, is a fundamental task in quantum information processing [13, 14]. While this is a well-studied field for discrete variable systems, a similar standing for continuous variable (CV) systems has not yet been achieved, as the first rigorous guarantees for learning CV quantum states have been proved only very recently [15, 16]. Tomographic protocols provide, in principle, a complete description of experimentally implemented gates [17, 18]. However, the number of measurements required is beyond concrete applications [19–23]. In particular, full quantum process tomography is not feasible in practice since it requires either an unpractical number of different input states [20, 21] or entangling the input state with an ancilla [24, 25]. Moreover, standard versions of the protocol suffer from state preparation and measurement (SPAM) errors.

For bosonic systems, additional challenges arise due to particularities of the infinite-dimensional Hilbert space [19, 26]. For instance, characterization protocols that rely on scrambling techniques via unitary designs are notably challenging to implement, since Gaussian unitaries only form a unitary 1-design [27, 28], and, more dramatically, unitary 2-designs for CV systems cannot exist, unless rigged Hilbert spaces are taken into account [29]. Such issues constraint the characterization of quantum gates to very specific settings, where implemented unitary operators (which may include non-Gaussian single-mode unitaries) are only benchmarked w.r.t. the input ensembles [30].

For discrete variable systems, randomized benchmarking (RB) [31–40] is the most widespread family of protocols for the estimation of average gate fidelities. Its popularity is due to its robustness against SPAM errors and its rather low demands on the measurement effort [41]. Recent efforts led to general guarantees for RB protocols with finite or compact groups [42, 44–47]. This generality is important when considering RB for CV systems, since unitary 2-designs, as in the standard formulation of RB, are not available [27–29]. For general groups, the RB signal consists of a linear combination of exponential decays, labelled by the relevant irreducible subrepresentations (irreps) [40, 42–44]. In the CV setting, we however expect many irreps and isolating the decay rates is likely infeasible in practice [44, 47]. These issues can be resolved using the recently proposed filtered RB protocol [42, 44, 47], which isolates contributions associated to individual irreps by performing a suitable post-processing of the data.

In this work, we introduce the first RB protocol for bosonic systems: *bosonic passive RB* (or passive RB for simplicity). Our protocol benchmarks passive (Gaussian) transformations – identified with the

[*] `mirko.arienzo@tuhh.de`

unitary group over m modes $\mathrm{U}(m)$ [48]. We perform the necessary representation-theoretic computations and evaluate relevant moments of $\mathrm{U}(m)$ to exploit the general guarantees of filtered RB [47]. From this perspective, Gaussian input states and measurements seems unfavorable due to infinitely many relevant irreps and thus decay rates. Instead, we consider experiments that start with the preparation of a Fock state $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$, and end with either a particle number resolving (PNR) measurement or a balanced heterodyne measurement at the end of each mode.

Our passive RB protocol. Repeat the following steps L times, for different sequence lengths $m \in \mathbb{M}$: Prepare $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$, and apply passive transformations $g_1, \ldots, g_m$ drawn i.i.d. from the Haar probability measure on $\mathrm{U}(m)$. Lastly, measure the output state, and store the outcome $\boldsymbol{x} \in \Omega$ together with the sampled unitaries. In the post-processing, we compute the estimator $\hat{F}_\lambda(m) = \frac{1}{L}\sum_{i=1}^{L} f_\lambda(\boldsymbol{x}^{(i)}, g_1^{(i)} \cdots g_m^{(i)})$ where f_λ is the *filter function* defined as

$$f_\lambda(\boldsymbol{x}, g) := \frac{1}{s_\lambda}\langle \boldsymbol{x}\,|\omega(g) \circ P_\lambda(\rho)|\boldsymbol{x}\rangle\,, \qquad (1)$$

where

$$s_\lambda = \frac{1}{\dim\lambda}\int_\Omega d\boldsymbol{x}\,\langle \boldsymbol{x}\,|P_\lambda(|\boldsymbol{x}\rangle\langle\boldsymbol{x}|)|\boldsymbol{x}\rangle\,. \qquad (2)$$

Here, ω is the representation of $\mathrm{U}(m)$ on density operators and P_λ is the projector onto an irrep λ of interest. Fit the data $(m, \hat{F}_\lambda(m))_{m\in\mathbb{M}}$ to an exponential model $A_\lambda\varphi_\lambda^m$ and report the *decay rates* φ_λ, which are a measure of the quality of the implementation [44, 47].

Importantly, the choice of ρ ensures that we can restrict the representation of $\mathrm{U}(m)$ to the invariant subspace of n particles. Hence, we consider the representation $\omega_n^M := \tau_n^m(\cdot)\tau_n^{m\dagger}$, where τ_n^m is the totally symmetric irrep of $\mathrm{U}(m)$ supported on the n-particle subspace. We show that ω_n^M decomposes as $\omega_n^M = \bigoplus_{k=0}^n \lambda_k$, where all λ_k are distinct, $\lambda_0 \equiv \mathbf{1}$ is the trivial irrep and $\lambda_1 \equiv \mathrm{Ad}$ is the adjoint irrep. The proof is based on an iterative procedure, using Young diagrams of τ_n^m and its dual, to compute the decomposition of ω_n^m for arbitrary n's and m's via Littlewood-Richardson's rules [49].

Main results. The general results of the filtered RB framework [47] directly guarantee that the expected signal $F_\lambda(m) = \mathbb{E}[\hat{F}_\lambda(m)]$ is well-approximated by an exponential decay, $F_\lambda(m) \approx A_\lambda\varphi_\lambda^m$. In particular, the approximation error decays exponentially in m (and faster than φ_λ^m). From the discrete variable setting, we expect that already very short sequences are sufficient to suppress this error and expose the decay. A crucial step in the post-processing is the evaluation of the filter function (1). Its computation is generally a hard problem, as it can be reduced to the computation of permanents or Hafnians, which lie at the heart of the complexity of (Gaussian) boson sampling.

Theorem 1. *Consider an input state $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ and either PNR or balanced heterodyne measurements. Then, we can evaluate the filter function* (1) *as a linear combination of permanents or Hafnians, respectively.*

We prove this result by applying a generalized Clebsch-Gordan decomposition to $\omega_n^m \simeq \tau_n^m \otimes \bar{\tau}_n^m$, resulting in an explicit block-diagonalization of ω_n^m [50, 51]. The projection onto an irrep λ then selects the relevant terms in the Clebsch-Gordan decomposition. Similarly, s_λ in Eq. (1) can be evaluated in terms of Clebsch-Gordan coefficients.

For the sample complexity of passive RB we can use Chebyshev's inequality to ensure $|\hat{F}_\lambda(m) - F_\lambda(m)| < \epsilon$ with probability $1-\delta$ given $L \geq \epsilon^{-2}\delta^{-1}\mathbb{E}[f_\lambda^2]$ samples. Using results in Ref. [47] we can reduce the computation of $\mathbb{E}[f_\lambda^2]$ to the noiseless second moment.

Theorem 2 (Variance bound)**.** *Assume that the input state of passive RB is a Fock state $|\boldsymbol{n}\rangle$ and we use either PNR or balanced heterodyne measurements, and the SPAM noise is non-malicious. Then*

$$\mathbb{E}[f_\lambda^2] \leq \mathbb{E}[f_\lambda^2]_{\text{ideal}} = \frac{\mathcal{C}}{s_\lambda^2}\,, \qquad (3)$$

where $\mathcal{C}$ is a suitable linear combination of Clebsch-Gordan coefficients.

The proof of this result relies on expressing the second moment $\mathbb{E}[f_\lambda^2]_{\text{ideal}}$ as a suitable integral of the representations $\lambda^{\otimes 2}$ and ω_n^m over $\mathrm{U}(m)$ [40, 47]. Schur's lemma then implies that the non-trivial contributions to this integral are given by the irreducible representations (irreps) of $\lambda^{\otimes 2}$ which are also contained in ω_n^m. We determine these irreps which allows us to finally write $\mathbb{E}[f_\lambda^2]_{\text{ideal}}$ in terms of suitable Clebsch-Gordan coefficients.

Finally, in the case $m = 2$ and PNR measurements, the latter admits a bound of the form $\mathbb{E}[f_{\lambda_k}^2] = O(d_\lambda^2 n^2)$. The latter upper bound can also be generalized to $m > 2$, by taking into account the additional multiplicities appearing in this case. However, we expect that these bounds are very loose and the variance is much smaller in practice.

Abstract. Randomized benchmarking (RB) is the most commonly employed protocol for the characterization of unitary gates in (discrete variable) quantum circuits due to its reasonable experimental requirements and robustness against state preparation and measurement (SPAM) errors. In this work, we introduce the first RB protocol for passive Gaussian transformations based on the recently developed filtered RB framework by Heinrich et al. [1]. We suggest a setting consisting of a Fock input state and either particle number resolving or heterodyne detectors. We provide a detailed procedure to post-process the experimental data and derive an analytical formula for the sampling complexity.

Keywords: bosonic randomized benchmarking, passive Gaussian transformations, LOP.

1 Introduction

Bosonic quantum systems play a major role for the design of quantum computing platforms. Most prominently, this includes photonic quantum computing as a popular proposal for real world implementations of quantum computers [2–7]. The biggest advantages of this model rely on the implementation of particle sources, detectors, and linear optical circuits on the same integrated chips [8–11], and access to mixed schemes for quantum error correction [12]. Bosonic systems also offer interesting non-universal models of computation to test quantum supremacy, such as boson sampling [13] and Gaussian boson sampling [14–18].

The characterization of quantum devices, and, in particular, of the involved unitary gates, is a fundamental task in quantum information processing [19, 20]. While this is a well-studied field for discrete variable systems, a similar standing for continuous variable (CV) systems has not yet been achieved, as the first rigorous guarantees for learning CV quantum states have been proved only very recently [21, 22]. Tomographic protocols provide, in principle, a complete description of experimentally implemented gates [23, 24]. However, the number of measurements required is beyond concrete applications [25–29]. In particular, full quantum process tomography is not feasible in practice since it requires either an unpractical number of different input states [26, 27] or entangling the input state with an ancilla [30, 31]. Moreover, standard versions of the protocol suffer from state preparation and measurement (SPAM) errors.

For bosonic systems, most challenges can be attributed to the particularities of the infinite-dimensional Hilbert space [25, 32]. For instance, characterization protocols that rely on scrambling techniques via unitary designs are notably challenging to implement, since Gaussian unitaries only form a unitary 1-design [33, 34], and, more dramatically, unitary 2-designs for CV systems cannot exist, unless rigged Hilbert spaces are taken into account [35]. Such issues constraint the characterization of quantum gates to very specific settings, where implemented unitary operators (which may include non-Gaussian single-mode unitaries) are only benchmarked w.r.t. the input ensembles [36].

For discrete variable systems, randomized benchmarking (RB) [37–46] is the most widespread family of protocols for the estimation of average gate fidelities. Its popularity is due to its robustness against SPAM errors and its rather low demands on the measurement effort [47]. The standard RB protocol is as follows: To a fixed initial state, apply a sequence of Haar-random (Clifford) unitaries, followed by a final *inversion gate* cancelling the action of the entire sequence. Then, the success probability of restoring the initial state decays exponentially with the length of the sequence, and the decay rate is a proxy for the average gate fidelity of the gate set. However, many variations of this theme exist.

Recent efforts led to general guarantees for RB protocols with finite or compact groups [1, 48–51]. This generality is important when considering RB of CV systems, since unitary 2-designs, as in the standard formulation of RB, are not available. However, these protocols still suffer from two crucial problems: First, the computation and experimental implementation of the inversion gate is generally challenging. Second, it is known that the RB signal consists of a linear combination of exponential decays, in correspondence with the relevant irreducible subrepresentations (irreps) of the used group [49, 52]. Isolating the decay rates is already difficult in practice if more than a few irreps are involved [1, 49], and may become impossible in the CV setting. To resolve these issues, filtered RB has been recently proposed [1, 48, 49]. This protocol omits the inversion gate and instead performs a suitable post-processing of the data. During the post-processing, contributions associated to individual ir-

*mirko.arienzo@tuhh.de

reps can be isolated in a SPAM-robust way, allowing to handle compact groups with many irreps.

In this work, we introduce the first RB protocol for bosonic systems: *bosonic passive RB* (or passive RB for simplicity). Our protocol benchmarks passive (Gaussian) transformations and allows to deduce statements about their average quality. We consider experiments where the input state is a Fock basis state and analyze two common measurement scenarios: Either the total number of particles is measured in each mode with a particle number resolving (PNR) detector, or each mode is measured with a (balanced) heterodyne detector. In these cases, passive RB resembles either boson sampling or Gaussian boson sampling experiments [13–15]. Arguably, the simplest experimental setting would instead involve Gaussian input states and measurements. In this case, however, we encounter infinitely many relevant irreps and thus decay rates, and it is unclear whether a meaningful analysis is possible.

By performing the necessary representation-theoretic computations, we can then rely on the general framework of filtered RB [1]. In particular, we derive explicit formulas for the so-called *filter function* used in the classical post-processing of the experimental data. Moreover, we give exact expressions and bounds on the variance of our estimators, thereby characterizing the sampling complexity of our protocol.

The classical post-processing essentially involves the simulation of (Gaussian) boson sampling experiments. This is akin to the discrete setting which requires the simulation of random circuits [1, 53]. Both settings thus involve computationally hard problems which, generically, cannot be avoided. However, specific choices of the initial Fock state may help to reduce the computational effort of the classical post-processing [54].

The remainder of this work is structured as follows: In Section 2 we highlight our main results. In particular, in Section 2.2 we spell out passive RB in full details, and discuss the different experimental settings. In Section 2.3 we show our performance guarantees including results on the sampling complexity for both PNR and heterodyne measurement schemes. In Section 3 the technical tools are introduced and Section 4 is devoted to the technical part of this manuscript. Section 4.1 is dedicated to the main technical result, i.e. we show the decomposition into irreps of the representation of passive transformations acting on states with a fixed number of particles. This result is used to isolate the signals, and is the main tool from which the general form of the post-processing procedure follows, in Section 4.2. Finally, in Section 4.3, we provide analytical expressions for the optimal sample complexity of filtered RB with bunched input states. Similar results in a setting with heterodyne measurements are discussed in Appendix H.

2 Main results

In the following, we introduce a scalable protocol for benchmarking Gaussian unitaries that preserve the total number of bosons of a quantum system, referred to as *passive transformations* from here on. We discuss different experimental settings which are commonly implemented within the framework of CV systems. In particular, we argue that Gaussian probe states and measurements impose additional challenges on RB-like experiments due the presence of an infinite number of irreps. As a consequence, it is unclear whether a meaningful RB experiment can be formulated on their basis. In contrast, using Fock basis states (or measurements) directly lead to a well-behaved protocol for the characterization of passive unitaries.

2.1 Notation

We consider a bosonic system of $m \in \mathbb{N}$ modes described by a set of pairs of bosonic field operators $\{a_k^\dagger, a_k\}_{k=1}^m$, where a_k and $a_k^\dagger$ are the k-th annihilation and creation operators, respectively, which satisfy the canonical commutation relations (CCRs)

$$[a_k, a_l^\dagger] = \delta_{k,l}\,, \quad [a_k, a_l] = [a_k^\dagger, a_l^\dagger] = 0\,, \quad k,l = 1,\ldots,m\,.$$

Here, $\delta_{k,l}$ is the usual Kronecker delta. Such a system is described by the Fock-Hilbert space $\mathcal{F}_m := \bigoplus_{n=0}^\infty \mathcal{H}_n^m$, where $\mathcal{H}_n^m$ is the subspace of n bosons distributed over m modes spanned by the *Fock* states

$$|\boldsymbol{n}\rangle \equiv |n_1,\ldots,n_m\rangle := \prod_{k=1}^m \frac{1}{\sqrt{n_k!}} a_k^{\dagger n_k} |\boldsymbol{0}\rangle\,, \qquad (1)$$

where $|\boldsymbol{n}| := \sum_{i=1}^m n_i = n$ and $|\boldsymbol{0}\rangle \equiv |0,\ldots,0\rangle$ denotes the vacuum state of m decoupled one-dimensional harmonic oscillators [55]. We shall also consider coherent states, defined as $|\alpha\rangle = e^{-|\alpha|^2/2}\sum_{n=0}^\infty \frac{\alpha^n}{\sqrt{n!}}|n\rangle$ for a single mode, with a straightforward extension to the multimode setting. The set of passive transformations is the group of unitary operators on $\mathcal{F}_m$ that leave the total number of particles invariant. These are exactly the unitaries which induce a transformation of the bosonic operators as $a_k \mapsto \sum_{l=1}^m U_{lk} a_l$ for a unitary matrix $U = (U_{lk})_{l,k=1}^m$. Hence, the group of passive transformations can be identified with the unitary group $\mathrm{U}(m)$ [56]. Practically, these can also be thought as multimode interferometers, which can be decomposed in quadratically many two-modes interferometers and phase shift transformations only [6, 58–61].

2.2 The passive randomized benchmarking protocol

The passive RB protocol is based on the filtered RB protocol [1, 48, 49], which consists of a *data collection phase* and a *post-processing phase*. We briefly state the protocol and justify it afterwards.

Description of the protocol. The passive RB protocol is based on the filtered RB protocol [1, 48, 49], which consists of a *data collection phase* and a *post-processing phase*. We briefly state the protocol in the bosonic case.

(I) **Data collection.** We propose to use a fixed number state $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ as input and perform particle number resolving (PNR) measurements described by the positive operator-valued measure (POVM) $\{|\boldsymbol{x}\rangle\langle\boldsymbol{x}|\}_{\boldsymbol{x}\in\mathbb{N}^m}$. For different sequence lengths $l \in \mathbb{L}$, repeat the following steps N times,

(i) Prepare the state ρ.

(ii) Apply passive transformations $g_1, \dots, g_l$ drawn i.i.d. from the Haar probability measure on $\mathrm{U}(m)$.

(iii) Measure the output state and store the outcome together with the sampled unitaries.

(II) **Post-processing.** Assuming the data $\{(\boldsymbol{x}^{(i)}, g_1^{(i)}, \dots, g_l^{(i)})\}_{i=1}^N$ has been gathered, compute the following mean estimator of a later-to-be-defined *filter function* f_λ, parametrized by suitable irreducible representations (irreps) λ of $\mathrm{U}(m)$:

$$\hat{F}_\lambda(l) = \frac{1}{N}\sum_{i=1}^{N} f_\lambda(\boldsymbol{x}^{(i)}, g_1^{(i)}, \dots, g_l^{(i)})\,. \tag{2}$$

We refer to the data series $(l, \hat{F}_\lambda(l))_{l\in\mathbb{L}}$ as the (filtered) *RB signal*. Finally, perform an exponential fit according to the model $\hat{F}_\lambda(l) = A_\lambda \varphi_\lambda^l$ to extract the *decay rates* $\{\varphi_\lambda\}_\lambda$.

The reasons for our choice of initial state and measurements are laid out in the discussion below, and possible variations are discussed at the end of this subsection (in particular Gaussian states and measurements).

We would like to emphasize that Haar-random sampling from $\mathrm{U}(m)$ can be substituted by any distribution which converges sufficiently fast to the Haar measure [1]. For the main part of this paper, we resort to the Haar measure to simplify the presentation.

Decay rates and fidelities. The decay rates can be combined into an average performance measure for passive transformations on the n-particle subspace using the formula [49]

$$F = (\dim \mathcal{H}_n^m)^{-2} \sum_\lambda d_\lambda \varphi_\lambda\,, \tag{3}$$

where the sum runs over all relevant irreps λ with dimensions d_λ, see Section 2.3. Although commonly done, we remind the reader that caution is advised if F is interpreted as the average *entanglement fidelity* of passive transformations. This is due to the inherent *gauge freedom* of RB, see Refs. [44, 49] for a detailed discussion. In particular, whether such an interpretation is justified or not cannot be deduced from RB results alone. We take the point of view of Ref. [49] in that RB decays rates and F in Eq. (3) should be regarded as quantities in the own right which serve as a benchmark for the average quality of the used unitaries. Besides the mentioned interpretational issues, RB decay rates for discrete variable systems are usually identified with *average gate fidelities* by a suitable affine transformation of Eq. (3). The concept of average gate fidelity is however not meaningful in the CV context due to divergent integrals in the definition. Nevertheless, the entanglement fidelity can still be defined for quantum channels restricted to finite-dimensional subspaces.

2.2.1 Discussion of the protocol

In the following, we justify the made choices based on the blueprint for filtered RB [1]. First, we identify the relevant unitary representation ω_n^m of the group $\mathrm{U}(m)$, which describes the ideal action of the unitaries as quantum channels. ω_n^m is called the *reference representation* in the RB literature and its irreps will play a central role. While the reference representation in the discrete setting is typically set as $\omega(g) = U_g(\,\cdot\,)U_g^\dagger$, where $g \mapsto U_g$ is the defining representation [1], there is a richer plethora of representations for CV systems. Moreover, this choice may also be related to the choice of initial state and measurement. In particular, the most straightforward –and experimentally simplest– RB protocol would involve an entirely Gaussian experiment with Gaussian state and measurement (the CV analogue of the usual stabilizer setting in discrete variables). In this case, the reference representation is however ill-behaved for the following reason: Any passive transformation can be described on $\mathcal{F}_m$ by a unitary representation $\tau^m : \mathrm{U}(m) \to \mathrm{U}(\mathcal{F}_m)$, where $\mathrm{U}(\mathcal{F}_m)$ is the group of unitary operators on $\mathcal{F}_m$. Since $\mathrm{U}(m)$ is compact, τ^m is completely reducible, and decomposes into infinitely many finite-dimensional irreps acting on the boson number subspaces [62]. Similarly, the reference representation $\omega \equiv \tau^m(\,\cdot\,)\tau^{m\dagger}$ decomposes into infinitely many irreps, which are not all supported on the number subspaces. This means we find infinitely many decay rates (each associated to one irrep) and it is unclear how to truncate those with a regularization argument, as the irreps lack a clear physical interpretation. On top of that, the decomposition of ω is not multiplicity-free[1], which complicates the post-processing and affects its numerical stability [49].

Before moving forward, we comment on the choice of the ensemble: Broadly speaking, *active* Gaussian transformations play a fundamental role in CV systems, for instance in the implementation of Gaussian boson sampling experiments [14, 15, 63]. However, benchmarking non-passive transformations pose many challenging issues, that head to the group of Gaussian transformations –that corresponds to the symplectic group $\mathrm{Sp}(2m,\mathbb{R})$ on m modes– being *non-compact*. This would imply that the general framework of filtered RB cannot be applied as it is, since it is specifically designed to deal with compact groups [1], and a generalization to the case of locally compact groups would be necessary. In particular, this would rise many technical challenges. Among them, and most prominently, one can find the non-existence of a probability Haar measure (since, by standard results in harmonic analysis, the Haar measure of a non-compact group cannot be finite) not clear to deal with. Similarly, the action

[1] Note that ω restricted to $\mathcal{B}(\mathcal{H}_n^m)$ is equal to ω_n^M and by Eq. (4), each λ_k appears in all ω_n^M for $n \geq k$.

of active transformations is determined by the full metaplectic representation of $\mathrm{Sp}(2m, \mathbb{R})$, which decomposes into infinite dimensional irreps only [64]. A priori, it is not clear how the conjugate action of such representation decomposes into irreps. On the other hand, naive extensions of standard RB to the group of active transformations will probably lead to experimental data which are too hard to analyze, as the contribution coming from different irreps would be 'entangled' and isolating it will likely be rather hard.

Hence, we consider an experiment where the initial state is supported on a finite-dimensional subspace of $\mathcal{F}_m$ such that there are finitely many relevant irreps of $\mathrm{U}(m)$. More precisely, we assume that an arbitrary Fock basis state can be prepared to avoid the problem of multiplicities (as e.g. for core states). Assuming the input state is $|\boldsymbol{n}\rangle$, with $n = \sum_{j=1}^{M} n_j$, any passive transformation acts on $|\boldsymbol{n}\rangle$ according to the totally symmetric irrep $\tau_n^m \colon \mathrm{U}(m) \to \mathrm{U}(\mathcal{H}_n^m)$. As we show in Section 4.1, the reference representation $\omega_n^M := \tau_n^m(\,\cdot\,)\tau_n^{m\dagger}$ is multiplicity-free, and we find

$$\omega_n^M = \bigoplus_{k=0}^{n} \lambda_k\,, \quad \lambda_0 \equiv \mathbf{1}\,,\ \lambda_1 \equiv \mathrm{Ad}\,, \tag{4}$$

where $\mathbf{1}$ denotes the trivial irrep and Ad the adjoint representation of $\mathrm{U}(m)$.

For our protocol, we consider two possible measurement settings. The first one consists of particle number resolving (PNR) detectors, implementing the POVM described by projectors onto Fock states, i.e. $\{|\boldsymbol{k}\rangle\langle\boldsymbol{k}|\}_{\boldsymbol{k}\in\mathbb{N}^m}$ [65, 66]. In this case, the experiment resembles -up to the choice of the input state and the POVM element- the Boson Sampling (BS) experiment originally proposed by Aaronson and Arkhipov [13]. In the second setting – discussed in Appendix H– we consider a balanced heterodyne measurement at the end of each mode, formally described by the coherent states POVM $\{|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}|\}_{\boldsymbol{\alpha}\in\mathbb{C}^m}$. This setup is similar to a Gaussian Boson Sampling (GBS) experiment [14, 15, 67].

Finally, we introduce the *filter function* which isolates the exponential decays for each irrep $\lambda = \lambda_k$ in the post-processing of the collected data. Let P_λ be the projector on the carrier space of λ and let d_λ be its dimension. Then, given the measurement channel $\mathcal{M}(A) := \int_\Omega d\boldsymbol{x}\, \langle \boldsymbol{x}\,|A|\boldsymbol{x}\rangle |\boldsymbol{x}\rangle\langle\boldsymbol{x}|$, we define the filter function as [1]

$$f_\lambda(\boldsymbol{x}, g) := s_\lambda^{-1} \langle \boldsymbol{x}\,|\omega_n^m(g)^\dagger \circ P_\lambda(\rho)\,|\boldsymbol{x}\rangle\,, \tag{5}$$

with

$$s_\lambda := \frac{1}{d_\lambda}\,\mathrm{Tr}[P_\lambda \mathcal{M}] \in \mathbb{R}_{\geq 0}\,. \tag{6}$$

Notably, s_λ can be zero if the measurement POVM augmented by passive transformations is not informationally complete. In this case, we formally set $f_\lambda = 0$ as there will be no contribution from this irrep and no post-processing is necessary.

A remaining open question is how to choose the input state $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$. This choice influences the overall magnitude of the RB signal since the latter scales with the overlap of the initial state with the irrep of interest [1]. For RB on discrete variable systems, the input state is typically chosen to be the all-zeros state $|0^n\rangle$, and, in fact, the choice of input state plays a minor role in this case. The underlying reason is that we typically have a single non-trivial irrep with respect to which all states are essentially equivalent. For CV systems, this is a more subtle question, as many more non-trivial irreps exist, and it seems that there is no clear preferred choice in this case. As the protocols is – beyond the scaling with overlap – independent of the choice of initial state, the input state should be chosen by practical considerations. Generating higher Fock states can be a challenging task [68–70], and it seems that Fock states with $n \leq m$ photons evenly distributed across all modes may be preferable from a practical point of view.

2.3 Performance guarantees

The filtered RB framework [1] implies a number of guarantees for the passive RB protocol under the *implementation map* model. In the latter, the noise is modeled by replacing the representation ω_n^M with an implementation map ϕ_n^M on $\mathrm{U}(m)$, which takes values in the set of quantum channels on $\mathcal{H}_n^M$. This model allows for highly gate-dependent noise, which, however, needs to be stationary and Markovian.

2.3.1 Signal form

Let us define the expected signal as $F_\lambda(m) := \mathbb{E}[\hat{F}_\lambda(m)]$. In the absence of noise, the expected signal is simply constant and of the form [1]:

$$F_\lambda(m) = \begin{cases} \mathrm{Tr}\,[\rho P_\lambda(\rho)] & \text{if } s_\lambda \neq 0\,, \\ 0 & \text{else}\,. \end{cases} \tag{7}$$

In the presence of noise, $F_\lambda(m)$ is no longer constant, but well-approximated by an exponential decay:

Proposition 1 ([1, Thm. 8], informal)**.** *Suppose that the noise is sufficiently weak (in a precise sense). Then, we have*

$$F_\lambda(m) \approx A_\lambda \varphi_\lambda^m\,, \tag{8}$$

up to an additive error $\alpha \geq 0$ which is suppressed exponentially in m, and $A_\lambda \in \mathbb{R}$, $\varphi_\lambda \leq 1$.

In fact, the filtered RB framework [1] gives some more precise conditions on the error suppression in the expected signal. In particular, it is sufficient to choose the sequence length as

$$m \geq \log \frac{d_\lambda}{s_\lambda} + 2 \log \frac{1}{\alpha} + 4\,, \tag{9}$$

where d_λ is the dimension of the irrep and s_λ is as in Eq. (5). Later in Sec. 4, we give an explicit formula for s_λ in terms of Clebsch-Gordan coefficients of $\mathrm{SU}(m)$, however, it is generally difficult to give bounds which are better than $s_\lambda^{-1} = O(d_\lambda)$. We later show that $d_{\lambda_k} \leq \binom{k+m-1}{k}^2$ (c.f. Proposition 5), which would yield sequences of length $O(k \log \frac{k+m-1}{k})$. However, we expect that none of these bounds is particularly tight (in fact, Eq. (9) is not tight in the first place [1]). Based on the performance of discrete RB, we expect that already very short sequences (of constant length) are in fact sufficient.

2.3.2 Evaluation of the filter function

At the heart of the post-processing phase lies the evaluation of the filter function (5). Clearly, for Gaussian input state and measurements, the latter can be simulated in polynomial time. However, such a setting may not be favorable in the context of RB as argued in the last section. Instead, we consider the setting described in Section 2.2, involving Fock input states and either PNR or balanced heterodyne measurements. Then, we show the following:

Theorem 2 (filter function – informal)**.** *Consider an input state of the form $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ and either PNR or balanced heterodyne measurements. Then, the filter function (5) is a suitable linear combination of permanents or Hafnians, respectively.*

Note that the computational complexity of evaluating permanents (or Hafnians) is central to the complexity-theoretic arguments for boson sampling (and Gaussian boson sampling). In fact, even approximating any of the two is known to be computationally hard [13–15, 71]. Nevertheless, these quantities can be computed efficiently in some scenarios [54, 67, 72–77].

We prove Theorem 2 in Section 4.2. Here, we briefly sketch the central steps: Note that the reference representation can be written as $\omega_n^m \simeq \tau_n^m \otimes \bar{\tau}_n^m$, where $\bar{\tau}_n^m$ is the dual (or contragredient) representation of τ_n^m. The irrep decomposition of $\tau_n^m \otimes \bar{\tau}_n^m$ has a natural interpretation as the generalization of the Clebsch-Gordan decomposition for the sum of two angular momenta in quantum mechanics [78]. Informally, there exists a unitary matrix CG –the *Clebsch-Gordan* matrix– that block-diagonalizes ω_n^m [79], such that

$$|\boldsymbol{n}, \boldsymbol{n}\rangle = \sum_{\lambda} \sum_{M\in\lambda} C^{M}_{\boldsymbol{n},\bar{\boldsymbol{n}}} |M\rangle \,, \tag{10}$$

where $\bar{\boldsymbol{n}}$ denotes the dual of $\boldsymbol{n}$ in a sense to be specified later, λ is an irrep of ω_n^m, M's form a basis in which ω_n^m is block diagonal, and $C^M_{\boldsymbol{n},\bar{\boldsymbol{n}}}$ is a (generalized) SU(m) Clebsch-Gordan coefficient. We refer to Section 3 for a discussion on dual vectors and the Clebsch-Gordan series for SU(m) and to Section 4.1 for the irrep decomposition of ω_n^m.

Then, the projection onto a specific irrep λ acts by eliminating all terms in Eq. (10) which do not correspond to the filtering irrep λ . In a similar fashion, the coefficient s_λ in Eq. (5) can be evaluated – for a fixed measurement setting – in terms of Clebsch-Gordan coefficients.

In general, the result of Theorem 2 does not guarantee that the filter function can be computed efficiently. This is due to the fact that any basis vector in the coupled basis generally decomposes into a linear combination of essentially all Fock states in $\mathcal{H}_n^m$, using the inverse Clebsch-Gordan matrix. While some terms may be simulated efficiently, there is no hope that, in general, all inner products can be evaluated efficiently, as, for instance, bosons may be scattered across all modes, making simulation algorithms scale exponentially with the number of bosons [54].

In the case of PNR measurements, we give an alternative expression for f_λ in Section 4.2 as a linear combination of matrix elements of the irrep λ. In the bosonic realization of the Lie algebra $\mathfrak{su}(m)$, these also correspond to permanents [81], however, of a different dimension.

2.3.3 Sampling complexity

Finally, we discuss the sample complexity of passive RB, i.e. the number of samples needed to guarantee that the estimator $\hat{F}_\lambda(m)$ is ϵ-close to its expected value $F_\lambda(m)$ with high probability. Recall from Eq. (2) that $\hat{F}_\lambda(m)$ is a mean estimator for the filter function f_λ. Since the latter is only poorly bounded, we intend to compute the variance $\mathrm{Var}[\hat{F}_\lambda(m)] = \mathrm{Var}[f_\lambda]/L$ (here the variance is still taken over length-m sequences). Then, we can use Chebyshev's inequality to ensure $|\hat{F}_\lambda(m) - F_\lambda(m)| < \epsilon$ with probability $1-\delta$ given $L \geq \epsilon^{-2}\delta^{-1}\,\mathrm{Var}[f_\lambda]$ samples.

In general, analyzing the variance $\mathrm{Var}[f_\lambda]$ can be quite cumbersome, as the underlying probability distribution is given by Born probabilities involving the noisy input state, the noisy transformations, and the noisy measurements. In the filtered RB framework [1] it is shown that –as long as the SPAM-noise is non-malicious– this problem can be reduced to analyzing the second moment $\mathbb{E}[f_\lambda^2]_{\text{ideal}}$ in the ideal, noiseless case. In other words, the presence of noise cannot decrease the efficiency of filtered RB. Here, non-malicious means that the overall effect of SPAM noise is to reduce the magnitude of the signal, measured by the SPAM constants.[2] Using $\mathrm{Var}[f_\lambda] \leq \mathbb{E}[f_\lambda^2]$, the following result then establishes a bound on the sampling complexity of passive RB:

Theorem 3 (Second moment of f_λ – informal)**.** *Assume that the input state is a Fock state $|\boldsymbol{n}\rangle$, we use either PNR or balanced heterodyne measurements, and the SPAM noise is non-malicious. Then, we have*

$$\mathbb{E}[f_\lambda^2] \leq \mathbb{E}[f_\lambda^2]_{\text{ideal}} = \frac{\mathcal{C}}{s_\lambda^2} \,, \tag{11}$$

where $\mathcal{C}$ is a suitable linear combination of Clebsch-Gordan coefficients.

The proof of Theorem 3 is postponed to Section 4.3 for PNR measurements and to Appendix H for Gaussian measurement. It relies on expressing the second moment $\mathbb{E}[f_\lambda^2]_{\text{ideal}}$ as a suitable integral of the representations $\lambda^{\otimes 2}$ and ω_n^m over the compact group G [1, 46]. Schur's lemma then implies that the non-trivial contributions to this integral are given by the irreps of $\lambda^{\otimes 2}$ which are also contained in ω_n^m. We determine these irreps which allows

[2] This is necessary as specially engineered noise can drastically change the behavior of the RB signal, for instance by relabeling the measurement outcomes. Similar assumptions can be found throughout the RB literature [47, 82].

us to finally write $\mathbb{E}[f_\lambda^2]_{\text{ideal}}$ in terms of suitable Clebsch-Gordan coefficients.

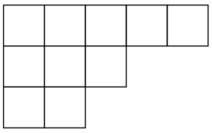
As we generally have $s_\lambda^{-1} \leq d_\lambda$, we have a naive upper bound $\mathbb{E}[f_{\lambda_k}^2] = O(s_{\lambda_k}^{-2})$. We however expect that these bounds are very loose and the variance is much smaller in practice.

3 Technical preliminaries

In this section, we review the main technical tools used in the proofs of our main results, shown in Section 4. First, we review irreps of SU(m) and the Clebsch-Gordan decomposition in terms of Gelfand–Tsetlin patterns, then we briefly review additional technical details concerning filtered randomized benchmarking.

3.1 Representations of SU(m)

Let $n \geq 0$ be a non-negative integer and let $\lambda = (\lambda_1, \ldots, \lambda_m)$ be a partition of n, i.e. $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_m \geq 0$ with $\sum_{i=0}^m \lambda_i = n$. Any such partition can be identified with a *Young diagram*, namely a collection of boxes arranged in left-justified rows with a weakly decreasing number of boxes in each row, where the i-th row contains λ_i boxes, e.g.



(12)

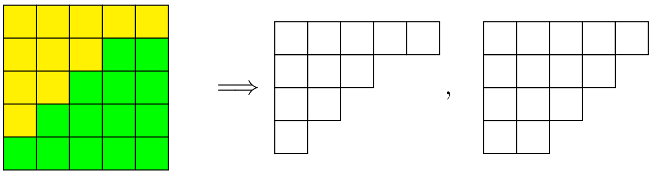
corresponds to $\lambda = (5, 3, 2)$. A *semi-standard Young tableaux* is a filling of a Young diagram with entries taken from any totally ordered set (here, $\mathbb{N}$) such that the entries are weakly increasing across each row and strictly increasing down each column. For instance,

$$\begin{array}{ccccc} 1 & 1 & 2 & 2 & 3 \\ 2 & 2 & 3 & & \\ 3 & 4 & & & \end{array}, \quad \begin{array}{ccccc} 1 & 1 & 1 & 1 & 1 \\ 2 & 2 & 3 & & \\ 3 & 4 & & & \end{array} \tag{13}$$

are semi-standard Young of shape $\lambda = (5, 3, 2)$.

By the theorem of the highest weight [84, Thms. 9.4 and 9.5], Young diagrams uniquely determine irreps of SU(m) up to constant shifts, namely, $(\lambda_1, \ldots, \lambda_m)$ and $(\lambda_1 + c, \ldots, \lambda_m + c)$ identify the same irrep for any integer c. Therefore, as the rank of SU(m) is $m - 1$, by convention we assume $\lambda_m = 0$ without loss of generality. In the following we will not distinguish between Young diagrams and the corresponding irreps, unless otherwise specified.

For a given irrep λ, the *dual (or contragredient)* representation λ^* defined as $\lambda(g) := \lambda(g^{-1})^T$ for each $g \in$ SU(m) is also irreducible, see [84, Prop 4.22]. In a fixed orthonormal basis, we also have $\lambda^* \cong \bar{\lambda}$, where $\bar{\lambda}(g) := \overline{\lambda(g)}$ for each $g \in$ SU(m) denotes the complex conjugate representation of λ. For any irrep $\lambda = (\lambda_1, \ldots, \lambda_m)$, this implies λ^* is identified by the *dual* Young diagram $\bar{\lambda} := (\lambda_1 - \lambda_m, \lambda_1, -\lambda_{m-1}, \ldots, \lambda_2 - \lambda_1, 0)$. More practically, $\bar{\lambda}$ is constructed by completing λ to a $(m-1) \times \lambda_1$ rectangle-shaped Young diagram: The newly added boxes form $\bar{\lambda}$. For instance,



(14)

are dual Young diagrams in SU(5).

For a fixed irrep λ of SU(m), semistandard Young tableaux of shape λ label an orthonormal basis of λ, sometimes referred as the *Weyl basis*. For instance, the Young tableaux

$$\begin{array}{cc} 1 & 1 \\ 2 & \end{array}, \quad \begin{array}{cc} 1 & 1 \\ 3 & \end{array}, \quad \begin{array}{cc} 1 & 2 \\ 2 & \end{array}, \quad \begin{array}{cc} 1 & 2 \\ 3 & \end{array},$$
$$\begin{array}{cc} 1 & 3 \\ 2 & \end{array}, \quad \begin{array}{cc} 1 & 3 \\ 3 & \end{array}, \quad \begin{array}{cc} 2 & 2 \\ 3 & \end{array}, \quad \begin{array}{cc} 2 & 3 \\ 3 & \end{array}.$$

identify an orthonormal basis for the SU(3) adjoint irrep $\lambda = (2, 1)$.

3.1.1 Gelfand-Tsetlin patterns

A more convenient way of labeling basis vectors for any irrep $\lambda = (\lambda_1, \ldots, \lambda_m)$ of SU(m) is by *Gelfand–Tsetlin (GT) patterns*. A GT pattern M of shape λ and length m is represented by a triangular table with m rows, the i-th row containing i integers (counting from the bottom to the top)

$$M = \begin{pmatrix} M_{1,m} & & M_{2,m} & & \cdots & & M_{m-1,m} & & M_{m,m} \\ & M_{1,m-1} & & M_{2,m-1} & \cdots & M_{m-2,m-1} & & M_{m-1,m-1} & \\ & & \ddots & & \vdots & & \cdot^{\cdot^{\cdot}} & & \\ & & & M_{1,2} & & M_{2,2} & & & \\ & & & & M_{1,1} & & & & \end{pmatrix}, \tag{15}$$

where $M_{i,m} = \lambda_i$ for every $i \in [m]$ (and, in particular, $M_{m,m} = 0$ by convention) and the entries satisfy the *interlacing* or *inbetweenness* condition:

$$M_{i,j+1} \geq M_{i,j} \geq M_{i+1,j+1} \tag{16}$$

for every $i \in [m-1]$ and $j \in [m-1]$. We denote the set of GT patterns of shape λ by GT(λ).

An orthonormal basis for λ –referred as the Gelfand–Tsetlin basis– is given by state vectors $\{|M\rangle\}$, where M is a valid GT patterns M with top row $\boldsymbol{M}_1 \equiv (M_{1,1}, \ldots, M_{1,m}) = \lambda$. Hence, the dimension of λ is equal to the number of such states, for which the following formula holds:

$$\dim\lambda = \prod_{1\leq i\leq j\leq m}\left(1+\frac{M_{i,m}-M_{j,m}}{j-i}\right) . \tag{17}$$

In terms of the GT basis, the highest weight vector of λ is identified by the pattern maximizing the inbetweenness conditions, namely

$$M_0 = \begin{pmatrix} M_{1,m} & & M_{2,m} & & \cdots & & M_{m-1,m} & & M_{m,m} \\ & M_{1,m} & & M_{2,m} & \cdots & M_{m-2,m} & & M_{m-1,m-1} & \\ & & \ddots & & \vdots & & \cdot^{\cdot^{\cdot}} & & \\ & & & M_{1,m} & & M_{2,m} & & & \\ & & & & M_{1,m} & & & & \end{pmatrix} \tag{18}$$

(likewise, the lowest weight vector of λ is obtained by minimizing the inbetweenness conditions).

GT patterns are in one-to-one correspondence with semi-standard Young tableaux. In fact, for a given Young tableau T of shape λ, the shape of the corresponding GT pattern M is the same shape as T and the $M_{j,k}$-th entry of M is given by the number of entries in the j-th row of T which are less or equal than k. Conversely, given a GT pattern M of shape λ, the shape of the corresponding Young tableau T is determined by the first row of M and $m_{j,k} - m_{j,k-1}$ is the number of k's in the j'th row of T. Throughout this work, we assume that all illegal coefficients are set to 0. For instance, the Young tableaux in Eq. (13) corresponds to the following GT patterns:

$$\begin{pmatrix} 5 & & 3 & & 2 & & 0 \\ & 5 & & 3 & & 2 & \\ & & 4 & & 2 & & \\ & & & 2 & & & \end{pmatrix}, \quad \begin{pmatrix} 5 & & 3 & & 2 & & 0 \\ & 5 & & 3 & & 1 & \\ & & 5 & & 2 & & \\ & & & 5 & & & \end{pmatrix}, \tag{19}$$

For a given GT pattern M, the *weight* of $|M\rangle$ is a $(m-1)$-ple defined as $w_M := (w_1^{(M)}, \ldots, w_{m-1}^{(M)})$, where each $w_i^{(M)}$ can be determined by M:

$$w_j^{(M)} = \sum_{i=1}^{j} M_{i,j} - \frac{1}{2}\left[\sum_{i=1}^{j-1} M_{i,j-1} + \sum_{i=1}^{j+1} M_{i,j+1}\right] , \tag{20}$$

which generalizes the notion of the magnetic quantum number m for SU(2) in the quantum theory of angular momentum to arbitrary many modes.

Notably, unlike the SU(2) case, weights do not uniquely identify the weight vectors, as the associated weight spaces may not be 1-dimensional [98–100]: Consider the tableau weight $w^T = (w_1^T, \ldots, w_m^T)$, where T is the semi-standard Young tableau associated with M and

$$w_i^T := \sum_{i=1}^{j} M_{i,j} - \sum_{i=1}^{j-1} M_{i,j-1} \tag{21}$$

is the total number of i entries in T. The weights w_M and w^T are clearly related since

$$w_i^{(M)} = \frac{1}{2}\left(w_i^T - w_{i+1}^T\right) \tag{22}$$

Then, for instance,

$$\begin{array}{|c|c|c|}\hline 1 & 2 & 2 \\ \hline 3 & 3 & \\ \cline{1-2}\end{array}\,, \quad \begin{array}{|c|c|c|}\hline 1 & 2 & 3 \\ \hline 2 & 3 & \\ \cline{1-2}\end{array}\,.$$

have clearly the same (tableau) weight for the SU(3) irrep $\lambda = (3, 2)$.

For a weight w, the dimension of the weight space is the *inner multiplicity* of such weight, and corresponds to the number of GT states (or, equivalently, to the number of semi-standard Young tableaux) with weight w. These amount to Kostka's numbers, and can be computed e.g. with recursive algorithms [95].

Dual GT patterns. For a given GT pattern M of shape λ, we define the *dual* GT pattern $\bar{M}$ of shape $\bar{\lambda}$ as the pattern with entries satisfying the relation

$$\bar{M}_{i,l} := M_{1,m} - M_{l-i+1,l} \, , \tag{23}$$

namely $\bar{M}$ is the GT pattern obtained by a constant shift of size $M_{1,m}$ of the GT pattern obtained by flipping all the elements of each row of M, with opposite sign. By construction, $\bar{M}$ is a basis state for the dual irrep $\lambda^* \cong \bar{\lambda}$ of λ. The conjugate operation is also such that each state $|M\rangle$ of λ is associated with a unique conjugate state $|\bar{M}\rangle$ of $\bar{\lambda}$. Specifically, the conjugation operation is such that [100]

$$|M\rangle = (-1)^{\varphi(M)}|\bar{M}\rangle \, , \tag{24}$$

for a suitable phase function that can be determined as follows: For a GT pattern M, define the function

$$s_M(k) = \sum_{j=1}^{k}\sum_{i=1}^{j} M_{i,j} \, , \tag{25}$$

which corresponds to the sum of the labels of M in the first k rows (counting from bottom to top). Then [100],

$$\varphi(M) = s_M(m-1) - s_{M_0}(m-1) \, , \tag{26}$$

where M_0 is defined in Eq. (18).

3.1.2 Symmetric irreps in SU(m)

In this section, we summarize a few basic facts concerning symmetric irreps of SU(m), as they are of central importance throughout this work.

By construction, the space of n particles over m modes is maximally symmetric under permutations over the modes. This implies that the action of $g \in$ SU(m) on such space is described by the irrep

$$\tau_n^m \equiv (n, \underbrace{0, \ldots, 0}_{m-1}) = \underbrace{\square\cdots\square}_{n} \, , \tag{27}$$

where the number of boxes has the interpretation of the number of particles in the system. Formally, the Young diagram on the r.h.s. labels the maximally symmetric irrep in $\mathrm{SU}(m)$. Notably, the weights of the maximally symmetric irreps uniquely identify GT basis elements, as it can be easily checked via the associated tableaux weights.

In $\mathcal{H}_n^m$, a common orthonormal basis is the *Fock basis*, given by Fock states $\{|\boldsymbol{n}\rangle \mid \boldsymbol{n} \in \mathbb{N}^m, \sum_{i=1}^m n_i = n\}$. We remark that the GT basis, as well as the Weyl basis, labels the same set of orthonormal vectors as the Fock basis. In fact, for symmetric irreps, $\boldsymbol{n}$ is exactly the tableau weight of the corresponding Young tableau, i.e. n_i is the number of boxes filled with i for each $i \in [m]$, e.g.

$$|3,2,1\rangle = \left|\begin{array}{|c|c|c|c|c|c|}\hline 1 & 1 & 1 & 2 & 2 & 3 \\ \hline\end{array}\right\rangle , \tag{28}$$

from which it follows the correspondence with the GT basis. In particular, for any Fock state $|\boldsymbol{n}\rangle = |n_1, \ldots, n_m\rangle$, the corresponding GT pattern will be denoted by N, and it is given as follows:

$$N = \begin{pmatrix} n & & & 0 & & \ldots & & 0 & & 0 \\ & \sum_{i=1}^{m-1} n_i & & & 0 & \ldots & 0 & & 0 & \\ & & & \ddots & & \vdots & & \iddots & & \\ & & & & n_1+n_2 & & 0 & & & \\ & & & & & n_1 & & & & \end{pmatrix} . \tag{29}$$

Accordingly, the complex conjugate representation (and therefore the dual representation) acts on the dual space $\hat{\mathcal{H}}_n^m \cong \mathcal{H}_n^m$ and it is identified by the Young diagram

$$\bar{\tau}_n^m = \underbrace{m-1\left\{\begin{array}{ccc} \square & \cdots & \square \\ \vdots & \cdots & \vdots \\ \square & \cdots & \square \end{array}\right.}_{n} . \tag{30}$$

which acts on the dual space $\hat{\mathcal{H}}_n^m \cong \mathcal{H}_n^m$. In this case, we remark that a Fock basis is lacking for $\bar{\tau}_n^m$, as such irrep is not symmetric (and therefore it is not physical w.r.t. bosonic systems). However, the GT basis exists for each irrep and, in this case, the basis elements are labeled by GT patterns $\bar{N}$ of the form

$$\bar{N} = \begin{pmatrix} n & & n & & \ldots & & & n & & 0 \\ & n & & n & \ldots & & n & & n_m & \\ & & \ddots & & \vdots & & & \iddots & & \\ & & & n & & \sum_{i=3}^m n_i & & & & \\ & & & & \sum_{i=2}^m n_i & & & & & \end{pmatrix} , \tag{31}$$

Cf. Eqs. (23) and (29).

3.1.3 Clebsch-Gordan coefficients

A crucial step for filtered RB is the decomposition of the reference representation into irreps. In this section, we recap the role of the Clebsch-Gordan series for $\mathrm{SU}(m)$ in the decomposition of any tensor product representation, which will be employed in the remaining of this work. This topic has been investigated extensively over the years due to its relevance in particle physics, so we refer to standard references such as [78, 103, 104] for further details.

For two given irreps π_1, π_2 of $\mathrm{SU}(m)$, we consider the (completely reducible) tensor product representation $\pi_1 \otimes \pi_2 \colon \mathrm{SU}(m) \to \mathrm{U}(\mathcal{H}_{\pi_1} \otimes \mathcal{H}_{\pi_2})$. By the compact version of Maschke's theorem [93, Thm. 5.2], we have

$$\pi_1 \otimes \pi_2 = \bigoplus_{\lambda} \lambda^{\oplus m_\lambda} , \tag{32}$$

where m_λ is the multiplicity of λ in $\pi_1 \otimes \pi_2$. For $\mathrm{SU}(m)$, such decomposition can be computed in terms of Young diagrams with *Littlewood-Richardson's rules* that we summarize in Appendix A.

In the context of second quantization, the decomposition of $\tau_n^m \otimes \bar{\tau}_n^m$ can be interpreted as the generalization of the Clebsch-Gordan decomposition for spin states in Quantum Mechanics to the case of Fock states[3] [79, 80, 85, 86]. Such decomposition implies that there exists a unitary matrix CG –here referred as the *Clebsch-Gordan matrix*– that realizes the basis transformation from the tensor product space to the direct sum space:

$$\mathrm{CG}\left(\tau_n^m \otimes \bar{\tau}_n^m\right) \mathrm{CG}^\dagger = \begin{pmatrix} \lambda_0 & & & \\ & \lambda_1 & & \\ & & \ddots & \\ & & & \lambda_n \end{pmatrix} . \tag{33}$$

CG is uniquely defined up to global phases, and by convention it is chosen to be real. Clebsch-Gordan coefficients are the matrix coefficients of the CG realizing such change of basis. In particular, Clebsch-Gordan coefficients describe the basis transformation from the tensor product basis to the direct sum space, spanned by the union of the coupled bases: For GT patterns $M_1 \in \mathrm{GT}(\pi_1), M_2 \in \mathrm{GT}(\pi_2)$, we have

$$|M_1, M_2\rangle = \sum_{M \in \mathrm{GT}(\lambda)} C_{M_1,M_2}^{M,r} |M, r\rangle , \tag{34}$$

where $r \in [m_\lambda]$ denotes the r-th copy of λ in $\pi_1 \otimes \pi_2$. Conversely,

$$|M, r\rangle = \sum_{M_1 \in \mathrm{GT}(\pi_1)} \sum_{M_2 \in \mathrm{GT}(\pi_2)} C_{M_1,M_2}^{M,r} |M_1, M_2\rangle . \tag{35}$$

By unitarity of CG, orthogonality relations hold true:

$$\sum_{M \in \mathrm{GT}(\lambda)} C_{M_1,M_2}^{M,r} C_{M_3,M_4}^{M,r} = \delta_{M_1,M_3} \delta_{M_2,M_4} , \tag{36}$$

$$\sum_{M_1 \in \mathrm{GT}(\pi_1)} \sum_{M_2 \in \mathrm{GT}(\pi_2)} C_{M_1,M_2}^{M,r} C_{M_1,M_2}^{M',r'} = \delta_{M,M'} \delta_{r,r'} . \tag{37}$$

As in the case of $\mathrm{SU}(2)$, selection rules for Clebsch-Gordan coefficients of $\mathrm{SU}(m)$ are available: For GT patterns $M_1 \in \mathrm{GT}(()\pi_1), M_2 \in \mathrm{GT}(()\pi_2), M \in \mathrm{GT}(()\lambda)$, $C_{M_1,M_2}^{M,r} = 0$ if

$$w_M \neq w_{M_1} + w_{M_2} , \tag{38}$$

where $w_{(\cdot)}$ is the weight defined in Eq. (20).

[3] This is true for any tensor product representation $\tau_1 \otimes \tau_2$, where τ_1, τ_2 are irreps of $\mathrm{SU}(m)$ [79].

3.2 Background on filter functions

In Section 2.2, we introduced the filter function (Eq. (5)) to isolate and analyze the exponential decays associated with each irreducible component of the reference representation ω_n^m. In this section, for the sake of completeness, we briefly motivate it in the bosonic case, before delving into the main technical results of this work. For a comprehensive discussion, we refer to [1].

Formally, one defines the filter function (dropping the explicit dependence from the input state ρ) as

$$f_\lambda(\boldsymbol{x}, g) = \langle \boldsymbol{x} \,|\, P_\lambda \circ S^+ \circ \omega_n^m(g)^\dagger(\rho) \,|\, \boldsymbol{x}\rangle\,, \tag{39}$$

where S^+ is the Moore-Penrose pseudo-inverse of the *frame operator* S defined as

$$\begin{aligned} S &:= \int_\Omega d\boldsymbol{x} \int_G d\mu_H(g)\; \mathrm{Tr}[\omega_n^m(g)^\dagger(|\boldsymbol{x}\rangle\langle\boldsymbol{x}|)(\cdot)] \\ &\quad \times \omega_n^m(g)(|\boldsymbol{x}\rangle\langle\boldsymbol{x}|) \\ &= \int_G d\mu_H(g)\, \omega_n^M(g)^\dagger \mathcal{M} \omega_n^M(g)\,, \end{aligned} \tag{40}$$

where $\mathcal{M} = \int_\Omega d\boldsymbol{x}\; \mathrm{Tr}[|\boldsymbol{x}\rangle\langle\boldsymbol{x}|(\cdot)]\, |\boldsymbol{x}\rangle\langle\boldsymbol{x}|$ is the (possibly infinite dimensional) measurement channel associated with the POVM $\{|\boldsymbol{x}\rangle\langle\boldsymbol{x}|\}_{\boldsymbol{x}\in\Omega}$.

This choice of filter function is such that, in the ideal case of a noise-free, perfect implementation of the gates, the filtered RB signal is of the form $F_\lambda(m) = \mathrm{Tr}[\rho P_\lambda \circ S^+ \circ S(\rho)]$, where S^+S is the projector onto the span of the POVM. In particular, in the special case of an informationally complete POVM, $F_\lambda(m) = \mathrm{Tr}[\rho P_\lambda(\rho)]$, i.e. the filtered signal is the overlap of ρ with the filtering irrep.

Then, Eq. (5) follows from the following observation: As the reference representation $\omega_n^m := \tau_n^m(\cdot)\tau_n^{m\dagger}$ preserves the number of particles, S act non-trivially on the n-th Fock sector only, i.e.

$$S = \begin{pmatrix} \mathbf{0} & & & & & \\ & \ddots & & & & \\ & & \mathbf{0} & & & \\ & & & S^{(n)} & & \\ & & & & \mathbf{0} & \\ & & & & & \ddots \end{pmatrix}, \tag{41}$$

where $S^{(n)}$ is obtained via the restriction of $\mathcal{M}$ to the subspace of n particles. Moreover, since $\omega_n^m := \tau_n^m(\cdot)\tau_n^{m\dagger}$ decomposes as $\bigoplus_{k=0}^n \lambda_k$, the following decomposition holds [1]:

$$S^{(n)} = \bigoplus_\lambda S_\lambda^{(n)}\,, \quad S_\lambda^{(n)} = s_\lambda \mathbb{1}_\lambda\,, \tag{42}$$

where the direct sum is over all irreps of ω_n^M and, in general [1],

$$s_\lambda = d_\lambda^{-1}\, \mathrm{Tr}[P_\lambda \mathcal{M}] = d_\lambda^{-1} \int_\Omega d\boldsymbol{x}\, \mathrm{Tr}[|\boldsymbol{x}\rangle\langle\boldsymbol{x}| P_\lambda(|\boldsymbol{x}\rangle\langle\boldsymbol{x}|)]\,. \tag{43}$$

Here, $d_\lambda \equiv \dim \mathcal{H}_\lambda$, with $\lambda \in \{\lambda_k\}_{k=0}^n$, and P_λ is the corresponding projector onto its carrier space. In the second step, we used the fact that the Bochner integral commutes with the trace since the latter is a continuous linear operator in the trace norm and the trace of $[|\boldsymbol{x}\rangle\langle\boldsymbol{x}|P_\lambda(|\boldsymbol{x}\rangle\langle\boldsymbol{x}|)]$ is finite.

3.3 Further notations

As the Clebsch-Gordan decomposition is naturally related with the direct sum decomposition of an Hilbert space of the form $\mathcal{H}_1 \otimes \mathcal{H}_2$, it will be convenient to introduce a vectorized notation for operators and superoperators on $\mathcal{H}_n^m$.

We consider the basis of linear operators $L(\mathcal{H}_n^m)$ given by $\Phi = \{|\boldsymbol{n}\rangle\langle\boldsymbol{m}|\}_{\boldsymbol{n},\boldsymbol{m}\in\mathbb{N}^m}$ with $\sum_{i=1}^m n_i = \sum_{i=1}^m m_i = n$. Any linear operator $A \in L(\mathcal{H}_n^m)$ can be vectorized to an element $|A\rangle \in \mathcal{H}_n^m \otimes \mathcal{H}_n^m$ w.r.t. Φ as

$$|A\rangle = \sum_{\boldsymbol{n},\boldsymbol{m}} \mathrm{Tr}[|\boldsymbol{m}\rangle\langle\boldsymbol{n}|A]|\boldsymbol{n},\boldsymbol{m}\rangle\,, \quad |\boldsymbol{n},\boldsymbol{m}\rangle \equiv |\boldsymbol{n}\rangle \otimes |\boldsymbol{m}\rangle\,. \tag{44}$$

Under vectorization, we have $\tau_n^m(\cdot)\tau_n^{m\dagger} \mapsto \tau_n^m \otimes \bar{\tau}_n^m$, where $\bar{\tau}_n^m$ denotes the complex conjugate representation of τ_n^m. Moreover, as long as it is clear from the context, we will not distinguish between super-operators and their corresponding quantities acting on $\mathcal{H}_1 \otimes \mathcal{H}_2$.

Hence, the filter function defined in Eq. (5) becomes

$$f_\lambda(\boldsymbol{x}, g) = \frac{1}{s_\lambda}\langle \boldsymbol{n},\boldsymbol{n} \,|\, P_\lambda(\tau_n^m \otimes \bar{\tau}_n^m)(g)^\dagger \,|\, \boldsymbol{x},\boldsymbol{x}\rangle\,, \tag{45}$$

with $s_\lambda = (\dim\lambda)^{-1} \sum_{\boldsymbol{x}\in\mathbb{N}^m} \langle \boldsymbol{x},\boldsymbol{x} \,|\, P_\lambda \,|\, \boldsymbol{x},\boldsymbol{x}\rangle$.

4 Passive RB with Fock states and measurements

Here, we provide proofs for the theorems introduced in Section 2: In Section 4.2 we prove Theorem 2 and in Section 4.3 we prove Theorem 3 based on notation and technical tools introduced in Section 3.

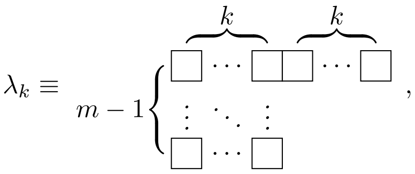
4.1 Clebsch-Gordan decomposition for the reference representation

In this section, we study the irrep decomposition of ω_n^M. As τ_n^m is irreducible, its dual is isomorphic to its complex conjugate representation (w.r.t. the Fock space). In particular, we have

$$\omega_n^M := \tau_n^m(\,\cdot\,)\tau_n^{m\dagger} \cong \tau_n^m \otimes \bar{\tau}_n^m\,. \tag{46}$$

In particular, we will restrict our focus on the irreps of $\mathrm{SU}(m)$ (or, equivalently, its corresponding Lie algebra $\mathfrak{su}(m)$) as τ_n^m can be extended to irreps of $\mathrm{U}(m)$ using nontrivial characters of the unit circle group (roughly speaking, resulting in a multiplication by a global phase), which becomes irrelevant for our aims, since it vanishes as we are interested in its conjugate action on $L(\mathcal{H}_n^m)$. The decomposition of ω_n^m into irreps can be computed using *Littlewood-Richardson's rules*, a general tool to classify the decomposition of tensor product representations. We refer to Appendix A for a brief overview on how they can be employed in the context of $\mathrm{SU}(m)$.

Lemma 4. *Let $\tau_n^m : \mathrm{SU}(m) \to \mathrm{U}(\mathcal{H}_n^m)$ be the irreducible representation of* $\mathrm{SU}(m)$ *on the space of n bosons distributed over m modes as in Eq.* (27). *Define the Young diagram*



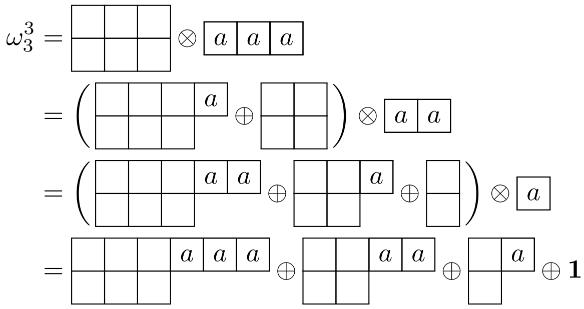
(47)

where λ_0 and λ_1 denote the trivial irrep and the adjoint irrep of $\mathrm{SU}(m)$*, respectively. Then, for any $n, m \in \mathbb{N} \setminus \{0\}$,*

$$\omega_n^M = \bigoplus_{k=0}^{n} \lambda_k \,, \tag{48}$$

where each λ_k, $k = 0, \dots, n$, appears exactly one time.

We prove this result in Appendix B. As an example, we have the following explicit decomposition of the conjugation for $n = m = 3$:



$$= \lambda_3 \oplus \lambda_2 \oplus \lambda_1 \oplus \mathbf{1} = \lambda_3 \oplus \omega_2^3 \,. \tag{49}$$

The dimension of λ_k admits a nice closed-form expression in terms of the dimension of the number subspace:

Proposition 5. *For any $k \in \mathbb{N}$, the following holds:*

$$\dim \lambda_k = \left(1 - \frac{k^2}{(k+m-1)^2}\right) (\dim \mathcal{H}_k^m)^2 \,. \tag{50}$$

We prove this fact in Appendix C.

Hence, we have an easy and algorithmic way to find the decomposition of the action $\tau_n^m \otimes \bar{\tau}_n^m$ into multiplicity-free irreps. We remark that this occurrence is a special case of the completely symmetric representation and its dual: In general, for a fixed representation, the conjugate action will not decompose into multiplicity-free irreps. Moreover, notice that the Young diagrams $\lambda_k, k = 1, \dots, n$ are associated with representations of real type, because each term in the decomposition is self-dual and multiplicity free.

4.2 Filter function for passive RB with PNR measurements

As an irrep decomposition of ω_n^m can be easily computed for any n and m (Cf. Lemma 4), we can evaluate explicit expressions for the filter function. This will provide the proof of Theorem 2.

By construction, $\omega_n^m = \tau_n^m(\cdot)\tau_n^{m\dagger} \cong \tau_n^m \otimes \bar{\tau}_n^m$ acts on elements $|\boldsymbol{n}, \boldsymbol{n}\rangle$ (from here on referred as the uncoupled basis). However, as pointed out in the Section 3.1.1, the second entry shall be suitably interpreted as a basis element of $\bar{\tau}_n^m$, which requires the specification of the relative phases of the states referred by the matrix coefficients. In particular, we have

$$|\boldsymbol{n}\rangle = |N\rangle = (-1)^{\varphi(N)} |\bar{N}\rangle \tag{51}$$

(Cf. Eqs. (23) and (29)). Hence,

$$\begin{aligned} \rho \cong |\boldsymbol{n}, \boldsymbol{n}\rangle &= |N, N\rangle = (-1)^{\varphi(N)} |N, \bar{N}\rangle \\ &= (-1)^{\varphi(N)} \sum_{k=0}^{n} \sum_{M \in \mathrm{GT}(\lambda_k)} C_{N,\bar{N}}^{M} \, |M\rangle \,, \end{aligned} \tag{52}$$

with $\{|N\rangle\}_{N \in \mathrm{GT}(\lambda_k)}$ being an orthonormal basis (referred as the coupled basis from here on) for the carrier space of λ_k. Notice that in Eq. (52) we do not need to specify the multiplicity index of states and Clebsch-Gordan coefficients since λ_k is multiplicity free for each $k = 0, \dots, n$.

Then, for a fixed irrep $\lambda \in \{\lambda_k\}_{k=0}^n$, we have $P_\lambda = X_\lambda X_\lambda^T$ [1], where $X_\lambda \colon \mathcal{H}_n^m \to \mathcal{H}_\lambda$ is an isometry whose matrix representation is given by the Clebsch-Gordan coefficients associated with the irrep λ. This implies

$$P_\lambda = \sum_{M \in \mathrm{GT}(\lambda)} |M\rangle\langle M| \,, \tag{53}$$

and the following relation holds true:

$$\begin{aligned} P_\lambda |N, \bar{N}\rangle &= \sum_{M \in \mathrm{GT}(\lambda)} \langle M | N, \bar{N}\rangle |M\rangle \\ &= \sum_{M \in \mathrm{GT}(\lambda)} C_{N,\bar{N}}^{M} |M\rangle \,, \end{aligned} \tag{54}$$

where, in the second equivalence, we used the identification $C_{N,\bar{N}}^{\lambda M} \equiv \langle \lambda M | N, \bar{N}\rangle$ and that – by the selection rules of Clebsch-Gordan coefficients – the sum is restricted to all the basis vectors such that the associated weight corresponds to the sum of the weights of the states $|N\rangle$ and $|\bar{N}\rangle$, Cf. Eq. (38). Specifically, by Eq. (23), we have

$$\begin{aligned} w_j^{(N)} + w_j^{(\bar{N})} &= \sum_{i=1}^{j} N_{i,j} - \frac{1}{2}\left(\sum_{i=1}^{j-1} N_{i,j-1} + \sum_{i=1}^{j+1} N_{i,j+1}\right) \\ &\quad + \sum_{i=1}^{j} \bar{N}_{i,j} - \frac{1}{2}\left(\sum_{i=1}^{j-1} \bar{N}_{i,j-1} + \sum_{i=1}^{j+1} \bar{N}_{i,j+1}\right) \\ &= \sum_{i=1}^{j} N_{1,m} - \frac{1}{2}\left(\sum_{i=1}^{j-1} N_{1,m} + \sum_{i=1}^{j+1} N_{1,m}\right) \\ &= 0 \,, \end{aligned} \tag{55}$$

which implies $w_N + w_{\bar{N}} = \mathbf{0}$. From the point of view of Young tableaux, this implies that in the tableau T_M –where $M \in \mathrm{GT}(\lambda)$ satisfies the latter selection rules– all the entries appear the same number of times. Moreover, the inner multiplicity $\gamma_{\lambda_k}(\mathbf{0})$ of $\mathbf{0}$ in λ_k for any $k \in \mathbb{N}$ can be easily computed and, in particular,

$$\gamma_{\lambda_k}(\mathbf{0}) = \binom{k+m-2}{k} . \tag{56}$$

We prove this result in Appendix D. This provides the number of non-zero terms in Eq. (54).

With these notations, we can prove the following technical result that will be used extensively in the rest of this work:

Lemma 6. *Let N, X be GT patterns, and let $\bar{N}, \bar{X}$ be their dual, respectively. Let τ_n^m be the n-particles maximally symmetric irrep of* $\mathrm{SU}(m)$ *and consider $\lambda_k \in \omega_n^m = \tau_n^m(\cdot)\tau_n^{m\dagger}$. Let P_{λ_k} be the projector onto λ_k. Then, the following holds:*

$$\begin{aligned}\langle N, \bar{N}\,|P_\lambda(\tau_n^m \otimes \bar{\tau}_n^m)(g)^\dagger|\,X, \bar{X}\rangle &= \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \\ \times \sum_{M' \in \mathrm{GT}(\lambda_k)} C^{M'}_{X,\bar{X}} \langle M\,|\lambda_k(g)^\dagger|\,M'\rangle \,. &\end{aligned} \tag{57}$$

Proof. By construction, P_{λ_k} selects the λ_k-th component of $|N, \bar{N}\rangle$, which can be conveniently isolated by the Clebsch-Gordan decomposition of $\omega_n^m \cong \tau_n^m \otimes \bar{\tau}_n^m$. This implies

$$\begin{aligned}\langle N, \bar{N}\,|P_\lambda(\tau_n^m \otimes \bar{\tau}_n^m)(g)^\dagger|\,X, \bar{X}\rangle &= \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \\ \times \langle M\,|\tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger|\,X, \bar{X}\rangle \,. &\end{aligned} \tag{58}$$

To compute the inner product, recall that $\tau_n^m \otimes \bar{\tau}_n^m = \bigoplus_{l=0}^n \lambda_l$ (Cf. Eq. (48)). In particular, observe that M is a basis element in λ_k, which implies the only non trivial contributions from $\tau_n^m \otimes \bar{\tau}_n^m$ are associated with its λ_k-th component. Likewise, the only relevant contributions to the inner product coming from $|X, \bar{X}\rangle$ are associated with its restriction to λ_k that can be expressed as

$$|X, \bar{X}\rangle\big|_{\lambda_k} = \sum_{M' \in \mathrm{GT}(\lambda_k)} C^{M'}_{X,\bar{X}} |M'\rangle \,. \tag{59}$$

Hence,

$$\begin{aligned}\langle M\,|\tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger|\,X, \bar{X}\rangle = &\sum_{M' \in \mathrm{GT}(\lambda_k)} C^{M'}_{X,\bar{X}} \\ &\times \langle M\,|\lambda_k(g)^\dagger|\,M'\rangle \,,\end{aligned} \tag{60}$$

from which the assertion follows. □

A first consequence, is the following explicit expression for the filter function defined in Eq. (5):

Theorem 7 (Restatement of Theorem 2 - PNR version)**.** *Let $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}| \cong |\boldsymbol{n}, \boldsymbol{n}\rangle = |N, N\rangle$ be a m modes state and let $\{|\boldsymbol{x}\rangle\langle\boldsymbol{x}|\}_{\boldsymbol{x}\in\mathbb{N}^m}$ be the Fock state POVM. Then, for a given irrep $\lambda_k \in \hat{\omega}_n^M$, and assuming $s_{\lambda_k} \neq 0$,*

$$\begin{aligned}f_{\lambda_k}(\boldsymbol{x}, g) = \frac{1}{s_{\lambda_k}}(-1)^{\varphi(N)+\varphi(X)} &\sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \\ \times \sum_{M' \in \mathrm{GT}(\lambda_k)} C^{M'}_{X,\bar{X}} &\langle M\,|\lambda_k(g)^\dagger|\,M'\rangle \,,\end{aligned} \tag{61}$$

where the sums are restricted to all basis states such that Eq. (55) is satisfied.

Proof. By Eq. (52), and denoting by N and X the GT patterns associated with $\boldsymbol{n}$ and $\boldsymbol{x}$, respectively, the filter function defined in Eq. (5) becomes

$$\begin{aligned}f_{\lambda_k}(X, g) &= \frac{1}{s_{\lambda_k}}\langle N, N\,|P_{\lambda_k}(\tau_n^m \otimes \bar{\tau}_n^m)(g)^\dagger|\,X, X\rangle \\ &= \frac{1}{s_{\lambda_k}}(-1)^{\varphi(N)+\varphi(X)} \\ &\times \langle N, \bar{N}\,|P_\lambda(\tau_n^m \otimes \bar{\tau}_n^m)(g)^\dagger|\,X, \bar{X}\rangle \\ &= \frac{1}{s_{\lambda_k}}(-1)^{\varphi(N)+\varphi(X)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \\ &\times \sum_{M' \in \mathrm{GT}(\lambda_k)} C^{M'}_{X,\bar{X}} \langle M\,|\lambda(g)^\dagger|\,M'\rangle \,.\end{aligned} \tag{62}$$

In the last line, we used Lemma 6. □

Notably, explicit expressions for the matrix elements of irreps of $\mathrm{SU}(m)$ are available, see for instance [89, Chapter 3] for $\mathrm{SU}(2)$ and [90, Chapter 9] for $\mathrm{SU}(m)$. Moreover, numerical implementations using the bosonic realization of the Lie algebra $\mathfrak{su}(m)$ are also available [81].

Alternatively, the f_λ also assumes the following form:

$$\begin{aligned}f_{\lambda_k}(X, g) &= \frac{1}{s_{\lambda_k}}(-1)^{\varphi(N)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \\ &\times \langle M\,|(\tau \otimes \bar{\tau})(g)^\dagger|\,X, X\rangle \\ &= \frac{1}{s_{\lambda_k}}(-1)^{\varphi(N)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \sum_{N_1, N_2 \in \mathrm{GT}(\tau_n^m)} \\ &\times C^M_{N_1,\bar{N}_2} \langle N_1, \bar{N}_2\,|\tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger|\,X, X\rangle \\ &= \frac{1}{s_{\lambda_k}}(-1)^{\varphi(N)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \sum_{N_1, N_2 \in \mathrm{GT}(\tau_n^m)} \\ &\times (-1)^{\varphi(N_2)} C^M_{N_1,\bar{N}_2} \langle N_1, N_2\,|\tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger|\,X, X\rangle \,,\end{aligned} \tag{63}$$

which is manifestly related to the computation of permanents [87], as each inner product resembles the boson sampling problem when expressed in the Fock basis:

$$\begin{aligned}&\langle N_1, N_2\,|\tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger|\,X, X\rangle = \\ &= \langle \boldsymbol{n}_1, \boldsymbol{n}_2\,|\tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger|\,\boldsymbol{x}, \boldsymbol{x}\rangle \\ &= \langle \boldsymbol{n}_2\,|\tau_n^m(g)|\,\boldsymbol{x}\rangle\langle \boldsymbol{x}\,|\tau_n^m(g)^\dagger|\,\boldsymbol{n}_1\rangle \\ &= \frac{1}{\boldsymbol{x}!\sqrt{\boldsymbol{n}_1!\boldsymbol{n}_2!}} \operatorname{Per}(\tau_n^m(g)_{\boldsymbol{n}_2,\boldsymbol{x}}) \operatorname{Per}(\tau_n^m(g)^\dagger_{\boldsymbol{x},\boldsymbol{n}_1}) \,,\end{aligned} \tag{64}$$

where $\operatorname{Per}(U_{\boldsymbol{n},\boldsymbol{m}})$ denotes the permanent of the matrix obtained by $\tau_n^m(g)$ by taking m_j copies of the j-th column of U and then by taking n_i copies of the i-th row of the resulting matrix, and we used the multi-index notation $\boldsymbol{n}! := n_1! \ldots n_m!$.

To compute the filter function, we shall provide expressions for the coefficients s_λ. In particular, we have the following result for Eq. (43):

Lemma 8. *Let λ_k be an irrep in ω_n^m. For a PNR measurement setting, the eigenvalues of the frame operator of the passive RB protocol are given by*

$$s_{\lambda_k} = \frac{1}{d_{\lambda_k}} \sum_{X \in \mathrm{GT}(\tau_n^m)} \sum_{M \in \mathrm{GT}(\lambda_k)} |C^M_{X,\bar{X}}|^2 . \tag{65}$$

where $|X\rangle \equiv |\boldsymbol{x}\rangle \in \mathcal{H}_n^m$.

Proof. First, recall that a single mode (ideal) PNR detector measures the number of particles in such mode [66]. In the case of m modes, the (ideal) POVM is therefore given by $\{|\mathbf{x}\rangle\langle\mathbf{x}| \equiv E_{\mathbf{x}}\}_{\mathbf{x}\in\mathbb{N}^m}$ and the (vectorized) measurement channel can be written as

$$\mathcal{M} := \sum_{\mathbf{x}\in\mathbb{N}^m} |\boldsymbol{x},\boldsymbol{x}\rangle\langle\boldsymbol{x},\boldsymbol{x}| = \sum_{n=0}^{\infty}\sum_{X\in\mathrm{GT}(\tau_n^m)} |X,X\rangle\langle X,X|\,. \tag{66}$$

Denoting by P_{λ_k} the projector onto $\lambda_k \in \hat{\omega}_n^M$, we have the following:

$$\begin{aligned} s_{\lambda_k} &= \frac{1}{d_{\lambda_k}} \sum_{\boldsymbol{x}\in\mathbb{N}^m} \langle \boldsymbol{x},\boldsymbol{x}\,|P_{\lambda_k}|\boldsymbol{x}\boldsymbol{x}\rangle \\ &= \frac{1}{d_{\lambda_k}} \sum_{X\in\mathrm{GT}(\tau_n^m)} \langle X,X\,|P_{\lambda_k}|X,X\rangle \\ &= \frac{1}{d_{\lambda_k}} \sum_{X\in\mathrm{GT}(\tau_n^m)} (-1)^{2\varphi(X)}\langle X,\bar{X}\,|P_{\lambda_k}|X,\bar{X}\rangle \\ &= \frac{1}{d_{\lambda_k}} \sum_{X\in\mathrm{GT}(\tau_n^m)}\sum_{M\in\mathrm{GT}(\lambda_k)} C^M_{X,\bar{X}}\langle X,\bar{X}|M\rangle \\ &= \frac{1}{d_{\lambda_k}} \sum_{X\in\mathrm{GT}(\tau_n^m)}\sum_{M\in\mathrm{GT}(\lambda_k)} |C^M_{X,\bar{X}}|^2\,, \end{aligned} \tag{67}$$

where in the second step we used the fact that P_{λ_k} acts non-trivially on the n particle subspace, and in the fourth step we used the fact that the phases $\varphi(X)$ introduced in the labeling of GT dual patterns are integers by construction, Cf. Eq. (26). □

Concretely, the time complexity of computing s_{λ_k} heavily relies on the efficient evaluation of the Clebsch-Gordan coefficients, since the sums are restricted to very few terms due to selection rules. In particular, one can evaluate all Clebsch-Gordan coefficients beforehand. Then, since the Clebsch-Gordan matrix is very sparse, the sum in Eq. (65) can be restricted to non-trivial terms only. Hence, as Clebsch-Gordan coefficients can be calculated in polynomial time [79, 92] for ≈ 20 modes before memory overhead limits the application of such algorithms [92], s_{λ_k} can also be evaluated efficiently for a moderate number of modes.

4.3 Moments of the filter function for PNR measurement settings

In this section, we provide explicit expressions for first two moments of probability of the filter function (5) w.r.t the ideal probability distribution $p(\boldsymbol{x}|g) = \langle\boldsymbol{x}\,|\omega_n^m(g)(\rho)|\boldsymbol{x}\rangle$, $\boldsymbol{x}\in\mathbb{N}^m$. In particular, the ideal second moment will provide an upper bound to the sampling complexity of the protocol, Cf. Section 2.3.

The following technical result will be useful:

Lemma 9. *Let N, X be GT patterns, and let $\bar{N}, \bar{X}$ be their dual, respectively. Let τ_n^m be the n-particles maximally symmetric irrep of* SU(m) *and consider $\lambda_k \in \omega_n^m = \tau_n^m(\cdot)\tau_n^{m\dagger}$. Then, the following holds:*

$$\begin{aligned}\langle X,\bar{X}\,|(\tau_n^m\otimes\bar{\tau}_n^m)(g)|N,\bar{N}\rangle = \sum_{j=0}^{n}\sum_{M,M'\in\mathrm{GT}(\lambda_j)} C^M_{X,\bar{X}} \\ \times\, C^{M'}_{N,\bar{N}}\langle M\,|\lambda_j(g)|M'\rangle\,. \end{aligned}\tag{68}$$

Proof. The expression follows immediately from the Clebsch-Gordan decomposition. More specifically, we have

$$|N,\bar{N}\rangle = \sum_{i=0}^{n}\sum_{M\in\mathrm{GT}(\lambda_i)} C^M_{N,\bar{N}}|M\rangle\,, \tag{69}$$

$$|M,\bar{M}\rangle = \sum_{j=0}^{n}\sum_{M'\in\mathrm{GT}(\lambda_j)} C^{M'}_{X,\bar{X}}|M'\rangle\,, \tag{70}$$

$$\tau_n^m\otimes\bar{\tau}_n^m = \bigoplus_{k=0}^{n}\lambda_k\,, \tag{71}$$

Cf. Eq. (52) and Eq. (48). Hence, since M and M' are basis elements of λ_i and λ_j, respectively,

$$\langle M\,|\lambda_k(g)|M'\rangle \neq 0 \tag{72}$$

only if $i = j = k$, from which the assertion follows. □

We will also need the following standard result in the representation theory of compact groups, often referred as Schur's orthogonality relations, see [93, Thm. 5.8]: For a given irrep λ of SU(m) (or, in general, of any compact group G), if $M_1, M_2, M_1', M_2' \in \mathrm{GT}(\lambda)$, then the following relation holds true:

$$\begin{aligned}\int dg\,\langle M_1\,|\lambda(g)|M_1'\rangle\langle M_2\,|\lambda(g)^\dagger|M_2'\rangle \\ = \frac{1}{\dim\lambda}\delta_{M_1,M_2}\delta_{M_1',M_2'}\,,\end{aligned}\tag{73}$$

where dg denotes the Haar measure on G.

Before we prove the main results of this section, it is worth to quickly consider the first moment $\mathbb{E}[f_\lambda]$, as the proof scheme is the same, but in the case of the second moment is hidden behind few additional technical details concerning the representations involved.

Lemma 10. *For a PNR measurement setting, $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ as input state, and an irrep λ_k of $\omega^{(n)} = \tau_n^m(\,\cdot\,)\tau_n^{m\dagger}$, the following holds:*

$$\mathbb{E}[f_\lambda] = \sum_{M\in\mathrm{GT}(\lambda_k)} |C^M_{N,\bar{N}}|^2\,, \tag{74}$$

where N is the GT pattern associated with $\boldsymbol{n}$, and $\bar{N}$ is its dual.

We prove this result in Appendix E.

In general, finding explicit expressions for the second moment $\mathbb{E}[f_\lambda^2]$ is more involved and the following technical result is necessary:

Lemma 11. *Let λ_k be a Young diagram as in Eq. (47) labeling an irrep of* $\mathrm{SU}(m)$*,* $m \geq 3$*. Then,*

$$\lambda_k \otimes \lambda_k = \bigoplus_{l=0}^{k} \lambda_l^{(l+1)} \oplus \bigoplus_{l=k+1}^{2k} \lambda_l^{(2k-l+1)} \oplus L\,, \tag{75}$$

where $\lambda_0 \equiv \mathbf{1}$, $\lambda_1 \equiv \mathrm{Ad}$, $\lambda_j^{(i)}$ denotes the i-th copy of λ_j in $\lambda_l^{\otimes 2}$, and L is a suitable direct sum of irreps which are not of the form λ_l for any $l \in \mathbb{N}$.

Specifically, all irreps λ_l in $\lambda_k^{\otimes 2}$ are computed by identifying all legal ways of combining two copies of λ_k to a fixed shape using Littlewood-Richardson's rules. This result is presented in Appendix F.

Hence, we derive an explicit expression for $\mathbb{E}[f_\lambda^2]$ using Eq. (73):

Theorem 12. *For a PNR measurement setting, $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ as input state, and an irrep λ_k of $\omega^{(n)} = \tau_n^m(\,\cdot\,)\tau_n^{m\dagger}$, the following holds:*

$$\mathbb{E}[f_{\lambda_k}^2] = \frac{1}{s_{\lambda_k}^2}(-1)^{\varphi(N)} \sum_{X \in \mathrm{GT}(\tau_n^m)} (-1)^{\varphi(X)} g_k(X,N)\,, \tag{76}$$

where $g_k(X,N)$ is a function of Clebsch-Gordan coefficients of the representations $\tau_n^m \otimes \bar{\tau}_n^m$ and $\lambda_k^{\otimes 2}$ given by

$$g_k(X,N) = \sum_{l=0}^{\min\{n,2k\}} \frac{1}{\dim\lambda_l} \sum_{r=1}^{m_l} \sum_{\substack{M,M',L,\\ L' \in \mathrm{GT}(\lambda_k)}} \sum_{R,R' \in \mathrm{GT}(\lambda_l)} \times C_{N,\bar{N}}^{M} C_{N,\bar{N}}^{M'} C_{X,\bar{X}}^{L} C_{X,\bar{X}}^{L'} C_{N,\bar{N}}^{R} C_{X,\bar{X}}^{R'} C_{M,M'}^{R,r} C_{L,L'}^{R',r} \tag{77}$$

where m_l is the multiplicity of λ_l in $\lambda_k^{\otimes 2}$ as in Lemma 11.

We prove this result in in Appendix G.

4.4 A worked out example

In the case of 2 modes systems, Clebsch-Gordan coefficients reduce to the usual ones, and the analysis of the filter function and its moments drastically simplifies. In this section, we show explicit expressions for such a case, which will highlight some technicalities implicit in the general case of $\mathrm{SU}(m)$.

In the $\mathrm{SU}(2)$ case, it is convenient to switch from the bosonic realization of the $\mathrm{SU}(2)$ algebra to its spin realization, where Clebsch-Gordan coefficients are naturally introduced. This task is accomplished by the Jordan-Schwinger map [62]: For given annihilation operators a_1, a_2 acting on a 2 mode system and satisfying the CCRs, the Jordan-Schwinger map is such that

$$J_1 := \frac{1}{2}\left(a_2^\dagger a_1 + a_1^\dagger a_2\right)\,, \tag{78}$$

$$J_2 := \frac{1}{2}\left(a_2^\dagger a_1 - a_1^\dagger a_2\right)\,, \tag{79}$$

$$J_3 := \frac{1}{2}\left(a_1^\dagger a_1 - a_2^\dagger a_2\right)\,, \tag{80}$$

where $[J_i, J_j] = i\epsilon_{ijk}J_k$, ϵ is the Levi-Civita's pseudo-tensor, and

$$J^2 = J_1^2 + J_2^2 + J_3^2 = \frac{n}{2}\left(\frac{n}{2}+1\right)\,, \tag{81}$$

$$n = n_1 + n_2\,, \quad n_i = a_i^\dagger a_i\,. \tag{82}$$

This implies the normalized states $|n_1, n_2\rangle$ correspond to the eigenstates $|jm\rangle$ of J^2 and J_3, with the identification [85, 86]

$$n_1 = j + m\,, \quad n_2 = j - m\,, \tag{83}$$

hence, in this section, we will consider an input state $\rho = |jm\rangle\langle jm|$ and the Fock state POVM becomes $\{|j'm'\rangle\langle j'm'|\}$, where $j' \in \frac{1}{2}\mathbb{N}$ and $m' = -j', \ldots, j'$. A spin state $|jm\rangle$ and its dual are identified by the GT patterns

$$\begin{pmatrix} 2j & & 0 \\ & j-m & \end{pmatrix}, \quad \begin{pmatrix} 2j & & 0 \\ & j+m & \end{pmatrix}, \tag{84}$$

respectively, which implies the following relation:

$$\overline{|jm\rangle} = (-1)^{j+m}|j-m\rangle\,. \tag{85}$$

Moreover, given any irrep λ_J of $\mathrm{SU}(2)$, the following relations hold:

$$P_J = \sum_{M=-J}^{J} |JM\rangle\langle JM|\,, \quad s_J = \frac{1}{2J+1}\,. \tag{86}$$

In particular, the expression for s_J follows from Eq. (65), the fact that the inner multiplicities of $\mathrm{SU}(2)$ basis vectors are 1 (or, equivalently, each weight is uniquely associated with a unique weight vector), and the $\mathrm{SU}(2)$ orthogonality relation $\sum_m |C_{jm,j-m}^{J0}|^2 = 1$.

In this case, with the identification $|x_1, x_2\rangle \mapsto |j\,l\rangle$, Eq. (61) becomes

$$f_J(l,g) = \frac{1}{2J+1}(-1)^{2j+m+l} C_{jm,j-m}^{J0} C_{jl,j-l}^{J0} \times \langle J0\,|\lambda_J(g)^\dagger|\,J0\rangle\,, \tag{87}$$

or, equivalently, it can be expressed as (Cf. Eq. (63))

$$\begin{aligned} f_J(l,g) &= \frac{(-1)^{2j+m}}{2J+1} C_{jm,j-m}^{J0} \sum_{m'=-j}^{j} (-1)^{m'} C_{jm',j-m'}^{J0} \\ &\quad \times \langle jm', j-m'\,|(\tau_n^2 \otimes \bar{\tau}_n^2)(g)^\dagger|\,x_1, x_2\rangle \\ &= \frac{(-1)^{2j+m}}{2J+1} C_{jm,j-m}^{J0} \sum_{m'=-j}^{j} (-1)^{m'} C_{jm',j-m'}^{J0} \\ &\quad \times |\langle x_1, x_2\,|\tau_n^2(g)|\,n_1', n_2'\rangle|^2 \\ &= \frac{(-1)^{2j+m}}{2J+1} \frac{1}{x_1!x_2!} C_{jm,j-m}^{J0} \sum_{m'=-j}^{j} \frac{(-1)^{m'}}{n_1'!n_2'!} \\ &\quad \times C_{jm',j-m'}^{J0} |\mathrm{Per}(\tau_n^2(g)_{(n_1',n_2'),(x_1,x_2)})|^2\,, \end{aligned} \tag{88}$$

where we set $|jm'\rangle = |n_1', n_2'\rangle$ by the inverse Jordan-Schwinger map.

The second moment expression also simplifies significantly. First, notice that, for a given representation

$\lambda_J \otimes \lambda_J$, each λ_K, with $K \in \{0, \dots, 2J\}$, is multiplicity free as all such irreps are clearly maximally symmetric. This implies the decomposition of $\lambda_J^{\otimes 2}$ is formally the same as the one of $\tau_n^2 \otimes \bar{\tau}_n^2$, i.e.

$$\underbrace{\square\cdots\square}_{k} = 1 \oplus \square\square \oplus \square\square\square\square \oplus \cdots \oplus \underbrace{\square\cdots\square}_{2k} \tag{89}$$

and the second moment expression of Theorem 12 simplifies to

$$\begin{aligned}\mathbb{E}[f_J^2] = {} & \frac{1}{s_J^2}(-1)^{2j}|C^{J0}_{jm,j-m}|^2 \sum_{l=-j}^{j}(-1)^{m+l}|C^{L}_{jl,j-l}|^2 \\ & \times \sum_{L=0}^{2\min(J,j)} \frac{1}{2L+1} C^{J0}_{jl,j-l} C^{L0}_{jm,j-m} |C^{L0}_{J0,J0}|^2 \,.\end{aligned} \tag{90}$$

5 Conclusions

Bosonic passive RB is the first RB protocol for the certification of bosonic passive transformations, built on top of general guarantees for filtered RB [1]. Compared to discrete versions of RB, where the defining representation typically determines the reference representation, in passive RB, a broader family of representations, which can be related to the choice of initial state and measurement, is available. This situation complicates the analysis since it made a careful choice of the reference representation necessary.

We analyzed the most common experimental settings for CV systems and argued Gaussian probe states and measurements add additional challenges: First, filtering onto infinitely many irreps appearing in the decomposition of the reference representation would be necessary. They generally present mixed symmetries lacking a clear physical interpretation making it hard to truncate the decomposition with regularization arguments. Also, from a more practical perspective, such irreps are not multiplicity-free, affecting the numerical stability of the post-processing [49]. Moreover, in contrast with RB for discrete variable systems, in CV systems, the choice of the input state influences the RB signal since each number subspace is the carrier space of a non-trivial irrep. We believe Gaussian input states pose additional challenges to RB experiments due to exponentially small overlaps with the number subspaces.

We then identified a well-behaved setting for passive RB with Fock basis states as initial states, ensuring the reference representation decomposes into finitely many multiplicity-free irreps. This allowed a certain degree of freedom in the measurement settings, and we considered the common cases of PNR, or balanced heterodyne detectors. For this setting, we derived explicit formulas needed for the post-processing of the experimental data. Moreover, we analyzed the sampling complexity of the protocol by deriving and bounding the variance of our estimators. Unfortunately, these bounds are quite loose and we expect a much smaller variance in practice.

On the technical side, our analytical results required the Clebsch-Gordan decomposition of ω_n^m, which, for general irreps of $\mathrm{SU}(m)$, is very known to pose significant challenges compared to the standard scenario of $\mathrm{SU}(2)$ [79, 86, 98–100], as irreps with mixed symmetries may appear. However, we found the maximally symmetric irreps are 'regular enough' to carry over a full analysis of the estimators and the sample complexity, as we derived analytical expressions for the frame operators for the POVMs associated with PNR and balanced heterodyne measurements.

A very natural question that arises is whether the passive RB protocol can be extended to active transformations. In this case, many technical difficulties prevent this generalization of filtered RB, as the latter is specifically designed for compact groups, while $\mathrm{Sp}(2m, \mathbb{R})$ (which correspond to the full group of Gaussian transformations) is non-compact (which in turns pose the interesting question of whether a non-compact filtered RB protocol can be formulated). Hence, it is still unclear how to design a meaningful RB protocol for active transformations, as isolating the contributions from different irreps is more challenging.

Finally, we note an analysis of the behavior of passive RB in the presence of *photon distinguishability* is still an open problem, which we believe can be tackled by suitable extensions of the filtered RB framework. However, we leave such problem for future work.

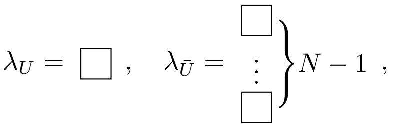
A Littlewood-Richardson's rules

In this section, summarize Littlewood-Richardson's rules for the decomposition into irreps of the tensor product of two irreps of $\mathrm{SU}(m)$. For more details, see for instance [78, Sec. C.3]. In particular, let us consider the unitary irreps $\pi_{\lambda_1}, \pi_{\lambda_2}$ of $\mathrm{SU}(m)$ associated with Young diagrams λ_1, λ_2. Then, the representation

$$\pi_{\lambda_1} \otimes \pi_{\lambda_2} : \mathrm{SU}(m) \ni g \mapsto \pi_{\lambda_1}(g) \otimes \pi_{\lambda_2}(g) \in \mathrm{U}(\mathcal{H}_{\lambda_1} \otimes \mathcal{H}_{\lambda_2}) \tag{91}$$

is in general reducible (in particular, it is completely reducible, since $\mathrm{SU}(m)$ is compact).

For instance, in standard RB [1], one is interested in the irrep $U \otimes \bar{U}$, where $U : \mathrm{SU}(m) \to \mathrm{U}(m)$ is the defining representation and $\bar{U}$ its dual. Diagrammatically, they correspond to

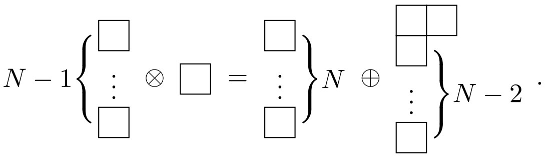


(92)

It is well known that

$$U \otimes \bar{U} = 1 \oplus \mathrm{Ad}, \tag{93}$$

where 1 denotes the trivial irrep and $\mathrm{Ad} : \mathrm{SU}(D) \ni g \mapsto \mathrm{Ad}_g \in \mathrm{Aut}(\mathfrak{su}(D))$ is the adjoint representation. Roughly speaking, the decomposition is achieved by combining the two Young diagrams in all possible ways, and summing up the results. In this case, there are only two possibilities that realize legal Young diagrams: λ_U can be attached on the right of the top row of $\lambda_{\bar{U}}$, or on the bottom of the column, i.e.



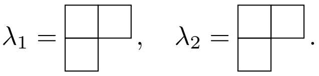
(94)

The first diagram on the r.h.s. is equivalent to the diagram with no boxes associated with the trivial irrep, while the second Young diagram identifies the adjoint representation acting on traceless matrices.

In general, *Littlewood-Richardson's rules* can be used to decompose the tensor product of two arbitrary irreps [78, 101, 102]. To spell out such rules, let us consider two Young diagrams λ_1, λ_2 associated with irreps of $\mathrm{SU}(m)$. The tensor product representation $\lambda_1 \otimes \lambda_2$ can be evaluated algorithmically as follows [102, Sec. 13.5.3] (or also [78, Sec. C.3]):

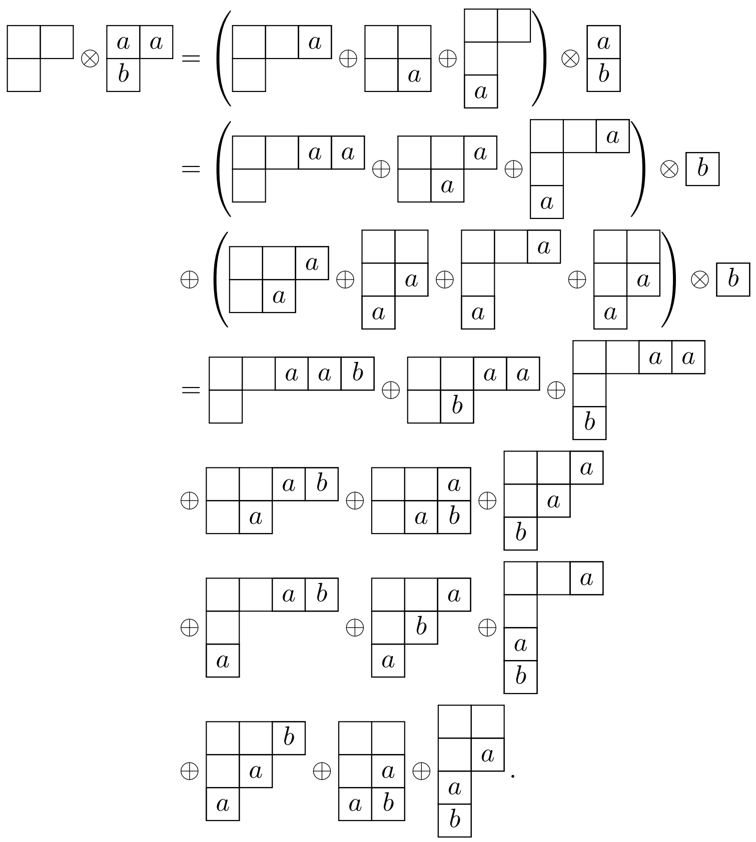
1. Assign distinct labels to boxes in each row of the Young diagram λ_2. For instance, the boxes in the first row will be labeled by 'a', the boxes in the second row by 'b' and so on.
2. Attach boxes labeled by a to λ_1 in all possible ways such that no two a's appear in the same column, and the result is still a proper Young diagram.
3. Repeat the steps above for all rows of λ_2.
4. Elimination rule: For each box, assign numbers n_a = number of a's above and right to it, n_b = number of b's above and right to it, and so on. If, at any point, the relations $n_a \geq n_b \geq n_c \geq n_d \geq \dots$ are not satisfied, discard this diagram.
5. Merging rule. If two diagrams are the same, then they are counted as the same if the labels are the same. Otherwise, they refer to distinct irreps.
6. Cancel columns with m boxes (since they correspond to constant shifts of the highest weight vector).
7. Remove all the labels after the cancellation and the merging steps.

Example 13. Let us consider the following diagrams:



(95)

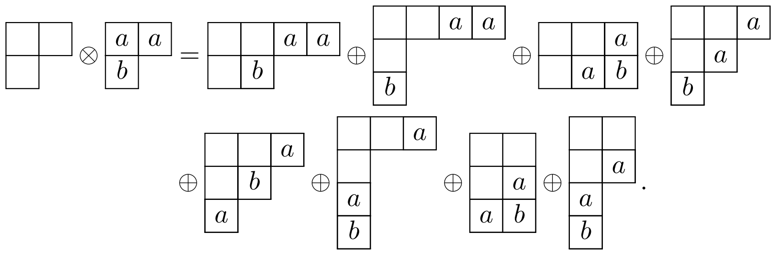
Assigning labels to λ_2 as in rule 1, and using the second and third rules, we get



(96)

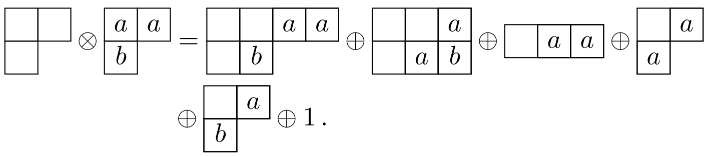
In the second step we got few equivalent diagrams with labels in the same positions, hence they have been merged according to the merging rule. Moreover, we ignored the diagrams with two a's in the same column, in agreement with the symmetric constraint.

By the elimination rule, all the diagrams with a b box attached on the top right shall be eliminated, yielding the following decomposition:



(97)

Finally, suppose for instance that these diagrams are associated with SU(3) irreps. Then, all columns with three boxes can be omitted, while any diagram with more than 3 boxes in a column is not allowed. This yields the following decomposition:



(98)

In the latter, notice that the diagram  appears with multiplicity 2 in the decomposition, as different labels are assigned to the two copies.

In the high energy literature [102], this decomposition is also written in terms of the dimension of the irrep associated with each Young diagram as

$$\mathbf{8}\otimes\bar{\mathbf{8}} = \mathbf{27}\oplus\mathbf{10}\oplus\mathbf{10}'\oplus\mathbf{8}\oplus\mathbf{8}\oplus\mathbf{1}\,. \qquad (99)$$

Here, **10**, **10′** indicates that the two irreps are inequivalent, while repeated dimensions denote the same irrep appear with a non-trivial multiplicity.

B Proof of Lemma 4

Lemma 14 (restatement of Lemma 4)**.** *Let $\tau_n^m : \mathrm{SU}(m) \to \mathrm{U}(\mathcal{H}_n^m)$ be the irreducible representation of $\mathrm{SU}(m)$ on the space of n bosons distributed over m modes as in Eq. (27). Define the Young diagram*

$$\lambda_k \equiv \quad m-1\left\{\begin{array}{l} \overbrace{\square\cdots\square}^{k}\overbrace{\square\cdots\square}^{k} \\ \vdots\ \ \ddots\ \ \vdots \\ \square\cdots\square \end{array}\right. , \tag{100}$$

where λ_0 and λ_1 denote the trivial irrep and the adjoint irrep of $\mathrm{SU}(m)$, respectively. Then, for any $n, m \in \mathbb{N} \setminus \{0\}$,

$$\omega_n^M = \bigoplus_{k=0}^{n} \lambda_k \, , \tag{101}$$

where each λ_k, $k = 0, \dots, n$, appears exactly one time.

Proof. We will prove the following equivalent fact by induction:

$$\omega_n^M = \lambda_n \oplus \omega_{n-1}^m \, , \quad \forall n \in \mathbb{N} \setminus \{0\} \, . \tag{102}$$

First, notice that

$$\omega_1^m = \quad m-1\left\{\begin{array}{l} \square\boxed{a} \\ \vdots \\ \square \end{array}\right. \oplus \mathbf{1} \equiv \lambda_1 \oplus \omega_0^m \, , \tag{103}$$

as $\omega_0^m = \mathbf{1}$ trivially.

The conjugate representation is associated with the tensor product of Young diagrams

$$m-1\left\{\begin{array}{l} \overbrace{\square\cdots\square}^{n} \\ \vdots\ \ \ddots\ \ \vdots \\ \square\cdots\square \end{array}\right. \otimes \underbrace{\square\cdots\square}_{n} \tag{104}$$

(swapping tensor factors does not influence the result). By Littlewood-Richardson's rules, we first have

$$\begin{aligned} m-1\left\{\begin{array}{l} \overbrace{\square\cdots\square}^{n} \\ \vdots\ \ \ddots\ \ \vdots \\ \square\cdots\square \end{array}\right. \otimes \overbrace{\boxed{a}\cdots\boxed{a}}^{n} &= \quad m-1\left\{\begin{array}{l} \overbrace{\square\cdots\square}^{n}\boxed{a} \\ \vdots\ \ \ddots\ \ \vdots \\ \square\cdots\square \end{array}\right. \otimes \overbrace{\boxed{a}\cdots\boxed{a}}^{n-1} \\ &\oplus \quad m-1\left\{\begin{array}{l} \overbrace{\square\cdots\square}^{n-1} \\ \vdots\ \ \ddots\ \ \vdots \\ \square\cdots\square \end{array}\right. \otimes \overbrace{\boxed{a}\cdots\boxed{a}}^{n-1} \, . \end{aligned} \tag{105}$$

Notice that the second term in the r.h.s. is by definition ω_{n-1}^m. Hence, we shall only prove that

$$m-1\left\{\begin{array}{l} \overbrace{\square\cdots\square}^{n}\boxed{a} \\ \vdots\ \ \ddots\ \ \vdots \\ \square\cdots\square \end{array}\right. \otimes \overbrace{\boxed{a}\cdots\boxed{a}}^{n-1} = \oplus_{k=0}^{n} \lambda_k \, . \tag{106}$$

For this purpose, let us consider the factor

$$\tilde{\lambda}_r^{(s)} := \quad m-1\left\{\begin{array}{l} \overbrace{\square\cdots\square}^{r}\overbrace{\boxed{a}\cdots\boxed{a}}^{s} \\ \vdots\ \ \ddots\ \ \vdots \\ \square\cdots\square \end{array}\right. . \tag{107}$$

Clearly, $\tilde{\lambda}_r^{(r)} = \lambda_r$ and $\tilde{\lambda}_0^{(0)} = \mathbf{1}$. Notice that

$$\begin{aligned}
\tilde{\lambda}_r^{(s)} \otimes \tau_l^m &= \left(m-1 \left\{ \begin{array}{l} \overbrace{\square \cdots \square}^{r}\overbrace{\boxed{a} \cdots \boxed{a}}^{s+1} \\ \vdots \ \ \ddots \ \ \vdots \\ \square \cdots \square \end{array} \right. \oplus \begin{array}{l} \overbrace{\square \cdots \square}^{r-1}\overbrace{\boxed{a} \cdots \boxed{a}}^{s} \\ \vdots \ \ \ddots \ \ \vdots \\ \square \cdots \square \end{array} \right) \otimes \overbrace{\boxed{a} \cdots \boxed{a}}^{l-1} \\
&= \left(\tilde{\lambda}_r^{(s+1)} \oplus \tilde{\lambda}_{r-1}^{(s)} \right) \otimes \tau_{l-1}^m \,.
\end{aligned} \tag{108}$$

With this notation, expanding the l.h.s. of Eq. (106) we get

$$\begin{aligned}
\tilde{\lambda}_n^{(1)} \otimes \tau_{n-1}^m &= \left(m-1 \left\{ \begin{array}{l} \overbrace{\square \cdots \square}^{n}\boxed{a}\boxed{a} \\ \vdots \ \ \ddots \ \ \vdots \\ \square \cdots \square \end{array} \right. \oplus \begin{array}{l} \overbrace{\square \cdots \square}^{n-1}\boxed{a} \\ \vdots \ \ \ddots \ \ \vdots \\ \square \cdots \square \end{array} \right) \otimes \overbrace{\boxed{a} \cdots \boxed{a}}^{n-2} \\
&= \left(\tilde{\lambda}_n^{(2)} \oplus \tilde{\lambda}_{n-1}^{(1)} \right) \otimes \tau_{n-2}^m \\
&= \left(\tilde{\lambda}_n^{(3)} \oplus \tilde{\lambda}_{n-1}^{(2)} \oplus \tilde{\lambda}_{n-1}^{(2)} \oplus \tilde{\lambda}_{n-2}^{(1)} \right) \otimes \tau_{n-3}^m \\
&= \left(\tilde{\lambda}_n^{(3)} \oplus \tilde{\lambda}_{n-1}^{(2)} \oplus \tilde{\lambda}_{n-2}^{(1)} \right) \otimes \tau_{n-3}^m \\
&\ \ \vdots \\
&= \left(\tilde{\lambda}_n^{(i)} \oplus \tilde{\lambda}_{n-1}^{(i-1)} \oplus \cdots \oplus \tilde{\lambda}_{n-i+1}^{(1)} \right) \otimes \tau_{n-i}^m \\
&\ \ \vdots \\
&= \bigoplus_{i=0}^{n} \tilde{\lambda}_{n-i}^{(n-i)} \\
&= \bigoplus_{k=0}^{n} \lambda_k \,.
\end{aligned} \tag{109}$$

In the latter, we used the merging rule for Young diagrams, see Appendix A.

Therefore, we have

$$\begin{aligned}
\omega_n^M &= \sum_{k=0}^{n} \lambda_k \oplus \omega_{n-1}^m = \sum_{k=0}^{n} \lambda_k \oplus \sum_{l=0}^{n-1} \lambda_l \\
&= \lambda_n \oplus \omega_{n-1}^m \,,
\end{aligned} \tag{110}$$

where we used the merging rule again. □

C Proof of Proposition 5

For convenience, we state again the proposition:

Proposition 15 (restatement of Proposition 5)**.** *For any $k \in \mathbb{N}$, the following holds:*

$$\dim \lambda_k = \left(1 - \frac{k^2}{(k+m-1)^2} \right) \left(\dim \mathcal{H}_k^m \right)^2 \,. \tag{111}$$

Proof. For any irrep $\lambda = (m_1, m_2, \ldots, m_m)$, the following fact holds: [79]

$$\dim \lambda = \prod_{1 \le j < j' \le m} \left(1 + \frac{m_j - m_{j'}}{j' - j} \right) \,. \tag{112}$$

Let us denote the irrep defined in Eq. (47) as $\lambda_k = (2k, k, \ldots, k, 0)$. Hence, notice the following facts:

- For $j = 1$ and $j' = 2, \ldots, m-1$ we obtain the contribution $\prod_{j'=2}^{m-1} \left(1 + \frac{k}{j'-1} \right)$.

- For $j = 1$ and $j' = m$ we obtain the contribution $1 + \frac{2k}{m-1}$.
- For $2 \le j < j' \le m-1$ all the products are equal to 1.
- For $2 \le j \le m-1$ and $j' = m$ we obtain the contribution $\prod_{j=2}^{m-1}\left(1 + \frac{k}{m-j}\right)$.

Using the latter facts, we have

$$\dim \lambda_k = \frac{2k+m-1}{m-1} \prod_{j=2}^{m-1} \frac{k+m-j}{m-j} \prod_{l=2}^{m-1} \frac{k+l-1}{l-1} = \frac{2k+m-1}{m-1} \left(\frac{1}{(M-2)!}\right)^2 \prod_{j=2}^{m-1}(k+m-j) \prod_{l=2}^{m-1}(k+l-1) \tag{113}$$

$$= \frac{2k+m-1}{m-1} \left(\frac{1}{(M-2)!}\right)^2 \left(\frac{1}{k}(k)_{m-1}\right)^2 = \frac{1}{k^2} \frac{2k+m-1}{m-1} \left(\frac{(k)_{m-1}}{(m-2)!}\right)^2 \tag{114}$$

$$= \frac{1}{k^2} \frac{2k+m-1}{m-1} (m-1)^2 \left(\frac{(k)_{m-1}}{(m-1)!}\right)^2 = \frac{(2k+m-1)(m-1)}{k^2} \left(\frac{(k+m-1)!}{k!(m-1)!} \frac{k}{k+m-1}\right)^2 \tag{115}$$

$$= \frac{(2k+m-1)(m-1)}{k^2} \frac{k^2(m-1)}{(k+m-1)^2} \binom{k+m-1}{m-1}^2 = \frac{(2k+m-1)(m-1)}{(k+m-1)^2} \binom{k+m-1}{m-1}^2 \tag{116}$$

$$= \left(1 - \frac{k^2}{(k+m-1)^2}\right) \left(\dim \mathcal{H}_k^m\right)^2 , \tag{117}$$

In Eq. (113) we factorized the denominators and observed that the factors range between 1 and $m-2$. In Eq. (114) we introduced the Pochhammer raising factorial symbol, defined as $(a)_k := a(a+1)\dots(a+k-1)$ for $a, k \in \mathbb{N}$. In Eq. (115) we recognized that, by definition,

$$\frac{(k)_{m-1}}{(m-2)!} = \binom{k+m-2}{m-1} = \frac{(k+m-2)!}{(k-1)!(m-1)!} \cdot \frac{k}{k} . \tag{118}$$

Finally, rearranging the terms and by symmetry of the binomial coefficient, the assertion followed. □

D Proof of Eq. 56

In this section, for convenience, we will say that a box in a Young tableau is a k-box if it is labeled by $k \in [m]$. Let $\mathrm{SSYT}(\lambda_k)$ be the set of semi-standard Young tableaux of shape λ_k and consider the set

$$\mathrm{SSYT}^{(\mathbf{0})}(\lambda_k) := \{T \mid T \in \mathrm{SSYT}(\lambda_k) \text{ s.t. } w_i^T = w_{i+1}^T \, \forall i \in [m-1]\} . \tag{119}$$

It follows that $\gamma_{\lambda_k}(\mathbf{0}) = |\mathrm{SSYT}^{(\mathbf{0})}(\lambda_k)|$ is the inner multiplicity of $\mathbf{0}$ in λ_k.

Clearly, $\gamma(w) = 1$ for each weight w in SU(2), and Eq. (56) holds trivially.

In a similar fashion, counting Young tableaux T_{λ_k} for SU(3) is straightforward: any Young tableau $T \in \mathrm{SSYT}^{(\mathbf{0})}(\lambda_k)$ contains the labels $\{1, 2, 3\}$ exactly k times, with the 1's forced to be placed in the first k boxes of the first row, otherwise T would not be a legal tableau. Then, if we consider a starting Young tableau of the form

$$\begin{array}{cccccc}
\multicolumn{3}{c}{\overbrace{\qquad\qquad}^{k}} & \multicolumn{3}{c}{\overbrace{\qquad\qquad}^{k}} \\
\boxed{1} & \cdots & \boxed{1} & \boxed{2} & \cdots & \boxed{2} \\
\boxed{3} & \cdots & \boxed{3} & & &
\end{array} \tag{120}$$

all remaining $T \in \mathrm{SSYT}^{(\mathbf{0})}(\lambda_l)$ can be obtained by permuting the last 2-box in the first row with the first 3-box in the second row. The total number of allowed swaps is k, which implies $\gamma_{\lambda_k}(\mathbf{0}) = k+1$.

Consider now $m > 3$ and suppose Eq. (56) holds for $k-1, m-1$. As in the previous case, the 1-boxes are fixed to be placed at the beginning of the first row. Suppose the m-boxes are all placed in the $m-1$-th row, i.e. we consider

$$\begin{array}{cccccc}
\multicolumn{3}{c}{\overbrace{\qquad\qquad}^{k}} & \multicolumn{3}{c}{\overbrace{\qquad\qquad}^{k}} \\
\boxed{1} & \cdots & \boxed{1} & \boxed{2} & \cdots & \boxed{2} \\
\vdots & \ddots & \vdots & & & \\
\boxed{m} & \ddots & \boxed{m} & & &
\end{array} . \tag{121}$$

As long as the last row is fixed to contain m-boxes only, the total number of such Young tableaux is $\binom{k+m-3}{k}$. Then, we only have to count the remaining allowed configurations of k-boxes. For this purpose, observe that the remaining allowed positions for m-boxes are only in the first row, and there are k such configurations. Hence, it is enough to count all possible configurations for each placement of m-boxes in the first row, which is given by

$$\binom{k-l+m-2}{k-l}, \tag{122}$$

where l is the number of free boxes in the first row of the tableau. Therefore, the total number of such configurations is

$$\begin{aligned}\sum_{l=1}^{k}\binom{(k-l)+m-2}{k-l} &= \sum_{j=0}^{k-1}\binom{j+m-2}{j} = \sum_{j=0}^{k-1}\binom{j+m-2}{m-2} \\ &= \binom{k+m-3}{k-1},\end{aligned} \tag{123}$$

where we used Fermat's identity

$$\sum_{j=0}^{n}\binom{j+a}{j} = \binom{a+n+1}{n}. \tag{124}$$

Therefore, by Pascal's identity, we have

$$\gamma_{\lambda_k}(\mathbf{0}) = \binom{k+m-3}{k} + \binom{k+m-3}{k-1} = \binom{k+m-2}{k}, \tag{125}$$

from which the assertion follows.

E Proof of Lemma 10

Lemma 16 (Restatement of Lemma 10)**.** *For a PNR measurement setting, $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ as input state, and an irrep λ_k of $\omega^{(n)} = \tau_n^m(\,\cdot\,)\tau_n^{m\dagger}$, the following holds:*

$$\mathbb{E}[f_\lambda] = \sum_{M\in\mathrm{GT}(\lambda_k)} |C^M_{N,\bar{N}}|^2, \tag{126}$$

where N is the GT pattern associated with $\boldsymbol{n}$, and $\bar{N}$ is its dual.

Proof. Since ρ is an n-particle state and ω_n^m is a passive transformation, the outcome of a PNR measurement must also be an n-particle Fock state. Hence, we have

$$\mathbb{E}[f_{\lambda_k}] := \frac{1}{s_{\lambda_k}}\sum_{\boldsymbol{x}\in\mathcal{H}_n^m}\int dg\,\langle \boldsymbol{n},\boldsymbol{n}\,|P_{\lambda_k}(\tau_n^m\otimes\bar{\tau}_n^m)(g)^\dagger\,|\boldsymbol{x},\boldsymbol{x}\rangle\langle\boldsymbol{x},\boldsymbol{x}\,|(\tau_n^m\otimes\bar{\tau}_n^m)(g)\,|\boldsymbol{n},\boldsymbol{n}\rangle \tag{127}$$

$$= \frac{1}{s_{\lambda_k}}\sum_{X\in\mathrm{GT}(\tau_n^m)}\int dg\,\langle N,\bar{N}\,|P_\lambda(\tau_n^m\otimes\bar{\tau}_n^m)(g)^\dagger\,|X,\bar{X}\rangle\langle X,\bar{X}\,|(\tau_n^m\otimes\bar{\tau}_n^m)(g)\,|N,\bar{N}\rangle \tag{128}$$

$$= \frac{1}{s_{\lambda_k}}\sum_{M\in\mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}}\sum_{X\in\mathrm{GT}(\tau_n^m)}\int dg\,\langle M\,|\lambda_k(g)^\dagger\,|X,\bar{X}\rangle\langle X,\bar{X}\,|\bigoplus_{j=0}^{n}\lambda_j(g)\,|N,\bar{N}\rangle\,. \tag{129}$$

The second line follows since the relative phases between $|M\rangle$ and $|\bar{M}\rangle$ highlighted in Eq. (24) are integers, and they appear an even number of times. In the third step, projected $|N,\bar{N}\rangle$ onto its λ_k-th component, Cf. Eq. (54). Accordingly, the only non-trivial contribution to the integral is determined by the λ_k-th component of $\tau_n^m\otimes\bar{\tau}_n^m$. Similarly, by orthogonality relations, the integral is non-zero only if $\lambda_j = \lambda_k$. Hence, it is enough to consider the restricted Clebsch-Gordan decomposition to the λ_k-th irrep, and the following holds:

$$\mathbb{E}[f_{\lambda_k}] = \frac{1}{s_{\lambda_k}} \sum_{M\in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \sum_{X\in\mathrm{GT}(\tau^m_n)} \int dg \, \langle M \,|\lambda_k(g)^\dagger|\, X,\bar{X}\rangle\langle X,\bar{X}\,|\lambda_k(g)|\,N,\bar{N}\rangle \tag{130}$$

$$= \frac{1}{s_{\lambda_k}} \sum_{M\in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \sum_{X\in\mathrm{GT}(\tau^m_n)} \sum_{M_1,M_2,M_3\in\mathrm{GT}(\lambda_k)} C^{M_1}_{X,\bar{X}} C^{M_2}_{X,\bar{X}} C^{M_3}_{N,\bar{N}} \tag{131}$$

$$\times \underbrace{\int dg\, \langle M\,|\lambda_k(g)^\dagger|\,M_1\rangle\langle M_2\,|\lambda_k(g)|\,M_3\rangle}_{=\frac{1}{\dim\lambda_k}\delta_{M,M_3}\delta_{M_1,M_2}} \tag{132}$$

$$= \frac{1}{\dim\lambda_k}\frac{1}{s_{\lambda_k}} \sum_{M\in \mathrm{GT}(\lambda_k)} |C^M_{N,\bar{N}}|^2 \sum_{X\in\mathrm{GT}(\tau^m_n)} \sum_{M_1\in\mathrm{GT}(\lambda_k)} |C^{M_1}_{X,\bar{X}}|^2 \tag{133}$$

$$= \sum_{M\in\mathrm{GT}(\lambda_k)} |C^M_{N,\bar{N}}|^2 . \tag{134}$$

In the second step, we expanded $|X,\bar{N}\rangle, |N,\bar{N}\rangle$ in the coupled basis, and restricted the decompositions to the λ_k-th components. In the third step, we used Schur's orthogonality relations to compute the integral, and in the final step we used the definition of the frame operator, and in particular the result in Lemma 8. □

F Proof of Lemma 11

Lemma 17 (Restatement of Lemma 11)**.** *Let λ_k be a Young diagram as in Eq. (47). Then, we have*

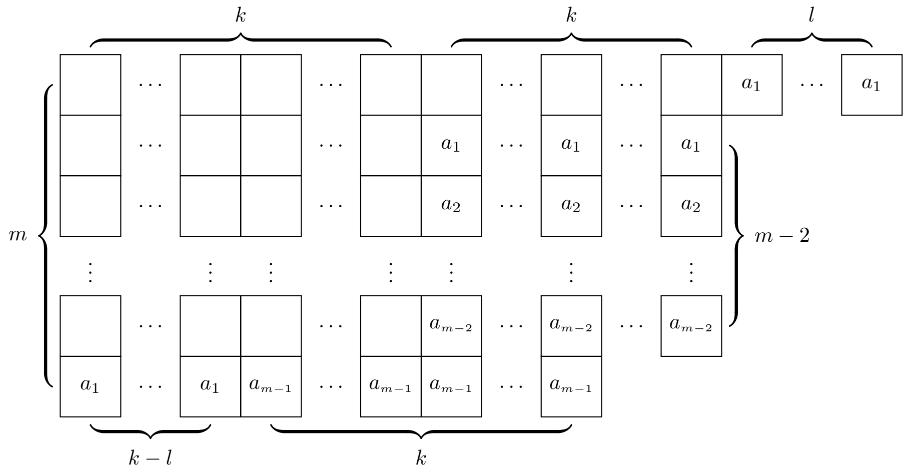
$$\lambda_k \otimes \lambda_k = \bigoplus_{l=0}^{k} \lambda_l^{l+1} \oplus \bigoplus_{l=k+1}^{2k} \lambda_l^{2k-l+1} \oplus L\,, \tag{135}$$

where $\lambda_0 \equiv \mathbf{1}$, $\lambda_1 \equiv \mathrm{Ad}$ as usual, and L is a suitable direct sum of Young diagrams which are not of the form λ_l for any $l \in \mathbb{N}$.

Proof. Consider for any $k \in \mathbb{N}$ the tensor product

$$\lambda_k \otimes \lambda_k = \begin{array}{cccccc} \boxed{} & \cdots & \boxed{} & \boxed{} & \cdots & \boxed{} \\ \boxed{} & \cdots & \boxed{} & & & \\ \vdots & \cdots & \vdots & & & \\ \boxed{} & \cdots & \boxed{} & & & \end{array} \otimes \begin{array}{cccccc} \boxed{a_1} & \cdots & \boxed{a_1} & \boxed{a_1} & \cdots & \boxed{a_1} \\ \boxed{a_2} & \cdots & \boxed{a_2} & & & \\ \vdots & \cdots & \vdots & & & \\ \boxed{a_{m-1}} & \cdots & \boxed{a_{m-1}} & & & \end{array} . \tag{136}$$

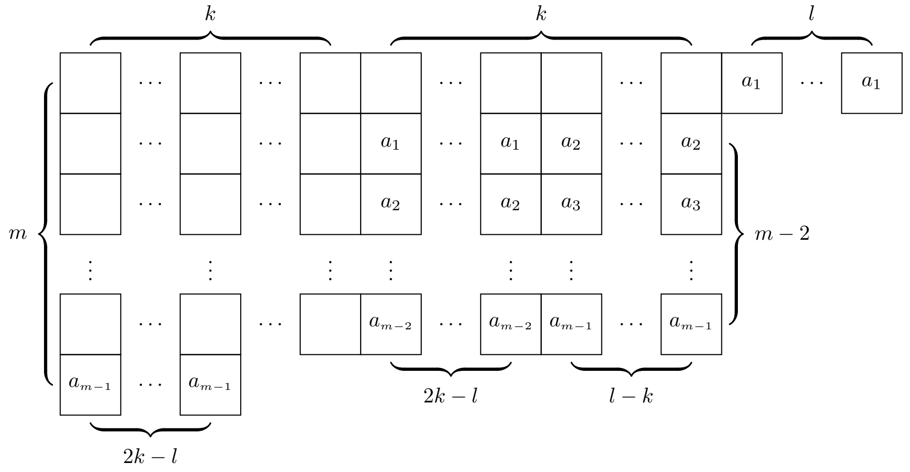
By Littlewood-Richardson's rules, the number of Young diagrams λ_l that can be constructed from $\lambda_k^{\otimes 2}$ is determined by all possible allowed configurations we can attach the a_1 boxes to the first λ_k, since the way the remaining a_i boxes, $i = 2, \dots, m-1$, are attached must follow accordingly. First, notice that only the a_1 boxes can be attached to the first row of the first copy of λ_k due to the elimination rule. Hence, we have two different 'generating' Young diagrams conditioned by whether $l \le k$ or $k+1 \le l \le 2k$. Suppose $l \le k$ at first. The a_1 boxes are attached to the first copy of λ_k as follows: The first l boxes are attached to the first row, the next k boxes are attached to the second row and the remaining $k-l$ boxes are attached to the m-th row. Then, all the a_i boxes, for any $i = 2, 3, \dots, m-2$ are attached to the $i+1$-th row. Finally, the a_{m-1} boxes are attached to the m-th row. The resulting Young diagram is given by



k
k
l
a₁ ⋯ a₁
a₁ ⋯ a₁ ⋯ a₁
a₂ ⋯ a₂ ⋯ a₂
m
m − 2
a_{m−2} ⋯ a_{m−2} ⋯ a_{m−2}
a₁ ⋯ a₁ a_{m−1} ⋯ a_{m−1} a_{m−1} ⋯ a_{m−1}
k − l
k

(137)

Suppose now $l \geq k+1$. The a_1 boxes are attached to the first copy of λ_k as follows: The first l boxes are attached to the first row, while the remaining ones are attached to the second row of λ_k. Then, for the a_i boxes, for any $i = 2, 3, \ldots, m-2$, the first $2k-l$ are attached to the i-th row of λ_k, while the remaining ones are attached to the $i+1$-th row of λ_k. The first a_{m-1} boxes are attached to the $m-1$-th row of T_k and the remaining ones will form the m-th row of the diagram. The resulting Young diagram is



(138)

For notation purpose, let us refer to the latter two Young diagrams as the generating Young diagrams.

At this point, we can generate all the remaining copies of λ_l in the following way:

1. For any $i = 1, \ldots, m-2$, replace the last a_i box in the $i+1$-th row with an a_{i+1} box.

2. Replace the first a_{m-1} box in the m-th row of the diagram with a_1.

It follows that the multiplicity of λ_l in the decomposition of $\lambda_k^{\otimes 2}$ is determined by the number of a_1 boxes in the second row of the generating Young diagram. □

G Proof of Theorem 12

Theorem 18 (Restatement of Theorem 12)**.** *For a PNR measurement setting, $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ as input state, and an irrep λ_k of $\omega^{(n)} = \tau_n^m(\,\cdot\,)\tau_n^{m\dagger}$, the following holds:*

$$\mathbb{E}[f_{\lambda_k}^2] = \frac{1}{s_{\lambda_k}^2}(-1)^{\varphi(N)} \sum_{X \in \mathrm{GT}(\tau_n^m)} (-1)^{\varphi(X)} g_k(X, N)\,, \tag{139}$$

where $g_k(X,N)$ is a function of Clebsch-Gordan coefficients of the representations $\tau_n^m \otimes \bar{\tau}_n^m$ and $\lambda_k^{\otimes 2}$ given by

$$g_k(X,N) = \sum_{l=0}^{\min\{n,2k\}} \frac{1}{\dim \lambda_l} \sum_{r=1}^{m_l} \sum_{\substack{M,M',L,\\ L' \in \mathrm{GT}(\lambda_k)}} \sum_{R,R' \in \mathrm{GT}(\lambda_l)} C^M_{N,\bar{N}} C^{M'}_{N,\bar{N}} C^L_{X,\bar{X}} C^{L'}_{X,\bar{X}} C^R_{N,\bar{N}} C^{R'}_{X,\bar{X}} C^{R,r}_{M,M'} C^{R',r}_{L,L'} \tag{140}$$

where m_l is the multiplicity of λ_l in $\lambda_k^{\otimes 2}$ as in Lemma 11.

Proof. For any irrep $\lambda_k \in \hat{\omega}_n^m$, and by relabeling the second entries as basis elements of the dual irrep $\bar{\tau}_n^m$, the second moment can be expressed as

$$\begin{aligned}
\mathbb{E}[f_{\lambda_k}^2] &:= \frac{1}{s_{\lambda_k}^2} \sum_{\boldsymbol{x}\in\mathcal{H}_n^m} \int dg \,\langle \boldsymbol{n},\boldsymbol{n}\,|P_{\lambda_k}(\tau_n^m \otimes \bar{\tau}_n^m)(g)^\dagger|\,\boldsymbol{x},\boldsymbol{x}\rangle^2 \langle \boldsymbol{x},\boldsymbol{x}\,|\tau_n^m\otimes\tau_n^m(g)|\,\boldsymbol{n},\boldsymbol{n}\rangle \\
&= \frac{1}{s_{\lambda_k}^2} \sum_{X\in\mathrm{GT}(\tau_n^m)} \int dg\,\langle N,N\,|P_{\lambda_k}(\tau_n^m\otimes\bar{\tau}_n^m)(g)^\dagger|\,X,X\rangle^2\langle X,X\,|\tau_n^m\otimes\tau_n^m(g)|\,N,N\rangle \\
&= \frac{1}{s_{\lambda_k}^2} \sum_{X\in\mathrm{GT}(\tau_n^m)} (-1)^{\varphi(N)+\varphi(X)} \int dg\,\langle N,\bar{N}\,|P_{\lambda_k}(\tau_n^m\otimes\bar{\tau}_n^m)(g)^\dagger|\,X,\bar{X}\rangle^2 \\
&\times \langle X,\bar{X}\,|\tau_n^m\otimes\tau_n^m(g)|\,N,\bar{N}\rangle \\
&= \frac{1}{s_{\lambda_k}^2}(-1)^{\varphi(N)} \sum_{X\in\mathrm{GT}(\tau_n^m)} (-1)^{\varphi(X)} g_k(X,N)\,,
\end{aligned} \tag{141}$$

where

$$g_k(X,N) \equiv \int dg\,\langle N,\bar{N}\,|P_{\lambda_k}(\tau_n^m\otimes\bar{\tau}_n^m)(g)^\dagger|\,X,\bar{X}\rangle^2\langle X,\bar{X}\,|\tau_n^m\otimes\tau_n^m(g)|\,N,\bar{N}\rangle\,. \tag{142}$$

By Lemmas 6 and 9, we obtain

$$\begin{aligned}
g_{k,l}(X,N) = &\sum_{M,M'\in\mathrm{GT}(\lambda_k)} C^{M}_{N,\bar{N}} C^{M'}_{N,\bar{N}} \sum_{L,L'\in\mathrm{GT}(\lambda_k)} C^{L}_{X,\bar{X}} C^{L'}_{X,\bar{X}} \sum_{j=0}^{n} \sum_{J,J'\in\mathrm{GT}(\lambda_j)} C^{J}_{X,\bar{X}} C^{J'}_{N,\bar{N}} \\
&\times \underbrace{\int dg\,\langle M,M'\,|\lambda_k(g)^{\dagger\otimes 2}|\,L,L'\rangle\langle J\,|\lambda_j(g)|\,J'\rangle}_{\equiv I}
\end{aligned} \tag{143}$$

We compute the integral with Schur's orthogonality relations. Specifically, this requires the irrep decomposition of $\lambda_k^{\otimes 2}$: By Lemma 11, we have

$$\langle M,M'\,|\lambda_k(g)^{\dagger\otimes 2}|\,L,L'\rangle = \langle M,M'\,|\bigoplus_{l=0}^{2k}\lambda_k^{\oplus m_l}(g)^\dagger|\,L,L'\rangle\,, \tag{144}$$

where $m_l \in \{0,1,\ldots,k\}$ is the multiplicity of λ_l in $\lambda_k^{\otimes 2}$ worked out in Lemma 11. Then, consider the following Clebsch-Gordan decompositions:

$$|M,M'\rangle = \sum_{i=0}^{2k}\sum_{R\in\mathrm{GT}(\lambda_i)} C^{R,r_i}_{M,M'}|R,r_i\rangle\,,\quad |L,L'\rangle = \sum_{h=0}^{2k}\sum_{R'\in\mathrm{GT}(\lambda_h)} C^{R',r_h}_{L,L'}|R',r_h\rangle\,, \tag{145}$$

where r_i, r_h denote the r_i-th and r_h-th copies of λ_i and λ_h in $\lambda_k^{\otimes 2}$, respectively. By orthogonality of irreps, it follows

$$\langle M,M'\,|\lambda_k(g)^{\dagger\otimes 2}|\,L,L'\rangle = \sum_{l=0}^{2k}\sum_{r=1}^{m_l}\sum_{R,R'\in\mathrm{GT}(\lambda_l)} C^{R,r}_{M,M'}C^{R',r}_{L,L'}\langle R,r\,|\lambda_l^{(r)}(g)^\dagger|\,R',r\rangle\,. \tag{146}$$

By Schur's orthogonality relations, this implies that the only non trivial contributions in I are associated with irreps λ_l which appears in the intersection of the sets of irreps of $\tau_n^m\otimes\bar{\tau}_n^m$ and $\lambda_k\otimes\lambda_k$, i.e. $j=l$ provided that λ_l appears in both decomposition. More specifically,

$$\begin{aligned}
I &= \sum_{l=0}^{2k}\sum_{r=1}^{m_l}\sum_{R,R'\in\mathrm{GT}(\lambda_l)} C^{R,r}_{M,M'}C^{R',r}_{L,L'}\int dg\,\langle R,r\,|\lambda_l^{(r)}(g)^\dagger|\,R',r\rangle\langle J\,|\lambda_j(g)|\,J'\rangle \\
&= \sum_{l=0}^{2k}\delta_{l,j}\sum_{r=1}^{m_l}\sum_{R,R'\in\mathrm{GT}(\lambda_l)} C^{R,r}_{M,M'}C^{R',r}_{L,L'}\int dg\,\langle R,r\,|\lambda_l^{(r)}(g)^\dagger|\,R',r\rangle\langle J\,|\lambda_l(g)|\,J'\rangle \\
&= \sum_{l=0}^{2k}\frac{1}{\dim\lambda_l}\delta_{l,j}\sum_{r=1}^{m_l}\sum_{R,R'\in\mathrm{GT}(\lambda_l)} C^{R,r}_{M,M'}C^{R',r}_{L,L'}\delta_{R,J'}\delta_{R',J}\,.
\end{aligned} \tag{147}$$

Therefore, we have

$$
\begin{aligned}
g_k(X,N) = & \sum_{M,M'\in\mathrm{GT}(\lambda_k)} C^{M}_{N,\bar{N}} C^{M'}_{N,\bar{N}} \sum_{L,L'\in\mathrm{GT}(\lambda_k)} C^{L}_{L,\bar{L}} C^{L'}_{X,\bar{X}} \sum_{j=0}^{n} \sum_{J,J'\in\mathrm{GT}(\lambda_j)} C^{J}_{X,\bar{X}} C^{J'}_{N,\bar{N}} \\
& \times \sum_{l=0}^{2k} \frac{1}{\dim\lambda_l} \delta_{l,j} \sum_{r=1}^{m_l} \sum_{R,R'\in\mathrm{GT}(\lambda_l)} C^{R,r}_{M,M'} C^{R',r}_{L,L'} \delta_{R,J'} \delta_{R',J} \\
= & \sum_{l=0}^{\min n,2k} \frac{1}{\dim\lambda_l} \sum_{r=1}^{m_l} \sum_{M,M'\in\mathrm{GT}(\lambda_k)} C^{M}_{N,\bar{N}} C^{M'}_{N,\bar{N}} \sum_{L,L'\in\mathrm{GT}(\lambda_k)} C^{L}_{L,\bar{L}} C^{L'}_{X,\bar{X}} \\
& \times \sum_{R,R'\in\mathrm{GT}(\lambda_l)} C^{R}_{N,\bar{N}} C^{R'}_{X,\bar{X}} C^{R,r}_{M,M'} C^{R',r}_{L,L'} ,
\end{aligned}
\tag{148}
$$

from which the assertion follows. □

H Passive RB with heterodyne measurement

In this section, we will use the usual multi-index notation [83, Sec. 9.1]: For elements $\boldsymbol{n}_1, \boldsymbol{n}_2 \in \mathcal{H}^m_n$, $\boldsymbol{n}_1 + \boldsymbol{n}_2$ denotes the component-wise sum. The multi-index factorial of $\boldsymbol{n} \in \mathcal{H}^m_n$ is defined as $\boldsymbol{n}! := n_1! \dots n_m!$. Also, for a given $\boldsymbol{\alpha} \in \mathbb{C}^m$, we consider the power $\boldsymbol{\alpha}^{\boldsymbol{n}} := \alpha_1^{n_1} \dots \alpha_m^{n_m}$, and we set $|\boldsymbol{\alpha}|^p := \alpha_1^p + \dots + \alpha_m^p$ for $p \geq 1$. We also use the shorthand notation

$$
\int d^2\boldsymbol{\alpha} \equiv \int d^2\alpha_1 \cdots \int d^2\alpha_m \,, \tag{149}
$$

where $d^2\alpha_i$ is the complex measure on $\mathbb{C}$. With this notation, the multi-mode coherent state $|\boldsymbol{\alpha}\rangle$ can be expanded as

$$
|\boldsymbol{\alpha}\rangle = e^{-|\boldsymbol{\alpha}|^2/2} \sum_{\boldsymbol{n}\in\mathcal{F}_m} \frac{\boldsymbol{\alpha}^{\boldsymbol{n}}}{\sqrt{\boldsymbol{n}!}} |\boldsymbol{n}\rangle \,. \tag{150}
$$

Consider now the following quantity for any $K \in 2\mathbb{N}$:

$$
I(\{\boldsymbol{n}_i\}_{i=1}^K) = \frac{1}{\sqrt{\boldsymbol{n}_1!\boldsymbol{n}_2!\dots\boldsymbol{n}_K!}} \int d^2\boldsymbol{\alpha}\, e^{-K/2|\boldsymbol{\alpha}|^2} \bar{\boldsymbol{\alpha}}^{\boldsymbol{n}_1+\dots\boldsymbol{n}_{K/2}} \boldsymbol{\alpha}^{\boldsymbol{n}_{K/2+1}+\dots\boldsymbol{n}_K} \,. \tag{151}
$$

The latter can be evaluated writing down the integral in polar coordinates and integrating by parts. Specifically, for the single-mode integral, and for any $c > 0$, we have

$$
\begin{aligned}
\int d^2\alpha\, e^{-c|\alpha|^2} \alpha^{a+b} \bar{\alpha}^{c+d} &= \int_0^\infty dr\, e^{-cr^2} r^{a+b+c+d+1} \int_0^{2\pi} d\theta\, e^{i\theta(a+b-c-d)} \\
&= \pi \left(\frac{a+b+c+d}{2}\right)!\, c^{-\frac{a+b+c+d}{2}} \delta_{a+b,c+d} \,.
\end{aligned}
\tag{152}
$$

Notice that the expression in parenthesis is a proper factorial due to the δ. This implies

$$
I(\{\boldsymbol{n}_i\}_{i=1}^K) = \frac{\pi^m}{(K/2)^n} \frac{(\boldsymbol{n}_1 + \dots + \boldsymbol{n}_{K/2})!}{\sqrt{\boldsymbol{n}_1!\dots\boldsymbol{n}_K!}} \delta_{\boldsymbol{n}_1+\dots+\boldsymbol{n}_{K/2}, \boldsymbol{n}_{K/2+1}+\dots+\boldsymbol{n}_K} \,. \tag{153}
$$

where $\delta_{\boldsymbol{n}_1+\dots+\boldsymbol{n}_{K/2}, \boldsymbol{n}_{K/2+1}+\dots+\boldsymbol{n}_K} = 1$ if $\sum_{i=1}^{K/2} \boldsymbol{n}_i = \sum_{i=K/2+1}^{K} \boldsymbol{n}_i$, and 0 otherwise, and we used the fact that $|\boldsymbol{n}_i| = n$ for each $i = 1, \dots K$.

The coherent state POVM $\{|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}|\}_{\alpha\in\mathbb{C}^m}$ is informationally complete [91], which implies $s_{\lambda_k} \neq 0$ for any $\lambda_k \in \hat{\omega}^M_n$ [1]. More specifically, we have:

Lemma 19. *Let $\lambda_k \in \hat{\omega}^M_n$. For a balanced heterodyne measurement setting, the eigenvalues of the frame operator of the filtered RB protocol are given by*

$$
s_{\lambda_k} = \frac{1}{d_{\lambda_k}} \frac{\pi^m}{2^n} \sum_{\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2} I_\varphi(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) \sum_{M\in\mathrm{GT}(\lambda_k)} C^{M}_{N_{\boldsymbol{n}_1},\bar{M}_{\boldsymbol{m}_1}} C^{M}_{N_{\boldsymbol{n}_2},\bar{M}_{\boldsymbol{m}_2}} \,, \tag{154}
$$

where $N_{\boldsymbol{n}_i}, M_{\boldsymbol{m}_i}$ are the GT patterns associated with $\boldsymbol{n}_1, \boldsymbol{m}_i$, respectively, and I_φ is given by

$$
I_\varphi(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) = (-1)^{\varphi(M_{\boldsymbol{m}_1})+\varphi(M_{\boldsymbol{m}_2})} I(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) \,. \tag{155}
$$

and

$$
I = \frac{\pi^m}{2^n} \sqrt{\frac{\boldsymbol{n}_1!\boldsymbol{n}_2!}{\boldsymbol{m}_1!\boldsymbol{m}_2!}} \binom{\boldsymbol{n}_1+\boldsymbol{n}_2}{\boldsymbol{n}_2} \delta_{\boldsymbol{n}_1+\boldsymbol{n}_2, \boldsymbol{m}_1+\boldsymbol{m}_2} \,. \tag{156}
$$

Proof. For the balanced heterodyne measurement setting the corresponding (ideal) POVM is $\{|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}| \equiv E_{\boldsymbol{\alpha}}\}_{\boldsymbol{\alpha}\in\mathbb{C}^m}$, where $|\boldsymbol{\alpha}\rangle = \bigotimes_{i=1}^m |\alpha_i\rangle$ is an m modes coherent state. The associated measurement channel is given by

$$\mathcal{M}(\cdot) := \int_{\mathbb{C}^m} d^2\boldsymbol{\alpha}\, \mathrm{Tr}[|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}|(\cdot)]\, |\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}| \,. \tag{157}$$

To evaluate Eq. (42), we use the multi-mode expansion defined in Eq. (150). Moreover, since P_{λ_k} is defined onto a subspace of $\mathcal{H}_n^m$, such expansions of the copies of $\boldsymbol{\alpha}$ are truncated. Hence, by Eq. (151), we have

$$\begin{aligned}
s_{\lambda_k} &= \frac{1}{d_{\lambda_k}} \int d^2\boldsymbol{\alpha}\, \mathrm{Tr}[|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}| P_{\lambda_k}(|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}|)] \\
&= \frac{1}{d_{\lambda_k}} \sum_{\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2\in\mathcal{H}_n^m} I(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2)\, \mathrm{Tr}[|\boldsymbol{n}_1\rangle\langle\boldsymbol{m}_1| P_{\lambda_k}(|\boldsymbol{n}_2\rangle\langle\boldsymbol{m}_2|)] \\
&= \frac{1}{d_{\lambda_k}} \sum_{\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2\in\mathcal{H}_n^m} I(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) \langle \boldsymbol{n}_1, \boldsymbol{m}_1 \,|P_{\lambda_k}|\, \boldsymbol{n}_2, \boldsymbol{m}_2\rangle \\
&= \frac{1}{d_{\lambda_k}} \sum_{\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2\in\mathcal{H}_n^m} I(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) \langle N_{\boldsymbol{n}_1}, M_{\boldsymbol{m}_1} \,|P_{\lambda_k}|\, N_{\boldsymbol{n}_2}, M_{\boldsymbol{m}_2}\rangle \\
&= \frac{1}{d_{\lambda_k}} \sum_{\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2\in\mathcal{H}_n^m} I_\varphi(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) \langle N_{\boldsymbol{n}_1}, \bar{M}_{\boldsymbol{m}_1} \,|P_{\lambda_k}|\, N_{\boldsymbol{n}_2}, \bar{M}_{\boldsymbol{m}_2}\rangle \\
&= \frac{1}{d_{\lambda_k}} \sum_{\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2\in\mathcal{H}_n^m} I_\varphi(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) \sum_{M\in\mathrm{GT}(\lambda_k)} C^M_{N_{\boldsymbol{n}_1},\bar{M}_{\boldsymbol{m}_1}} C^M_{N_{\boldsymbol{n}_2},\bar{M}_{\boldsymbol{m}_2}} \,,
\end{aligned} \tag{158}$$

where in the last step we used the definition of P_{λ_k} to compute the inner product, i.e.

$$\begin{aligned}
\langle N_{\boldsymbol{n}_1}, \bar{M}_{\boldsymbol{m}_1} \,|P_{\lambda_k}|\, N_{\boldsymbol{n}_2}, \bar{M}_{\boldsymbol{m}_2}\rangle &= \sum_{M\in\mathrm{GT}(\lambda_k)} \langle N_{\boldsymbol{n}_1}, \bar{M}_{\boldsymbol{m}_1} \,|\, M\rangle\langle M \,|\, N_{\boldsymbol{n}_2}, M_{\boldsymbol{m}_2}\rangle \\
&= \sum_{M\in\mathrm{GT}(\lambda_k)} C^M_{N_{\boldsymbol{n}_1},\bar{M}_{\boldsymbol{m}_1}} C^M_{N_{\boldsymbol{n}_2},\bar{M}_{\boldsymbol{m}_2}} \,.
\end{aligned} \tag{159}$$

By Eq. (153), we have

$$I(\boldsymbol{n}_1,\boldsymbol{n}_2,\boldsymbol{m}_1,\boldsymbol{m}_2) = \frac{\pi^m}{2^n} (\boldsymbol{n}_1 + \boldsymbol{n}_2)!\, \delta_{\boldsymbol{n}_1+\boldsymbol{n}_2, \boldsymbol{m}_1+\boldsymbol{m}_2} \,. \tag{160}$$

Finally, since

$$(\boldsymbol{n}_1 + \boldsymbol{n}_2)! = \boldsymbol{n}_1! \boldsymbol{n}_2! \binom{\boldsymbol{n}_1 + \boldsymbol{n}_2}{\boldsymbol{n}_2} \,, \tag{161}$$

with

$$\binom{\boldsymbol{n}_1 + \boldsymbol{n}_2}{\boldsymbol{n}_2} \equiv \binom{n_{1,1} + n_{2,1}}{n_{2,1}} \cdots \binom{n_{1,m} + n_{2,m}}{n_{2,m}} \,, \tag{162}$$

Eq. (156) follows. □

A result similar to Eq. (63) is available for heterodyne detectors. We remark that, in principle, it could be possible to workout an expression analogous to Eq. (61). However, we find it less intuitive in the interpretation, as it would correspond to a weighted sum of matrix coefficients of λ_k. Instead, we can express the filter function as a linear combination of Hafnians, in agreement with Gaussian boson sampling experiments:

Theorem 20 (Restatement of Theorem 2 - heterodyne version)**.** *Let $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ be a m modes state and let $\{|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}|\}_{\boldsymbol{\alpha}\in\mathbb{C}^m}$ be the coherent state POVM. Then, for a given irrep $\lambda_k \in \hat{\omega}_n^m$, the filter function is given by*

$$f_{\lambda_k}(\boldsymbol{\alpha}, g) = \frac{(-1)^{\varphi(N)}}{d_{\lambda_k}} \sum_{M\in\mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \sum_{N_1,N_2\in\mathrm{GT}(\tau_n^m)} (-1)^{\varphi(N_2)} C^M_{N_1,\bar{N}_2} \langle N_1, N_2 \,|\, \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{\alpha}, \boldsymbol{\alpha}\rangle \,. \tag{163}$$

Proof. The proof is analogous to the PNR case. We go through each step again for clarity. By a slight generalization of Lemma 6 to include coherent state measurements, we have

$$f_{\lambda_k}(\boldsymbol{\alpha}, g) = \frac{1}{d_{\lambda_k}} \langle \boldsymbol{n}, \boldsymbol{n} \,|\, P_{\lambda_k} \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{\alpha}, \boldsymbol{\alpha} \rangle \tag{164}$$

$$= \frac{1}{d_{\lambda_k}} (-1)^{\varphi(N)} \langle N, \bar{N} \,|\, P_{\lambda_k} \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{\alpha}, \boldsymbol{\alpha} \rangle \tag{165}$$

$$= \frac{1}{d_{\lambda_k}} (-1)^{\varphi(N)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \langle M \,|\, \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{\alpha}, \boldsymbol{\alpha} \rangle \tag{166}$$

$$= \frac{1}{d_{\lambda_k}} (-1)^{\varphi(N)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \sum_{N_1, N_2 \in \mathrm{GT}(\tau_n^m)} C^M_{N_1,\bar{N}_2} \langle N_1, \bar{N}_2 \,|\, \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{\alpha}, \boldsymbol{\alpha} \rangle \tag{167}$$

$$= \frac{1}{d_{\lambda_k}} (-1)^{\varphi(N)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \sum_{N_1, N_2 \in \mathrm{GT}(\tau_n^m)} (-1)^{\varphi(N_2)} C^M_{N_1,\bar{N}_2} \tag{168}$$

$$\times \langle N_1, N_2 \,|\, \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{\alpha}, \boldsymbol{\alpha} \rangle \,, \tag{169}$$

where $\boldsymbol{n}_1, \boldsymbol{n}_2$ are Fock states associated with GT states N_1, N_2, respectively. By writing

$$\langle N_1, N_2 \,|\, \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{\alpha}, \boldsymbol{\alpha} \rangle = \langle \boldsymbol{n}_2 \,|\, \tau_n^m(g) \,|\, \boldsymbol{\alpha} \rangle \langle \boldsymbol{\alpha} \,|\, \tau_n^m(g)^\dagger \,|\, \boldsymbol{n}_1 \rangle \tag{170}$$

we see that f_{λ_k} is given by a suitable combination of Hafnians [14]. □

H.1 Moments for the heterodyne measurement setting

In this section, we provide explicit expressions for first two moments of probability of the filter function (5) in the case of heterodyne measurements, for which the ideal probability distribution is $p(\boldsymbol{\alpha}|g) = \langle \boldsymbol{\alpha} \,|\, \omega_n^m(g)(\rho) \,|\, \boldsymbol{\alpha} \rangle$, $\boldsymbol{\alpha} \in \mathbb{C}^m$. In particular, the ideal second moment will provide an upper bound to the sampling complexity of the protocol, Cf. Section 2.3. As in Section 4.3, the proofs rely on the application of Schur's orthogonality relations, see Eq. (73).

Lemma 21. *For a heterodyne measurement setting, $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$ as input state, and an irrep λ_k of $\omega^{(n)} = \tau_n^m(\,\cdot\,)\tau_n^{m\dagger}$, the following holds:*

$$\mathbb{E}[f_{\lambda_k}] = \frac{1}{d_{\lambda_k} s_{\lambda_k}} \sum_{\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{m}_1, \boldsymbol{m}_2} I_\varphi(\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{m}_1, \boldsymbol{m}_2) \sum_{M \in \mathrm{GT}(\lambda_k)} |C^M_{N,\bar{N}}|^2 \sum_{S \in \mathrm{GT}(\lambda_k)} C^S_{N_{\boldsymbol{n}_1}, \bar{M}_{\boldsymbol{m}_1}} C^S_{N_{\boldsymbol{n}_2}, \bar{M}_{\boldsymbol{m}_2}} \,, \tag{171}$$

where I_φ is as in Lemma 19.

Proof. As in the proof of Lemma 19, considering the multi-mode expansion of $\boldsymbol{\alpha}$, only the n-particle component provides non-trivial contribution to the first moment, since ω_n^m acts non trivially on $\mathcal{H}_n^m$ only. Recalling Eq. (151), it follows

$$\mathbb{E}[f_{\lambda_k}] = \frac{1}{s_{\lambda_k}} \int d^2\boldsymbol{\alpha} \int dg \ \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{n}| P_{\lambda_k} \circ \omega_n^m(|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}|)] \, \mathrm{Tr}[|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}| \omega_n^m(g)(|\boldsymbol{n}\rangle\langle\boldsymbol{n}|)] \tag{172}$$

$$= \frac{1}{s_{\lambda_k}} \sum_{\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{m}_1, \boldsymbol{m}_2} I(\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{m}_1, \boldsymbol{m}_2) \int dg \ \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{n}| P_{\lambda_k} \circ \omega_n^m(g)^\dagger(|\boldsymbol{n}_1\rangle\langle\boldsymbol{m}_1|)] \tag{173}$$

$$\times \mathrm{Tr}[|\boldsymbol{n}_2\rangle\langle\boldsymbol{m}_2| \omega_n^m(g)(|\boldsymbol{n}\rangle\langle\boldsymbol{n}|)] \,. \tag{174}$$

In particular,

$$H \equiv \int dg \ \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{n}| P_{\lambda_k} \circ \omega_n^m(g)^\dagger(|\boldsymbol{n}_1\rangle\langle\boldsymbol{m}_1|)] \, \mathrm{Tr}[|\boldsymbol{n}_2\rangle\langle\boldsymbol{m}_2| \omega_n^m(g)(|\boldsymbol{n}\rangle\langle\boldsymbol{n}|)] \tag{175}$$

$$= \int dg \, \langle \boldsymbol{n}, \boldsymbol{n} \,|\, P_{\lambda_k} \tau_n^m \otimes \bar{\tau}_n^m(g)^\dagger \,|\, \boldsymbol{n}_1, \boldsymbol{m}_1 \rangle \langle \boldsymbol{n}_2, \boldsymbol{m}_2 \,|\, \tau_n^m \otimes \bar{\tau}_n^m(g) \,|\, \boldsymbol{n}, \boldsymbol{n} \rangle \tag{176}$$

$$= (-1)^{\varphi(N)} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \int dg \, \langle M \,|\, \lambda_k(g)^\dagger \,|\, N_{\boldsymbol{n}_1}, M_{\boldsymbol{m}_1} \rangle \langle N_{\boldsymbol{n}_2}, M_{\boldsymbol{m}_2} \,|\, \bigoplus_{j=0}^{n} \lambda_j(g) \,|\, N, N \rangle \tag{177}$$

$$= (-1)^{\varphi(M_{\boldsymbol{m}_1}) + \varphi(M_{\boldsymbol{m}_2})} \sum_{M \in \mathrm{GT}(\lambda_k)} C^M_{N,\bar{N}} \int dg \, \langle M \,|\, \lambda_k(g)^\dagger \,|\, N_{\boldsymbol{n}_1}, \bar{M}_{\boldsymbol{m}_1} \rangle \tag{178}$$

$$\times \langle N_{\boldsymbol{n}_2}, \bar{M}_{\boldsymbol{m}_2} \,|\, \bigoplus_{j=0}^{n} \lambda_j(g) \,|\, N, \bar{N} \rangle \,. \tag{179}$$

The latter can be computed by slight modifications of Lemmas 6 and 9. In particular, by orthogonality relations, the integral is non-zero only if $j = k$ and for basis vectors of λ_k. In other words, it is enough to restrict the Clebsch-Gordan decompositions to the λ_k-th component:

$$|N_{\boldsymbol{n}_1}, M_{\boldsymbol{m}_1}\rangle|_{\lambda_k} = \sum_{S_1 \in \mathrm{GT}(\lambda_k)} C^{S_1}_{N_{\boldsymbol{n}_1}, \bar{M}_{\boldsymbol{m}_1}} |S_1\rangle \,,$$

$$|N_{\boldsymbol{n}_2}, M_{\boldsymbol{m}_2}\rangle|_{\lambda_k} = \sum_{S_2 \in \mathrm{GT}(\lambda_k)} C^{S_2}_{N_{\boldsymbol{n}_2}, \bar{M}_{\boldsymbol{m}_2}} |S_2\rangle \,,$$

$$|N, \bar{N}\rangle|_{\lambda_k} = \sum_{S_3 \in \mathrm{GT}(\lambda_k)} C^{S_3}_{N, \bar{N}} |S_3\rangle \,.$$

Therefore, by Eq. (73), we have

$$H = \frac{1}{d_{\lambda_k}} (-1)^{\varphi(M_{\boldsymbol{m}_1}) + \varphi(M_{\boldsymbol{m}_2})} \sum_{M \in \mathrm{GT}(\lambda_k)} |C^{M}_{N, \bar{N}}|^2 \sum_{S \in \mathrm{GT}(\lambda_k)} C^{S}_{N_{\boldsymbol{n}_1}, \bar{M}_{\boldsymbol{m}_1}} C^{S}_{N_{\boldsymbol{n}_2}, \bar{M}_{\boldsymbol{m}_2}} \tag{180}$$

from which the assertion follows recalling the definition of I_φ. □

Lastly, we have the following explicit expression for the second moment:

Theorem 22. *Consider a passive RB experiment with balanced heterodyne measurement setting, initial Fock state* $\rho = |\boldsymbol{n}\rangle\langle\boldsymbol{n}|$, *and* λ *is an irrep of* $\omega^M_n = \tau^m_n(\,\cdot\,)\tau^{m\dagger}_n$. *Then, the following holds:*

$$\mathbb{E}[f^2_{\lambda_k}] = \frac{1}{s^2_{\lambda_k}} (-1)^{\varphi(N)} \sum_{\substack{\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{n}_3, \\ \boldsymbol{m}_1, \boldsymbol{m}_2, \boldsymbol{m}_3}} (-1)^{\sum_{i=1}^3 \varphi(M_i)} I((\boldsymbol{n}_i), (\boldsymbol{m}_i)) g^{(\varphi)}_k(\boldsymbol{N}, \boldsymbol{M}, N) \,, \tag{181}$$

where $\boldsymbol{N} = (N_1, N_2, N_3), \boldsymbol{M} = (M_1, M_2, M_3)$ *with* $N_i \equiv N(\boldsymbol{n}_i), M_i \equiv M(\boldsymbol{m}_i)$ *are GT patterns associated with* $\boldsymbol{n}_i, \boldsymbol{m}_i$, *respectively,* $I((\boldsymbol{n}_i), (\boldsymbol{m}_i)) \equiv I(\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{n}_3, \boldsymbol{m}_1, \boldsymbol{m}_2, \boldsymbol{m}_3)$ *is as in Eq.* (153) *and*

$$\begin{aligned} g_k(\boldsymbol{N}, \boldsymbol{M}, N) = &\sum_{l=0}^{\min\{n,2k\}} \frac{1}{d_{\lambda_k}} \sum_{r=1}^{m_l} \sum_{M, M', L, L' \in \mathrm{GT}(\lambda_k)} \sum_{R, R' \in \mathrm{GT}(\lambda_l)} C^{M}_{N, \bar{N}} C^{M'}_{N, \bar{N}} C^{R,r}_{M, M'} C^{R}_{N, \bar{N}} C^{R'}_{N_3, \bar{M}_3} \\ &\times C^{L}_{N_1, \bar{M}_1} C^{L'}_{N_2, \bar{M}_2} C^{R',r}_{L, L'} \,. \end{aligned} \tag{182}$$

Proof. By Eqs. (150) and (151), we have, for any λ_k,

$$\mathbb{E}[f^2_{\lambda_k}] = \frac{1}{s^2_{\lambda_k}} \int d^2\boldsymbol{\alpha} \int dg \ \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{n}| P_{\lambda_k} \circ \omega^m_n(g)^\dagger (|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}|)]^2 \, \mathrm{Tr}[|\boldsymbol{\alpha}\rangle\langle\boldsymbol{\alpha}| \omega^m_n(g)(|\boldsymbol{n}\rangle\langle\boldsymbol{n}|)] \tag{183}$$

$$= \frac{1}{s^2_{\lambda_k}} \sum_{\substack{\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{n}_3, \\ \boldsymbol{m}_1, \boldsymbol{m}_2, \boldsymbol{m}_3}} I((\boldsymbol{n}_i), (\boldsymbol{m}_i)) \int dg \ \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{m}| P_{\lambda_k} \circ \omega^m_n(g)^\dagger (|\boldsymbol{n}_1\rangle\langle\boldsymbol{m}_1|)] \tag{184}$$

$$\times \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{n}| P_{\lambda_k} \circ \omega^m_n(g)^\dagger (|\boldsymbol{n}_2\rangle\langle\boldsymbol{m}_2|)] \, \mathrm{Tr}[|\boldsymbol{n}_3\rangle\langle\boldsymbol{m}_3| \omega^m_n(g)(|\boldsymbol{n}\rangle\langle\boldsymbol{n}|)] \tag{185}$$

$$\equiv \frac{1}{s^2_{\lambda_k}} \sum_{\substack{\boldsymbol{n}_1, \boldsymbol{n}_2, \boldsymbol{n}_3, \\ \boldsymbol{m}_1, \boldsymbol{m}_2, \boldsymbol{m}_3}} I((\boldsymbol{n}_i), (\boldsymbol{m}_i)) g^{(\varphi)}_k(\boldsymbol{N}, \boldsymbol{M}, N) \,. \tag{186}$$

Introducing GT patterns, we have

$$g^{(\varphi)}_k(\boldsymbol{N}, \boldsymbol{M}, N) \equiv \int dg \ \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{m}| P_{\lambda_k} \circ \omega^m_n(g)^\dagger (|\boldsymbol{n}_1\rangle\langle\boldsymbol{m}_1|)] \, \mathrm{Tr}[|\boldsymbol{n}\rangle\langle\boldsymbol{n}| P_{\lambda_k} \circ \omega^m_n(g)^\dagger (|\boldsymbol{n}_2\rangle\langle\boldsymbol{m}_2|)] \tag{187}$$

$$\times \mathrm{Tr}[|\boldsymbol{n}_3\rangle\langle\boldsymbol{m}_3| \omega^m_n(g)(|\boldsymbol{n}\rangle\langle\boldsymbol{n}|)] \tag{188}$$

$$= \int dg \, \langle \boldsymbol{n}, \boldsymbol{n} \,|P_{\lambda_k} \tau^m_n \otimes \bar{\tau}^m_n(g)^\dagger \,|\boldsymbol{n}_1, \boldsymbol{m}_1\rangle\langle \boldsymbol{n}, \boldsymbol{n} \,|P_{\lambda_k} \tau^m_n \otimes \bar{\tau}^m_n(g)^\dagger \,|\boldsymbol{n}_2, \boldsymbol{m}_2\rangle \tag{189}$$

$$\times \langle \boldsymbol{n}_3, \boldsymbol{m}_3 \,|\tau^m_n \otimes \bar{\tau}^m_n(g)|\boldsymbol{n}, \boldsymbol{n}\rangle \tag{190}$$

$$= (-1)^{\varphi(N) + \varphi(M_1) + \varphi(M_2) + \varphi(M_3)} \sum_{M, M' \in \mathrm{GT}(\lambda_k)} C^{M}_{N, \bar{N}} C^{M'}_{N, \bar{N}} \tag{191}$$

$$\times \int dg \, \langle M, M' \,|\lambda_k(g)^{\otimes 2\dagger} \,|N_1, \bar{M}_1, N_2, \bar{M}_2\rangle\langle N_3, \bar{M}_3 \,|\bigoplus_{j=0}^{n} \lambda_j(g)|N, \bar{N}\rangle \tag{192}$$

$$\equiv (-1)^{\varphi(N) + \sum_{i=1}^3 \varphi(M_i)} g_k(\boldsymbol{N}, \boldsymbol{M}, N) \,. \tag{193}$$

We compute the integral as in the proof of Theorem 12: Consider the decomposition of $\lambda_l^{\otimes 2}$ as in Lemma 11. Then, by orthogonality of the matrix coefficients, the non-trivial contributions to the integral come from irreps that appear –with their multiplicities– in both ω_n^m and $\lambda_k^{\otimes 2}$. In this way, the latter integral reduces to

$$\sum_{l=0}^{\min\{n,2k\}} \sum_{r=1}^{m_l} \int dg \, \langle M, M' \, | \lambda_l^{(r)}(g)^\dagger \, | N_1, \bar{M}_1, N_2, \bar{M}_2 \rangle \langle N_3, \bar{M}_3 \, | \lambda_l(g) | N, \bar{N} \rangle \, . \tag{194}$$

Given the Clebsch-Gordan decompositions

$$|M, M'\rangle = \sum_{R \in \mathrm{GT}(\lambda_l)} C^{R,r}_{M,M'} |R, r\rangle \, , \tag{195}$$

$$|N_3, \bar{M}_3\rangle = \sum_{J \in \mathrm{GT}(\lambda_l)} C^{J}_{N_3,\bar{M}_3} |J\rangle \, , \tag{196}$$

$$|N, \bar{N}\rangle = \sum_{J' \in \mathrm{GT}(\lambda_l)} C^{J'}_{N,\bar{N}} |J'\rangle \, , \tag{197}$$

$$|N_1, \bar{M}_1, N_2, \bar{M}_2\rangle = \sum_{L,L' \in \mathrm{GT}(\lambda_k)} C^{L}_{N_1,\bar{M}_1} C^{L'}_{N_2,\bar{M}_2} |L, L'\rangle \, , \tag{198}$$

$$|L, L'\rangle = \sum_{R' \in \mathrm{GT}(\lambda_l)} C^{R' r}_{L,L'} |R', r\rangle \, , \tag{199}$$

from which it follows

$$\int dg \, \langle R, r \, | \lambda_l^{(r)}(g)^\dagger \, | R', r\rangle \langle J \, | \lambda_l(g) | J' \rangle = \frac{1}{d_{\lambda_l}} \delta_{R,J'} \delta_{R',J} \, . \tag{200}$$

Hence,

$$\begin{aligned} g_k(\boldsymbol{N}, \boldsymbol{M}, N) = & \sum_{l=0}^{\min\{n,2k\}} \frac{1}{d_{\lambda_k}} \sum_{r=1}^{m_l} \sum_{M,M',L,L' \in \mathrm{GT}(\lambda_k)} \sum_{R,R' \in \mathrm{GT}(\lambda_l)} C^{M}_{N,\bar{N}} C^{M'}_{N,\bar{N}} C^{R,r}_{M,M'} C^{R}_{N,\bar{N}} C^{R'}_{N_3,\bar{M}_3} \\ & \times C^{L}_{N_1,\bar{M}_1} C^{L'}_{N_2,\bar{M}_2} C^{R',r}_{L,L'} \, , \end{aligned} \tag{201}$$

and the assertion follows with a suitable sorting of all the terms. □

Simulating non-completely-positive Actions via Exponentiation of Hermitian-preserving Maps

Fuchuan Wei, Zhenhuan Liu, Guoding Liu, Zizhao Han, Dong-Ling Deng, and Zhengwei Liu

The full version of this paper can be found at arXiv:2308.07956.

I. INTRODUCTION

Principles of quantum mechanics dictate that quantum operations must act on and output density matrices, which are positive matrices with a unit trace [1]. Thus, a valid quantum operation must be completely positive and trace-preserving (CPTP). As depicted in Fig. 1(a), the set of CPTP maps represents only a small subset of all linear maps [2]. In practical terms, the CPTP constraint limits the performance of many quantum tasks.

In entanglement detection and quantification, positive but not completely positive maps [3] serve as crucial tools. By deciding the positivity of output matrices generated by acting positive maps on subsystems, corresponding entanglement criteria exhibit strong detection capabilities. Moreover, the entanglement negativity, which quantifies the violation of the positive partial transposition criterion, represents an easily computable and operationally meaningful entanglement measure [4]. However, due to their lack of complete positivity, verifying positive map criteria often requires highly joint operations or exponential repetition times [5–7].

In quantum error mitigation [8, 9], the core idea is applying the inverse map of the noise channel to noisy states. However, since the inverse maps of noise channels are always non-completely-positive (non-CP), techniques such as probabilistic error cancellation [10–12] are adopted to statistically realize these inverse maps, recovering only noiseless expectation values rather than noiseless states, limiting the range of applications.

Existing approaches for realizing non-CP maps are restricted in the level of quantum states and aim to prepare outputs of non-CP maps in some indirect ways. Methods based on structural approximation [13, 14] and Petz recovery map [15, 16] employ CPTP maps to approximate non-CP maps. However, the approximate channel may largely deviate from the target non-CP map. The multicopy extension method [17] utilizes a joint CPTP map acting on multiple copies of input states to produce a single output of the non-CP map, making it feasible only when the output remains a density matrix. Probabilistic error cancellation [10–12] decomposes the non-CP map into a linear combination of some CPTP maps, realizing the non-CP map only in a statistical manner.

An effective and practical approach to implementing non-CP maps remains elusive. In this work, we address this crucial problem by proposing a systematic approach to efficiently simulate the actions of all Hermitian-preserving maps.

II. THE ALGORITHM

Although the output of a Hermitian-preserving map, $\mathcal{N}(\rho)$, might not necessarily be a density matrix but rather a general Hermitian matrix, Hermitian matrices still have physical meanings, such as Hamiltonians determining evolutions of physical systems. Therefore, by exponentiating a Hermitian-preserving map $\mathcal{N}(\cdot)$, we define a new map, $e^{-i\mathcal{N}(\cdot)t}$, which maps an input state to a unitary evolution. This new map contains all the information of the Hermitian-preserving map $\mathcal{N}$.

To realize the map $e^{-i\mathcal{N}(\cdot)t}$, we design a quantum algorithm called *Hermitian-preserving map exponentiation* (HME), as depicted in Fig. 1(c). The HME algorithm begins with preparing two quantum systems, the target state ρ will be prepared on the first system, while the second system serves as a quantum memory to keep the state on which the evolution of $e^{-i\mathcal{N}(\rho)t}$ is applied. Based on the desired accuracy, the non-CP map $\mathcal{N}$, and the total evolution time t, one determines an appropriate Hamiltonian H and a short time period Δt. Subsequently, one repeats the following steps for a total of $K = t/\Delta t$ times:

1. Prepare the target state ρ on the first system.

2. Evolve the two systems jointly using $e^{-iH\Delta t}$.

Theorem 1 (Validation of HME). *For a short time period Δt, we have*

$$\mathrm{Tr}_1\left(e^{-iH\Delta t}(\rho\otimes\sigma)e^{iH\Delta t}\right) = e^{-i\mathcal{N}(\rho)\Delta t}\sigma e^{i\mathcal{N}(\rho)\Delta t} + \mathcal{O}(\Delta t^2). \quad (1)$$

Here, Tr_1 denotes the partial trace over the first system, $\mathcal{N}$ represents the target Hermitian-preserving map, $H = \Lambda_{\mathcal{N}}^{T_1}$ with $\Lambda_{\mathcal{N}} = (\mathcal{I}\otimes\mathcal{N})\,|\Phi^+\rangle\langle\Phi^+|$ being the Choi matrix for $\mathcal{N}$, $|\Phi^+\rangle = \sum_i |ii\rangle$ denotes the unnormalized maximally entangled state, and T_1 represents the partial transposition operation on the first system.

The density matrix exponentiation algorithm [18, 19], which has been proved to exhibit exponential speedup compared to single-copy strategies in certain tasks [20], can be regarded as a special case of HME by setting $\mathcal{N}$ to be the identity map. Given that Hermitian-preserving maps are significantly more general than CPTP maps and encompass a wide range of crucial non-CP maps, HME has the potential to be a key tool in various quantum information processing tasks.

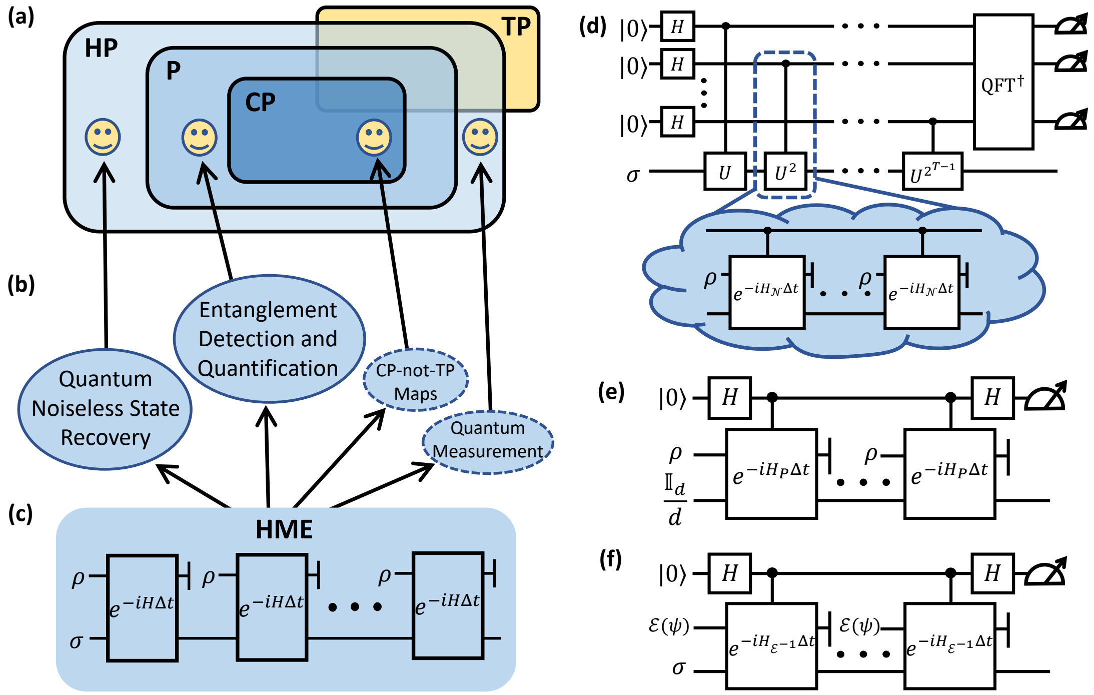


FIG. 1. (a) Diagrammatic representation of different types of maps, including CP (completely positive), P (positive), HP (Hermitian-preserving), and TP (trace-preserving) maps. Physical maps lie in the intersection of CP and TP. The smiling faces represent the maps used in the four applications listed in (b). (c) Circuit diagram for HME, comprising three components: sequential input of identical states ρ, the evolved state σ preserved using quantum memory, and joint Hamiltonian evolution. (d) The circuit of the HME-based entanglement detection protocol, which is constructed by combining the HME and quantum phase estimation algorithms. The controlled unitary evolutions are approximately realized by HME, where $H_{\mathcal{N}}$ is the Hamiltonian for implementing $\mathcal{N} = \mathcal{P}_A \otimes \mathcal{I}_B$. (e) The circuit for estimating entanglement negativity. (f) The circuit of our error mitigation protocol.

III. PERFORMANCE ANALYSIS

HME realizes the evolution of $e^{-i\mathcal{N}(\rho)t}$ by sequentially inputting the target state ρ. Thus, an essential indicator for analyzing the performance of HME is the number of copies needed for realizing the desired evolution with an error up to ϵ. According to Theorem 1, the difference between the ideal and real channels for a single step of the experiment is a second-order term. Thus the error could be suppressed by choosing a shorter time slice Δt, or equivalently, by using more copies of ρ.

Theorem 2 (Upper bound of sample complexity)**.** *Let $\mathcal{N}$ be an arbitrary Hermitian-preserving map, the HME algorithm shown in Fig. 1(c) requires at most*

$$\mathcal{O}\left(\epsilon^{-1}\|H\|_\infty^2 t^2\right) \tag{2}$$

copies of sequentially inputting state ρ to ensure that $\|\mathcal{Q}_t - \mathcal{U}_t\|_\diamond \le \epsilon$ holds for arbitrary ρ. Here, $H = \Lambda_{\mathcal{N}}^{T_1}$, $\mathcal{Q}_t = \mathcal{Q}_{\Delta t}^{\circ K}$ represents the real channel with $\mathcal{Q}_{\Delta t}(\sigma) := \mathrm{Tr}_1\left[e^{-iH\Delta t}(\rho\otimes\sigma)e^{iH\Delta t}\right]$ and $K = t/\Delta t$, $\mathcal{U}_t$ is the ideal evolution channel corresponding to $e^{-i\mathcal{N}(\rho)t}$, and $\|\cdot\|_\diamond$ denotes the diamond norm.

We also analyze the lower bound of sample complexity for exponentiating Hermitian-preserving maps, considering the ability to perform arbitrary physical operations.

Theorem 3 (Lower bound of sample complexity)**.** *Let $\mathcal{N} \in T(\mathcal{H},\mathcal{K})$ be a Hermitian-preserving map and set $0 < \epsilon \le 1/6$, and $t \ge \frac{15\pi\epsilon}{4R_*}$. Even using highly joint operations, the minimum number of ρ needed to realize the evolution of $e^{-i\mathcal{N}(\rho)t}$ with ϵ accuracy in diamond distance satisfies*

$$f_{\mathcal{N}}(\epsilon,t) \ge \Omega\left(\epsilon^{-1}R_*^2 t^2\right), \tag{3}$$

where $R_* := \max\limits_{A\in\mathscr{F}} R\left[\mathcal{N}(A)\right]$. $R[\cdot] = \lambda_{max}(\cdot) - \lambda_{min}(\cdot)$ denotes the spectral gap defined as the difference between the largest and the lowest eigenvalues of the processed matrix. The feasible region $\mathscr{F}$ is defined as $\mathscr{F} = \Big\{A \in L(\mathcal{H}) : A^\dagger = A, \mathrm{Tr}(A) = 0, \|A\|_1 = 1, [\mathcal{N}(A^+),\mathcal{N}(A^-)] = 0\Big\}$, where A^+ and A^- are the positive and negative parts of A.

Combining Theorem 2 and Theorem 3, we can conclude that HME represents the **optimal** protocol for exponentiating certain Hermitian-preserving maps, including the identity map $\mathcal{I}$ and the inverse map of local amplitude damping noise $(\mathcal{E}_\gamma^{\otimes n})^{-1}$.

IV. ENTANGLEMENT DETECTION AND QUANTIFICATION

One direct application of HME lies in entanglement detection and quantification, as positive maps are Hermitian-preserving. In entanglement detection, we incorporate HME into the quantum phase estimation algorithm [1, 21], as shown in Fig. 1(d), to propose a new entanglement detection protocol. We demonstrate through an example that the HME-based protocol can offer **exponential advantages** compared to all single-copy approaches.

Theorem 4 (Informal)**.** *The HME-based protocol requires at most $\mathcal{O}(1)$ copies of ρ to accomplish an entanglement detection task with a success probability of at least $2/3$. In contrast, all single-copy approaches require $\Omega(d^{1/4})$ copies of ρ to achieve the same task with a success probability of at least $2/3$.*

Moreover, by combining the HME and Hadamard test algorithm [22], as illustrated in Fig. 1(e), we develop the **first** protocol to unbiasedly estimate entanglement negativity $N(\rho)$. Compared to the tomography-based protocol which has sample complexity $\theta(\epsilon^{-2}d^4)$, HME-based protocol has sample complexity at most $\widetilde{\mathcal{O}}(\epsilon^{-3}d^3)$. Additionally, the HME-based protocol exhibits an exponential advantage in terms of classical memory requirements.

Theorem 5. *One needs an expected number of $\widetilde{\mathcal{O}}\left(\log(\delta^{-1})\epsilon^{-3}d^2d_A\left\|\rho^{T_A}\right\|_1\right)$ copies of ρ to ensure $\left|\hat{N}(\rho)-N(\rho)\right| \leq \epsilon$ with a probability of at least $1-\delta$. Here, the $\widetilde{\mathcal{O}}$ notation suppresses logarithmic expressions for d and ϵ. Besides, the sampling times scales as $M = \mathcal{O}\left(\log(\delta^{-1})\epsilon^{-2}d\left\|\rho^{T_A}\right\|_1\right)$, and the copies of ρ needed in a single run of circuit in Fig. 1(e) when setting $t=(2l-1)$ scales as $K(l)=\widetilde{\mathcal{O}}(\epsilon^{-1}dd_Al)$.*

V. MANAGING QUANTUM NOISES

Building upon HME, we propose a new protocol to handle quantum noises named *quantum noiseless state recovery*. This protocol enables the recovery of a noiseless state from multiple copies of noisy states, given that the description of the noise channel is known.

We consider a similar setting as quantum error mitigation, where the ideal noiseless state ψ is generated by an ideal noiseless circuit, $\psi = \mathcal{U}(|0\rangle\langle 0|)$, while the existence of noise will change it to $\mathcal{E}(\psi) = \mathcal{E}\circ\mathcal{U}(|0\rangle\langle 0|)$. By sequentially inputting multiple copies of $\mathcal{E}(\psi)$ into the circuit depicted in Fig. 1(c) and choosing an appropriate Hamiltonian, we can approximately realize the evolution of $e^{-i\mathcal{E}^{-1}\circ\mathcal{E}(\psi)t} = e^{-i\psi t}$ with arbitrary accuracy. Using the circuit depicted in Fig. 1(f), we can extract the noiseless state ψ from the evolution $e^{-i\psi\pi}$.

Theorem 6. *Let $\mathcal{E}$ be an invertible noise map. Denote $H_{\mathcal{E}^{-1}} := \Lambda^{T_1}_{\mathcal{E}^{-1}}$ as the Hamiltonian corresponding to the inverse noise channel, and let $F := \langle\psi|\,\sigma\,|\psi\rangle$ be the fidelity between $|\psi\rangle\langle\psi|$ and σ. Then we need at most $\mathcal{O}\left(\log(\delta^{-1})\epsilon^{-1}F^{-2}\|H_{\mathcal{E}^{-1}}\|_\infty^2\right)$ copies of $\mathcal{E}(|\psi\rangle\langle\psi|)$ to approximately produce $|\psi\rangle\langle\psi|$ with trace distance smaller than ϵ and a success probability at least $1-\delta$.*

In contrast to existing methods such as quantum error mitigation and quantum error correction, our protocol can recover the desired noiseless state from multiple noisy states, establishing a new approach for combating quantum noises. Compared to quantum error mitigation, our protocol has the ability to **recover noiseless states**, at the expense of a deeper circuit. Additionally, compared to quantum error correction, our protocol requires fewer ancilla qubits and does not necessitate access to the noiseless state at the beginning.

VI. DISCUSSION

HME has potential in other scenarios, as listed in Fig. 1(b). Utilizing the Hermitian-preserving map $\mathcal{N}_O(\rho) = \mathrm{Tr}(O\rho)\,|1\rangle\langle 1|$, HME enables the encoding of expectation values into relative phases of reference states. One can then measure the reference state to extract the value of $\mathrm{tr}(O\rho)$. This HME-based phase encoding operation may also exhibit some advantages for other applications such as gradient estimation [23, 24]. Consider maps of the form $\mathcal{N}(\rho) = P\rho P^\dagger$, where P can be an arbitrary rectangular matrix. In the task of linear combination of unitaries [25], the matrix P is chosen as the sum of several unitaries, allowing for producing an arbitrary pure state or realizing a desired Hamiltonian evolution. Additionally, in quantum imaginary time evolution [26–28], P is set as $e^{-\beta H}$, where β represents the inverse temperature and H is a Hamiltonian. By increasing β, one can prepare a pure state that approximates the ground state of H to arbitrary precision.

Integrated spin-wave quantum memory

Zong-Quan Zhou[1] *

[1] *CAS key Laboratory of Quantum Information, University of Science and Technology of China, Hefei, 230026, China*

Abstract. Optical quantum memory is an essential component for overcoming channel losses in large-scale quantum networks. Now, quantum memories are marching toward miniaturization and integration for large-scale practical applications. I will introduce the state-of-the-art technologies for fabricating integrated quantum memories in rare-earth ions doped crystals [1]. Several achievements from our group will be highlighted, including telecom integrated quantum memories for applications in quantum repeaters [2,3,4], and the integrated spin-wave quantum memories for applications in transportable quantum memories [5,6].

Keywords: quantum memories, quantum repeaters, spin-wave storage

An optical quantum memory is a device that can store photonic quantum information and release it after a controlled time. It is an essential component for overcoming channel losses in large-scale quantum networks. Optical quantum memories have been demonstrated with various physical systems including atomic gases, single atoms in optical cavities, and rare-earth-ion doped solids. Now, quantum memories are marching toward miniaturization and integration for large-scale practical applications. Solid state systems stand as a natural choice due to the physical stability and ease of micro or nano fabrication using well-established techniques. In the past decade, considerable efforts have been devoted to developing photonic integrated quantum memories, that is, quantum memories based on micro/nano-photonic structures manufactured in solids. Remarkable performances have been achieved with integrated quantum memories, with the advantages of lower laser/electric power requirements, small volumes, large storage densities, and easy implementations. In our recent review [1], the basic concepts of optical quantum memories, the state-of-the-art technologies for fabricating integrated quantum memories in rare-earth ions doped crystals, and recent advances are introduced, and the roadmap for developing practically useful devices for applications in quantum networks is discussed.

In particular, I will introduce our recent achievements in two aspects. First, for applications in quantum repeaters [2], we have developed integrated quantum memories at the telecom wavelength using Erbium based material. On-demand storage of photonic qubits [3] and tunable single photon emitter [4] are both demonstrated at the telecom C band. Second, for applications in transportable quantum memories [5], we have developed integrated spin-wave quantum memories using Europium based material [6]. Qubits encoded with single-photon-level inputs are stored as the spin-wave excitation with a fidelity of 94.9 (1.2)%, which is far beyond the maximal fidelity that can be obtained with any classical device. The latest achievements in long-lived spin-wave quantum storage will also be discussed.

Experimental Quantum State Tomography of Multimode Gaussian States

Chan Roh[1] * Geunhee Gwak[1] Young-Do Yoon[1] Young-Sik Ra[1]

[1] *Department of Physics, Korea Advanced Institute of Science and Technology, Daejeon 34141, Korea*

Abstract. We report a quantum state tomography method which can reliably reconstruct multimode Gaussian states. Our method is free from the issue of yielding a non-physical quantum state and exhibits higher reconstruction fidelity than the conventional method. Moreover, we experimentally reconstruct the covariance matrix of the multimode Gaussian states by the method and decompose the covariance matrix to extract full information of the thermal noise and the mulitimode squeezing inside the state.

Keywords: Quantum state tomography, Gaussian state, Maximum-likelihood estimation

A multimode Gaussian state is an essential quantum resource for quantum information processing in continuous variable systems, offering large-scale entanglement in a deterministic manner [1]. Many experimental studies have realized a multimode Gaussian state for quantum computation, quantum communication, and quantum sensing. Moreover, the generation of multimode Gaussian states paves a way to study multimode quantum systems, such as multipartite entanglement. Therefore, to certify generation and investigate quantum features of the multimode Gaussian state, we need to fully characterize the states by quantum state tomography [2].

Quantum state tomography in continuous-variable mostly reconstructs the density operator of the target state by quadrature measurement [3]. However, obtaining density operators of multimode Gaussian states is challenging since the dimension of a density operator grows exponentially with increasing mode number. Fortunately, we can also obtain complete information on the multimode Gaussian state by obtaining the covariance matrix of the state [1]. The dimension of the covariance matrix is proportional to the square of the system size, so reconstructing a covariance matrix is the efficient method for quantum state tomography of the multimode Gaussian state.

The conventional method for reconstructing the covariance matrix is achieved by directly estimating the covariance of quadrature operators from homodyne measurement. Through this direct method, the full covariance matrix of the two-mode squeezed state [4] and some part of the covariance matrix (without $\hat{x}\hat{p}$ correlation) of the 8-mode and 16-mode Gaussian state [5] are obtained experimentally. However, reconstructing full covariance matrices of multimode Gaussian states has remained elusive in experiments. In addition, the direct method can simply acquire the covariance matrix, but statistical errors from a finite number of data reduce fidelity. Even worse, the errors would make the resultant covariance matrix not satisfy the uncertainty principle, which means that the result is unphysical. As for the unphysical consequences, we are unable to analyze the multimode Gaussian state through the covariance matrix.

In this work, we develop an efficient quantum state tomography method for multimode Gaussian states by reconstructing full and physical covariance matrices of the states. We parameterize the covariance matrices to satisfy the uncertainty principle and update the parameters by maximum likelihood estimation (MLE) through quadrature data. The data are gathered from single mode homodyne detection after mode mixer. To substantiate the effectiveness of our method, we conduct benchmarks of the MLE method against the conventional direct reconstruction of covariance matrices. The outcomes of the MLE method always satisfy the uncertainty principle in a limited number of data, while the direct method often fails to satisfy the physical condition. Moreover, our method reconstructs covariance matrices more precisely than the direct method for various target states. These shows that the MLE method can effectively conduct quantum state tomography for multimode Gaussian states.

Our MLE method (Fig. 1) starts with parameterizing a covariance matrix. A covariance matrix $\boldsymbol{V}$ of an M-mode Gaussian state can be decomposed as [7]

$$\boldsymbol{V} = \boldsymbol{S}\mathrm{diag}(\boldsymbol{\lambda},\boldsymbol{\lambda})\boldsymbol{S}^T, \tag{1}$$

where $\boldsymbol{S}$ is a $2M \times 2M$ symplectic matrix, and $\boldsymbol{\lambda} = (\lambda_1, ..., \lambda_M)$. The uncertainty principle for the covariance matrix

$$\boldsymbol{V} + i\boldsymbol{\Omega} \geq 0, \quad \boldsymbol{\Omega} = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{I} \\ -\boldsymbol{I} & \boldsymbol{0} \end{bmatrix} \tag{2}$$

is translated to constraints for symplectic eigenvalues $\lambda_m \geq 1$, which can be parameterized as $\lambda_m = \kappa_m^2 + 1$

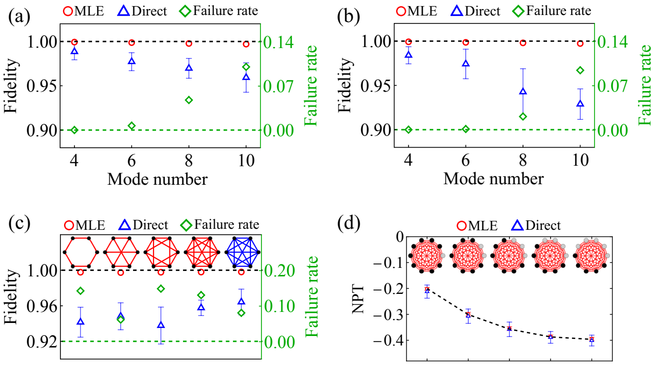

Figure 2: (a) and (b) are performances of MLE and direct reconstruction method depending on the mode number of target states, GHZ state (a), and completely connected cluster state (b), respectively. (c) Performance for various six-mode Gaussian states. The red graphs and the blue graph indicate cluster states and a six-mode GHZ state, respectively. Green points show failure probability of the direct reconstruction method from 1,000 repetitions. We set sampling per measured mode number $N_s = 10,000$. (d) Bipartite entanglement test of 10-mode completely connected cluster state. Reconstructed matrices are used to test entanglement between two subsets (black and white).

for $\kappa_m \in \mathbf{R}$. We parameterize the symplectic matrix $\boldsymbol{S}$ as

$$\boldsymbol{S} = (\boldsymbol{I} + \boldsymbol{\Omega T}/2)(\boldsymbol{I} - \boldsymbol{\Omega T}/2)^{-1}, \tag{3}$$

where $\boldsymbol{T}$ is a $2M \times 2M$ real symmetric matrix. In this way, we can parameterize any multimode covariance matrix under physical constraints. Next, the MLE method updates the parameters $\boldsymbol{T}$ and $\boldsymbol{\kappa} = (\kappa_1, ..., \kappa_M)$. Let us set χ as the dataset of whole measurement results, which contains quadrature data from homodyne measurements in single mode and superposed mode. The dataset χ is used for calculating log-likelihood function $\mathcal{L} = \ln P(\chi|\boldsymbol{V}(\boldsymbol{T}, \boldsymbol{\kappa}))$, which means the logarithm of the conditional probability that χ measured in the Gaussian state with covariance matrix $\boldsymbol{V}(\boldsymbol{T}, \boldsymbol{\kappa})$. The parameters are updated to maximize the likelihood function by the likelihood function by the gradient ascent method.

We further highlight the advantages of our MLE method over the conventional direct reconstruction method for obtaining covariance matrices of multimode Gaussian state. To compare the performances of both methods, we set target multimode Gaussian states and generate measurement data by simulation. We compare the results of reconstructing covariance matrices by the MLE method and the conventional direct. Figure 2(a-b) shows the fidelities of the reconstructed result of MLE and direct method for GHZ states (a) and completely-connected cluster states (b). As the number of modes increases, the fidelity of the direct method decreases. However, the MLE method shows high fidelities close to one. In addition, we compare both methods for various six-mode Gaussian states in Fig. 2 (c). The MLE method outperforms the direct method in terms of fidelity.

Moreover, we implement entanglement test of the 10-mode completely connected cluster state by using reconstructed covariance matrices from MLE method and direct method. Ten modes were divided into two subsets, and the separability between each subset was investigated using Peres-Horodecki separability criterion for continuous variable systems [6]. In Fig. 2 (d), black and white vertexes of the graphs denote biparitite subsets, and the results of test is plotted as red (MLE method) and blue (direct method) dots. MLE method reconstructs covariance matrix of the 10-mode cluster state more precisely, so that make the results of the inseparability test more close to the theoretical values (black line).

Reconstructed covariance matrices can be used for analyzing multimode Gaussian states. Gaussian state can be decomposed by sequence of multimode thermal noise and squeezing operation on the vacuum state, as Fig. 3 (a). If we know the thermal noise and squeezing modes and their respective degrees, we can perfectly understand the Gaussian state that we obtain. In this way, we have analyzed the ten-mode Gaussian state with the covariance matrix obtained through the experiment. We experimentally generate a 10-mode completely connected cluster state and reconstruct its covariance matrix by the MLE method (Fig. 3 (b)). The reconstructed covariance matrix is already expressed by Williamson decomposition as Eq.(1), and we can decompose the symplectic matrix $\boldsymbol{S}$ as

$$\boldsymbol{S} = \boldsymbol{O}_1 \boldsymbol{D}_s \boldsymbol{O}_2 \tag{4}$$

based on Bloch-Messiah decomposition [8]. $\boldsymbol{O_1}$ and $\boldsymbol{O_2}$ are orthogonal symplectic matrices, $\boldsymbol{D}_s = \mathrm{diag}(e^{-r}, ..., e^{-r}, e^{r}, ..., e^{r})$ is the symplectic matrix for the squeezing operation, and r is the squeezing parameter. If we set $\boldsymbol{O}_s = \boldsymbol{O}_1$ and $\boldsymbol{O}_t = \boldsymbol{O}_s\boldsymbol{O}_2$, then the covariance matrix is expressed as

$$\boldsymbol{V} = \boldsymbol{O}_s \boldsymbol{D}_s \boldsymbol{O}_s^T \boldsymbol{O}_t \boldsymbol{\Lambda} \boldsymbol{O}_t^T \boldsymbol{O}_s^T \boldsymbol{D} \boldsymbol{O}_s. \tag{5}$$

O_s and O_t correspond to the multimode linear operations for squeezing modes ($\hat{O}_s$) and thermal noise modes ($\hat{O}_t$) in Fig. 3 (a), respectively. These decomposition elements (5) let us know the thermal noise and squeezing modes and their respective degrees.

Figure 3 (c) shows the thermal noise (up, purple) and squeezing (down, light blue) inside the 10-mode cluster state. Thermal photon number is obtained by $n_m^{\mathrm{th}} = (\lambda_m - 1)/2$, and squeezing level is $10\log_{10}e^{-2r}$. Plus, modes containing each thermal noise (squeezing) can be obtained from $\boldsymbol{O}_t$. $\boldsymbol{O}_t$ is the orthogonal symplectic matrix, so it can be expressed as

$$\boldsymbol{O}_t = \begin{bmatrix} \boldsymbol{X}_t & -\boldsymbol{Y}_t \\ \boldsymbol{Y}_t & \boldsymbol{X}_t \end{bmatrix}. \tag{6}$$

Rows of $\boldsymbol{X}_t - i\boldsymbol{Y}_t$ are the thermal noise (squeezing) modes, and the intensity and phase information of each mode is shown at Fig. 3 (d). Similarly, Fig. 3 (e) shows the squeezing modes obtained from $\boldsymbol{O}_s$.

In this work, we develop an efficient quantum state tomography method for multimode Gaussian states by

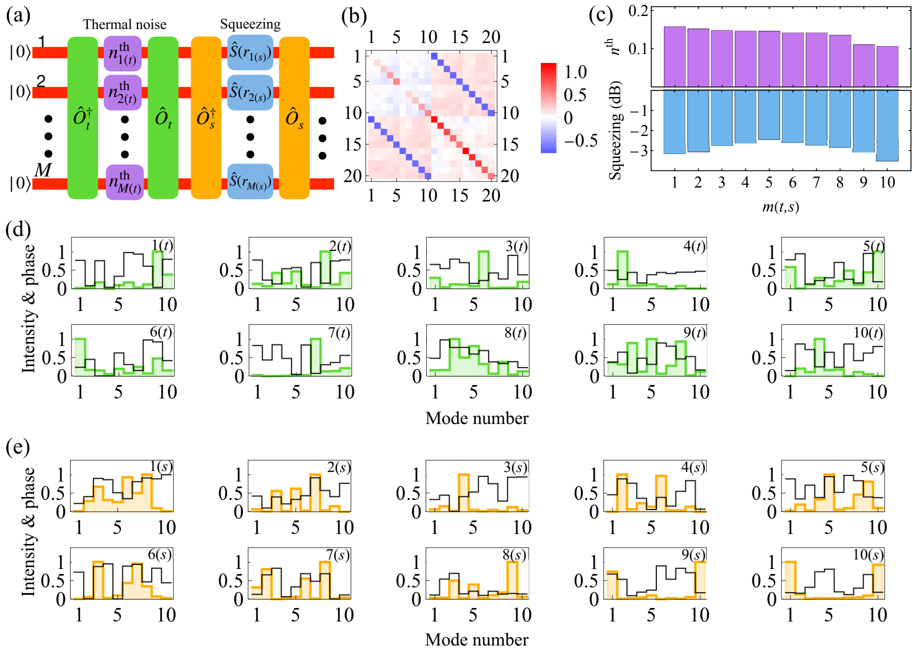

Figure 3: (a) Decomposition of a multimode Gaussian state. Subscripts t and s indicates thermal noise mode and pure squeezing mode, respectively. (b) Experimentally reconstructed covariance matrix of 10-mode completely connected cluster state. Identity matrix is subtracted to remove vacuum noise. (c) Mean photon number of thermal noise (up) and squeezing level (down) of each mode. (d) Thermal noise modes and (e) Pure squeezing mode. Each graph shows the mode in which thermal noise and squeezing operation corresponding to (b) is contained.

reconstructing full and physical covariance matrices of the states. We parameterize the covariance matrices to satisfy the uncertainty principle and update the parameters by maximum likelihood estimation (MLE) through quadrature data. The data are gathered from single mode homodyne detection after mode mixer. To substantiate the effectiveness of our method, we conduct benchmarks of the MLE method against the conventional direct reconstruction of covariance matrices. The outcomes of the MLE method always satisfy the uncertainty principle in a limited number of data, while the direct method often fails to satisfy the physical condition. Moreover, our method reconstructs covariance matrices more precisely than the direct method for various target states. These shows that the MLE method can effectively conduct quantum state tomography for multimode Gaussian states.

We have implemented the multimode quantum state tomography of multimode Gaussian state experimently by the MLE method. We reconstruct the covariance matrix of the 10-mode cluster state and analyze the state by the covariance matrix. We decompose the covariance matrix and extract full information of thermal noise and multimode squeezing inside the state.

Our MLE method will be valuable quantum state tomography method for multimode Gaussian state. Since the MLE method is able to reconstruct covariance matrices of Gaussian state precisely, we can implement analysis for multimode Gaussian states based on covariance matrices, e.g., quantum entanglement test, steering test, calculating quantum fisher information, etc. We expect that the MLE method will facilitate future studies to uncover multimode CV quantum systems.

Abstract. We introduce a feasible scheme [arXiv:2305.189006v4] to produce high-rate long-distance entanglement using hybrid-entangled (HE) states between continuous variables (CV) and discrete variables (DV). The key idea is to yield a DV-entangled pair between distant locations by adjusting the CV part to be robust against transmission losses. We also benchmark the shared entanglement in an entanglement-based (EB) quantum key distribution (QKD) protocol. Our results show that HE-states enables EB-QKD with standard telecommunication fibers for 300 km promising an alternative tool for practical long-distance entanglement-sharing that provides a testbed for further applications in quantum information processing.

Keywords: Hybrid states, entanglement sharing, quantum communication.

1 Introduction

Generation of high-rate entanglement between distant locations is crucial for fundamental tests of quantum theory as well as various information processing tasks such as loophole-free Bell tests [1, 2], quantum teleportation [3], device-independent (DI) quantum-key-distribution (QKD) protocol [4, 5, 6]. It also allows to achieve higher detection efficiencies, a crucial requirement in both loophole-free Bell tests and DI-QKD, by means of heralded qubit amplifiers [7] or photonic precertification schemes [8, 9], whose practicality is currently limited by the rates achieved after transmission.

An operational benchmark of the shared entanglement can be set by its performance in a practical task such as, however not limited to, an entanglement-based (EB) QKD protocol. These protocols are traditionally analyzed using two different kinds of physical systems, namely discrete variable (DV) and continuous variable (CV) systems only, which offer their own set of advantages and limitations [10, 11, 12]. Alongside remarkable sucesses with these systems [13, 14, 15], despite an extensive theoretical and experimental analysis, the quest for an optimal physical system to potentially use for sharing high-rate long-distance entanglement still remains open.

Nonetheless, there exists a different class of physical states, with cross-system entanglement between CV and DV systems, which are formally known as hybrid entangled (HE) states [16, 17]. However, despite their generation in a wide range of experimental setups [18, 19, 20] and importance in quantum information science and technology [21, 30, 23, 24, 25, 26], such states remain largely unexplored.

Here, by harnessing these strongly correlated HE states [27, 28, 29], we propose an altenate scheme for sharing high-rate entanglement. We show that two parties who are hundreds of kms apart, can efficiently generate a DV entangled-pair by exploiting entanglement-swapping [30] over the respective CV parts by a third party in the midway. We further access the operationally significance of our HE-state based scheme for long-distance entanglement-sharing in a practical information processing task such EB-QKD with the shared DV entanglement.

Our results indicate that the HE-states enables to achieve secure key rate at a distance of 300 km with practical homodyne detectors (55% efficiency) and on-off detectors (80% efficiency) [31], at telecommunication wavelength (check [31] for further detail). While the long transmission distance stems from the robustness of the coherent state against transmission losses, our scheme offers two major advantages such as (i) elimination of major limiting factors of DV EB-QKD, which include high precision Bell-state-measurement as well as the photon-number-splitting attack by by considering entanglement swapping over the CV system and (ii) elimination of the requirement of near-unit efficiency for the homodyne detectors in CV EB-QKD.

2 Entanglement-sharing with hybrid states

2.1 Hybrid states:

Let $|n\rangle$ and $|\alpha\rangle$ represent to the photon-number-states (PNS) and a coherent state of a quantized light respectively. For the remainder of this paper we denote the PNS as the DV system and the coherent state as the CV system. As a consequence, an HE state is defined [16, 17] as an entangled pair between the DV and CV systems as

$$|\psi\rangle_{a_1a_2} = \frac{1}{\sqrt{2}}\left(|0\rangle_{a_1}|\alpha\rangle_{a_2} + |1\rangle_{a_1}|-\alpha\rangle_{a_2}\right), \qquad (1)$$

where a_1 and a_2 are the two modes pertaining to the DV and CV parts, respectively. Kindly check the [31] for further discussion on the generation of such states.

§h.jeong37@gmail.com

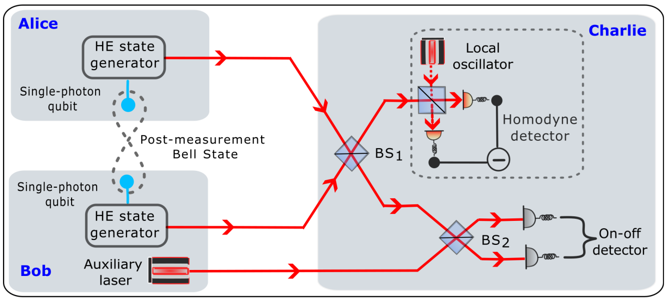

Figure 1: Schematic for generating DV entangled states between Alice and Bob using HE states. Alice and Bob send their CV parts to Charlie, who then mixes the incoming signals at a balanced beam splitter (BS), say BS$_1$. He then mixes one of output signals of (BS$_1$) with the additional coherent signal sent by Bob at a second BS, say BS$_2$, followed by a joint measurement implemented by on-off detectors. The remaining output signal of BS$_1$ is then subjected to homodyne detection. Upon declaration of the results by Charlie, Alice and Bob obtain a DV entangled pair.

2.2 Protocol for entanglement sharing:

Let us consider that two distant parties, say Alice and Bob, each of them having access to bipartite HE-states $|\psi\rangle_{a_1a_2}$ and $|\psi\rangle_{b_1b_2}$ given by Eq. (1). Our scheme for entanglement-sharing, as schematically represented in Fig. 1 (a), (see [31] for detail) proceeds as described below

Step 1: Alice and Bob transmit their CV parts (corresponding to modes a_2 and b_2 respectively) to a third untrusted party, say Charlie, through a lossy quantum channel with transmittance T $(0 \leq T \leq 1)$. Additionally, Bob also sends another coherent state, $|\sqrt{2}\alpha\rangle$, to Charlie separately through a similar quantum channel.

We quantify the impact of the loss in the transmission channel on the HE-states by considering the output entanglement, measured by logarithmic negativity, in Fig. 2, where $0 \leq R \leq 1$ stand for the normalised loss-parameter. We observe that there exists an optimal value of α for a fixed value of photon loss which, in the case of a significantly lossy channel, approaches $\alpha = 0.5$. This behaviour of HE states can be qualitatively understood in terms of the interplay between entanglement and the fragility of the initial HE-state [31].

Step 2: Next, Charlie mixes the two incoming modes via a beam splitter (BS), labelled as BS$_1$. He, then further mixes one of the output modes of BS$_1$ with the additional coherent state, sent by Bob, though a second BS (BS$_2$). Subsequently, he now performs a joint projective measurements on the output of BS$_2$ implemented by on-off detectors and declares the outcome (check [31] for detail). The protocol continues only in the case when both the detectors click, otherwise the parties start afresh.

Step 3: After a successful projective measurement, Charlie now performs a homodyne measurement on the residual output of BS$_1$ announces the results publicly.

Step 4: After receiving of the results of a successful projective measurement and the homodyne measurement by Charlie, Alice and Bob end up with the final normalized single-photon-Bell-state in modes a_1 and b_1 as

$$\rho_{a_1b_1} = \frac{1}{2}\left[\begin{array}{l}|01\rangle\langle 01| + |10\rangle\langle 10| \\ \quad + h\left(g\,|01\rangle\langle 10| + g^*\,|10\rangle\langle 01|\right)\end{array}\right] \quad (2)$$

with probability $P_0 = \frac{\left(1-e^{-\eta_o T\alpha^2}\right)^2}{2}$, where $h = e^{-4(1-T\eta_h)\alpha^2}$, $g = e^{4\mathrm{i}\sqrt{T\eta_h}\alpha p}$ and p is the result of the homodyne measurement. η_h and η_0 are the efficiencies of the homodyne detector and the on-off detectors respectively.

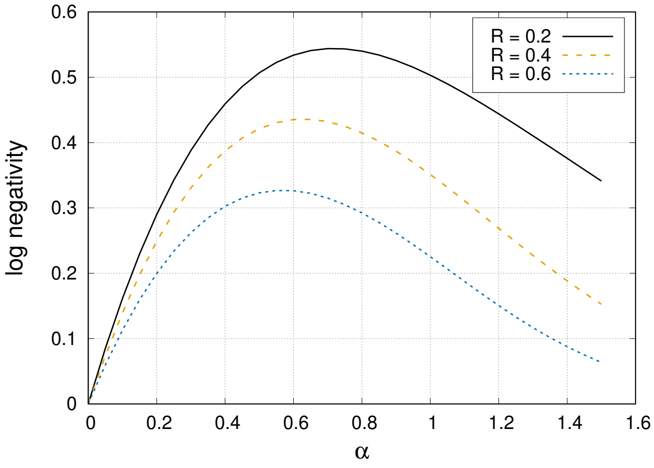

Figure 2: Logarithmic negativity of the HE state undergoing photon-loss over the CV part as a function of the coherent amplitude α.

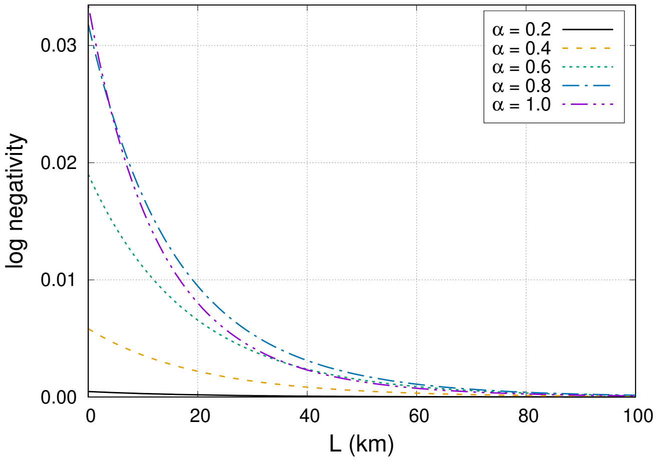

Figure 3: Logarithmic negativity of the state $\rho_{a_1b_1}$ as a function of the transmission distance (L) for different values of coherent amplitude α. We assume $p = \frac{\pi}{2}$.

3 Simulation results on shared entanglement

The final shared entanglement depends on a number of parameters such as the channel transmittance $T = 10^{-l\frac{L/2}{10}}$, where $l = 0.2$ dB/km (standard channel loss at telecommunication wavelength [11]) and L is the

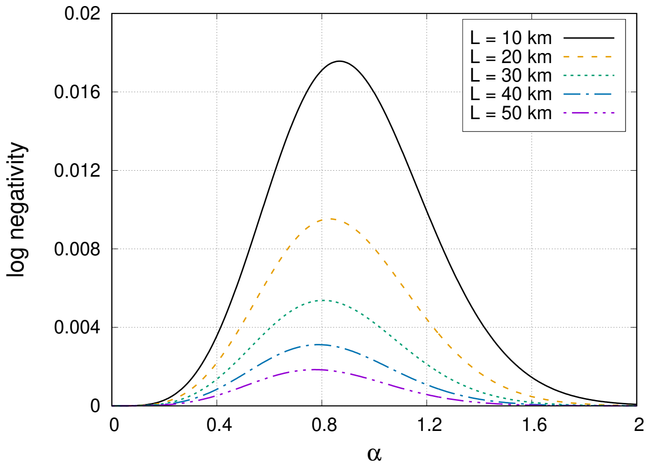

Figure 4: Logarithmic negativity of the state $\rho_{a_1b_1}$ as a function of the transmission distance L for different values of coherent amplitude α. We consider $p = \frac{\pi}{2}$.

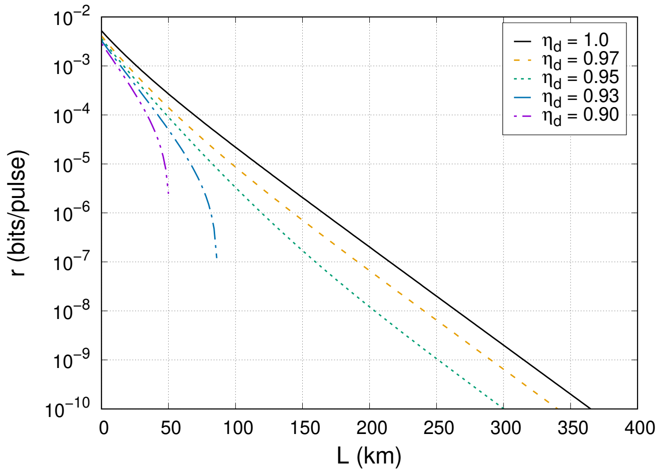

Figure 5: Secure key rate as a function of total transmission distance L for different values of η_d in the optimal case, i.e., $\alpha = 0.5$. $p = \frac{\pi}{2}$.

total transmission distance between Alice and Bob. The detection efficiencies are also set (standard in telecommunication setup) as $\eta_h = 0.55$ and $\eta_0 = 0.8$ [31].

In Figs. 3 and 4 we plot the shared entanglement with the total transmission length (L) and the coherent amplitude (α) respectively. We observe that while the shared entanglement decreases exponentially with L, at a given distance (equivalently loss) there exists an optimal value of α, say α_{opt}. For sufficiently long transmission distance ($L \geq 150$ Km), α_{opt} for sharing entanglement becomes close to 0.5 (not shown in the Fig. 4). It may be noted that, at a given distance, the α_{opt} for shared DV-entanglement may be different than the α_{opt} for the original HE state (Fig. 2).

4 Benchmarking the shared entanglement in EB-QKD

Let us now consider that the efficiency of the single-photon-detectors of Alice and Bob, required for key generation, is given by η_d ($0 \leq \eta_d \leq 1$). With these inefficient detectors, the secure key rate [31] for the shared state (2) is given as

$$\begin{aligned} r &\geq P_0\left[I(A:B) - \chi(A:E)\right] \\ &= P_0\Big\{1 - \eta_d + \frac{1}{2}\left[(1+h)\log_2(1+h) + (1-h)\log_2(1-h)\right] \\ &\quad -\frac{1}{2}\left[(2-\eta_d)\log_2(2-\eta_d) - (1-\eta_d)\log_2(1-\eta_d)\right]\Big\}, \end{aligned} \tag{3}$$

where $I(A:B)$ and $\chi(A:E)$ are the mutual information between Alice and Bob and the Holevo information between Alice and and adversary Eve respectively. For a detail discussion on the assumptions and other requirements kindly look at [31].

Here also, we notice that the optimal value of α that maximizes the secured key rate coincides with the α_{opt} for shared entanglement, i.e., $\alpha = 0.5$ (see [31] for detail). As a consequence, in Fig. 5 we plot the secure key rate as a function of the total transmission distance L for different values of η_d with $\alpha = 0.5$. As it is evident, under low detection errors ($\eta_d = 0.97$ and 0.95), a secure key rate can be achieved for transmission distances around 300 km indicating that the resultant entangled state is useful. However, the maximum achievable distance drastically falls off as η_d is decreased up to $\eta_d = 0.90$ (corresponds to 10% detection error).

5 Conclusion

To summarize, we have proposed a scheme to harness the cross-system correlation in HE-states for sharing long-distance high-rate entanglement that efficiently removes the practical limitations of conventional approaches based on DV only or CV only systems. We have further showcased the efficacy of the shared DV-entanglement in a practical task such as EB-QKD where with a realistic detectors and transmission channel one can obtain a secure key rate of $\sim 10^{-10}$ bits/pulse at a distance of 300 km with 5% detection error at the telecommunication wavelength (1550 nm).

A major limitation of our protocol stems from the non-deterministic generation of the HE states with fidelity ≈ 0.75 for $\alpha = 0.5$ [18]. This could be easily overcome with the use of polarization qubits [32, 33, 34] with a possible deterministic generation of HE-states using quantum walks [35]. It may also be noted that in the current scheme, it is sufficient to consider *loss-only* channel as the general *lossy and noisy* channel closely approximates the former under practical conditions [31].

Nonetheless, current proposal for long-distance entanglement-sharing provides a multipurpose test bed, beyond the paradigm of EB-QKD protocols. This represents HE-states as a promising alternative for practical entanglement distribution that serves as a central core in various information processing applications such as DI-QKD protocols [36], quantum networks [37], network steering [39].

We introduce a feasible scheme to produce high-rate long-distance entanglement which uses hybrid entanglement (HE) between continuous variables (CV) and discrete variables (DV). We show that HE can effectively remove the experimental limitations of existing CV and DV systems to produce long range entanglement. We benchmark the resulting DV entangled states using an entanglement-based quantum key distribution (EB-QKD) protocol. We show that, using HE states, EB-QKD is possible with standard telecommunication fibers for 300 km. The key idea is using the CV part, which can be adjusted to be robust against photon losses, for increasing the transmission distance, while using the DV part for achieving high secure key rates. Our results point out that HE states provide a clear advantage for practical long-distance and high-rate entanglement generation that may lead to further applications in quantum information processing.

I. INTRODUCTION

Generation of high-rate entanglement between distant locations is crucial for fundamental tests of quantum theory and many applications. For example, it is needed for extending the current distances and rates of loophole-free Bell tests [1, 2], quantum steering [3], and quantum teleportation [4], which so far are only feasible for relatively short ranges. It is also needed for increasing the transmission distance and the key rate of entanglement-based quantum key distribution (EB-QKD) protocols, most notably device-independent QKD [5–7], which currently suffers from both these issues. Moreover, higher-rates in distant locations will also allow us to achieve higher detection efficiencies (which are needed both for loophole-free Bell tests and device-independent QKD) by means of heralded qubit amplifiers [8] or photonic precertification schemes [9–11], whose practicality is currently limited by the rates achieved after transmission.

A benchmark of high-rate entanglement over long distances, from an operational perspective, can be set by its performance in an information processing task such as an EB-QKD protocol. These protocols can be broadly classified into two distinct classes: (i) those using discrete variable (DV) entangled states and (ii) those that use continuous variable (CV) entangled states, where each class has its own set of advantages and limitations [12–14]. As an example, DV EB-QKD protocols offer composable security proofs with good key rate, but they require precise Bell-state or single-photon measurements at extremely low temperatures, which are hard to perform even in laboratory conditions. On the other hand, CV EB-QKD protocols generally require Gaussian states which are comparatively easier to prepare, but their performance is limited by the requirement of almost ideal homodyne detectors at telecommunication wavelength [13, 15, 16]. As a consequence, despite an extensive theoretical and experimental analysis on both types of systems, the quest for an optimal physical system which can be potentially used to share high-rate entanglement remains open.

Nonetheless, there exists a different class of physical systems where the entanglement is between CV and DV systems and are formally known as hybrid entangled (HE) states [17–22]. These strongly correlated [23–25] cross-system entangled states play a crucial role in various quantum information processing tasks, including quantum computation, communication, and tests of Bell non-locality [25–33], and have been efficiently generated in a wide range of experimental setups [34–38]. Consequently, it becomes interesting to observe whether such hybrid states can be used to share entanglement among distant locations without the limitations faced by CV and DV systems.

Here, we propose a scheme based on HE states as an initial resource which produces high-rate DV entanglement between extremely far apart locations. We provide a characterization of such states and show that it is possible to share entanglement between locations which are hundreds of kms apart. We further assess the quality of shared entanglement in the context of EB-QKD. We show that, by bringing forth the best of both CV and DV systems, with HE states, it is possible to achieve secure key rate at a distance of 300 km by using practical homodyne detectors with efficiency $\eta_h = 0.55$ [39–43] (which is a reasonable value at telecommunication wavelengths [40]) and on-off detectors with efficiency $\eta_0 = 0.8$ [44]. Note that we use the key rates and transmission distances only to quantify the quality of the entanglement; our central goal is to show the advantage of using HE states

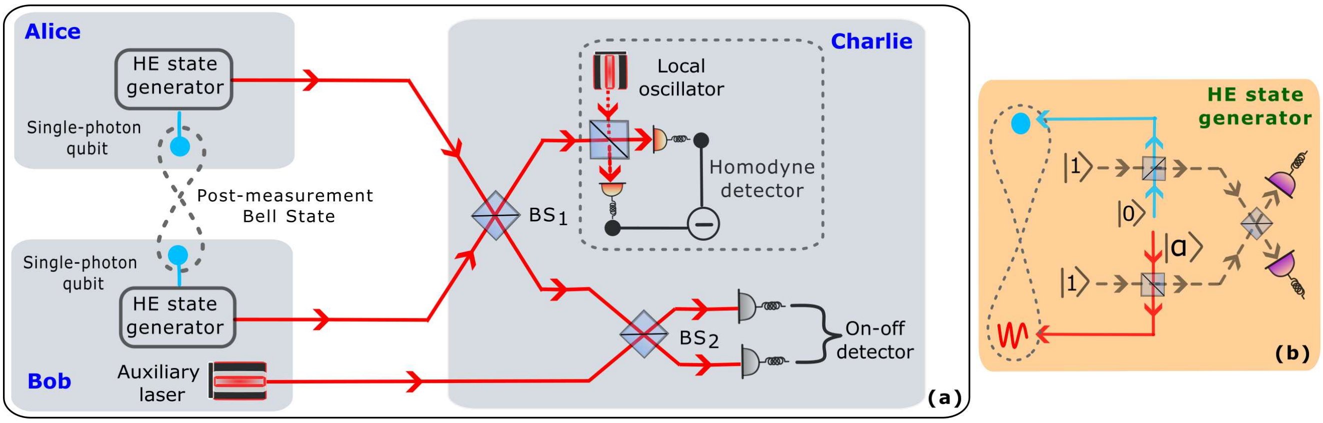

FIG. 1. (a) Scheme for generating DV entangled states between Alice and Bob using HE states. The DV part (cyan) and the CV part (red) of the HE state stand for the single-photon state and coherent state, respectively. Alice and Bob send the CV part of their individual HE states to Charlie, who then mixes the incoming signals at a balanced beam splitter (BS$_1$), and uses one of the output modes for homodyne measurement with efficiency η_h. The other outgoing signal of BS$_1$ is used for a post-selection measurement by on-off detectors with efficiency η_0, after mixing it at another balanced BS (BS$_2$) with the additional coherent signal sent by Bob. Upon declaration of the results by Charlie, Alice and Bob obtain a DV entangled pair which is used for secure key generation. (b) Scheme for generating HE states. Two ancilla single photons (gray, dashed line) are mixed with vacuum and coherent states at the two BSs. The outgoing ancilla photons are then mixed with each other at a second BS. When the detector placed at the output of the second BS clicks, then the HE state between single-photon and the coherent state is obtained.

to achieve entanglement over longer distances, which is a crucial tool enabling a wide range of fundamental tests in physics and quantum information processing applications.

Our scheme hinges on generating a single-photon DV entangled state between two distant parties by exploiting CV entanglement swapping [33] by a third party located midway. It offers three major advantages as compared to earlier CV and DV EB-QKD protocols. These are: (i) Elimination of major limiting factors of DV EB-QKD, which include high precision Bell state or single-photon measurements as well as the photon-number-splitting attack by an eavesdropper by considering entanglement swapping over the CV system. (ii) Elimination of the requirement of near-unit efficiency for the homodyne detectors used for key generation in CV EB-QKD. (iii) Long transmission distance at telecommunication wavelength stemming from the robustness of the multiphoton coherent state against transmission losses and using practical devices.

This article is organized as follows. In Sec. II, we provide some brief introduction to HE states. We then propose a protocol to share DV entanglement among distant locations by using HE states as an initial resource. We also characterize the resulting entanglement using logarithmic negativity and show that it can be non-zero even when the parties are separated hundreds of kilometers apart. In Sec. III, we benchmark the usefulness of the resultant entangled states by demonstrating our scheme as an EB-QKD protocol using practical devices. In Sec. IV, we conclude our results by arguing that our protocol provides a practical solution to the problem long distance entanglement generation which is a central requirement in several information processing tasks.

II. ENTANGLEMENT SHARING WITH HYBRID STATES

In this section we first provide a brief description of HE states. Subsequently, we detail our protocol to share long distance entanglement using these states.

A. Hybrid entangled states

Let $|0\rangle$ and $|1\rangle$ correspond to photon number states in the Fock basis and $|\alpha\rangle$ correspond to a coherent state of a quantized light with coherent amplitude α. For the remainder of this paper we will represent the number of photons as a DV system, while the coherent state represents a CV system. We define a HE state as an entangled pair, where the entanglement is between the DV and CV degrees of freedom. Mathematically, such HE states can be written as

$$|\psi\rangle_{a_1a_2} = \frac{1}{\sqrt{2}}\left(|0\rangle_{a_1}|\alpha\rangle_{a_2} + |1\rangle_{a_1}|-\alpha\rangle_{a_2}\right), \qquad (1)$$

where a_1 and a_2 are the two modes pertaining to the DV and CV parts, respectively.

We stress that HE states with small coherent amplitudes ($\alpha \lesssim 1$) are experimentally available. They have been generated experimentally in various settings such as conditional photon subtraction on a coherent state [34] as well as photon subtraction on two squeezed states [35] (see Appendix A for further details). While these techniques produce HE states with non-unit probability, it should be noted that typical methods to generate standard entangled photon pairs, *e.g.*, the parametric down conversion, also does so non-deterministically. In Fig. 1(b), we outline the linear optics based schematic for generating HE-states as originally described in [34].

B. Protocol for entanglement sharing

We consider two distant parties, Alice and Bob, each of them having access to bipartite HE states $|\psi\rangle_{a_1a_2}$ and $|\psi\rangle_{b_1b_2}$ given by Eq. (1). We consider these as initial resource states which will be used to share a DV entangled state between the parties. We provide a step-by-step description of the protocol, schematically represented in Fig. 1(a), while a detailed mathematical calculation can be found in Appendix B.

Step 1: Alice and Bob generate HE states $|\psi\rangle_{a_1a_2}$ and $|\psi\rangle_{b_1b_2}$ in their respective laboratories. Both parties transmit the CV part of their systems, corresponding to modes a_2 and b_2, respectively, to a third untrusted party, Charlie, who lies midway between them, through a lossy quantum channel with transmittance T $(0 \leq T \leq 1)$. Additionally, Bob also transmits the state $\left|\sqrt{2}\alpha\right\rangle$ to Charlie separately through a similar quantum channel. After passing through channels with transmission losses, Charlie receives the mode a_2 from Alice, the mode b_2 from Bob, and the additional state $\left|\sqrt{2T}\alpha\right\rangle$ from Bob, which we label by mode c. While a general quantum channel between the parties will comprise of both transmission loss and thermal noise, here, for simplicity, we only consider lossy quantum channels with no noise. In Appendix F 4 we demonstrate that the scenario involving a practical level of thermal noise closely matches our current findings.

The effect of a quantum state passing through a noisy channel can be seen as the system undergoing photon loss. In Fig. 2, we plot the logarithmic negativity of the HE state when its CV part undergoes photon loss as a function of the coherent amplitude α (see appendix C for detail). We find that there exists an optimal value of α for a fixed value of photon loss. We denote the photon loss fraction by R such that $R = 0$ and $R = 1$ correspond to no photon loss and complete photon loss, respectively. For a significantly lossy channel, we find that the optimal value of α approaches $\alpha = 0.5$. This value becomes important when we benchmark the resultant DV entangled state by a EB-QKD protocol.

This behaviour of HE states can be qualitatively understood in terms of the interplay between entanglement and the fragility of the initial HE state. Starting from the initial separable state at $\alpha = 0$, the HE state becomes more entangled as α increases. An increase in α also corresponds to an increase in the average number of photons, which can be understood as an increase in the mean energy of the system. However, with an increase in the mean energy, the state becomes more vulnerable to decoherence. This behaviour is similar to what is also shown in Ref. [45] for superposition of coherent states, and the advantage of using small amplitudes under photon losses was demonstrated in the context of teleportation [46]. As a consequence, with increase in α beyond an optimal value, the HE state becomes extremely fragile under noise leading to a drop in entanglement when the multiphoton part passes through a noisy quantum channel.

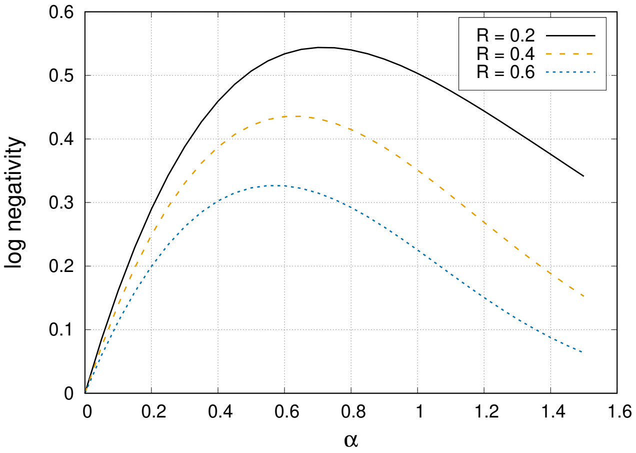

FIG. 2. Logarithmic negativity of the HE state undergoing photon-loss over the CV part as a function of the coherent amplitude α. R $(0 \leq R \leq 1)$ stands for the normalized strength of loss.

Step 2: Next, Charlie mixes the two incoming modes a_2 and b_2 via a beam splitter (BS), labelled as BS$_1$ in Fig. 1 with two output modes which we can label as $a_2^{'}$ and $b_2^{'}$. In our protocol we are specifically interested in the vacuum state contributions from the mode $a_2^{'}$. To extract this contribution, Charlie mixes this mode though a second BS (BS$_2$) with mode c with output modes labelled as $a_2^{''}$ and $c^{'}$. Charlie now performs a projective measurement, $\mathcal{M} = \{\Pi_0, \mathbb{1} - \Pi_0\}$, where $\Pi_0 = (\mathbb{1} - |0\rangle\langle 0|)_{a_2^{''}} \otimes (\mathbb{1} - |0\rangle\langle 0|)_{c^{'}}$. This measurement is accomplished by using on-off detectors (that only detect the presence of photons) on each of the modes $a_2^{''}$ and $c^{'}$. Charlie then publicly announces the outcome of the projective measurement which is considered to be successful only if the result Π_0 is obtained, i.e., both detectors click. In that case, the protocol continues. Otherwise, the measurement is deemed unsuccessful and the parties must repeat the aforementioned steps again. In order to model realistic detectors, we consider imperfect on-off detectors with efficiency η_0.

Step 3: After a successful projective measurement (as dictated in Step 2), Charlie performs a homodyne measurement on mode $b_2^{'}$ and, again, announces the results publicly. We consider that homodyne measurements have efficiency η_h.

Step 4: After a public announcement of the results of a successful projective measurement and the homodyne measurement by Charlie, Alice and Bob end up with the final normalized single-photon-Bell-state in modes a_1 and b_1 as

$$\rho_{a_1b_1} = \frac{1}{2}\left[\begin{aligned} &|01\rangle\langle 01| + |10\rangle\langle 10| \\ &+ h\left(g\,|01\rangle\langle 10| + g^*\,|10\rangle\langle 01|\right)\end{aligned}\right], \tag{2}$$

with probability

$$P_0 = \frac{\left(1 - e^{-\eta_o T\alpha^2}\right)^2}{2}, \tag{3}$$

where $h = e^{-4(1-T\eta_h)\alpha^2}$, $g = e^{4\mathrm{i}\sqrt{T\eta_h}\alpha p}$, g^* is the conjugate of g, and p is the result of the homodyne measurement.

C. Shared DV-entanglement between the parties

The entanglement of the final DV entangled state shared between the parties depends on a number of parameters. However, the quantities of most interest are the transmission length and the coherent amplitude.

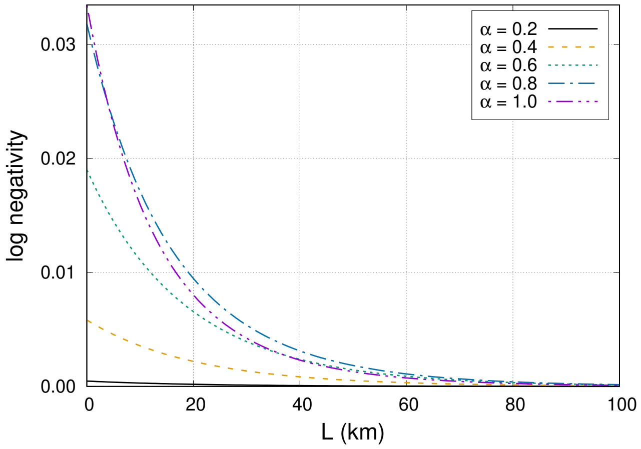

FIG. 3. Logarithmic negativity of the state $\rho_{a_1b_1}$ as a function of the transmission distance (L) for different values of coherent amplitude α. We assume detection efficiencies $\eta_h = 0.55$ for the homodyne detectors, $\eta_0 = 0.8$ for the on-off detectors, and $p = \frac{\pi}{2}$.

In Fig. 4 we plot the logarithmic negativity of the state $\rho_{a_1b_1}$ as a function of the transmission distance for different values of the coherent amplitude α. We assume that the transmittance of both the channels is given by T_A and T_B, respectively, such that, $T_A = 10^{-l\frac{L_{AC}}{10}}$ and $T_B = 10^{-l\frac{L_{BC}}{10}}$, where $l = 0.2$ dB/km is the standard channel loss for telecommunication wavelength [47, 48] and L_{AC} and L_{BC} are the transmission distances between Alice-Charlie and Bob-Charlie respectively. To simplify the scenario, we also assume that Charlie is midway between Alice and Bob such that $L_{AC} = L_{BC} = L/2$ such that the total transmission distance is L. We find that the entanglement of the final state decreases exponentially with the total transmission distance. As an example, at $L = 100$ km the logarithmic negativity is 1.3×10^{-4} for coherent amplitude $\alpha = 0.6$.

Next, in Fig. 3 we plot the logarithmic negativity as a function of the coherent amplitude α for different transmission distances. As it is evident from the Fig. that the shared-entanglement varies non-monotonically on the coherent amplitude (α). We observe that as the transmission distance increases, the optimal value of α becomes less than unity. For higher transmission distance ($L \geq 150$ Km) this optimal value becomes close to $\alpha = 0.5$ (not shown in the Fig.). It is found that there also exists an optimal value of α that offers maximum entanglement at a given distance which may be different than the optimal value of α which maximizes the entanglement of the original HE state (as shown in Fig. 2).

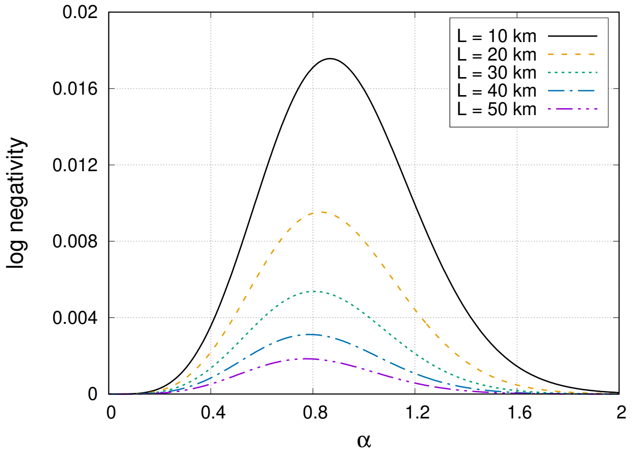

FIG. 4. Logarithmic negativity of the state $\rho_{a_1b_1}$ as a function of the transmission distance L for different values of coherent amplitude α. We assume detection efficiencies $\eta_h = 0.55$ for the homodyne detectors, $\eta_0 = 0.8$ for the on-off detectors, and $p = \frac{\pi}{2}$.

III. QUANTUM KEY DISTRIBUTION USING HE STATES

In this section we benchmark the quality of the shared entangled state in terms of an EB QKD protocol which we set up around the scheme presented in Sec. II B. We also consider an eavesdropper, Eve, who may collaborate with Charlie to determine the secure key that is being shared between Alice and Bob. Additionally, in our protocol we make the following assumptions:

1. We assume that Alice and Bob have access to secure laboratories in which they can perform well characterized measurements. Moreover, the measurement devices of Alice and Bob are assumed to be immune to any side-channel attack since no unwanted system may enter or exit the secure laboratories. In the protocol, the DV modes a_1 and b_1 with Alice and Bob, respectively, are assumed to be in these secure laboratories and do not directly take part in the transmission. On the other hand, the CV modes a_2 and b_2 are not assumed to be in secure laboratories and as such are vulnerable to eavesdropping attacks.

2. We also assume that the quantum channels between Alice-Charlie and Bob-Charlie are characterized by transmission losses only, with no thermal noise. We justify this assumption by demonstrating, in Appendix. F 4, the scenario with no thermal noise approximates the scenario with some practical value of the same with more than 98% fidelity. This assumption is only required to manage the calculation complexity of evaluating the final DV state between Alice and Bob.

3. We also consider a third party, Charlie, who is assumed to be untrusted and can collaborate with an eavesdropper, Eve. In the worst case scenario, we assume that he is identified as Eve herself. The QKD protocol, as described in the main text, dictates that Charlie performs certain measurements and publicly declare the outcomes so that Alice and Bob can share an entangled state. In principle, as an eavesdropper, we assume that Charlie may not perform the operations as dictated by the protocol. However, it is required for him to supply some outcomes to the specified measurements to activate the correlations between Alice and Bob. However, if these outcomes are tampered with or even fabricated, the correlations between Alice and Bob will decrease. It is then possible for Alice and Bob to detect the presence of Eve by various methods including state tomography since the parties know the final state they should potentially share. More details on this assumption and the concept of secure laboratories can be found in Ref. [49].

A. Steps in evaluating key rate

It should be noted that the steps of the QKD protocol directly follow after step 4 in Sec. II B as

Step 5: For the case in which Alice and Bob share $\rho_{a_1 b_1}$, they perform two-outcome measurements $\mathcal{M}_A$ and $\mathcal{M}_B$ on their respective subsystems to generate a raw key. The choice of measurements is made prior to starting the protocol and the information about this choice is usually publicly available. In our protocol, they perform Pauli measurements corresponding to σ_Z on their respective subsystems to generate a raw key. The length of the raw key that the parties can generate is quantified by the mutual information $I(A:B)$ between them for the observable σ_Z.

Step 6: Alice and Bob then estimate the amount of information that an adversary, Eve, can have on their raw key. This information is quantified by the Holevo bound $\chi(A:E)$ between Alice and Eve. In our protocol we consider the Holevo bound to quantify the knowledge about the coherent amplitude α, results of the on-off and homodyne measurement which are publicly declared and are actively used in generating the final state between Alice and Bob. These results can be used by Eve and as such must be taken care of in the security analysis.

B. Simulation results on the secured key rate

Our protocol comprises of two quantum channels: one between Alice and Charlie and another between Bob and Charlie. As before, we consider that the transmittance of both the channels is given by T_A and T_B, respectively, such that, $T_A = 10^{-l\frac{L_{AC}}{10}}$ and $T_B = 10^{-l\frac{L_{BC}}{10}}$, where $l = 0.2$ dB/km is the standard channel loss for telecom wavelength [47, 48] and $L_{AC} = L_{BC} = L/2$ are the transmission distances between Alice-Charlie and Bob-Charlie respectively such that the total transmission distance is L.

Moreover, we consider that the detectors of Alice and Bob have efficiency η_d such that the error rate is given as $Q = 1 - \eta_d$. With these inefficient detectors, the final secure key rate (See Appendix E for a detailed analysis) for the state given in Eq. (2) is given as

$$
\begin{aligned}
r &\geq P_0 \left[I(A:B) - \chi(A:E) \right] \\
&= P_0 \left\{ 1 - \eta_d + \frac{1}{2}\left[(1+h)\log_2(1+h) + (1-h)\log_2(1-h) \right] \right. \\
&\quad \left. - \frac{1}{2}\left[(2-\eta_d)\log_2(2-\eta_d) - (1-\eta_d)\log_2(1-\eta_d) \right] \right\},
\end{aligned}
\tag{4}
$$

where it can be seen that the secure key rate only depends on the parameters h (from Eq. (2)), the detector efficiency of Alice and Bob and the probability with which the final state is prepared.

Generally, for an experimental realization of the QKD protocol, the labs of Alice and Bob are fixed at some distance L. As seen in the main text, α cannot be chosen arbitrarily, as there exists an optimal value which can either maximize the key rate or the total transmission distance. In Fig. 5, we plot the maximum transmission distance as a function of the coherent amplitude for various values of secure key rate with ideal detector $\eta_d = 0$. We observe that there exists an optimal value $\alpha \approx 0.5$ which maximizes the total transmission distance for any value of the secure key rate.

In Fig. 6 we plot the secure key rate as a function of the total transmission distance L for different values

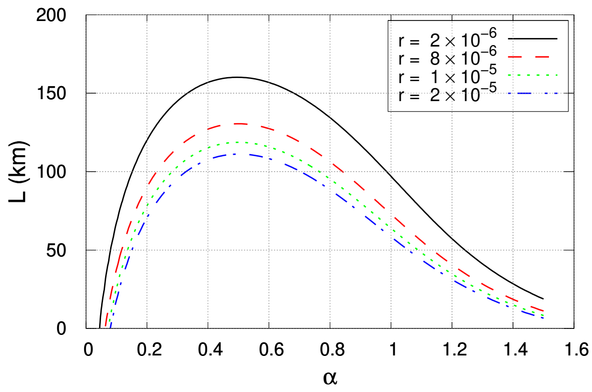

FIG. 5. The total transmission distance as a function of the coherent amplitude for different values of the secure key rate. We fix the channel loss at $l = 0.2$ dB/km which corresponds to losses in standard optical fibres. We also fix $\eta_d = 0$ for this analysis. The optimal value of α which maximizes the transmission distance is found to be the same in each case. The unit for the secure key rate r is bits/pulse.

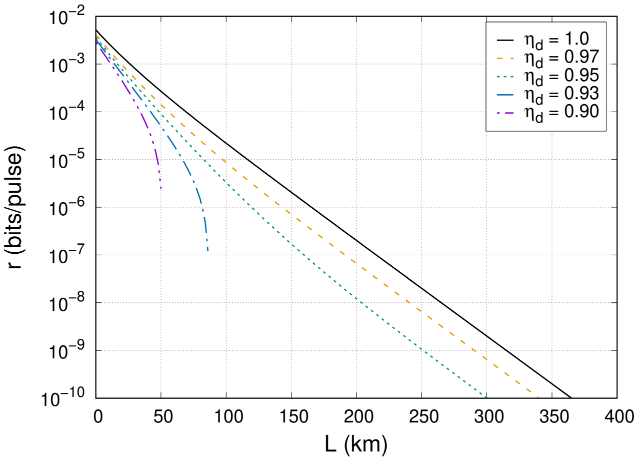

FIG. 6. Secure key rate as a function of total transmission distance L for different values of η_d in the optimal case, i.e., $\alpha = 0.5$. We assume detection efficiencies $\eta_h = 0.55$ for the homodyne detectors, $\eta_0 = 0.8$ for the on-off detectors, and $p = \frac{\pi}{2}$.

of η_d. We choose the parameters $\eta_h = 0.55$, $\eta_0 = 0.8$, and $p = \frac{\pi}{2}$ to be as realistic as possible and simulate the results for a standard telecom fiber with $l = 0.2$dB/km. Furthermore, the value of the coherent amplitude α is chosen to maximize the secure key rate over long transmission distances instead of entanglement. For our analysis we choose $\alpha = 0.5$ to optimize the total distance. It is also approximately the same value that optimizes the logarithmic negativity of an HE state when its CV part undergoes high photon loss. It is seen that under lower errors on Alice's and Bob's side ($\eta_d = 0.97$ and 0.95), a secure key rate can be achieved for transmission distances around 300 km indicating that the resultant entangled state is useful. However, the maximum achievable distance drastically falls off as η_d is increased up to $\eta_d = 0.90$.

IV. DISCUSSION AND CONCLUSION

We have shown that HE states between CV and DV systems provide a robust practical solution to the problem of achieving long-distance high-rate entanglement. Both requirements are fundamental for a number of applications. In this paper we have bench marked the usefulness of the prepared entangled state using an EB-QKD protocol, as it is both a fundamental application and a multipurpose test bed. In an EB-QKD setup, our results indicate that HE states bring forth the best of both CV and DV systems, resulting in a secure key rate of $\sim 10^{-9}$ bits/pulse at a distance of 250 km with 5% detection in-efficiency. This, in itself, represents a significant contribution. All this, without using an ultra low-loss fibre (with channel loss $l = 0.16$ dB/km at 1550 nm [50]), which allowed an earlier result to achieve transmission distances higher than 400 km. With such a fibre, our approach would allow us to achieve $\sim 10^{-10}$ bits/pulse at a distance of 300 km for $\eta_d = 0.95$.

In our analysis, it should be noted that, for the sake of simplicity, we do not consider any thermal noise in the channels. However, one can qualitatively show that incorporating a practical value for such thermal noise will not significantly affect our results (see Appendix F for detail). We leave the detailed quantitative analysis in the presence of thermal noise for future works and acknowledge that it involves lengthy analytical calculations that may have insignificant impact on our findings.

The feasibility of our protocol relies in the fact that HE states with small coherent amplitudes ($\alpha < 1$) can be generated in the lab by several non-deterministic techniques [34, 35] and the generation rate is comparable to the rate of entangled photon pairs in parametric down conversion setups. As an example, it is possible to prepare HE states where CV and DV parts correspond to photon number state and coherent state, respectively, with fidelity ≈ 0.75 for $\alpha = 0.5$ [34]. While the rate of generation in the source is comparable to that of parametric down conversion sources, losses during transmission are reduced, so the effective rate at destination increases. The fidelity of the preparation could be a limiting factor. However, this can be mitigated by using other forms of HE states, most notably with the CV and DV modes corresponding to cat states and polarization, respectively, which offer exceptionally good fidelity of preparation as well as rate of generation [51–55]. We also note that a recent result indicates that it is also possible to deterministically generate HE states with high fidelity [56]

However, it should be noted that there will be effects from phase modulations and phase mismatch in a practical implementation of our scheme. Commercially available lasers, used in generation of HE states, generally do not have well defined phase stabilization while the optical fibres, used for transmission, may introduce non-linear effects on the signals. This causes additional concerns for phase-locking and phase-tracking to ensure successful interference at Charlie's end. Although such issues have been managed in the context of twin-field (TF) QKD [57], it remains unclear to us whether a similar architecture can be useful in our setup as well and we leave it as an open avenue for future discussions.

Our results highlight the significance of HE states as a resource in high-rate remote entanglement generation, which plays a crucial role in enhancing many quantum information processing tasks such as quantum internet [58, 59], quantum digital signature [60, 61], and network steering [62]. We believe that our scheme has the potential to drive a new generation of experimental developments in quantum information technology.

[44] While a photon-number-resolving-detector (PNRD) measures the number of photons detected, an on-off detector only indicates whether a photon is detected or not. As a consequence, an on-off detector is much less demanding than a PNRD. Recent advances in technology has led to development of single-photon detectors with efficiencies as high as 0.84–0.91 [63–65] with the use of high-contrast-grating in nanophotonics settings. This, in turn, implies that the efficiency of an on-off detector can be safely approximated up to 0.80 (if not more).

Appendix A: Generation of the hybrid entangled state

In this section we outline a process, using a setup in line with Ref. [34], that can be used to experimentally generate a hybrid entangled (HE) state of the form

$$|\psi\rangle_{ab} = \frac{1}{\sqrt{2}}\left(|0\rangle_a |\alpha\rangle_b + |1\rangle_a |-\alpha\rangle_b\right) \tag{A1}$$

between modes a and b, where $|0\rangle$ and $|1\rangle$ correspond to photon number states, and $|\alpha\rangle$ is the coherent state with coherent amplitude α.

$|n\rangle$ and $|\alpha\rangle$ correspond to, respectively, the energy eigenstate and coherent state of a quantized electromagnetic field, where n is the number of photons in the state. It is possible to realize the energy eigenstates as a single-photon qubit by only considering the photon number states corresponding to $|0\rangle$ and $|1\rangle$. This is our discrete variable (DV) system and the multiphoton coherent state is our continuous variable (CV) system. The key idea of HE state generation hinges on conditional photon addition and erasing the path information of photon addition. There are several ways of achieving photon addition. This includes a model which uses single photon sources and beam splitters (BS) and another model which uses a parametric-down-converter (PDC) with a weak pump. Since the BS setup and the PDC are equivalent [66], here we use the BS model for photon addition. The following is a step-by-step description of the generation of the HE state in Fig. 1(b) of the main text.

Step 1: A vacuum state $|0\rangle$ in mode a is mixed with a single-photon state $|1\rangle$ in mode c using a BS (BS$_1$) with transmittance T. Similarly, a coherent state $|\alpha\rangle$ in mode c is mixed with another single-photon state in mode d using another BS (BS$_2$) with transmittance T. The output states from each of these two BSs are

$$\begin{aligned}|\psi\rangle^{\mathrm{BS}_1}_{ac} &= \sqrt{1-T}\,|1\rangle_a |0\rangle_c + \sqrt{T}\,|0\rangle_a |1\rangle_c \\ |\psi\rangle^{\mathrm{BS}_2}_{bd} &= \sqrt{1-T}\hat{b}^\dagger\,|\alpha\rangle_b |0\rangle_d + \sqrt{T}\,|\alpha\rangle_b |1\rangle_d\,,\end{aligned} \tag{A2}$$

where $\hat{b}^\dagger$ is the creation operator acting on mode b and $|\psi\rangle^{\mathrm{BS}_1}_{ac}$ is the output state from BS$_1$, while $|\psi\rangle^{\mathrm{BS}_2}_{bd}$ is the output state from BS$_2$. The BS transmittance T can be fine-tuned according to experimental requirements to yield maximum probability for photon addition. Therefore, the 4-mode state at the output of BS$_1$ and BS$_2$ is

$$|\psi\rangle^{\mathrm{BS}_{1,2}}_{ab,cd} = \sqrt{T(1-T)}\left(|1\rangle_a |\alpha\rangle_b \otimes |0\rangle_c |1\rangle_d + |0\rangle_a \hat{b}^\dagger |\alpha\rangle_b \otimes |1\rangle_c |0\rangle_d\right) + (1-T)\,|1\rangle_a \hat{b}^\dagger |\alpha\rangle_b \otimes |0\rangle_c |0\rangle_d + T\,|0\rangle_a |\alpha\rangle_b \otimes |1\rangle_c |1\rangle_d\,. \tag{A3}$$

Step 2: The outgoing single-photon modes (shown by gray dashed-lines in Fig. 1(b) of the main text) from both BS$_1$ and BS$_2$ are mixed with each other using a another BS (BS$_3$) with transmittance τ. This leads to a 4-mode state at the output of BS$_3$ which can be written as

$$\begin{aligned}|\psi\rangle^{\mathrm{BS}_3}_{ab,cd} = \sqrt{T(1-T)}\Big[&|1\rangle_a |\alpha\rangle_b \otimes \Big(-\sqrt{1-\tau}\,|0\rangle_c |1\rangle_d + \sqrt{\tau}\,|1\rangle_c |0\rangle_d\Big) + |0\rangle_a \hat{b}^\dagger |\alpha\rangle_b \otimes \Big(\sqrt{1-\tau}\,|1\rangle_c |0\rangle_d + \sqrt{\tau}\,|0\rangle_c |1\rangle_d\Big)\Big] \\ &+ (1-T)\,|1\rangle_a \hat{b}^\dagger |\alpha\rangle_b \otimes |0\rangle_c |0\rangle_d + T\,|0\rangle_a |\alpha\rangle_b \otimes \Big(\sqrt{1-\tau}\,|2\rangle_c |0\rangle_d + \sqrt{\tau}\,|0\rangle_c |2\rangle_d\Big).\end{aligned} \tag{A4}$$

Step 3: We now detect the output modes of BS$_3$ via single-photon detectors D$_1$ and D$_2$. Since the total photon number at the output of BS$_3$ is 1, it indicates that both D$_1$ and D$_2$ cannot click simultaneously. We post-select the state when only the detector D$_1$ clicks and discard the runs whenever the detector D$_2$ clicks. After post-selection, the state between modes a and b is

$$\begin{aligned}|\psi\rangle^{\mathrm{D}_1}_{ab} &= \langle 1|_c \langle 0|_d\, |\psi\rangle^{\mathrm{BS}_3}_{ab,cd} \\ &= \sqrt{T(1-T)}\left(\sqrt{\tau}\,|1\rangle_a |\alpha\rangle_b + \sqrt{1-\tau}\,|0\rangle_a \hat{b}^\dagger |\alpha\rangle_b\right).\end{aligned} \tag{A5}$$

We can now use the fact that n-photon-added coherent state is a good approximation to another coherent state with amplified amplitude, i.e., $\frac{\hat{b}^{\dagger n}}{\sqrt{N}}|\alpha\rangle \approx |g\alpha\rangle$ [34], where N is the corresponding normalization constant and $g \geq 1$ is the amplification factor. This leads to the result $\hat{b}^\dagger |\alpha\rangle_b \approx \frac{1}{\sqrt{1-\alpha^2}}|g\alpha\rangle_b$, where g is properly chosen. Then, by setting $\tau = \frac{1+\alpha^2}{2+\alpha^2}$ and using the approximation we get,

$$|\psi\rangle^{\mathrm{D}_1}_{ab} \approx \sqrt{\frac{T(1-T)}{2+\alpha^2}}\Big(|1\rangle_a |\alpha\rangle_b + |0\rangle_a |g\alpha\rangle_b\Big). \tag{A6}$$

Step 4: Next, we displace the mode b by performing a displacement operator on this mode given by $D_b\left(-\frac{\alpha+g\alpha}{2}\right) = \exp\left[-\frac{\alpha+g\alpha}{2}(\hat{b}^\dagger - \hat{b})\right]$, where $\hat{b}$ is the annihilation operator. This leads to the final normalized HE state

$$|\psi\rangle_{ab} = \frac{1}{\sqrt{2}}\left(|0\rangle_a |\alpha_f\rangle_b + |1\rangle_a |-\alpha_f\rangle_b\right), \tag{A7}$$

where $\alpha_f = \frac{(g-1)\alpha}{2}$.

Appendix B: Shared entangled state between Alice and Bob

In this section, we calculate the the state obtained after performing the entanglement swapping operation by Charlie. We also calculate the states obtained after every step of the protocol starting from the initial resource of HE states. The steps of the protocol are detailed in the main manuscript.

1. Initial states and channel transmission

We denote the two hybrid entangled states with Alice and Bob as

$$\begin{aligned}|\psi\rangle_{a_1a_2} &= \frac{1}{\sqrt{2}}\left(|0\rangle_{a_1}|\alpha\rangle_{a_2} + |1\rangle_{a_1}|-\alpha\rangle_{a_2}\right)\\ |\psi\rangle_{b_1b_2} &= \frac{1}{\sqrt{2}}\left(|0\rangle_{b_1}|\alpha\rangle_{b_2} + |1\rangle_{b_1}|-\alpha\rangle_{b_2}\right),\end{aligned} \tag{B1}$$

respectively. The initial 4-mode resource state can be written as

$$\begin{aligned}|\psi\rangle_{\substack{a_1a_2\\b_1b_2}} &= |\psi\rangle_{a_1a_2}|\psi\rangle_{b_1b_2}\\ &= \frac{1}{2}\left(|00\rangle_{a_1b_1}|\alpha\rangle_{a_2}|\alpha\rangle_{b_2} + |11\rangle_{a_1b_1}|-\alpha\rangle_{a_2}|-\alpha\rangle_{b_2}\right.\\ &\quad\left.+|01\rangle_{a_1b_1}|\alpha\rangle_{a_2}|-\alpha\rangle_{b_2} + |10\rangle_{a_1b_1}|-\alpha\rangle_{a_2}|\alpha\rangle_{b_2}\right),\end{aligned} \tag{B2}$$

where $|ij\rangle_{a_1b_1} = |i\rangle_{a_1}|j\rangle_{b_1}\ \forall i,j \in \{0,1\}$.

Alice and Bob both send their multiphoton part (modes a_2 and b_2) to a third distant party Charlie for mixing and subsequent measurements through a noisy/lossy channel with transmittance T. Such channels could be modelled in terms of an effective beam splitter (BS) with transmittance T, where the input state is fed at one of the inputs of the BS while the other input is initialised as a vacuum state. The action of a BS with transmittance T on the input modes is given by a unitary U_T^{ab} implementing the following transformation:

$$\begin{pmatrix}\hat{a}\\ \hat{b}\end{pmatrix} \rightarrow \begin{pmatrix}\hat{a}'\\ \hat{b}'\end{pmatrix} = \begin{pmatrix}\sqrt{T} & \sqrt{1-T}\\ -\sqrt{1-T} & \sqrt{T}\end{pmatrix}\begin{pmatrix}\hat{a}\\ \hat{b}\end{pmatrix}. \tag{B3}$$

$T = \frac{1}{2}$ corresponds to a balanced $(50:50)$ BS. As a consequence, the action of the channel on a coherent state ($|\alpha\rangle$) in mode a is described as $U_T^{ab}|\alpha\rangle_a \otimes |0\rangle_b \rightarrow |\alpha\rangle_{a'} \otimes |0\rangle_{b'} = \left|\sqrt{T}\alpha\right\rangle_a \otimes \left|\sqrt{1-T}\alpha\right\rangle_b$, where U_T^{ab} is the corresponding BS unitary operation. Subsequently, the resultant state is obtained by tracing over the ancillary mode b.

Similarly, the noisy transmission of modes a_2 and b_2 could be described by using two BSs with transmittance T, each one in the paths of modes a_2 and b_2 with ancillary modes given by f_a and f_b, respectively. The resultant noisy/lossy state is obtained by tracing over the ancillary modes (f_a and f_b). Therefore, the total input state to Charlie before mixing is

$$\begin{aligned}|\psi\rangle_{\substack{a_1,b_1;a_2',b_2'\\ f_a',f_b'}} &= U_T^{(a_2,f_a)} \otimes U_T^{(b_2,f_b)}\,|\psi\rangle_{\substack{a_1a_2\\b_1b_2}} \otimes |0\rangle_{f_a}|0\rangle_{f_b}\\ &= \frac{1}{2}\Bigg(|00\rangle_{a_1b_1}\left|\sqrt{1-T}\alpha\right\rangle_{f_a}\left|\sqrt{1-T}\alpha\right\rangle_{f_b}\left|\sqrt{T}\alpha\right\rangle_{a_2}\left|\sqrt{T}\alpha\right\rangle_{b_2} + |11\rangle_{a_1b_1}\left|-\sqrt{1-T}\alpha\right\rangle_{f_a}\left|-\sqrt{1-T}\alpha\right\rangle_{f_b}\left|-\sqrt{T}\alpha\right\rangle_{a_2}\left|-\sqrt{T}\alpha\right\rangle_{b_2}\\ &\quad + |01\rangle_{a_1b_1}\left|\sqrt{1-T}\alpha\right\rangle_{f_a}\left|-\sqrt{1-T}\alpha\right\rangle_{f_b}\left|\sqrt{T}\alpha\right\rangle_{a_2}\left|-\sqrt{T}\alpha\right\rangle_{b_2} + |10\rangle_{a_1b_1}\left|-\sqrt{1-T}\alpha\right\rangle_{f_a}\left|\sqrt{1-T}\alpha\right\rangle_{f_b}\left|-\sqrt{T}\alpha\right\rangle_{a_2}\left|\sqrt{T}\alpha\right\rangle_{b_2}\Bigg),\end{aligned} \tag{B4}$$

where $U_T^{(a_2,f_a)}$ and $U_T^{(b_2,f_b)}$ are the BS unitary operations corresponding to the respective channels with transmittance T. Charlie now mixes the incoming multiphoton modes (a_2 and b_2) through a balanced BS (BS_1) leading to the four mode entangled state

$$
\begin{aligned}
|\psi\rangle^{\mathrm{BS}_1}_{\substack{a_1,b_1;a_2^{''},b_2^{''}\\ f_a^{'},f_b^{'}}} &= U^{(a_2,b_2)}_{\mathrm{BS}_1}\,|\psi\rangle_{\substack{a_1,b_1;a_2^{'},b_2^{'}\\ f_a^{'},f_b^{'}}}\\
&= \frac{1}{2}\Bigg(|00\rangle_{a_1b_1}\left|\sqrt{1-T}\alpha\right\rangle_{f_a}\left|\sqrt{1-T}\alpha\right\rangle_{f_b}|0\rangle_{b_2}\left|\sqrt{2T}\alpha\right\rangle_{a_2}+|11\rangle_{a_1b_1}\left|-\sqrt{1-T}\alpha\right\rangle_{f_a}\left|-\sqrt{1-T}\alpha\right\rangle_{f_b}|0\rangle_{b_2'}\left|-\sqrt{2T}\alpha\right\rangle_{a_2}\\
&\quad+|01\rangle_{a_1b_1}\left|\sqrt{1-T}\alpha\right\rangle_{f_a}\left|-\sqrt{1-T}\alpha\right\rangle_{f_b}\left|\sqrt{2T}\alpha\right\rangle_{b_2}|0\rangle_{a_2}+|10\rangle_{a_1b_1}\left|-\sqrt{1-T}\alpha\right\rangle_{f_a}\left|\sqrt{1-T}\alpha\right\rangle_{f_b}\left|-\sqrt{2T}\alpha\right\rangle_{b_2}|0\rangle_{a_2}\Bigg).
\end{aligned}
\tag{B5}
$$

It can be seen from Eq. (B5) that, in the total 4-mode entangled state after mixing by Charlie, the vacuum state contribution in mode a_2 appears with probability 1/2. Our primary aim is to postselect the state (B5) in $|0\rangle_{a_2}$.

2. State after the on-off measurement

The additional coherent state sent by Bob to Charlie $(|\sqrt{2}\alpha\rangle)$ becomes $\left|\sqrt{2T}\alpha\right\rangle$ as a result of transmission through lossy channel. As is described in [34], for this purpose Charlie first mixes the outgoing a_2 mode with this additional state $\left(\left|\sqrt{2T}\alpha\right\rangle\right)$ in mode c through the second balanced beam splitter (BS$_2$). Consequently, the state after the mixing at BS$_2$ is given by

$$
\begin{aligned}
|\psi\rangle^{\mathrm{BS}_2}_{\substack{a_1,b_1;b_2^{''}\\ f_a^{'},f_b^{'}\\ a_2^{'''},c^{'}}} &= U^{(a_2,c)}_{\mathrm{BS}_1}\,|\psi\rangle^{\mathrm{BS}_1}_{\substack{a_1,b_1;a_2^{''},b_2^{''}\\ f_a^{'},f_b^{'}}}\otimes\left|\sqrt{2T}\alpha\right\rangle_c\\
&= \frac{1}{2}\Bigg(|00\rangle_{a_1b_1}\left|\sqrt{1-T}\alpha\right\rangle_{f_a}\left|\sqrt{1-T}\alpha\right\rangle_{f_b}|0\rangle_{b_2}\left|2\sqrt{T}\alpha\right\rangle_{a_2}|0\rangle_c\\
&\quad+|11\rangle_{a_1b_1}\left|-\sqrt{1-T}\alpha\right\rangle_{f_a}\left|-\sqrt{1-T}\alpha\right\rangle_{f_b}|0\rangle_{b_2}|0\rangle_{a_2}\left|-2\sqrt{T}\alpha\right\rangle_c\\
&\quad+|01\rangle_{a_1b_1}\left|\sqrt{1-T}\alpha\right\rangle_{f_a}\left|-\sqrt{1-T}\alpha\right\rangle_{f_b}\left|\sqrt{2T}\alpha\right\rangle_{b_2}\left|\sqrt{T}\alpha\right\rangle_{a_2}\left|-\sqrt{T}\alpha\right\rangle_c\\
&\quad+|10\rangle_{a_1b_1}\left|-\sqrt{1-T}\alpha\right\rangle_{f_a}\left|\sqrt{1-T}\alpha\right\rangle_{f_b}\left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left|\sqrt{T}\alpha\right\rangle_{a_2}\left|-\sqrt{T}\alpha\right\rangle_c\Bigg).
\end{aligned}
\tag{B6}
$$

As it can be seen from Eq. (B6), if both the detectors at the output of BS$_2$ click then the contribution can arise only from the respective part in (B6), i.e., from the part containing $|0\rangle_{a_2}$. Experimentally, this could be achieved unambiguously by performing the operation $\Pi_0 = (\mathbf{I} - |0\rangle\langle 0|)\otimes(\mathbf{I}-|0\rangle\langle 0|)$ on (B6) using two *on-off* detectors at both the output ports of BS$_2$.

However, here we consider *non-ideal* detectors with efficiency η_o $(0 \le \eta_o \le 1)$. Similar to the case of transmission channels, this could be analysed by considering two additional BS with transmittance η_o and two ancillary modes g_a and g_c for modes a_2 and c, respectively. Therefore, before the *on-off* detectors, the total state is given by

$$
\begin{aligned}
|\psi\rangle^{tot}_{\substack{a_1,b_1;b_2^{''}\\ f_a^{'},f_b^{'},g_a^{'},g_c^{'}\\ a_2^{''''},c^{''}}} &= U_{\eta_o}^{(a_2,g_a)} \otimes U_{\eta_o}^{(c,g_c)} \,|\psi\rangle^{\mathrm{BS}_2}_{\substack{a_1,b_1;b_2^{''}\\ f_a^{'},f_b^{'}\\ a_2^{'''},c^{'}}} \otimes |0\rangle_{g_a} |0\rangle_{g_c} \\
&= \frac{1}{2}\Bigg[|00\rangle_{a_1b_1} |0\rangle_{b_2^{''}} \left|\sqrt{1-T}\alpha\right\rangle_{f_a} \left|\sqrt{1-T}\alpha\right\rangle_{f_b} \left|2\sqrt{T(1-\eta_o)}\alpha\right\rangle_{g_a} |0\rangle_{g_c} \left|2\sqrt{T\eta_o}\alpha\right\rangle_{a_2} |0\rangle_c \\
&\quad + |11\rangle_{a_1b_1} |0\rangle_{b_2} \left|-\sqrt{1-T}\alpha\right\rangle_{f_a} \left|-\sqrt{1-T}\alpha\right\rangle_{f_b} |0\rangle_{g_a} \left|-2\sqrt{T(1-\eta_o)}\alpha\right\rangle_{g_c} |0\rangle_{a_2} \left|-2\sqrt{T\eta_o}\alpha\right\rangle_c \\
&\quad + \Bigg(|01\rangle_{a_1b_1} \left|\sqrt{2T}\alpha\right\rangle_{b_2} \left|\sqrt{1-T}\alpha\right\rangle_{f_a} \left|-\sqrt{1-T}\alpha\right\rangle_{f_b} + |10\rangle_{a_1b_1} \left|-\sqrt{2T}\alpha\right\rangle_{b_2} \left|-\sqrt{1-T}\alpha\right\rangle_{f_a} \left|\sqrt{1-T}\alpha\right\rangle_{f_b} \Bigg) \\
&\qquad \left|\sqrt{T(1-\eta_o)}\alpha\right\rangle_{g_a} \left|-\sqrt{T(1-\eta_o)}\alpha\right\rangle_{g_c} \left|\sqrt{T\eta_0}\alpha\right\rangle_{a_2} \left|-\sqrt{T\eta_o}\alpha\right\rangle_c \Bigg] \\
&= \frac{1}{2}\Bigg[|00\rangle_{a_1b_1} |0\rangle_{b_2} \left|\sqrt{T'}\alpha\right\rangle_{f_a} \left|\sqrt{T'}\alpha\right\rangle_{f_b} \left|2\sqrt{T\eta_o'}\alpha\right\rangle_{g_a} |0\rangle_{g_c} \left|2\sqrt{T\eta_o}\alpha\right\rangle_{a_2} |0\rangle_c \\
&\quad + |11\rangle_{a_1b_1} |0\rangle_{b_2} \left|-\sqrt{T'}\alpha\right\rangle_{f_a} \left|-\sqrt{T'}\alpha\right\rangle_{f_b} |0\rangle_{g_a} \left|-2\sqrt{T\eta_o'}\alpha\right\rangle_{g_c} |0\rangle_{a_2} \left|-2\sqrt{T\eta_o}\alpha\right\rangle_c \\
&\quad + \Bigg(|01\rangle_{a_1b_1} \left|\sqrt{2T}\alpha\right\rangle_{b_2} \left|\sqrt{T'}\alpha\right\rangle_{f_a} \left|-\sqrt{T'}\alpha\right\rangle_{f_b} \;+\; |10\rangle_{a_1b_1} \left|-\sqrt{2T}\alpha\right\rangle_{b_2} \left|-\sqrt{T'}\alpha\right\rangle_{f_a} \left|\sqrt{T'}\alpha\right\rangle_{f_b} \Bigg) \\
&\quad \left|\sqrt{T\eta_o'}\alpha\right\rangle_{g_a} \left|-\sqrt{T\eta_o'}\alpha\right\rangle_{g_c} \left|\sqrt{T\eta_0}\alpha\right\rangle_{a_2} \left|-\sqrt{T\eta_o}\alpha\right\rangle_c \Bigg], \qquad \text{(B7)}
\end{aligned}
$$

where $T' = 1 - T$ and $\eta_o' = 1 - \eta_o$.

Charlie is now supposed to make the measurement of $\Pi_0^{a_2,c} = (\mathbb{1} - |0\rangle\langle 0|)_{a_2} \otimes (\mathbb{1} - |0\rangle\langle 0|)_c$ on the state in Eq. (B7). After the measurement of these operators (Π_0) the total state collapses to $\rho^0_{a_1,b_1;b_2} = \mathrm{tr}_{\substack{f_a,f_b\\ g_a,g_c\\ a_2,c}}\Big(|\psi_0\rangle\langle\psi_0| \Big)/N_0$, where $|\psi_0\rangle = \Pi_0^{a_2,c} |\psi\rangle^{tot}_{\substack{a_1,b_1;b_2^{''}\\ f_a^{'},f_b^{'},g_a^{'},g_c^{'}\\ a_2^{''''},c^{''}}}$ and the normalization constants are $N_0 = \mathrm{tr}_{\substack{a_1,b_1,a_2,b_2,c\\ f_a,f_b,g_a,g_c}}\Big(|\psi_0\rangle\langle\psi_0| \Big)$. It must be noted that the state $\rho^0_{a_1,b_1;b_2}$ is obtained with probability $P_0 = \mathrm{tr}_{\substack{a_1,b_1\\ b_2}}\left(\rho^0_{a_1,b_1;b_2}\right)$.

Let us look at the result first

$$
\begin{aligned}
\Pi_0^{a_2,c} |\alpha\rangle_{a_2} |\beta\rangle_c &= \Big(\mathbb{1}_{a_2} \otimes \mathbb{1}_c - |0\rangle_{a_2}\langle 0| \otimes \mathbb{1}_c - \mathbb{1}_{a_2} \otimes |0\rangle_c\langle 0| + |0\rangle_{a_2}\langle 0| \otimes |0\rangle_c\langle 0| \Big) |\alpha\rangle_{a_2} |\beta\rangle_c \\
&= |\alpha\rangle_{a_2} |\beta\rangle_c - e^{-\alpha^2/2} |0\rangle_{a_2} |\beta\rangle_c - e^{-\beta^2/2} |\alpha\rangle_{a_2} |0\rangle_c + e^{-(\alpha^2+\beta^2)/2} |0\rangle_{a_2} |0\rangle_c . \qquad \text{(B8)}
\end{aligned}
$$

leading to

$$
\begin{aligned}
&\Pi_0^{a_2,c} |\alpha\rangle_{a_2} |0\rangle_c = \Pi_0^{a_2,c} |0\rangle_{a_2} |\alpha\rangle_c = 0 \\
&\Pi_0^{a_2,c} |\alpha\rangle_{a_2} |-\alpha\rangle_c = |\alpha\rangle_{a_2} |-\alpha\rangle_c - e^{-\alpha^2/2} |0\rangle_{a_2} |-\alpha\rangle_c - e^{-\alpha^2/2} |\alpha\rangle_{a_2} |0\rangle_c + e^{-\alpha^2} |0\rangle_{a_2} |0\rangle_c . \qquad \text{(B9)}
\end{aligned}
$$

Deploying the results of Eq. (B9) in Eq. (B7), we obtain

$$
\begin{aligned}
&|\psi_0\rangle = \Pi_0^{a_2,c}\,|\psi\rangle^{tot}_{\substack{a_1,b_1;b_2^{''}\\ f_a^{'},f_b^{'},g_a^{'},g_c^{'}\\ a_2^{''''},c^{''}}}\\
&= \frac{1}{2}\Big[|00\rangle_{a_1b_1}|0\rangle_{b_2}\left|\sqrt{T'}\alpha\right\rangle_{f_a}\left|\sqrt{T'}\alpha\right\rangle_{f_b}\otimes\left|2\sqrt{T\eta_o'}\alpha\right\rangle_{g_a}|0\rangle_{g_c}\times 0\\
&\quad + |11\rangle_{a_1b_1}|0\rangle_{b_2}\left|-\sqrt{T'}\alpha\right\rangle_{f_a}\left|-\sqrt{T'}\alpha\right\rangle_{f_b}\otimes|0\rangle_{g_a}\left|-2\sqrt{T\eta_o'}\alpha\right\rangle_{g_c}\times 0\\
&\quad + \left(|01\rangle_{a_1b_1}\left|\sqrt{2T}\alpha\right\rangle_{b_2}\left|\sqrt{T'}\alpha\right\rangle_{f_a}\left|-\sqrt{T'}\alpha\right\rangle_{f_b} + |10\rangle_{a_1b_1}\left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left|-\sqrt{T'}\alpha\right\rangle_{f_a}\left|\sqrt{T'}\alpha\right\rangle_{f_b}\right)\otimes\left|\sqrt{T\eta_o'}\alpha\right\rangle_{g_a}\left|-\sqrt{T\eta_o'}\alpha\right\rangle_{g_c}\otimes\\
&\quad\left(\left|\sqrt{\eta_oT}\alpha\right\rangle_{a_2}\left|-\sqrt{\eta_oT}\alpha\right\rangle_{c} - e^{-\eta_oT\alpha^2/2}|0\rangle_{a_2}\left|-\sqrt{\eta_oT}\alpha\right\rangle_{c} - e^{-\eta_oT\alpha^2/2}\left|\sqrt{\eta_oT}\alpha\right\rangle_{a_2}|0\rangle_{c} + e^{-\eta_oT\alpha^2}|0\rangle_{a_2}|0\rangle_{c}\right)\Big]\\
&= \frac{1}{2}\left(|01\rangle_{a_1b_1}\left|\sqrt{2T}\alpha\right\rangle_{b_2}\left|\sqrt{T'}\alpha\right\rangle_{f_a}\left|-\sqrt{T'}\alpha\right\rangle_{f_b} + |10\rangle_{a_1b_1}\left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left|-\sqrt{T'}\alpha\right\rangle_{f_a}\left|\sqrt{T'}\alpha\right\rangle_{f_b}\right)\otimes\\
&\quad\left|\sqrt{T\eta_o'}\alpha\right\rangle_{g_a}\left|-\sqrt{T\eta_o'}\alpha\right\rangle_{g_c}\otimes|\Psi\rangle_{a_2c}\,, \qquad \text{(B10)}
\end{aligned}
$$

where

$$
|\Psi\rangle_{a_2c} = \left|\sqrt{\eta_oT}\alpha\right\rangle_{a_2}\left|-\sqrt{\eta_oT}\alpha\right\rangle_{c} - e^{-\eta_oT\alpha^2/2}|0\rangle_{a_2}\left|-\sqrt{\eta_oT}\alpha\right\rangle_{c} - e^{-\eta_oT\alpha^2/2}\left|\sqrt{\eta_oT}\alpha\right\rangle_{a_2}|0\rangle_{c} + e^{-\eta_oT\alpha^2}|0\rangle_{a_2}|0\rangle_{c}\,. \qquad \text{(B11)}
$$

It can be further shown that

$$
\begin{aligned}
&\mathrm{tr}\Big(|\Psi\rangle_{a_2c}\langle\Psi|\Big) = \mathrm{tr}\Big[\Big(\left\langle\sqrt{\eta_oT}\alpha\middle|\sqrt{\eta_oT}\alpha\right\rangle\left\langle-\sqrt{\eta_oT}\alpha\middle|-\sqrt{\eta_oT}\alpha\right\rangle + e^{-\eta_oT\alpha^2}\langle 0|0\rangle\left\langle-\sqrt{\eta_oT}\alpha\middle|-\sqrt{\eta_oT}\alpha\right\rangle\\
&\quad + e^{-\eta_oT\alpha^2}\left\langle\sqrt{\eta_oT}\alpha\middle|\sqrt{\eta_oT}\alpha\right\rangle\langle 0|0\rangle + e^{-2\eta_oT\alpha^2}\langle 0|0\rangle\langle 0|0\rangle\Big) + 2\Big(-e^{-\eta_oT\alpha^2/2}\left\langle 0\middle|\sqrt{\eta_oT}\alpha\right\rangle\left\langle-\sqrt{\eta_oT}\alpha\middle|-\sqrt{\eta_oT}\alpha\right\rangle\\
&\quad - e^{-\eta_oT\alpha^2/2}\left\langle\sqrt{\eta_oT}\alpha\middle|\sqrt{\eta_oT}\alpha\right\rangle\left\langle 0\middle|-\sqrt{\eta_oT}\alpha\right\rangle + e^{-\eta_oT\alpha^2}\left\langle 0\middle|\sqrt{\eta_oT}\alpha\right\rangle\left\langle 0\middle|-\sqrt{\eta_oT}\alpha\right\rangle\Big)\\
&\quad + 2\Big(e^{-\eta_oT\alpha^2}\left\langle\sqrt{\eta_oT}\alpha\middle|0\right\rangle\left\langle 0\middle|-\sqrt{\eta_oT}\alpha\right\rangle - e^{-3\eta_oT\alpha^2/2}\langle 0|0\rangle\left\langle 0\middle|-\sqrt{\eta_oT}\alpha\right\rangle\Big) - 2\,e^{-3\eta_oT\alpha^2/2}\left\langle 0\middle|\sqrt{\eta_oT}\alpha\right\rangle\langle 0|0\rangle\Big]\\
&= \Big(1 + e^{-\eta_oT\alpha^2} + e^{-\eta_oT\alpha^2} + e^{-2\eta_oT\alpha^2}\Big) + 2\Big(-e^{-\eta_oT\alpha^2} - e^{-\eta_oT\alpha^2} + e^{-2\eta_oT\alpha^2}\Big) + 2\Big(e^{-2\eta_oT\alpha^2} - e^{-2\eta_oT\alpha^2}\Big) - 2e^{-2\eta_oT\alpha^2}\\
&= 1 - 2e^{-\eta_oT\alpha^2} + e^{-2\eta_oT\alpha^2} = \Big(1 - e^{-\eta_oT\alpha^2}\Big)^2. \qquad \text{(B12)}
\end{aligned}
$$

Hence

$$
\begin{aligned}
&\mathrm{tr}_{\substack{f_a,f_b\\ g_a,g_c\\ a_2,c}}\Big(\left|\psi_0\right\rangle \left\langle\psi_0\right| \Big)\\
&= \frac{\left(1-e^{-\eta_o T\alpha^2}\right)^2}{4}\mathrm{tr}_{f_a,f_b}\Bigg[\Bigg(\left|01\right\rangle_{a_1b_1}\left\langle 01\right| \otimes \left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right| \otimes \left|\sqrt{T'}\alpha\right\rangle_{f_a}\left\langle\sqrt{T'}\alpha\right| \otimes \left|-\sqrt{T'}\alpha\right\rangle_{f_b}\left\langle-\sqrt{T'}\alpha\right|\\
&\qquad + \left|10\right\rangle_{a_1b_1}\left\langle 10\right| \otimes \left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right| \otimes \left|-\sqrt{T'}\alpha\right\rangle_{f_a}\left\langle-\sqrt{T'}\alpha\right| \otimes \left|\sqrt{T'}\alpha\right\rangle_{f_b}\left\langle\sqrt{T'}\alpha\right|\\
&\qquad + \left|01\right\rangle_{a_1b_1}\left\langle 10\right| \otimes \left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right| \otimes \left|\sqrt{T'}\alpha\right\rangle_{f_a}\left\langle-\sqrt{T'}\alpha\right| \otimes \left|-\sqrt{T'}\alpha\right\rangle_{f_b}\left\langle\sqrt{T'}\alpha\right|\\
&\qquad + \left|10\right\rangle_{a_1b_1}\left\langle 01\right| \otimes \left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right| \otimes \left|-\sqrt{T'}\alpha\right\rangle_{f_a}\left\langle\sqrt{T'}\alpha\right| \otimes \left|\sqrt{T'}\alpha\right\rangle_{f_b}\left\langle-\sqrt{T'}\alpha\right|\Bigg)\Bigg]\\
&\qquad \times \mathrm{tr}_{g_a,g_c}\Big[\left|\sqrt{T\eta_o'}\alpha\right\rangle_{g_a}\left\langle\sqrt{T\eta_o'}\alpha\right| \otimes \left|-\sqrt{T\eta_o'}\alpha\right\rangle_{g_c}\left\langle-\sqrt{T\eta_o'}\alpha\right|\Big]\\
&= \frac{\left(1-e^{-\eta_o T\alpha^2}\right)^2}{4}\Big[\left|01\right\rangle_{a_1b_1}\left\langle 01\right| \otimes \left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right| + \left|10\right\rangle_{a_1b_1}\left\langle 10\right| \otimes \left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right|\\
&\qquad + \Big(\left|01\right\rangle_{a_1b_1}\left\langle 10\right| \otimes \left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right| + \left|10\right\rangle_{a_1b_1}\left\langle 01\right| \otimes \left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right|\Big)e^{-4(1-T)\alpha^2}\Big],
\end{aligned}
\tag{B13}
$$

where $\mathrm{tr}\Big(\left|\alpha\right\rangle \left\langle-\alpha\right| \Big) = e^{-2\alpha^2}$. Corresponding probability and normalization constant are

$$
\begin{aligned}
P_0 = N_0 &= \mathrm{tr}_{\substack{a_1,b_1\\ b_2}}\left[\mathrm{tr}_{\substack{f_a,f_b\\ g_a,g_c\\ a_2,c}}\Big(\left|\psi_0\right\rangle \left\langle\psi_0\right| \Big)\right]\\
&= \frac{\left(1-e^{-\eta_o T\alpha^2}\right)^2}{2}.
\end{aligned}
\tag{B14}
$$

This leads to the normalized state

$$
\begin{aligned}
\rho^0_{a_1,b_1,b_2} &= \frac{1}{N_0}\mathrm{tr}_{\substack{f_a,f_b\\ g_a,g_c\\ a_2,c}}\Big(\left|\psi_0\right\rangle \left\langle\psi_0\right| \Big)\\
&= \frac{1}{2}\Big[\left|01\right\rangle_{a_1b_1}\left\langle 01\right| \otimes \left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right| + \left|10\right\rangle_{a_1b_1}\left\langle 10\right| \otimes \left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right|\\
&\qquad + \Big(\left|01\right\rangle_{a_1b_1}\left\langle 10\right| \otimes \left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right| + \left|10\right\rangle_{a_1b_1}\left\langle 01\right| \otimes \left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right|\Big)e^{-4(1-T)\alpha^2}\Big].
\end{aligned}
\tag{B15}
$$

3. Final state obtained after the homodyne measurement

Charlie now performs the homodyne measurement along the quadrature X_θ on mode b_2. Here also we consider that that the homodyne instruments are not perfect. Rather the efficiency of the homodyne detector is given by η_h. Similar to the earlier cases here also the imperfect homodyne detector could be modeled as a passive beam splitter with transmittance η_h. Now the action of the imperfect homodyne measurement along quadrature X_θ will lead to the resultant unnormalized state $\rho_{\mathrm{un}}^{\mathrm{hom},0} = \left\langle X_\theta\right|_{b_2} \mathrm{tr}_{h_b}\left[\left(U_{\eta_h}^{h_b,b_2}\right)\rho^0_{a_1,b_1;b_2}\otimes\left|0\right\rangle_{h_b}\left\langle 0\right|\left(U_{\eta_h}^{h_b,b_2}\right)^\dagger\right]\left|X_\theta\right\rangle_{b_2}$ with normalization $N_0^{\mathrm{hom}} = \mathrm{tr}_{a_1,b_1}\left(\rho_{\mathrm{un}}^{\mathrm{hom},0}\right)$, where X_θ in a mode a is defined as $X_\theta = (ae^{\mathrm{i}\theta} + a^\dagger e^{-\mathrm{i}\theta})/2$ and with the eigenvalue equation as X_θ defined as $X_\theta\left|X_\theta\right\rangle = x_\theta\left|X_\theta\right\rangle$.

Thus, after the homodyne measurement by Charlie, the residual normalized state between Alice and Bob will be

$$\rho_{a_1,b_1} = \frac{\rho_{\mathrm{un}}^{\mathrm{hom},0}}{N_0^{\mathrm{hom}}}. \tag{B16}$$

In this work we consider the measurement of quadrature operator for the choice of $\theta = \frac{\pi}{2}$, i.e., we consider the *momentum-like* quadrature operator P. Now the measurement of P for a coherent state $|\alpha\rangle$ is $\langle P|\alpha\rangle = \frac{1}{\pi^{1/4}} e^{-p^2/2} e^{-\alpha^2 - \mathrm{i}\sqrt{2}\alpha p}$. Now,

$$\begin{aligned}
&\mathrm{tr}_{h_b}\left[\left(U_{\eta_h}^{h_b,b_2}\right)\rho^0_{a_1,b_1;b_2}\otimes|0\rangle_{h_b}\langle 0|\left(U_{\eta_h}^{h_b,b_2}\right)^\dagger\right] \\
&= \frac{1}{2}\mathrm{tr}_{h_b}\left\{\left(U_{\eta_h}^{h_b,b_2}\right)\left[|01\rangle_{a_1b_1}\langle 01|\otimes\left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right| + |10\rangle_{a_1b_1}\langle 10|\otimes\left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right|\right.\right. \\
&\quad\left.\left. + \left(|01\rangle_{a_1b_1}\langle 10|\otimes\left|\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T}\alpha\right| + |10\rangle_{a_1b_1}\langle 01|\otimes\left|-\sqrt{2T}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T}\alpha\right|\right)e^{-4(1-T)\alpha^2}\right]\otimes|0\rangle_{h_b}\langle 0|\left(U_{\eta_h}^{h_b,b_2}\right)^\dagger\right\} \\
&= \frac{1}{2}\mathrm{tr}_{h_b}\left[|01\rangle_{a_1b_1}\langle 01|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right|\otimes\left|\sqrt{2T\eta_h'}\alpha\right\rangle_{h_b}\left\langle\sqrt{2T\eta_h'}\alpha\right|\right. \\
&\quad + |10\rangle_{a_1b_1}\langle 10|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right|\otimes\left|-\sqrt{2T\eta_h'}\alpha\right\rangle_{h_b}\left\langle-\sqrt{2T\eta_h'}\alpha\right| \\
&\quad + \left(|01\rangle_{a_1b_1}\langle 10|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right|\otimes\left|\sqrt{2T\eta_h'}\alpha\right\rangle_{h_b}\left\langle-\sqrt{2T\eta_h'}\alpha\right|\right. \\
&\quad\left.\left. + |10\rangle_{a_1b_1}\langle 01|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right|\otimes\left|-\sqrt{2T\eta_h'}\alpha\right\rangle_{h_b}\left\langle\sqrt{2T\eta_h'}\alpha\right|\right)e^{-4(1-T)\alpha^2}\right] \\
&= \frac{1}{2}\left[|01\rangle_{a_1b_1}\langle 01|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right| + |10\rangle_{a_1b_1}\langle 10|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right|\right. \\
&\quad\left. + \left(|01\rangle_{a_1b_1}\langle 10|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right| + |10\rangle_{a_1b_1}\langle 01|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right|\right)e^{-4T(1-\eta_h')\alpha^2}e^{-4(1-T)\alpha^2}\right] \\
&= \frac{1}{2}\left[|01\rangle_{a_1b_1}\langle 01|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right| + |10\rangle_{a_1b_1}\langle 10|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right|\right. \\
&\quad\left. + \left(|01\rangle_{a_1b_1}\langle 10|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right| + |10\rangle_{a_1b_1}\langle 01|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right|\right)e^{-4(1-T\eta_h)\alpha^2}\right],
\end{aligned} \tag{B17}$$

which leads to

$$\begin{aligned}
\rho_{\mathrm{un}}^{\mathrm{hom},0} &= \langle P|_{b_2}\,\mathrm{tr}_{h_b}\left[\left(U_{\eta_h}^{h_b,b_2}\right)\rho^0_{a_1,b_1;b_2}\otimes|0\rangle_{h_b}\langle 0|\left(U_{\eta_h}^{h_b,b_2}\right)^\dagger\right]|P\rangle_{b_2} \\
&= \frac{1}{2}\langle P|_{b_2}\left[|01\rangle_{a_1b_1}\langle 01|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right| + |10\rangle_{a_1b_1}\langle 10|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right|\right. \\
&\quad\left. + \left(|01\rangle_{a_1b_1}\langle 10|\otimes\left|\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle-\sqrt{2T\eta_h}\alpha\right| + |10\rangle_{a_1b_1}\langle 01|\otimes\left|-\sqrt{2T\eta_h}\alpha\right\rangle_{b_2}\left\langle\sqrt{2T\eta_h}\alpha\right|\right)e^{-4(1-T\eta_h)\alpha^2}\right]|P\rangle_{b_2} \\
&= \frac{e^{-p^2}}{2\sqrt{\pi}}\left[|01\rangle_{a_1b_1}\langle 01|\,e^{-4T\eta_h\alpha^2} + |10\rangle_{a_1b_1}\langle 10|\,e^{-4T\eta_h\alpha^2}\right. \\
&\quad\left. + \left(|01\rangle_{a_1b_1}\langle 10|\,e^{-4T\eta_h\alpha^2-4\mathrm{i}\sqrt{T\eta_h}\alpha p} + |10\rangle_{a_1b_1}\langle 01|\,e^{-4T\eta_h\alpha^2+4\mathrm{i}\sqrt{T\eta_h}\alpha p}\right)e^{-4(1-T\eta_h)\alpha^2}\right] \\
&= \frac{e^{-p^2}e^{-4T\eta_h\alpha^2}}{2\sqrt{\pi}}\left[|01\rangle_{a_1b_1}\langle 01| + |10\rangle_{a_1b_1}\langle 10| + \left(|01\rangle_{a_1b_1}\langle 10|\,e^{-4\mathrm{i}\sqrt{T\eta_h}\alpha p} + |10\rangle_{a_1b_1}\langle 01|\,e^{4\mathrm{i}\sqrt{T\eta_h}\alpha p}\right)e^{-4(1-T\eta_h)\alpha^2}\right],
\end{aligned} \tag{B18}$$

with $N_0^{\mathrm{hom}} = \mathrm{tr}_{a_1,b_1}\left(\rho_{\mathrm{un}}^{\mathrm{hom},0}\right) = \frac{e^{-p^2}e^{-4T\eta_h\alpha^2}}{\sqrt{\pi}}$.

Therefore,

$$\begin{aligned}\rho_{a_1,b_1} &= \frac{\rho_{\rm un}^{\rm hom,0}}{N_0^{\rm hom}}\\ &= \frac{1}{2}\left[|01\rangle_{a_1b_1}\langle 01| + |10\rangle_{a_1b_1}\langle 10| + \left(|01\rangle_{a_1b_1}\langle 10|\, e^{-4\mathrm{i}\sqrt{T\eta_h}\alpha p} + |10\rangle_{a_1b_1}\langle 01|\, e^{4\mathrm{i}\sqrt{T\eta_h}\alpha p}\right) e^{-4(1-T\eta_h)\alpha^2}\right]\\ &= \frac{1}{2}\left[|01\rangle_{a_1b_1}\langle 01| + |10\rangle_{a_1b_1}\langle 10| + h\left(g\,|01\rangle_{a_1b_1}\langle 10| + g^*\,|10\rangle_{a_1b_1}\langle 01|\right)\right], \end{aligned} \tag{B19}$$

where $h = e^{-4(1-T\eta_h)\alpha^2}$ and $g = e^{-4\mathrm{i}\sqrt{T\eta_h}\alpha p}$. The probability of obtaining this final state is given by (B14) $P_0 = \frac{\left(1-e^{-\eta_o T\alpha^2}\right)^2}{2}$.

Appendix C: Logarithmic negativity of hybrid entangled states undergoing photon loss

In our protocol we use the CV part of the HE state for transmission via a lossy quantum channel. It can be shown that under photon losses in the CV part, an HE state can still retain correlations for a particular value of α.

We analyse the amount of correlations that a HE state retains after its CV system is transmitted via a lossy quantum channel. Upon transmission the CV part undergoes photon loss which is directly dependent on the value of α chosen. We show that the correlations in a HE state after its CV part has undergone transmission loss is a non-monotonic function of its coherent amplitude. Specifically, we evaluate the logarithmic negativity [67, 68] of the initial HE state as a function of transmission loss. We find that for $\alpha \approx 0.5$, the HE state is highly robust against noise.

Let us consider the HE state

$$|\psi\rangle_{ab} = \frac{1}{\sqrt{2}}\Big(|0\rangle_a|\alpha\rangle_b + |1\rangle_a|{-\alpha}\rangle_b\Big). \tag{C1}$$

Suppose that the mode b undergoes photon loss. The process of photon loss can be equivalently modeled as passage through a beam splitter with reflectivity R ($0 \leq R \leq 1$) while the other input to the beam splitter is taken to be vacuum. In such a case, the beam splitter matrix is $\begin{pmatrix}\sqrt{1-R} & \sqrt{R}\\ -\sqrt{R} & \sqrt{1-R}\end{pmatrix}$, where $R = 0$ and $R = 1$ stand for zero photon loss and complete photon loss, respectively. To that end, let us consider that the mode b passes through such a beam splitter while the other input is at $|0\rangle$ in mode c. As a consequence, the total state after passage through the beam splitter becomes

$$|\psi\rangle_{ab}\otimes|0\rangle_c \xrightarrow{\text{bs}} \frac{1}{\sqrt{2}}\left(|0\rangle_a\left|\sqrt{1-R}\alpha\right\rangle_b\left|\sqrt{R}\alpha\right\rangle_c + |1\rangle_a\left|-\sqrt{1-R}\alpha\right\rangle_b\left|-\sqrt{R}\alpha\right\rangle_c\right). \tag{C2}$$

Subsequently, the two-mode state in modes a and b after photon loss is obtained by tracing over the ancillary mode c as

$$\begin{aligned}\rho_{ab}^{\rm loss} &= \mathrm{tr}_c\left[\frac{1}{2}\left(\left|0,\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 0,\sqrt{1-R}\alpha\right|\otimes\left|\sqrt{R}\alpha\right\rangle_c\left\langle\sqrt{R}\alpha\right| + \left|1,-\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 1,-\sqrt{1-R}\alpha\right|\otimes\left|-\sqrt{R}\alpha\right\rangle_c\left\langle-\sqrt{R}\alpha\right|\right.\right.\\ &\quad\left.\left.+\left|0,\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 1,-\sqrt{1-R}\alpha\right|\otimes\left|\sqrt{R}\alpha\right\rangle_c\left\langle-\sqrt{R}\alpha\right| + \left|1,-\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 0,\sqrt{1-R}\alpha\right|\otimes\left|-\sqrt{R}\alpha\right\rangle_c\left\langle\sqrt{R}\alpha\right|\right)\right]\\ &= \frac{1}{2}\left(\left|0,\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 0,\sqrt{1-R}\alpha\right| + \left|1,-\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 1,-\sqrt{1-R}\alpha\right| + e^{-2R\alpha^2}\left|0,\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 1,-\sqrt{1-R}\alpha\right|\right.\\ &\quad\left.+e^{-2R\alpha^2}\left|1,-\sqrt{1-R}\alpha\right\rangle_{ab}\left\langle 0,\sqrt{1-R}\alpha\right|\right)\\ &= \frac{1}{2}\left[|0\rangle_a\langle 0|\otimes\left|\sqrt{1-R}\alpha\right\rangle_b\left\langle\sqrt{1-R}\alpha\right| + |1\rangle_a\langle 1|\otimes\left|-\sqrt{1-R}\alpha\right\rangle_b\left\langle-\sqrt{1-R}\alpha\right|\right.\\ &\quad\left.+e^{-2R\alpha^2}\left(|0\rangle_a\langle 1|\otimes\left|\sqrt{1-R}\alpha\right\rangle_b\left\langle-\sqrt{1-R}\alpha\right| + |1\rangle_a\langle 0|\otimes\left|-\sqrt{1-R}\alpha\right\rangle_b\left\langle\sqrt{1-R}\alpha\right|\right)\right].\end{aligned} \tag{C3}$$

In order to evaluate the entanglement content in this state, we use logarithmic negativity as a measure of entanglement. For a bipartite state $\rho_{ab}^{\rm loss}$ it is defined as $E_N\left(\rho_{ab}^{\rm loss}\right) = \log_2\left|\left|\left(\rho_{ab}^{\rm loss}\right)^{\rm P.T.}\right|\right|_1$, where $||.||_1$ is the trace norm and P.T. stands for partial transpose over any one of the modes a or b. We evaluate the logarithmic negativity for the state after photon loss in Eq. (C3) numerically and is shown in the main text.

Appendix D: Logarithmic negativity of the shared entangled states

In order to evaluate the entanglement content in this state, we use logarithmic negativity as a measure of entanglement. For a bipartite state $\rho_{a_1b_1}$ it is defined as $E_N\left(\rho_{a_1b_1}\right) = \log_2 \left|\left|\rho^{\text{P.T.}}_{a_1b_1}\right|\right|_1$, where $||.||_1$ is the trace norm and P.T. stands for partial transpose over any one of the modes a_1 or b_1. Here, we evaluate the logarithmic negativity for the shared entangled state between Alice and Bob (B19) under partial transposition over mode b_1. The resultant state after the partial transpose is written as

$$\rho^{\text{P.T.}}_{a_1,b_1} = \frac{1}{2}\left[\left|01\right\rangle_{a_1b_1}\left\langle 01\right| + \left|10\right\rangle_{a_1b_1}\left\langle 10\right| \right. \\ \left. + h\left(g\left|00\right\rangle_{a_1b_1}\left\langle 11\right| + g^{*}\left|11\right\rangle_{a_1b_1}\left\langle 00\right|\right)\right], \tag{D1}$$

where $h = e^{-4(1-T\eta_h)\alpha^2}$ and $g = e^{-4\mathrm{i}\sqrt{T\eta_h}\alpha p}$. This leads to the eigenvalues of $\rho^{\text{P.T.}}_{a_1,b_1}$ as $\lambda_1 = \lambda_2 = \frac{1}{2}$, $\lambda_3 = \frac{h}{2}$ and $\lambda_4 = -\frac{h}{2}$. As a consequence, the logarithmic negativity of $\rho_{a_1b_1}$ is given as

$$E_N\left(\rho_{a_1b_1}\right) = \log_2\left(\sum_{k=1}^{4}\left|\lambda_k\right|\right) = \log_2\left(1+h\right). \tag{D2}$$

However, it should be noted that the final state, $\rho_{a_1b_1}$, is only produced with a probability P_0. Consequently, the entanglement between the parties is effectively given as $E_n\left(\rho_{a_1b_1}\right) = P_0\log_2\left(1+h\right)$. The reason for multiplying with the probability P_0 is because it determines the rate of generation of the resultant entangled state. As an example consider $\alpha = 0$, the HE state (A1) is effectively a separable state and therefore cannot yield any correlations after swapping. This behavior is captured by the fact that the final entangled state is produced with probability 0. However, if we only look at the state $\rho_{a_1b_1}$, we find that it is maximally entangled with logarithmic negativity equal to 1. Therefore, it is necessary to include the rate of production in the analysis of entanglement of the final state.

Appendix E: Analysis of secure key rate

In this section we first provide a description of the optimal strategy of an eavesdropper Eve, namely an entangling cloner attack. Next, provide a detailed analysis of the secure key rate under this strategy by Eve.

1. Evaluating the secured key rate

In order to evaluate the secure key rate, we assume the existence of an eavesdropper Eve with system E. We assume that Eve can potentially collaborate with the untrusted party Charlie while also having access to the two quantum channels which are used to transmit the CV systems. We also consider that Eve can perfrom an entangling cloner attack on each of two the quantum channels [48, 69, 70]. However, the most general attack strategy with Eve is a two-mode correlated attack (one mode for each quantum channel). Since, Alice and Bob use a CV system for transmission purposes, the aforementioned attacks have been shown to be the optimal choices in such a case. Moreover, since the quantum channels are assumed to be non-interacting and spatially well separated, the two-mode correlated attack reduces to two independent single-mode entangling cloner attacks.

Specifically, a single mode entangling cloner attack assumes that Eve can split the incoming CV states in both the channels independently using a BS with transmittance T which equal to the loss of the Alice-Charlie and Bob-Charlie channels (assuming that the loss in both the channels is same). The two input modes for this BS correspond to the quantum state being transmitted and a vacuum state (or a thermal state if we consider thermal noise in the channels). Eve, then stores the reflected states in a quantum memory while the transmitted states are sent to Charlie via identity channels having no loss. Subsequently, Eve can then perform a joint measurement on the two retained states (corresponding to Alice-Charlie and Bob-Charlie channels) which are stored in a quantum memory and try to guess the key of Alice or Bob based on the outcomes observed. However, Alice and Bob can estimate the transmission losses of their respective channels given by T. As a consequence, the maximum information that can obtained by Eve becomes a function of the channel loss parameter T and the publicly declared results by Charlie which in turn is bounded by the Holevo bound $\chi(A:E)$ [48, 70].

Since, Alice and Bob share the state $\rho_{a_1b_1}$ with probability for a detailed derivation) P_0, the secure key rate r between Alice and Bob is then given as

$$r \geq P_0\left[I(A:B) - \chi(A:E)\right] \ \ \text{s.t.} \ \ \mathrm{P}_0 = \frac{\left(1-\mathrm{e}^{-\eta_o \mathrm{T}\alpha^2}\right)^2}{2}. \tag{E1}$$

Evaluating the mutual information between Alice and Bob is relatively simple and is accomplished by using their observed joint statistics. If Alice and Bob perform a measurement corresponding to observables A and B, the mutual information between the two parties sharing a state ρ_{ab} is given as $I(A:B) = H(A)+H(B)-H(A,B)$, where $H(A)$ (and $H(B)$) is the Shannon entropy corresponding to the observable A (and B) measured on the state $\rho_a = \mathrm{tr}_b\left(\rho_{ab}\right)$ and, $H(A,B)$ is the Shannon entropy of the observables jointly measured on the state ρ_{ab}.

2. Calculation of $I(A:B)$ and $\chi(A:E)$

In order to evaluate the mutual information we first look at the final state that is shared between Alice and Bob which is given as

$$\begin{aligned}\rho_{a_1b_1} = \frac{1}{2}\Big[&\left|01\right\rangle_{a_1b_1}\left\langle 01\right| + \left|10\right\rangle_{a_1b_1}\left\langle 10\right| \\ &+h\left(g\left|01\right\rangle_{a_1b_1}\left\langle 10\right| + g^*\left|10\right\rangle_{a_1b_1}\left\langle 01\right|\right)\Big], \end{aligned} \tag{E2}$$

where $h = e^{-4(1-T\eta_h)\alpha^2}$ and $g = e^{-4\mathrm{i}\sqrt{T\eta_h}\alpha p}$ with the reduced states of Alice and Bob as

$$\rho_{a_1} = \rho_{b_1} = \frac{1}{2}\left(\left|0\right\rangle\left\langle 0\right| + \left|1\right\rangle\left\langle 1\right|\right). \tag{E3}$$

In the QKD protocol we consider that both Alice and Bob choose the observable $M = \sigma_Z$ to generate a key. The corresponding projective measurement can then be written as $\{\Pi_0, \Pi_1\}$, where $\Pi_0 = \left|0\right\rangle\left\langle 0\right|$ and $\Pi_1 = \mathbb{1} - \Pi_0 = \left|1\right\rangle\left\langle 1\right|$. We also consider that the photon number detectors are imperfect having efficiency η_d. A general m-photon detector with efficiency η_d is described by the measurement operators

$$\Pi_m(\eta_d) = \eta_d^m \sum_k (1-\eta_d)^k \left|k+m\right\rangle\left\langle k+m\right|. \tag{E4}$$

In view of the fact that in our scheme we have only two outcomes (corresponding to Π_0 and $\mathbb{1}-\Pi_0$), an imperfect measurement of σ_Z then corresponds to measurement operators

$$\Pi_0(\eta_d) = \left|0\right\rangle\left\langle 0\right| + (1-\eta_d)\left|1\right\rangle\left\langle 1\right|, \tag{E5a}$$

$$\Pi_1(\eta_d) = \mathbb{1} - \Pi_0 = \eta_d\left|1\right\rangle\left\langle 1\right|. \tag{E5b}$$

We first consider the imperfect measurement of σ_Z on Alice's reduced state ρ_{a_1}. The outcome $\Pi_0(\eta_d)$ occurs with probability $p_0 = \frac{1}{2}\left[1 + (1-\eta_d)\right] = \frac{2-\eta_d}{2}$ while the outcome $\Pi_1(\eta_d)$ occurs with probability $p_1 = 1 - p_0 = \frac{\eta_d}{2}$. As a consequence, the Shannon entropy of imperfectly measuring σ_Z on Alice's reduced state is given as

$$\begin{aligned} H(\sigma_3) &= -p_0\log_2 p_0 - p_1\log_2 p_1 \\ &= -\left(\frac{2-\eta_d}{2}\right)\log_2\left(\frac{2-\eta_d}{2}\right) - \frac{\eta_d}{2}\log_2\frac{\eta_d}{2}. \\ &= 1 - \frac{2-\eta_d}{2}\log_2(2-\eta_d) - \frac{\eta_d}{2}\log_2\eta_d \end{aligned} \tag{E6}$$

Similarly, it can be seen that the same expression also holds true for the imperfect measurement of σ_Z on Bob's reduced state. The measurement operators corresponding to the case when Alice and Bob jointly (and imperfectly) measure σ_Z on their respective reduced states are

$$\begin{aligned}\Pi_{00}(\eta_d) = {}&\left|00\right\rangle\left\langle 00\right| + (1-\eta_d)^2\left|11\right\rangle\left\langle 11\right| + (1-\eta_d)\left|01\right\rangle\left\langle 01\right| \\ &+ (1-\eta_d)\left|10\right\rangle\left\langle 10\right|, \end{aligned} \tag{E7a}$$

$$\Pi_{01}(\eta_d) = \eta_d\left|01\right\rangle\left\langle 01\right| + \eta_d(1-\eta_d)\left|11\right\rangle\left\langle 11\right|, \tag{E7b}$$

$$\Pi_{10}(\eta_d) = \eta_d\left|10\right\rangle\left\langle 10\right| + \eta_d(1-\eta_d)\left|11\right\rangle\left\langle 11\right|, \tag{E7c}$$

$$\Pi_{11}(\eta_d) = \eta_d^2\left|11\right\rangle\left\langle 11\right|, \tag{E7d}$$

which occur with probabilities $p_{00} = 1-\eta_d$, $p_{01} = \frac{\eta_d}{2}$, $p_{10} = \frac{\eta_d}{2}$, and $p_{11} = 0$, respectively. As a consequence, the Shannon entropy for the joint measurement becomes

$$\begin{aligned} H(\sigma_Z,\sigma_Z) &= -p_{00}\log_2 p_{00} - p_{01}\log_2 p_{01} - p_{10}\log_2 p_{10} - p_{11}\log_2 p_{11} \\ &= -(1-\eta_d)\log_2(1-\eta_d) - \eta_d\log_2\frac{\eta_d}{2} = \eta_d - (1-\eta_d)\log_2(1-\eta_d) - \eta_d\log_2\eta_d. \end{aligned} \tag{E8}$$

The mutual information between Alice and Bob cab then be written as

$$\begin{aligned} I(A:B) &= H(\sigma_Z) + H(\sigma_Z) - H(\sigma_Z,\sigma_Z) \\ &= (2-\eta_d) - \left[(2-\eta_d)\log_2(2-\eta_d) - (1-\eta_d)\log_2(1-\eta_d)\right]. \end{aligned} \tag{E9}$$

Evidently, in absence of any imperfection ($\eta_d = 1$) one obtains perfect correlation, i.e, $\lim_{\eta_d\to 1} I(A:B) = 1$. Next, we evaluate the Holevo bound $\chi(A:E)$.

In order to evaluate the Holevo bound, we assume that Eve has access to a purification of the state $\rho_{a_1b_1}$, which we denote by $\rho_{a_1b_1E}$, such that $\rho_e = \mathrm{tr}_{a_1b_1}(\rho_{a_1b_1e})$ is the reduced state of Eve. Moreover, we also assume that Alice's measurement outcomes are represented by rank-1 operators. Since $\rho_{a_1b_1e}$ is pure by definition, we have $S(\rho_{a_1b_1}) = S(\rho_e)$, where $S(X)$ is the Von Neumann entropy of a system X. Moreover, if Alice's measurement outcomes are represented by rank-1 operators, then the reduced state of Bob and Eve conditioned on Alice's outcome x, given by $\rho_{b_1e|x}$, is also pure. Therefore, by definition of Von Neumann entropy, we have $S(\rho_{e|x}) = S(\rho_{b_1|x})$, where $\rho_{b_1|x}$ is the reduced state of Bob conditioned on Alice's outcome x. In this case, the Holevo bound can then be written as [49]

$$\chi(A:E) = S(\rho_{a_1b_1}) - \sum_x p_x S\left(\rho_{b_1|x}\right). \tag{E10}$$

For the state $\rho_{a_1b_1}$ as given in Eq. (E2), its eigenvalues are given as $\lambda_\pm = \frac{1\pm h}{2}$ leading to the von-Neumann entropy as

$$\begin{aligned} S(\rho_{a_1b_1}) &= -\lambda_+ \log_2 \lambda_+ - \lambda_- \log_2 \lambda_- \\ &= -\left(\frac{1+h}{2}\right)\log_2\left(\frac{1+h}{2}\right) - \left(\frac{1-h}{2}\right)\log_2\left(\frac{1-h}{2}\right) \\ &= 1 - \frac{1}{2}\left[(1+h)\log_2(1+h) + (1-h)\log_2(1-h)\right]. \end{aligned} \tag{E11}$$

On the other hand, the reduced states of Bob corresponding to the two outcomes of the imperfect measurement of σ_Z by Alice are given as

$$\begin{aligned} \rho_{b_1|0} &= \frac{\mathrm{tr}_{a_1}\left[\rho_{a_1b_1}\Pi_0(\eta_d)\right]}{\mathrm{tr}\left[\rho_{a_1b_1}\Pi_0(\eta_d)\right]} \\ &= \frac{1}{2-\eta_d}\left(|1\rangle\langle 1| + (1-\eta_d)|0\rangle\langle 0|\right), \end{aligned} \tag{E12a}$$

$$\rho_{b_1|1} = \frac{\mathrm{tr}_{a_1}\left[\rho_{a_1b_1}\Pi_1(\eta_d)\right]}{\mathrm{tr}\left[\rho_{a_1b_1}\Pi_1(\eta_d)\right]} = |1\rangle\langle 1|, \tag{E12b}$$

that lead to

$$\begin{aligned} \sum_{x=0}^{1} p_x S\left(\rho_{b_1|x}\right) &= \frac{2-\eta_d}{2}\left[-\left(\frac{1}{2-\eta_d}\right)\log_2\left(\frac{1}{2-\eta_d}\right)\right. \\ &\left. - \left(\frac{1-\eta_d}{2-\eta_d}\right)\log_2\left(\frac{1-\eta_d}{2-\eta_d}\right)\right] \\ &= \frac{1}{2}\left[(2-\eta_d)\log_2(2-\eta_d) - (1-\eta_d)\log_2(1-\eta_d)\right]. \end{aligned} \tag{E13}$$

As a consequence, the Holevo bound can be written as

$$\begin{aligned} \chi(A:E) &= S(\rho_{a_1b_1}) - \sum_x p_x S\left(\rho_{b_1|x}\right) \\ &= 1 - \frac{1}{2}\left[(1+h)\log_2(1+h) + (1-h)\log_2(1-h)\right] \\ &- \frac{1}{2}\left[(2-\eta_d)\log_2(2-\eta_d) - (1-\eta_d)\log_2(1-\eta_d)\right]. \end{aligned} \tag{E14}$$

By plugging the mutual information given in Eq. (E9) and the Holevo bound, given in Eq. (E14), in the secure key rate, given by Eq. (E1), we obtain

$$\begin{aligned} r &\geq p_0\left[I(A:B) - \chi(A:E)\right] \\ &= p_0\left\{1 - \eta_d + \frac{1}{2}\left[(1+h)\log_2(1+h) + (1-h)\log_2(1-h)\right]\right. \\ &\left. - \frac{1}{2}\left[(2-\eta_d)\log_2(2-\eta_d) - (1-\eta_d)\log_2(1-\eta_d)\right]\right\}. \end{aligned} \tag{E15}$$

Appendix F: Fidelity between the HE states passed through loss-only and lossy+noise channels

In this section, we analyze the impact of thermal noise present in the quantum channel between Alice (Bob) and Charlie. We show that the final state after a loss-only channel is almost equivalent to the final state after passing through a channel characterized by loss and thermal noise. Using this result, we aim to reduce the complexity of the calculation by only focusing on loss-only quantum channels connecting all the parties.

1. General state after channel transmission

Let us consider that an incoming signal passes through a lossy channel having transmittance T with additional thermal noise. Mathematically, the channel transmission can be written as $U_{\mathrm{ch}} : \rho_{\mathrm{s,in}} \to \rho_{\mathrm{s,out}}$, where $\rho_{\mathrm{s,in}}$ ($\rho_{\mathrm{s,in}}$) is input (output) state of the channel. Such transmission can be modeled as follows. First, the incoming state (in mode a) is mixed with an ancilla initialized in a thermal state (in mode b) via a beam splitter (BS) with transmittance T and two output modes. Subsequently, output of the quantum channel is obtained by tracing out the outgoing ancilla mode of the BS.

The action of a BS with transmittance T is described in terms of a unitary operation U_T^{ab} on the input modes a and b that leads to the transformation matrix between the input and the output modes, labelled by a' and b', as

$$\begin{pmatrix} \hat{a} \\ \hat{b} \end{pmatrix} \to \begin{pmatrix} \hat{a}' \\ \hat{b}' \end{pmatrix} = \begin{pmatrix} \sqrt{T} & \sqrt{1-T} \\ -\sqrt{1-T} & \sqrt{T} \end{pmatrix}\begin{pmatrix} \hat{a} \\ \hat{b} \end{pmatrix}, \tag{F1}$$

where $\hat{a}$ corresponds to the annihilation operator for the mode a and $T = 0.5$ represents a balanced (50 : 50) BS. As a consequence, the action of the channel on a coherent state ($|\alpha\rangle$) in mode a is described as $U_T^{ab}|\alpha\rangle_a \otimes |\beta\rangle_b \to |\alpha\rangle_{a'} \otimes |\beta\rangle_{b'} = \left|\sqrt{T}\alpha + \sqrt{1-T}\beta\right\rangle_a \otimes \left|\sqrt{T}\beta - \sqrt{1-T}\alpha\right\rangle_b = \left|\sqrt{T}\alpha + \sqrt{1-T}\beta, \sqrt{T}\beta - \sqrt{1-T}\alpha\right\rangle_{ab}$.

Let us consider that, in the coherent state basis, the incoming signal is in the quantum state given by $\rho_{\mathrm{s,in}} = \int \frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}C(\alpha,\beta)|\alpha\rangle_a\langle\beta|$ while the ancilla thermal state described as $\rho_{\mathrm{anc,th}} = (1-x)\sum_k x^k |k\rangle_b\langle k| = (1-x)\int\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}e^{-\frac{|\eta|^2+|\zeta|^2}{2}+x\eta^*\zeta}|\eta\rangle_b\langle\zeta|$, where $x = \frac{\bar{n}}{1+\bar{n}}$ such that $\bar{n}$ is the average number of thermal photon. In view of the action of a BS on the coherent states, one can easily show that

$$\begin{aligned}
\rho_{\text{out}} &= U_T^{ab}\rho_{\text{s,in}} \otimes \rho_{\text{anc,th}} \left(U_T^{ab}\right)^\dagger \\
&= (1-x)\int \frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}C(\alpha,\beta)e^{-\frac{|\eta|^2+|\zeta|^2}{2}+x\eta^*\zeta}\left[U_T^{ab}\left|\alpha,\eta\right\rangle_{ab}\left\langle\beta,\zeta\right|\left(U_T^{ab}\right)^\dagger\right] \\
&= (1-x)\int \frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}C(\alpha,\beta)e^{-\frac{|\eta|^2+|\zeta|^2}{2}+x\eta^*\zeta}\left|\sqrt{T}\alpha+\sqrt{1-T}\eta,\sqrt{T}\eta-\sqrt{1-T}\alpha\right\rangle \\
&\quad \otimes\left\langle\sqrt{T}\beta+\sqrt{1-T}\zeta,\sqrt{T}\zeta-\sqrt{1-T}\beta\right|. \qquad \text{(F2)}
\end{aligned}$$

Consequently, the channel output signal state becomes

$$\begin{aligned}
&U_{\text{ch}}:\rho_{\text{s,in}}\to\rho_{\text{s,out}}=\text{Tr}_{\text{anc}}\left(\rho_{\text{out}}\right) \\
&= (1-x)\int \frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}C(\alpha,\beta)e^{-\frac{|\eta|^2+|\zeta|^2}{2}+x\eta^*\zeta}\left|\sqrt{T}\alpha+\sqrt{1-T}\eta\right\rangle_a\left\langle\sqrt{T}\beta+\sqrt{1-T}\zeta\right| \\
&\quad\times\left\langle\sqrt{T}\zeta-\sqrt{1-T}\beta\middle|\sqrt{T}\eta-\sqrt{1-T}\alpha\right\rangle \\
&= (1-x)\int \frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}C(\alpha,\beta)e^{-\frac{1-T}{2}\left(|\alpha|^2+|\beta|^2\right)+(1-T)\alpha\beta^*}e^{-\frac{1+T}{2}\left(|\eta|^2+|\zeta|^2\right)+x\eta^*\zeta+T\eta\zeta^*} \\
&\quad\times e^{\sqrt{T(1-T)}\left[\frac{\alpha^*\eta+\alpha\eta^*}{2}+\frac{\beta^*\zeta+\beta\zeta^*}{2}-(\beta^*\eta+\alpha\zeta^*)\right]}\left|\sqrt{T}\alpha+\sqrt{1-T}\eta\right\rangle_a\left\langle\sqrt{T}\beta+\sqrt{1-T}\zeta\right| \\
&= (1-x)\int \frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}C(\alpha,\beta)e^{-\frac{1-T}{2}\left(|\alpha|^2+|\beta|^2\right)+(1-T)\alpha\beta^*}e^{-\frac{1+T}{2}\left(|\eta|^2+|\zeta|^2\right)+x\eta^*\zeta+T\eta\zeta^*} \\
&\quad\times e^{\sqrt{T(1-T)}\left[\frac{\alpha^*\eta+\alpha\eta^*}{2}+\frac{\beta^*\zeta+\beta\zeta^*}{2}-(\beta^*\eta+\alpha\zeta^*)\right]}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}\left|\lambda\right\rangle\left\langle\omega\right|\left\langle\lambda\middle|\sqrt{T}\alpha+\sqrt{1-T}\eta\right\rangle\left\langle\sqrt{T}\beta+\sqrt{1-T}\zeta\middle|\omega\right\rangle \\
&= (1-x)\int \frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}C(\alpha,\beta)e^{-\frac{1-T}{2}\left(|\alpha|^2+|\beta|^2\right)+(1-T)\alpha\beta^*}e^{-\frac{1+T}{2}\left(|\eta|^2+|\zeta|^2\right)+x\eta^*\zeta+T\eta\zeta^*} \\
&\quad\times e^{\sqrt{T(1-T)}\left[\frac{\alpha^*\eta+\alpha\eta^*}{2}+\frac{\beta^*\zeta+\beta\zeta^*}{2}-(\beta^*\eta+\alpha\zeta^*)\right]}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}\left|\lambda\right\rangle\left\langle\omega\right|e^{-\frac{|\lambda|^2+|\sqrt{T}\alpha+\sqrt{1-T}\eta|^2}{2}+\lambda^*\left(\sqrt{T}\alpha+\sqrt{1-T}\eta\right)} \\
&\quad\times e^{-\frac{|\omega|^2+|\sqrt{T}\beta+\sqrt{1-T}\zeta|^2}{2}+\left(\sqrt{T}\beta^*+\sqrt{1-T}\zeta^*\right)\omega} \\
&= (1-x)\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}}\left|\lambda\right\rangle\left\langle\omega\right|\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}C(\alpha,\beta)e^{-\frac{|\alpha|^2+|\beta|^2}{2}+(1-T)\alpha\beta^*+\sqrt{T}(\lambda^*\alpha+\omega\beta^*)} \\
&\quad\times\int\frac{d^2\eta}{\pi}\frac{d^2\zeta}{\pi}e^{-\left(|\eta|^2+|\zeta|^2\right)+x\eta^*\zeta+T\eta\zeta^*}e^{-\sqrt{T(1-T)}(\beta^*\eta+\alpha\zeta^*)+\sqrt{1-T}(\lambda^*\eta+\omega\zeta^*)} \\
&= \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\left|\lambda\right\rangle\left\langle\omega\right|\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}C(\alpha,\beta)e^{-\frac{|\alpha|^2+|\beta|^2}{2}+\frac{1-T}{1-Tx}\alpha\beta^*+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\beta^*)}. \qquad \text{(F3)}
\end{aligned}$$

In the case of a loss-only channel, i.e., in absence of additional thermal noise ($x=0$), Eq. (F3) reduces to

$$\begin{aligned}
&\lim_{x\to0}U_{\text{ch}}:\rho_{\text{s,in}}\to\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}C(\alpha,\beta)e^{-\frac{1-T}{2}\left(|\alpha|^2+|\beta|^2\right)+(1-T)\alpha\beta^*}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2+T\left(|\alpha|^2+|\beta|^2\right)}{2}+\sqrt{T}(\lambda^*\alpha+\omega\beta^*)}\left|\lambda\right\rangle\left\langle\omega\right| \\
&=\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}C(\alpha,\beta)e^{-\frac{1-T}{2}\left(|\alpha|^2+|\beta|^2\right)+(1-T)\alpha\beta^*}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}\left|\lambda\right\rangle\left\langle\lambda\middle|\sqrt{T}\alpha\right\rangle\left\langle\sqrt{T}\beta\middle|\right\rangle\omega\left\langle\omega\right| \\
&=\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}C(\alpha,\beta)e^{-\frac{1-T}{2}\left(|\alpha|^2+|\beta|^2\right)+(1-T)\alpha\beta^*}\left|\sqrt{T}\alpha\right\rangle\left\langle\sqrt{T}\beta\right|. \qquad \text{(F4)}
\end{aligned}$$

2. Hybrid state after channel transmission

In our protocol, each party transmits a coherent state through a quantum channel which may have transmission loss as well as thermal noise. In the following, we evaluate all possible terms that may arise when the parties transmit the continuous variable part through the aforementioned channel. In such a case, Eq. (F3) leads to

$$\begin{aligned} U_{\mathrm{ch}}: |\gamma\rangle\langle\gamma| \rightarrow & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\delta^2\left(\beta-\gamma\right)\delta^2\left(\alpha-\gamma\right) \\ & \times e^{-\frac{|\alpha|^2+|\beta|^2}{2}+\frac{1-T}{1-Tx}\alpha\beta^*+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\beta^*)} \\ = & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\times e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\gamma+\omega\gamma^*)} \\ = & e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2}\frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\gamma+\omega\gamma^*)}\,|\lambda\rangle\langle\omega|\,, \end{aligned} \tag{F5}$$

$$\begin{aligned} U_{\mathrm{ch}}: |\gamma\rangle\langle-\gamma| \rightarrow & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\delta^2\left(\beta+\gamma\right)\delta^2\left(\alpha-\gamma\right) \\ & \times e^{-\frac{|\alpha|^2+|\beta|^2}{2}+\frac{1-T}{1-Tx}\alpha\beta^*+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\beta^*)} \\ = & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\times e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\gamma-\omega\gamma^*)} \\ = & e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2}\frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\gamma-\omega\gamma^*)}\,|\lambda\rangle\langle\omega|\,, \end{aligned} \tag{F6}$$

$$\begin{aligned} U_{\mathrm{ch}}: |-\gamma\rangle\langle\gamma| \rightarrow & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\delta^2\left(\beta-\gamma\right)\delta^2\left(\alpha+\gamma\right) \\ & \times e^{-\frac{|\alpha|^2+|\beta|^2}{2}+\frac{1-T}{1-Tx}\alpha\beta^*+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\beta^*)} \\ = & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\times e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2+\frac{\sqrt{T}(1-x)}{1-Tx}(-\lambda^*\gamma+\omega\gamma^*)} \\ = & e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2}\frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega-\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\gamma-\omega\gamma^*)}\,|\lambda\rangle\langle\omega|\,, \end{aligned} \tag{F7}$$

$$\begin{aligned} U_{\mathrm{ch}}: |-\gamma\rangle\langle-\gamma| \rightarrow & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\int\frac{d^2\alpha}{\pi}\frac{d^2\beta}{\pi}\delta^2\left(\beta+\gamma\right)\delta^2\left(\alpha+\gamma\right) \\ & \times e^{-\frac{|\alpha|^2+|\beta|^2}{2}+\frac{1-T}{1-Tx}\alpha\beta^*+\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\beta^*)} \\ = & \frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\times e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2-\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\gamma+\omega\gamma^*)} \\ = & e^{-\frac{T(1-x)}{1-Tx}|\gamma|^2}\frac{1-x}{1-Tx}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega-\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\gamma+\omega\gamma^*)}\,|\lambda\rangle\langle\omega|\,. \end{aligned} \tag{F8}$$

A hybrid-entangled (HE) state (A7) defined as

$$|\psi\rangle_{\mathrm{he}} = \frac{1}{\sqrt{2}}\left(|0,\alpha\rangle + |1,-\alpha\rangle\right), \tag{F9}$$

for which the multiphoton coherent state part is transmitted through a general (both lossy and noisy) channel. Using the results obtained above it can be seen that, after the transmission, the final state is

$$\begin{aligned}\rho^{\mathrm{ch,he}}(T,x) &= U_{\mathrm{ch}} : \rho_{\mathrm{he}} = U_{\mathrm{ch}} : \frac{1}{2}\left(|0\rangle\langle 0| \otimes |\alpha\rangle\langle\alpha| + |0\rangle\langle 1| \otimes |\alpha\rangle\langle -\alpha| + |1\rangle\langle 0| -\alpha\rangle\langle\alpha| + |1\rangle\langle 1| \otimes |-\alpha\rangle\langle -\alpha|\right)\\ &= \frac{e^{-\frac{T(1-x)}{1-Tx}|\alpha|^2}}{2}\frac{1-x}{1-Tx}\int \frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi} e^{-\frac{|\lambda|^2+|\omega|^2}{2}+\frac{x(1-T)}{1-Tx}\lambda^*\omega}\,|\lambda\rangle\langle\omega|\\ &\otimes\left[e^{\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\alpha^*)}\,|0\rangle\langle 0| + e^{\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha-\omega\alpha^*)}\,|0\rangle\langle 1| + e^{-\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha-\omega\alpha^*)}\,|1\rangle\langle 0| + e^{-\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\alpha^*)}\,|1\rangle\langle 1|\right].\end{aligned}\tag{F10}$$

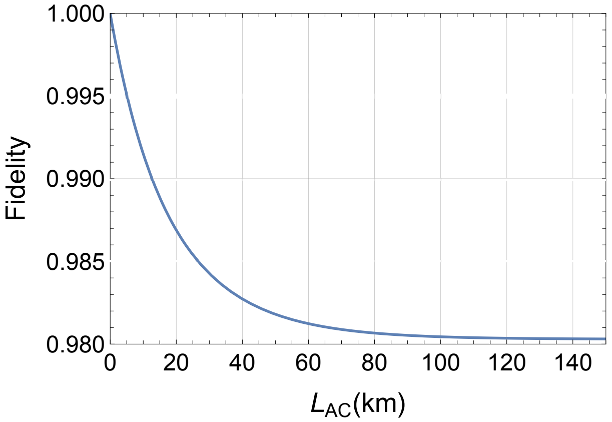

FIG. 7. Dependence of fidelity between the states obtained from initial HE state after transmission through loss-only and both loss+noise channels.

3. HE-state at Charlie's end after transmission through loss-only channel and a general channel

Let us consider that Alice and Bob prepare their individual HE states $|\psi\rangle_{a_1a_2}$ and $|\psi\rangle_{b_1b_2}$ as

$$|\psi\rangle_{a_1a_2} = \frac{1}{\sqrt{2}}\left(|0,\alpha\rangle_{a_1a_2} + |1,-\alpha\rangle_{a_1a_2}\right) \tag{F11a}$$

$$|\psi\rangle_{b_1b_2} = \frac{1}{\sqrt{2}}\left(|0,\alpha\rangle_{b_1b_2} + |1,-\alpha\rangle_{b_1b_2}\right), \tag{F11b}$$

where $|0,\alpha\rangle_{a_1a_2} = |0\rangle_{a_1}|\alpha\rangle_{a_2}$. Using Eq. (F10) one can show that total 4-mode state at the input of Charlie after passing through a general channel is given by

$$\begin{aligned}
&\rho_{\text{in,tot}}(T,x)=\rho^{\text{ch}}_{a_1a_2}\otimes\rho^{\text{ch}}_{b_1b_2}\\
&=\frac{e^{-\frac{2T(1-x)}{1-Tx}|\alpha|^2}}{4}\left(\frac{1-x}{1-Tx}\right)^2\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}\frac{d^2\chi}{\pi}\frac{d^2\xi}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2+|\chi|^2+|\xi|^2}{2}+\frac{x(1-T)}{1-Tx}(\lambda^*\omega+\chi^*\xi)}\left|\lambda\right\rangle_{a_2}\left\langle\omega\right|\otimes\left|\chi\right\rangle_{b_2}\left\langle\xi\right|\\
&\otimes\left[e^{\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\alpha^*)}\left|0\right\rangle_{a_1}\left\langle0\right|+e^{\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha-\omega\alpha^*)}\left|0\right\rangle_{a_1}\left\langle1\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha-\omega\alpha^*)}\left|1\right\rangle_{a_1}\left\langle0\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}(\lambda^*\alpha+\omega\alpha^*)}\left|1\right\rangle_{a_1}\left\langle1\right|\right]\\
&\otimes\left[e^{\frac{\sqrt{T}(1-x)}{1-Tx}(\chi^*\alpha+\xi\alpha^*)}\left|0\right\rangle_{b_1}\left\langle0\right|+e^{\frac{\sqrt{T}(1-x)}{1-Tx}(\chi^*\alpha-\xi\alpha^*)}\left|0\right\rangle_{b_1}\left\langle1\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}(\chi^*\alpha-\xi\alpha^*)}\left|1\right\rangle_{b_1}\left\langle0\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}(\chi^*\alpha+\xi\alpha^*)}\left|1\right\rangle_{b_1}\left\langle1\right|\right]\\
&=\frac{e^{-\frac{2T(1-x)}{1-Tx}|\alpha|^2}}{4}\left(\frac{1-x}{1-Tx}\right)^2\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}\frac{d^2\chi}{\pi}\frac{d^2\xi}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2+|\chi|^2+|\xi|^2}{2}+\frac{x(1-T)}{1-Tx}(\lambda^*\omega+\chi^*\xi)}\left|\lambda,\chi\right\rangle_{a_2b_2}\left\langle\omega,\xi\right|\\
&\otimes\Bigg[\Bigg(e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle0,0\right|+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle0,1\right|\\
&+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle0,0\right|+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle0,1\right|\Bigg)\\
&+\Bigg(e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle1,1\right|\\
&+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle1,1\right|\Bigg)\\
&+\Bigg(e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle0,0\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle0,1\right|\\
&+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle0,0\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle0,1\right|\Bigg)\\
&+\Bigg(e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*-\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle1,1\right|\\
&+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda^*+\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle1,1\right|\Bigg)\Bigg].
\end{aligned}\tag{F12}$$

It should be noted, in absence of the additional thermal noise ($x\to0$) the transmission channel simply becomes simply a loss-only channel and the state at the input of Charlie (after transmission) can be written as

$$\begin{aligned}
&\rho_{\text{in,tot}}(T)=\lim_{x\to0}\rho_{\text{in,tot}}(T,x)\\
&=\frac{e^{-2T|\alpha|^2}}{4}\int\frac{d^2\lambda}{\pi}\frac{d^2\omega}{\pi}\frac{d^2\chi}{\pi}\frac{d^2\xi}{\pi}e^{-\frac{|\lambda|^2+|\omega|^2+|\chi|^2+|\xi|^2}{2}}\left|\lambda,\chi\right\rangle_{a_2b_2}\left\langle\omega,\xi\right|\\
&\otimes\Bigg[\Bigg(e^{\sqrt{T}[(\lambda^*+\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle0,0\right|+e^{\sqrt{T}[(\lambda^*+\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle0,1\right|+e^{\sqrt{T}[(\lambda^*-\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle0,0\right|\\
&+e^{\sqrt{T}[(\lambda^*-\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle0,1\right|\Bigg)+\Bigg(e^{\sqrt{T}[(\lambda^*+\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{\sqrt{T}[(\lambda^*+\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|0,0\right\rangle_{a_1b_1}\left\langle1,1\right|\\
&+e^{\sqrt{T}[(\lambda^*-\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{\sqrt{T}[(\lambda^*-\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|0,1\right\rangle_{a_1b_1}\left\langle1,1\right|\Bigg)\\
&+\Bigg(e^{-\sqrt{T}[(\lambda^*-\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle0,0\right|+e^{-\sqrt{T}[(\lambda^*-\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle0,1\right|+e^{-\sqrt{T}[(\lambda^*+\chi^*)\alpha-(\omega+\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle0,0\right|\\
&+e^{-\sqrt{T}[(\lambda^*+\chi^*)\alpha-(\omega-\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle0,1\right|\Bigg)+\Bigg(e^{-\sqrt{T}[(\lambda^*-\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{-\sqrt{T}[(\lambda^*-\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|1,0\right\rangle_{a_1b_1}\left\langle1,1\right|\\
&+e^{-\sqrt{T}[(\lambda^*+\chi^*)\alpha+(\omega-\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle1,0\right|+e^{-\sqrt{T}[(\lambda^*+\chi^*)\alpha+(\omega+\xi)\alpha^*]}\left|1,1\right\rangle_{a_1b_1}\left\langle1,1\right|\Bigg)\Bigg].
\end{aligned}\tag{F13}$$

4. Fidelity between HE-states at Charlie's end after transmission through loss-only channel and a general channel

In this subsection we evaluate how different the state given in Eq. (F12) is from the one given in Eq. (F13) for a given loss and thermal noise. In order to estimate it we evaluate the fidelity between the states given by Eq. (F12) and Eq. (F13) as

$$
\begin{aligned}
F &= \mathrm{tr}\left[\rho_{\mathrm{in,tot}}(\mathrm{T})\rho_{\mathrm{in,tot}}(\mathrm{T,x})\right]\\
&= \frac{e^{-2T\frac{2-x(1+T)}{1-Tx}|\alpha|^2}}{16}\left(\frac{1-x}{1-Tx}\right)^2\int\frac{d^2\Lambda_i}{\pi^8}e^{-\left(|\lambda_1|^2+|\omega_1|^2+|\chi_1|^2+|\xi_1|^2+|\lambda_2|^2+|\omega_2|^2+|\chi_2|^2+|\xi_2|^2\right)+(\omega_2^*\lambda_1+\xi_2^*\chi_1+\omega_1^*\lambda_2+\xi_1^*\chi_2)}\\
&\quad\times\Bigg[\Bigg(e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha+(\omega_1+\xi)\alpha_1^*]+\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha+(\omega_2+\xi_2)\alpha^*]}+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha+(\omega_1-\xi)\alpha_1^*]+\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha+(\omega_2+\xi_2)\alpha^*]}\\
&\quad+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha+(\omega_1+\xi)\alpha_1^*]+\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha+(\omega_2-\xi_2)\alpha^*]}+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha+(\omega_1-\xi)\alpha_1^*]+\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha+(\omega_2-\xi_2)\alpha^*]}\Bigg)\\
&\quad+\Bigg(e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha-(\omega_1-\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha-(\omega_2+\xi_2)\alpha^*]}+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha-(\omega_1+\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha-(\omega_2+\xi_2)\alpha^*]}\\
&\quad+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha-(\omega_1-\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha-(\omega_2-\xi_2)\alpha^*]}+e^{\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha-(\omega_1+\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha-(\omega_2-\xi_2)\alpha^*]}\Bigg)\\
&\quad+\Bigg(e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha-(\omega_1+\xi_1)\alpha^*]+\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha-(\omega_2-\xi_2)\alpha^*]}+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha-(\omega_1-\xi_1)\alpha^*]+\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha-(\omega_2-\xi_2)\alpha^*]}\\
&\quad+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha-(\omega_1+\xi_1)\alpha^*]+\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha-(\omega_2+\xi_2)\alpha^*]}+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha-(\omega_1-\xi_1)\alpha^*]+\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha-(\omega_2+\xi_2)\alpha^*]}\Bigg)\\
&\quad+\Bigg(e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha+(\omega_1-\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha+(\omega_2-\xi_2)\alpha^*]}+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*-\chi_1^*)\alpha+(\omega_1+\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha+(\omega_2-\xi_2)\alpha^*]}\\
&\quad+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha+(\omega_1-\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*-\chi_2^*)\alpha+(\omega_2+\xi_2)\alpha^*]}+e^{-\frac{\sqrt{T}(1-x)}{1-Tx}[(\lambda_1^*+\chi_1^*)\alpha+(\omega_1+\xi_1)\alpha^*]-\sqrt{T}[(\lambda_2^*+\chi_2^*)\alpha+(\omega_2+\xi_2)\alpha^*]}\Bigg)\Bigg],
\end{aligned}
\tag{F14}
$$

where $d^2\Lambda_i = d^2\lambda_i d^2\omega_i d^2\chi_i d^2\xi_i$ $(i = 1, 2)$.

Let us now consider a generic integral as

$$
\begin{aligned}
I_1 &= \frac{e^{-2T\frac{2-x(1+T)}{1-Tx}|\alpha|^2}}{16}\left(\frac{1-x}{1-Tx}\right)^2\int\frac{d^2\Lambda_i}{\pi^8}e^{-\left(|\lambda_1|^2+|\omega_1|^2+|\chi_1|^2+|\xi_1|^2+|\lambda_2|^2+|\omega_2|^2+|\chi_2|^2+|\xi_2|^2\right)+(\omega_2^*\lambda_1+\xi_2^*\chi_1+\omega_1^*\lambda_2+\xi_1^*\chi_2)}\\
&\quad\times e^{[(A_1\lambda_1^*+B_1\chi_1^*)\alpha+(C_1\omega_1+D_1\xi_1)\alpha_1^*]+[(A_2\lambda_2^*+B_2\chi_2^*)\alpha+(C_2\omega_2+D_2\xi_2)\alpha^*]}\\
&= \frac{e^{-2T\frac{2-x(1+T)}{1-Tx}|\alpha|^2}}{16}\left(\frac{1-x}{1-Tx}\right)^2\int\frac{d^2\lambda_1}{\pi}\frac{d^2\omega_1}{\pi}\frac{d^2\chi_1}{\pi}\frac{d^2\xi_1}{\pi}e^{-\left(|\lambda_1|^2+|\omega_1|^2+|\chi_1|^2+|\xi_1|^2\right)+(A_1\lambda_1^*+B_1\chi_1^*)\alpha+(C_1\omega_1+D_1\xi_1)\alpha_1^*}\\
&\quad\times\int\frac{d^2\lambda_2}{\pi}\frac{d^2\omega_2}{\pi}\frac{d^2\chi_2}{\pi}\frac{d^2\xi_2}{\pi}e^{-\left(|\lambda_2|^2+|\omega_2|^2+|\chi_2|^2+|\xi_2|^2\right)+(\omega_2^*\lambda_1+\xi_2^*\chi_1+\omega_1^*\lambda_2+\xi_1^*\chi_2)+(A_2\lambda_2^*+B_2\chi_2^*)\alpha+(C_2\omega_2+D_2\xi_2)\alpha^*}\\
&= \frac{e^{-2T\frac{2-x(1+T)}{1-Tx}|\alpha|^2}}{16}\left(\frac{1-x}{1-Tx}\right)^2\int\frac{d^2\lambda_1}{\pi}\frac{d^2\omega_1}{\pi}\frac{d^2\chi_1}{\pi}\frac{d^2\xi_1}{\pi}e^{-\left(|\lambda_1|^2+|\omega_1|^2+|\chi_1|^2+|\xi_1|^2\right)+(A_1\lambda_1^*+B_1\chi_1^*)\alpha+(C_1\omega_1+D_1\xi_1)\alpha_1^*}\\
&\quad\times e^{(A_2\omega_1^*+B_2\xi_1^*)\alpha+(C_2\lambda_1+D_2\chi_1)\alpha^*}\\
&= \frac{e^{-2T\frac{2-x(1+T)}{1-Tx}|\alpha|^2}}{16}\left(\frac{1-x}{1-Tx}\right)^2 e^{[(A_1C_2+A_2C_1)+(B_1D_2+B_2D_1)]|\alpha|^2}.
\end{aligned}
\tag{F15}
$$

Using the result of the generic integral (F15), from (F14) we get

$$
\begin{aligned}
F &= \frac{e^{-2T\frac{2-x(1+T)}{1-Tx}|\alpha|^2}}{16}\left(\frac{1-x}{1-Tx}\right)^2\times 16e^{4T\frac{(1-x)}{1-Tx}}\\
&= e^{-\frac{2Tx(1-T)}{1-Tx}|\alpha|^2}\left(\frac{1-x}{1-Tx}\right)^2.
\end{aligned}
\tag{F16}
$$

This analysis is important because a fully general calculation, in which we consider the quantum channels to be characterized by transmission loss and thermal noise is far more involved and lengthy to perform than if we only consider the quantum channels to be characterized by transmission loss only. This can be seen from the form of the 4-mode states at Charlie's input before the entanglement-swapping operation. In view of the result represented in Fig. 7, we believe that a consideration of such a general channel may not yield any significantly different result from a loss-only channel at the cost of a very difficult, lengthy and complicated calculation. It may be noted that in the case of a loss-only channel the ancilla thermal state is replaced by a vacuum state. This simplifies the calculation greatly as now we can proceed with a pure state approach in which the total state is a pure state. In this case, it is possible to take a partial trace over the ancilla after Charlie's operations. This simplifies the overall calculation. However, such a simplification is not possible when we consider an ancilla in the thermal state for which the overall state is mixed. This increases the number of terms to be calculated by four times in comparison with the pure state approach.
