Phase shadow: A noise-tolerant path to global quantum property estimation

(Dated: May 13, 2026)

Measuring global quantum properties—such as the fidelity to complex multipartite states—is an essential yet experimentally challenging task. Classical shadow estimation offers favorable sample complexity but typically relies on deep circuits difficult to realize on current platforms. We propose the *robust phase shadow* (RPS), a framework based on random circuits with controlled-Z as the unique entangling gate type, tailored to architectures like trapped ions and neutral atoms. Leveraging tensor diagrammatic reasoning, we show that RPS matches the performance of Clifford-based methods. Importantly, our approach supports a noise-robust extension via classical post-processing, enabling reliable estimation under arbitrary gate-dependent Pauli noise where existing techniques fail. Additionally, we design an efficient post-processing algorithm resolving computational bottlenecks. Our results provide a scalable route for estimating global properties in noisy quantum systems.

The arXiv version is available at <https://arxiv.org/abs/2507.13237>.

Learning the properties of quantum many-body systems is a cornerstone of quantum information science, essential for verification, benchmarking, and variational algorithms [1–4]. Classical shadow estimation [5, 6] has emerged as a paradigm-shifting technique, offering a rigorous bound on sample complexity that bypasses full quantum state tomography. The protocol generally involves evolving the system under a random unitary ensemble and performing computational basis measurements. However, a fundamental tension exists in the choice of this ensemble: while random Pauli measurements are efficient for local observables, estimating global properties—such as fidelities to entangled states—typically requires global Clifford circuits to achieve practical variance bounds. Unfortunately, on *near-term intermediate scale quantum* (NISQ) devices, implementing deep global Clifford unitaries incurs significant overhead. The accumulating gate errors not only degrade the signal but, more critically, destroy the unbiasedness guarantee of the shadow estimator [5, 7–9].

To address this, various strategies have been proposed to mitigate noise or approximate global unitaries with shallow circuits [10–12]. Yet, existing robust protocols often rely on idealized assumptions, such as global depolarizing channels or gate-independent error rates. In realistic experimental settings, noise is highly structured and varies significantly between different gates (gate-dependent noise) [13–15]. When the mitigation model fails to capture these fine-grained details, the resulting estimator retains a residual bias, rendering high-precision verification impossible.

In this work, we first propose the *robust phase shadow* (RPS) schemes. This protocol is built upon a hardware-efficient ensemble generated by random diagonal gates (specifically, layers of controlled-Z gates) and single-qubit Cliffords, utilizing the mathematical structure of graph states [16, 17]. Unlike deep global Cliffords, the RPS circuit structure is shallow

and natively implementable on platforms like superconducting circuits [18], cold atoms, and trapped ions [19, 20] (Fig. 1). By focusing on phase-encoded information, RPS provides a resource-efficient pathway to estimate off-diagonal elements and verify entanglement without full tomography.

Crucially, to bridge the gap between this shallow architecture and realistic hardware imperfections, we extend our framework to *generalized RPS*. While standard methods treat noise as a mean-field average, generalized RPS systematically incorporates arbitrary gate-dependent Pauli noise [21]. We construct a refined estimator that tracks the Heisenberg evolution of Pauli operators through the specific circuit realization. By weighting the estimator with a trajectory-dependent attenuation factor derived from fine-grained calibration data, generalized RPS eliminates the bias induced by heterogeneous gate errors. This generalization ensures that the advantages of the shallow RPS architecture can be fully realized even in the presence of complex, non-uniform noise environments.

Statistical property of phase circuits. Consider an n -qubit system. The random unitary takes the form $U = H^{\otimes n} U_A \in \mathcal{E}_{\text{phase}}$, where U_A consists of random CZ gates on all pairs (graph state structure) and random S gates [22, 23]. Defining

FIG. 1. Outline of the (robust) phase shadow framework. (a) The random phase circuit CZ-S-H before measurement. (b) Connection of random twirlings between phase and Haar ensembles. (c) The measurement channel derived from Proposition 1.

FIG. 2. (a) An illustration of Eq. (1) of $m = 2$ case. The union of the two permutation unitaries $\mathbb{I}_D^{\otimes 2} \cup \mathbb{S}_D = \mathbb{I}_D^{\otimes 2} + \mathbb{S}_D - \Delta_D$, with the parity projector Δ_D being their intersection, say $\mathbb{I}_D^{\otimes 2} \cap \mathbb{S}_D = \Delta_D$. For $D = 2$, the corresponding matrix representation is also shown. (b) A tensor diagram illustration of the (noiseless) measurement channel. By tracing the first copy, one obtains the output proportional to $\mathbb{I}_D + \rho_f$. (c) In the presence of noise, the moment function expands from a compact form (left) to a sum of 3^n tensor-product terms (right), each built from qubit-level operators Δ_2 , $(\mathbb{S}_2 - \Delta_2)$, $(\mathbb{I}_2^{\otimes 2} - \Delta_2)$, as shown by the colored blocks.

the m -th moment function $\mathbf{M}_{\mathcal{E}}^{(m)} := D^{-1} \mathbb{E}_{U \sim \mathcal{E}} \sum_{\mathbf{b}} \Phi_{U, \mathbf{b}}^{\otimes m}$ where $\Phi_{U, \mathbf{b}} := U^\dagger |\mathbf{b}\rangle \langle \mathbf{b}| U$, we derive the properties of $\mathcal{E}_{\text{phase}}$.

Proposition 1 (2nd and 3rd moments). *The $m = 2, 3$ -th moment functions of the diagonal ensemble $\mathcal{E}_{\text{phase}}$ are given by*

$$\mathbf{M}_{\mathcal{E}_{\text{phase}}}^{(m)} := D^{-m} \bigcup_{\pi \in \mathcal{S}_m} V_n(\pi), \quad (1)$$

where $V_n(\pi)$ is the unitary representation of permutation π , and $\bigcup$ denotes the bitwise OR operation in the computational basis.

Unlike the Haar ensemble [24, 25] which involves a sum $\sum_{\pi}$, the phase ensemble involves a union. For $m = 2$, this yields $\mathbf{M}_{\mathcal{E}_{\text{phase}}}^{(2)} = D^{-2} (\mathbb{I}_D^{\otimes 2} + \mathbb{S}_D - \Delta_D)$, where Δ_D is the parity

projector (intersection of Identity and Swap). This compact structure is key to our protocol.

Phase shadow framework. The shadow estimation process induces a quantum channel $\mathcal{M}_{\mathcal{E}}(\rho) = D \text{tr}_1(\rho \otimes \mathbb{I} \mathbf{M}_{\mathcal{E}}^{(2)})$. Although $\mathcal{E}_{\text{phase}}$ is not a 2-design [24], we can construct an unbiased estimator for the off-diagonal part of the state, $\rho_f = \rho - \rho_d$. The diagonal part ρ_d is efficiently estimated via computational basis measurements.

Theorem 1 (Unbiased recovery). *Using ensemble $\mathcal{E}_{\text{phase}}$, the single-shot unbiased estimator of ρ_f is $\hat{\rho}_f := D \Phi_{U, \mathbf{b}} - \mathbb{I}$. For observable O , the estimator $\hat{o}_f = \text{tr}(O \hat{\rho}_f)$ has variance*

$$\text{Var}(\hat{o}_f) \leq 3 \|O_f\|_2^2, \quad (2)$$

where O_f is the off-diagonal part of O .

Combining this with $\hat{\rho}_d$ from direct measurement, the total sample complexity for global observables scales similarly to full Clifford shadows, $N \sim \log(L)$, but with significantly reduced hardware requirements.

Robust estimation under realistic noise. Gate-dependent noise is a major bottleneck [26]. We focus on the noisy CZ layer, modeling noise as $\widetilde{\text{CZ}}_{i,j} := \text{CZ}_{i,j} \circ \mathcal{D}_{ij}$, where $\mathcal{D}_{ij}$ is a Pauli channel (e.g., ZZ noise common in flux-tunable couplers or Rydberg interactions [27]). This breaks the compact moment function into 3^n terms (Fig. 2(c)). Standard estimators become biased (Fig. 3). However, we find the noisy channel $\tilde{\mathbf{M}}_{\mathcal{E}}^{(2)}$ admits a Pauli decomposition:

Proposition 2 (Pauli decomposition). *Under uniform gate noise p_e , the noisy second moment is*

$$\tilde{\mathbf{M}}_{\mathcal{E}_{\text{phase}}}^{(2)} = D^{-3} \sum_{P \in \mathcal{P}_n} \sigma_P P \otimes P, \quad (3)$$

where coefficients σ_P are efficiently computable functions of p_e and the Pauli weight of P .

Crucially, σ_P is non-zero for off-diagonal Paulis. This allows channel inversion.

FIG. 3. (a) Variance of fidelity estimation (noiseless). (b) Fidelity of GHZ* state using RPS vs PS under noise ($N = 50,000$). RPS maintains unbiasedness. (c) Post-processing time scaling.

Theorem 2 (Robust phase shadow). *The unbiased estimator under noisy CZ gates is*

$$\hat{\rho}_{f, \text{robust}} := \sum_{P \in \mathbf{P}_n / \mathbf{Z}_n} \sigma_P^{-1} \text{tr}(\Phi_{U, \mathbf{b}} P) P. \quad (4)$$

The variance scales as $\text{Var}(\hat{O}_f) \lesssim \Theta(1)e^{n^2 p_e/2} \|O_f\|_2^2$.

This exponential scaling is the price of error mitigation [28, 29], but for near-term devices ($np_e \ll 1$), the overhead is manageable.

Efficient post-processing. While Eq. (4) involves a sum over Paulis, for stabilizer states $O = \Psi$, we prove the post-processing is efficient.

Proposition 3 (Stabilizer observables). *For stabilizer observables, the expected post-processing time of RPS is $O(n^3)$.*

This relies on the fact that the number of shared stabilizers between a random phase circuit and the target state remains $O(1)$ on average. We provide a Tableau-based algorithm [30] in the Supplementary Material to implement this efficiently.

Generalized robust phase shadows. We extend RPS to arbitrary gate-dependent Pauli noise and general Clifford structures. Let circuit U consist of d layers of gates g_j , each followed by a local Pauli channel Λ_j . To construct the estimator, we track the Heisenberg evolution of the measured Pauli observable P backwards through the circuit. At each layer j , the Pauli operator P_j transforms as $P_{j-1} = g_j^\dagger P_j g_j$. The noise channel Λ_j attenuates the signal according to its eigenvalue equation $\Lambda_j(P_j) = \alpha_{j, P_j} P_j$, where $\alpha_{j, P_j} \in [-1, 1]$ represents the fidelity of gate j with respect to Pauli P_j . The circuit-dependent attenuation factor is defined as the accumulated product along this trajectory: $\sigma(P, U) = \prod_{j=1}^d \alpha_{j, P_j}$. This factor precisely captures the signal decay specific to the exact sequence of gates and noise instances traversed by P .

Theorem 3 (Generalized RPS). *The generalized estimator*

$$\hat{\rho}_{\text{gen}} = \sum_P \sigma(P, U)^{-1} \text{tr}(\Phi_{U, \mathbf{b}} P) P \quad (5)$$

is an unbiased estimator of the ideal state ρ . For stabilizer states, the variance of estimating an observable O is bounded by $\|O\|_{\text{shadow}}^2 \leq \mathbb{E}_U [\max_P \sigma(P, U)^{-4}]$.

This framework allows using fine-grained calibration data for each gate (α_{j, P_j}), rather than a mean error rate. This is particularly crucial for hardware with asymmetric noise (e.g., Z -bias) or varying gate qualities, bridging the gap between hardware constraints and verification needs. While the variance scales with the inverse square of the path fidelity, it avoids the pessimistic global scaling of standard methods by leveraging the structure of the Clifford circuit.

To validate the efficiency of the generalized RPS framework, we perform numerical simulations under realistic gate-dependent noise, including the conventional ZZ -error model

and gate-dependent depolarizing noise with non-uniform error rates across gates and qubits.

As shown in Fig. 4, the generalized RPS estimator remains unbiased over all noise levels by inverting the corresponding noise channel Λ_j for each gate, in agreement with Theorem 3. In contrast, the original *robust shadow estimation* (RSE) protocol [11], which assumes gate-independent noise, still exhibits residual systematic bias. This highlights the importance of gate-dependent noise inversion for accurate global property estimation.

We further apply the generalized framework to standard random Clifford measurements. The results confirm that strict unbiasedness is not tied to the specific -S-CZ-H- phase-shadow circuit structure. Moreover, Fig. 4(c,d) shows that generalized RPS achieves substantially lower variance than the generalized Clifford estimator, mainly due to the reduced circuit depth of the phase-shadow ensemble.

Discussion. RPS enables robust estimation of global properties using hardware-native resources. By balancing local randomness with global structure, it avoids the costs of full Cliffords while handling realistic gate-dependent noise. The generalized framework further accommodates arbitrary architectures and Pauli errors (obtainable via randomized compiling [21, 31]). With variance overheads within reach of current platforms (e.g., Rydberg arrays [20]), RPS is a promising, simple and hardware-tailored tool for benchmarking and error mitigation. Future work includes extending to other native gates (iSWAP) and cross-platform verification. On a higher level, we expect such increasingly simple and hardware-tailored robust schemes of read-out and benchmarking to become important when scaling up quantum hardware while maintaining predictive power, and eventually reaching a regime of *fault-tolerant application-scale quantum* (FASQ) [32] machines.

Methods. Code and data are available at [33].

FIG. 4. Comparison of generalized RPS against unmitigated baselines and standard *robust shadow estimation* (RSE). Generalized RPS (orange/green) maintains unbiasedness across noise levels where RSE (purple) retains residual bias due to mean-field approximations.

Quantum data hiding with two-qubit separable states

Donghoon Ha¹

Kyung Hee University, Yongin 17104, Republic of Korea*

Abstract. We consider the discrimination of two-party quantum states and provide a quantum data-hiding scheme using two-qubit separable states. We first provide a bound on the optimal local discrimination of two-party quantum states, and establish a sufficient condition under which a two-party quantum state ensemble can be used to construct a data-hiding scheme. We illustrate this condition with examples of two-qubit state ensembles consisting of two orthogonal separable states. As our data-hiding scheme can be implemented with separable states of the lowest possible dimension, its practical realization becomes significantly more attainable.

The full manuscript is available at arXiv:2512.15095.

Keywords: quantum data hiding, minimum-error discrimination, two-qubit separable states

1 Introduction

Quantum data hiding is a quantum communication protocol in which information is encoded into multi-party quantum systems shared among multiple players [1–3]. Under the restriction of *local operations and classical communication* (LOCC), the encoded data cannot be recovered, even with unrestricted classical collaboration. The information becomes accessible only through global operations beyond LOCC, necessitating genuinely non-local resources such as shared entanglement or quantum channels.

The initial quantum data-hiding scheme was shown through two-qubit orthogonal entangled states [4]. In this scheme, one classical bit is asymptotically hidden under LOCC measurements but can be perfectly recovered once the players are allowed to perform global measurements. Since then, a variety of quantum data-hiding schemes with different structural features and resource requirements have been developed [5–8]. Nonetheless, it remains an open problem which types of quantum correlations are necessary for quantum data hiding.

Surprisingly, quantum data hiding does not necessarily require entanglement [9–11]. The first data-hiding scheme based on separable states employs nonorthogonal states, in which one classical bit is hidden and recovered through asymptotic procedures [9]. More recently, it was also shown that a quantum data-hiding scheme can be constructed using orthogonal separable states [10, 11]. However, it remains unclear whether quantum data hiding can be achieved using two-qubit orthogonal separable states, that is, orthogonal separable states of the lowest possible dimension.

Here, we present a quantum data-hiding scheme based on two-qubit orthogonal separable states exhibiting local indistinguishability. In our scheme, the local indistinguishability of the states is exploited to asymptotically hide one classical bit under LOCC constraints by repeatedly employing separable states of the lowest possible dimension. As the number of repetitions increases,

the information accessible about the hidden bit using LOCC measurements decays exponentially, approaching the level of random guessing. This feature makes the practical realization of our scheme significantly more attainable. Moreover, the orthogonality of the states guarantees the global distinguishability to perfectly recover the hidden bit even without invoking any asymptotic procedure when full cooperation is allowed and global measurements are permitted.

2 Preliminaries

2.1 Two-party quantum state discrimination

Let us consider the situation of discriminating two-party quantum states ρ_0 and ρ_1 which are prepared with probabilities η_0 and η_1 , respectively. We represent this situation as an ensemble

$$\mathcal{E} = \{\eta_0, \rho_0; \eta_1, \rho_1\}. \quad (1)$$

To guess the state prepared from the ensemble $\mathcal{E}$ in Eq. (1), we employ the decision rule using a measurement

$$\mathcal{M} = \{M_0, M_1\}, \quad (2)$$

where obtaining the measurement outcomes corresponding to M_0 or M_1 indicates that the prepared state is inferred to be ρ_0 or ρ_1 , respectively. The *minimum-error discrimination* of $\mathcal{E}$ is to achieve the maximum average probability of correctly guessing the prepared state from $\mathcal{E}$, that is,

$$p_G(\mathcal{E}) = \max_{\mathcal{M}} \sum_{i \in \{0,1\}} \eta_i \text{Tr}(\rho_i M_i), \quad (3)$$

where the maximum is taken over all possible measurements [12].

Definition 1 *A Hermitian operator E on $\mathcal{H}$ is called positive partial transpose (PPT) if the partially transposed operator is positive semidefinite, that is,*

$$E^{\text{PT}} \succeq 0, \quad (4)$$

where the superscript PT denotes the partial transposition [13, 14].

*freddie1@khu.ac.kr

A measurement is called an *LOCC measurement* if it can be implemented by LOCC, and a measurement $\{M_i\}_i$ is called a *PPT measurement* if M_i is PPT for all i . It is known that any LOCC measurement is a PPT measurement [15]. Under the restriction to LOCC measurements, we denote by $p_L(\mathcal{E})$ the maximum average probability of correctly guessing the prepared state from $\mathcal{E}$ in Eq. (1), that is,

$$p_L(\mathcal{E}) = \max_{\text{LOCC } \mathcal{M}} \sum_{i \in \{0,1\}} \eta_i \text{Tr}(\rho_i M_i). \quad (5)$$

Similarly, we denote

$$p_{\text{PPT}}(\mathcal{E}) = \max_{\text{PPT } \mathcal{M}} \sum_{i \in \{0,1\}} \eta_i \text{Tr}(\rho_i M_i), \quad (6)$$

where the maximum is taken over all possible PPT measurements. From the definitions, we have

$$\frac{1}{2} \leq \max\{\eta_0, \eta_1\} \leq p_L(\mathcal{E}) \leq p_{\text{PPT}}(\mathcal{E}) \leq p_G(\mathcal{E}). \quad (7)$$

2.2 Two-party quantum data hiding

For the ensemble $\mathcal{E}$ in Eq. (1) and a positive integer L , we define

$$\begin{aligned} \eta_{\vec{b}} &= \eta_{b_1} \times \cdots \times \eta_{b_L}, \\ \rho_{\vec{b}} &= \rho_{b_1} \otimes \cdots \otimes \rho_{b_L}, \quad \vec{b} = (b_1, \dots, b_L) \in \mathbb{Z}_2^L \end{aligned} \quad (8)$$

where $\mathbb{Z}_2^L$ is the Cartesian product of L copies of $\{0,1\}$, that is,

$$\mathbb{Z}_2^L = \{(b_1, \dots, b_L) \mid b_1, \dots, b_L \in \{0,1\}\}. \quad (9)$$

We then write $\mathcal{E}^{\otimes L}$ for the L -fold ensemble of $\mathcal{E}$, that is,

$$\mathcal{E}^{\otimes L} = \{\eta_{\vec{b}}, \rho_{\vec{b}}\}_{\vec{b} \in \mathbb{Z}_2^L}, \quad (10)$$

where each state $\rho_{\vec{b}}$ is prepared with probability $\eta_{\vec{b}}$, for $\vec{b} \in \mathbb{Z}_2^L$. For each vector $\vec{b} = (b_1, \dots, b_L) \in \mathbb{Z}_2^L$, we define $\omega_2(\vec{b})$ as the modulo-2 sum of all the entries in $\vec{b}$, that is,

$$\omega_2(\vec{b}) = b_1 \oplus \cdots \oplus b_L \in \{0,1\} \quad (11)$$

where $\oplus$ is the modulo-2 addition.

Let us consider the situation of guessing $\omega_2(\vec{b})$ of the prepared state $\rho_{\vec{b}}$ from the ensemble $\mathcal{E}^{\otimes L}$ in Eq. (10). This situation is equivalent to guessing the prepared state from the two-state ensemble

$$\mathcal{E}^{(L)} = \{\eta_0^{(L)}, \rho_0^{(L)}; \eta_1^{(L)}, \rho_1^{(L)}\} \quad (12)$$

where the states $\rho_0^{(L)}$ and $\rho_1^{(L)}$ are prepared with the probabilities $\eta_0^{(L)}$ and $\eta_1^{(L)}$, respectively, and

$$\begin{aligned} \eta_i^{(L)} &= \sum_{\substack{\vec{b} \in \mathbb{Z}_2^L \\ \omega_2(\vec{b})=i}} \eta_{\vec{b}}, \\ \rho_i^{(L)} &= \frac{1}{\eta_i^{(L)}} \sum_{\substack{\vec{b} \in \mathbb{Z}_2^L \\ \omega_2(\vec{b})=i}} \eta_{\vec{b}} \rho_{\vec{b}}, \quad i = 0, 1. \end{aligned} \quad (13)$$

Now, we consider an *orthogonal* quantum state ensemble $\mathcal{E} = \{\eta_0, \rho_0; \eta_1, \rho_1\}$ satisfying

$$\lim_{L \rightarrow \infty} p_{\text{PPT}}(\mathcal{E}^{(L)}) = \frac{1}{2}. \quad (14)$$

By using the ensemble $\mathcal{E}$, we can construct a quantum data-hiding scheme that conceals one classical bit [7]. The scheme is given as follows.

The hider, acting as the dealer, first prepares a state ρ_{b_1} from $\mathcal{E}$ with the corresponding probability η_{b_1} for $b_1 \in \{0,1\}$ and distributes it between Alice and Bob. The hider repeats this process L times so that a state ρ_{b_l} is prepared with probability η_{b_l} in the l th repetition for $l = 1, \dots, L$. This whole procedure is equivalent to the situation where the hider first prepares a state $\rho_{\vec{b}}$ from the L -fold ensemble of $\mathcal{E}$ with the corresponding probability $\eta_{\vec{b}}$ for $\vec{b} = (b_1, \dots, b_L) \in \mathbb{Z}_2^L$ and distributes it between Alice and Bob. For the state $\rho_{\vec{b}}$ shared between Alice and Bob, the classical bit $\omega_2(\vec{b})$ is denoted by y , that is,

$$y = \omega_2(\vec{b}). \quad (15)$$

To conceal one classical bit $x \in \{0,1\}$, the hider broadcasts to Alice and Bob the classical information z where

$$z = x \oplus y. \quad (16)$$

As the bit z in Eq. (16) is broadcast to Alice and Bob, guessing the bit x becomes equivalent to guessing the bit y in Eq. (15). Since guessing y is equivalent to guessing the prepared state from $\mathcal{E}^{(L)}$ in Eq. (12), the maximum average probability of correctly guessing x is equal to that of correctly guessing the prepared state from $\mathcal{E}^{(L)}$, that is, $p_G(\mathcal{E}^{(L)})$. Similarly, the maximum average probability of correctly guessing x using only LOCC measurements becomes $p_L(\mathcal{E}^{(L)})$.

Since the orthogonality of the states in $\mathcal{E}$ implies mutual orthogonality among the states of $\mathcal{E}^{\otimes L}$, it follows from the definitions of $\rho_0^{(L)}$ and $\rho_1^{(L)}$ in Eq. (13) that the states of $\mathcal{E}^{(L)}$ are orthogonal, and therefore

$$p_G(\mathcal{E}^{(L)}) = 1. \quad (17)$$

In other words, the classical bit x is fully revealed when Alice and Bob are allowed to collaborate and perform global measurements. On the other hand, Eq. (14) implies

$$\lim_{L \rightarrow \infty} p_L(\mathcal{E}^{(L)}) = \frac{1}{2}, \quad (18)$$

since Inequality (7) shows that $p_L(\mathcal{E}^{(L)})$ is bounded below by $1/2$ and above by $p_{\text{PPT}}(\mathcal{E}^{(L)})$ for each positive integer L . Thus, $p_L(\mathcal{E}^{(L)})$ can be arbitrarily close to $1/2$ by choosing L sufficiently large. In other words, the globally accessible bit x is perfectly concealed asymptotically if Alice and Bob are only able to use LOCC measurements.

3 Main results

For the ensemble $\mathcal{E}$ in Eq. (1), the following theorem establishes a sufficient condition under which $p_{\text{PPT}}(\mathcal{E}^{(L)})$ converges exponentially to $1/2$ as L increases.

Theorem 2 For an ensemble $\mathcal{E} = \{\eta_0, \rho_0; \eta_1, \rho_1\}$ with

$$\Lambda_{\mathcal{E}}^{\text{PT}} = \Lambda_{\mathcal{E}} \quad (19)$$

where

$$\Lambda_{\mathcal{E}} = \eta_0 \rho_0 - \eta_1 \rho_1, \quad (20)$$

if there exist a positive integer k and a Hermitian operator H satisfying

$$H + H^{\text{PT}} = \Lambda_{\mathcal{E}}^{\otimes k}, \quad (21a)$$

$$4 \text{Tr} |H| \text{Tr} |H^{\text{PT}}| < 1, \quad (21b)$$

then

$$p_{\text{PPT}}(\mathcal{E}^{(L)}) \leq \frac{1}{2} + \frac{1}{2} (4 \text{Tr} |H| \text{Tr} |H^{\text{PT}}|)^{\frac{L-k+1}{2k}} \quad (22)$$

for any positive integer L . In this case, $p_{\text{PPT}}(\mathcal{E}^{(L)})$ converges exponentially to $1/2$ as L increases.

Now, we provide the following examples of *two-qubit* state ensembles consisting of two orthogonal separable states. These ensembles can be used to construct a quantum data-hiding scheme that conceals one classical bit.

Example 1 Let us consider the $2 \otimes 2$ orthogonal separable state ensemble $\mathcal{E} = \{\eta_0, \rho_0; \eta_1, \rho_1\}$ consisting of

$$\begin{aligned} \eta_0 &= \frac{1}{2}, \quad \rho_0 = \frac{1}{2} |0\rangle\langle 0| \otimes |+\theta\rangle\langle +\theta| \\ &\quad + \frac{1}{2} |+\theta\rangle\langle +\theta| \otimes |0\rangle\langle 0|, \\ \eta_1 &= \frac{1}{2}, \quad \rho_1 = \frac{1}{2} |1\rangle\langle 1| \otimes |1\rangle\langle 1| \\ &\quad + \frac{1}{2} |-\theta\rangle\langle -\theta| \otimes |-\theta\rangle\langle -\theta| \end{aligned} \quad (23)$$

where

$$\begin{aligned} |+\theta\rangle &= \cos \theta |0\rangle + \sin \theta |1\rangle, \\ |-\theta\rangle &= \sin \theta |0\rangle - \cos \theta |1\rangle, \quad 0 \leq \theta \leq \frac{\pi}{3}. \end{aligned} \quad (24)$$

Note that the states ρ_0 and ρ_1 are orthogonal due to $\langle +\theta | -\theta \rangle = 0$. We also note that Eq. (19) is satisfied by the states and probabilities in Eq. (23) because $|\pm\theta\rangle\langle \pm\theta|$ is invariant under transposition [14].

For $k = 2$, there exists a Hermitian operator satisfying Eq. (21a) and

$$\begin{aligned} \text{Tr} |H| &= \frac{3 - \cos^4 \theta + \sqrt{4 \cos^4 \theta + \sin^8 \theta}}{8} =: f_0(\theta), \\ \text{Tr} |H^{\text{PT}}| &= \frac{1 + \sin^2 \theta + \cos \theta \sqrt{\cos^2 \theta + \sin^4 \theta}}{4} =: f_1(\theta). \end{aligned} \quad (25)$$

For the case when

$$4f_0(\theta)f_1(\theta) < 1, \quad (26)$$

it follows from Theorem 2 that $p_{\text{PPT}}(\mathcal{E}^{(L)})$ converges exponentially to $1/2$ as L increases, that is,

$$p_{\text{PPT}}(\mathcal{E}^{(L)}) \leq \frac{1}{2} + \frac{1}{2} [4f_0(\theta)f_1(\theta)]^{\frac{L-1}{4}} \quad (27)$$

for any positive integer L . In this case, the two-qubit separable state ensemble $\mathcal{E}$ in Example 1 can be used to construct a quantum data-hiding scheme that conceals one classical bit. The details of a quantum data-hiding scheme are given in Sec. 2.2. In particular, we have

$$\begin{aligned} &4f_0(\theta)f_1(\theta) \\ &= \begin{cases} \frac{(39 + \sqrt{577})(10 + \sqrt{39})}{1024} \approx 0.9998, & \theta = \frac{\pi}{6}, \\ \frac{(11 + \sqrt{17})(6 + \sqrt{6})}{128} \approx 0.9983, & \theta = \frac{\pi}{4}. \end{cases} \end{aligned} \quad (28)$$

Abstract. We address an experimentally motivated question: Which quantum strategies attain the maximal loophole-free nonlocality in the presence of inefficient detectors? For any Bell inequality and any specification of detection efficiencies, the optimal strategies are those that maximally violate a tilted version of the Bell inequality in ideal conditions. We utilize a Jordan’s lemma and Gröbner basis-based proof technique to analytically derive self-testing statements for the entire family of doubly-tilted CHSH inequalities and numerically demonstrate their robustness. These results enable us to reveal the insufficiency of even high levels of the Navascués–Pironio–Acín hierarchy to saturate the maximum quantum violation of these inequalities.

Keywords: Bell nonlocality, self-testing, detection loophole, device-independent quantum information, CHSH inequality, semidefinite programming.

1 Motivation

The commercial deployment of photonic Device-Independent Quantum Cryptography (DIQC) faces significant challenges, predominantly stemming from the inefficiency of current photonic detectors. In practical scenarios, detector efficiency is limited ($\eta_0 < 1$), and the effective detection efficiency declines exponentially with distance when using optical fibers, as expressed by $\eta = \eta_0 \cdot 10^{-\frac{\alpha l}{10}}$, where l is the length in kilometers, and α represents fiber attenuation. Achieving nonlocal correlations—an essential resource for DIQC requires overcoming the detection loophole, which arises when detectors fail to register all events, potentially allowing classical explanations for the observed correlations. The exponential decay of effective efficiency combined with a prohibitively high critical detection efficiency of nonlocal correlations severely impacts the feasibility of nonlocal correlations, limiting the distance across which they can be experimentally realized. However, for real-world applications to be effective, mere violation of a Bell inequality is insufficient.

Instead, the efficacy of such applications requires a high degree of detection effective (loophole-free) nonlocality [1]. Consequently, in this work, we pose and solve a largely overlooked application-oriented question:

Which quantum strategies yield the maximum loophole-free nonlocality in the presence of inefficient detectors?

By addressing this question, we aim to bridge the gap between theoretical quantum cryptography and its practical implementation. Our goal is to identify optimal quantum strategies that can mitigate the limitations imposed by detector inefficiencies, thereby paving the way for secure, commercial quantum communication systems that operate effectively under real-world conditions.

2 Main idea

In this work we analytically derive self-testing statements for the entire family of doubly-tilted CHSH inequalities as a function of the detection efficiencies via a novel proof technique based on Gröbner basis elimination and Jordan’s lemma. We find that the optimal quantum strategy entails non-maximally incompatible observables for both parties and a partially entangled two-qubit state, with the optimal

*ektapanwar18@gmail.com

observables of a party also depending on the detection efficiency of the other party.

The analytical self-testing statements enable us to recover, up to arbitrary precision, the maximum quantum violation of the doubly-tilted CHSH inequalities. We compare these values with the corresponding upper bounds from the Navascués–Pironio–Acín (NPA) hierarchy [2]. Strikingly, even higher levels (up to level 10) cannot saturate the maximal violation of the doubly-tilted CHSH inequalities.

Consequently, the Sum-of-squares decompositions (SOS) [3] based self-testing technique turns out to be analytically intractable for the doubly-tilted CHSH inequalities. We conclude by discussing implications of our self-testing statements towards device-independent cryptography with inefficient detectors and the complexity of characterizing the set of quantum correlations via the NPA hierarchy and the SOS decompositions self-testing method.

3 Results in the CHSH scenario

We summarize the main results as follows:

- *Lemma 1:-* We demonstrate that for any Bell inequality and any specification of detection efficiencies, the quantum strategies that yield the maximum loophole-free violation are the ones that maximally violate a tilted version of the Bell inequality.
- *Theorem 1 & 2:-* As our main result, we derive analytical *self-testing* statements for the family of tilted CHSH inequalities, entailing the analytical expressions for the maximum quantum violation and the ensuing optimal quantum strategy (Fig.1).

4 Exploding NPA levels in the simplest Bell Scenario

Besides our application oriented primary results, the analytical expressions we obtained enabled us to uncover a foundationally relevant phenomenon. Retrieving the exact expression for the maximum violation of the doubly tilted CHSH inequalities as a function of η_A, η_B , the traditional methods, such as the NPA hierarchy and SOS decomposition method, turned out to be intractable. We find that even level 10 of the NPA hierarchy does not yield tight upper bounds on the maximal violation of the symmetrically tilted CHSH inequalities as $\alpha \rightarrow 1$ (FIG. 2, 3).

Figure 1: *Maximum loophole-free violation of the CHSH inequality.* Plot of the tilted Bell inequality against the detection efficiencies $\eta_A, \eta_B \in [\frac{1}{2}, 1]$. The solid red line shows Bob's critical detection efficiency, $\eta_B = \frac{\eta_A}{3\eta_A - 1}$.

Figure 2: *Increasing levels for the tight NPA upper bounds:* Minimum NPA hierarchy level required to saturate bounds; $\alpha = 2(\frac{1-\eta_B}{\eta_B})$, $\beta = 2(\frac{1-\eta_A}{\eta_A})$.

Crucially, it remains unclear if *any* finite level of NPA will be enough to characterize all extremal quantum correlations in the CHSH scenario. This effect renders the traditional SOS decomposition method impractical for deriving analytical self-testing statements, and we rely on Jordan's lemma [4] to retrieve analytical self-testing statements in Theorem 1 and 2.

5 Impact of the work

Results in the article are formalized as *self-testing* statements, the most accurate form of quantum device certification. Apart from the applied significance of our contribution, the analytical results allow us to reveal several pivotal features of the set of quantum correlations in the simplest case. The most significant of these is the rapid rise in complexity

Figure 3: Difference $c_{Q_L}(\alpha, \alpha) - c_Q(\alpha, \alpha)$ for levels $L \in \{7, 8, 9, 10\}$ of the NPA hierarchy and analytical solution.

of characterizing nonlocal quantum correlations as the efficiencies approach their critical values, which renders the trusted traditional tools like SOS and NPA impractical.

These results then raise the question of whether the complexity of the characterization of extremal nonlocal quantum correlation, as measured by the minimum level of the NPA hierarchy required to saturate the maximal quantum violation of the associated Bell inequality, is related to the partial incompatibility of the quantum measurements realizing them.

Conditional channel entropy sets fundamental limits on thermodynamic quantum information processing

The thermodynamic resourcefulness of quantum channels primarily depends on their underlying causal structure and their ability to generate quantum correlations. We quantify this interplay within the resource theory of athermality for bipartite quantum channels in the presence of a side channel acting as memory, referred to as the resource theory of conditional athermality. For channels with trivial output Hamiltonians, we characterize the optimal one-shot rates for distilling the identity gate from a given channel, as well as the cost of simulating the channel using the identity gate, under conditional Gibbs-preserving superchannels. We show that these rates have a direct trade-off relation with the conditional channel entropies, attributing operational significance to signaling in quantum processes. Furthermore, we establish an asymptotic equipartition property for the conditional channel min-entropy for classes of channels that are either tele-covariant or no-signaling from the non-conditioning input to the conditioning output. As a consequence, we demonstrate asymptotic reversibility of the resource theory for these channels. The asymptotic conditional athermality capacity of a tele-covariant channel is half the superdense coding capacity of its Choi state. Our work establishes the conditional channel entropy as a primitive information-theoretic concept for quantum processes, elucidating its potential for wider applications in quantum information science.

I. INTRODUCTION

A. Motivation and Background

Quantum processes, also called quantum channels, are able to generate correlations such as entanglement in quantum systems that have no classical counterpart [1]. They encompass quantum states, measurements, and their transformations, thereby providing a general description of physical systems, their dynamics, and measurement processes in quantum theory. All quantum information processing and computation can be understood as transformations of states and gates, where these transformations correspond to compositions of quantum channels, including state preparation and measurement. Motivated by these basic and practical considerations, it is pertinent to understand how thermodynamic constraints limit the synthesis of bipartite quantum channels and the extraction of unitary gates locally from such channels.

To address this, we pose the following two related questions for an arbitrary bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$:

- To synthesize a single copy of $\mathcal{N}$ from a decoupled bipartite channel $\text{id} \otimes Q$ via conditional Gibbs-preserving superchannels, what is the minimum dimension of the identity (or any unitary) gate id required, for some side channel Q ?
- To extract a decoupled channel $\text{id} \otimes Q$ from a single use of $\mathcal{N}$ via conditional Gibbs-preserving superchannels, what is the maximum possible dimension of id , for some side channel Q ?

* himanshubadhani@gmail.com

† das.seed@iiit.ac.in

The restriction of allowed physical transformations for synthesis or extraction to conditional Gibbs-preserving superchannels implicitly encodes thermodynamic constraints, as will become clear in later discussions.

The answers to these questions provide fundamental limitations on the formation and distillation of bipartite quantum channels in the presence of a quantum side channel. We show that the one-shot and asymptotic optimal rates for an arbitrary channel under the action of conditional Gibbs-preserving superchannels are characterized by channel divergences between the given channel and a decoupled channel of the form $\mathcal{T}^\beta \otimes Q$, where $\mathcal{T}^\beta$ is the absolutely thermal channel that always outputs the thermal state with inverse temperature β . The conditional Gibbs-preserving superchannels Ω preserve conditional thermality, $\Omega(\mathcal{T}^\beta \otimes Q) = \mathcal{T}^\beta \otimes Q'$ for some channel Q' . The absolutely thermal channel has maximum channel entropy and minimum channel free energy [2, 3]. When the channels have trivial output Hamiltonians, the one-shot and asymptotic optimal rates are related to the conditional channel entropies introduced in [4] (see also [5]). This provides a clear operational interpretation of conditional channel entropies.

The transformation of a bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ to $\text{id} \otimes Q$ incurs erasure of the intricate causal structure of $\mathcal{N}$. $\text{id} \otimes Q$ is decoupled and has no correlation generating ability, while $\mathcal{N}$ can be rich in correlation generating abilities. If $\mathcal{N}$ has any signaling or causal influence from $A' \rightarrow B$, $B' \rightarrow A$, or both then that needs to be erased. Analogously, the transformation of $\text{id} \otimes Q$ to $\mathcal{N}$ requires synthesis or preparation of intricate causal structure from a decoupled one. Our results highlight the interplay between the causal structure of a bipartite quantum channel [6–8], its ability to manipulate bipartite correlations [9–13], the cost of its synthesis, and its usefulness for extracting local unitary operations. We make several contributions toward determining fundamental limits on the conversion of bipartite channels under conditional Gibbs-preserving superchannels. In particular, the properties of conditional channel entropies capture how causal structure influences both the distillation yield and the formation cost of bipartite quantum channels. We present our main results in Section IB and discuss their relations to prior works in Section IC; see preliminaries in Section II.

B. Main Results

We analyze quantum information processing under thermodynamic constraints. We consider a canonical and physically motivated scenario where the interaction between two systems and transformations are in general described by bipartite quantum channels. A natural, freely occurring process is depicted by a bipartite quantum channel called conditional absolutely thermal channel that is tensor-product of quantum channels $\mathcal{T}^\beta \otimes Q$: the first is a absolutely thermalizing process $\mathcal{T}^\beta$ that drives all inputs to equilibrium (thermal or Gibbs state γ^β [20]) with a bath at inverse temperature β and the side channel Q , by contrast, represents non-equilibrating dynamics. We focus on two related aspects of quantum processes: a) resource theory of the conditional athermality of quantum processes, b) the properties of conditional channel min-entropy and its interconnectedness with the underlying causal structure of the given bipartite channel (Table I). The two aspects are related as the optimal one-shot conditional athermality distillation yield and formation cost of a bipartite quantum channel depend on its conditional channel entropies.

We formalize the framework of the resource theory of conditional athermality for bipartite quantum channels. We consider the conditional absolutely thermal channels $\mathcal{T}^\beta \otimes Q$ as free objects, where $Q_{B' \rightarrow B}$ is any quantum channel and $\mathcal{T}_{A' \rightarrow A}^\beta(\cdot) = \text{tr}(\cdot)\gamma_A^\beta$ for a given thermal state γ_A^β . To show the conditional athermal resourcefulness of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ relative to free objects, we write $(\mathcal{N}, \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B})$ for some side channel Q . The free operations are conditional Gibbs-preserving superchannels (CGPSs) Θ^β that preserve conditionally absolute thermalization,

Conditional min-entropy: quantum states ρ_{AB} vs. channels $\mathcal{N}_{A'B' \rightarrow AB}$	
Definition	$S_\infty(A B)_\rho := -\inf_{\sigma \in \text{St}(B)} D_\infty(\rho_{AB} \ \mathbb{1}_A \otimes \sigma_B)$ [14, 15]
	$S_\infty[A B]_\mathcal{N} := -\inf_{Q \in \text{Ch}(B', B)} D_\infty[\mathcal{N} \ \mathcal{R}_{A' \rightarrow A}^1 \otimes Q_{B' \rightarrow B}]$ [4]
Dimensional bounds	$-\log \min\{ A , B \} \leq S_\infty(A B)_\rho \leq \log A $ [14]
	$-\log \min\{ A' B' B , A' ^2 A \} \leq S_\infty[A B]_\mathcal{N} \leq \log A $
Minimal value	$S_\infty(A B)_\rho = -\log \min\{ A , B \}$ iff ρ_{AB} is a maximally entangled state. [15]
	$S_\infty[A B]_\mathcal{N} = -\log \min\{ A' B' B , A' ^2 A \}$ iff $\mathcal{N}_{A'B' \rightarrow AB}$ is a maximally entangling operation.
Negative values	$S_\infty(A B) < 0$ implies ρ_{AB} is (NPT) entangled. [16]
	$S_\infty[A B]_\mathcal{N} < -\log A $ implies $\mathcal{N}_{A'B' \rightarrow AB}$ is signaling from $A' \rightarrow B$. $S_\infty[A B]_\mathcal{N} < -\log A' $ implies $\mathcal{N}_{A'B' \rightarrow AB}$ is (NPT) entangling.
Nonnegative values	For all PPT states ρ_{AB} , $S_\infty(A B) \geq 0$. [16]
	For all completely PPT-preserving channels $\mathcal{N}_{A'B' \rightarrow AB}$, $S_\infty[A B]_\mathcal{N} \geq -\log A' $.
Maximum value	$S_\infty(A B) = \log A $ iff $\rho_{AB} = \pi_A \otimes \omega_B$ for any $\omega \in \text{St}(B)$. [16]
	$S_\infty[A B]_\mathcal{N} = \log A $ iff $\mathcal{N}_{A'B' \rightarrow AB} = \mathcal{R}_{A' \rightarrow A}^\pi \otimes Q_{B' \rightarrow B}$ for any $Q \in \text{Ch}(B', B)$.
Asymptotic equipartition property	$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon(A^n B^n)_{\rho^{\otimes n}} = S(A B)_\rho$. [17]
	In general, $\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n B^n]_{\mathcal{N}^{\otimes n}} \leq \inf_{\psi \in \text{St}(RA'B')} S(A RB)_{\mathcal{N}(\psi)}$ and $\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n B^n]_{\mathcal{N}^{\otimes n}} \leq S(R_A A R_B B)_{\Phi^\mathcal{N}} - \log A' $. If $\mathcal{N}$ is no-signaling from $A' \rightarrow B$ or tele-covariant, then $\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n B^n]_{\mathcal{N}^{\otimes n}} = S[A B]_\mathcal{N}$.

TABLE I. We compare features between the conditional min-entropies of an arbitrary bipartite quantum state ρ_{AB} and an arbitrary bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$. $S[A|B]_\mathcal{N}$ is the von Neumann conditional entropy of $\mathcal{N}$ [4] and $S(A|B)_\rho$ is the von Neumann conditional entropy of ρ [18, 19]. $\mathcal{R}^1(\cdot) := \text{tr}(\cdot) \mathbb{1}$ and $\Phi_{R_A A' R_B B'}^\mathcal{N} := \mathcal{N}(\Phi_{R_A A'} \otimes \Phi_{R_B B'})$ is the Choi state of $\mathcal{N}$, where $\Phi_{R_A A'}$ denotes a maximally entangled state. For a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, $S[A|B]_\mathcal{N} = S(R_A A | R_B B)_{\Phi^\mathcal{N}} - \log |A'|$ if $\mathcal{N}$ is tele-covariant and $S[A|B]_\mathcal{N} = \inf_{\psi \in \text{St}(RA'B')} S(A|RB)_{\mathcal{N}(\psi)}$ if $\mathcal{N}$ is no-signaling from $A' \rightarrow B$ [4].

meaning that $\Theta^\beta(\mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}) = \mathcal{T}_{C' \rightarrow C}^\beta \otimes Q'_{D' \rightarrow D}$ for some side channels Q, Q' . The standard resource units are taken to be the conditional identity channels ($\text{id} \otimes Q, \mathcal{R}^\pi \otimes Q$) and they are resource equivalent to conditional unitary channels ($\mathcal{U} \otimes Q, \mathcal{R}^\pi \otimes Q$), where $\gamma_A^\beta = \pi_A := \frac{1}{|A|} \mathbb{1}_A$ for trivial Hamiltonian $\hat{H}_A \propto \mathbb{1}_A$ and $\mathcal{R}^\pi(\cdot) := \text{tr}(\cdot) \pi$.

We consider resource interconversion under CGPSs Θ^β up to an error $\varepsilon \in [0, 1]$ and determine the exact one-shot rates for both the resource distillation yield $\text{Dist}^\varepsilon(\mathcal{N}, \mathcal{T}^\beta)$ and the formation cost

$\text{Cost}^\varepsilon(\mathcal{N}, \mathcal{T}^\beta)$ of an arbitrary channel $\mathcal{N}_{A'B' \rightarrow AB}$, $A' \simeq A$, ([Theorem 1](#)):

$$\text{Dist}^{(1,\varepsilon)}(\mathcal{N}, \mathcal{T}^\beta) = \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D_H^{\varepsilon^2}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}], \quad (1)$$

$$\text{Cost}^{(1,\varepsilon)}(\mathcal{N}, \mathcal{T}^\beta) = \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D_\infty^\varepsilon[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}], \quad (2)$$

where $D_H^\varepsilon[\cdot \| \cdot]$ and $D_\infty^\varepsilon[\cdot \| \cdot]$ are hypothesis-testing and max channel relative entropies respectively [21]. $\text{Dist}^{(1,\varepsilon)}(\mathcal{N}, \mathcal{T}^\beta)$ is the maximum number of conditional identity id_2 channels that can be distilled from a single-use of a bipartite resource channel $(\mathcal{N}, \mathcal{T}^\beta \otimes Q)$ under CGPSs for the worst-possible side channel Q . $\text{Cost}^{(1,\varepsilon)}(\mathcal{N}, \mathcal{T}^\beta)$ is the minimum number of conditional qubit identity id_2 channels that needs to be diluted to prepare a single copy of a bipartite resource channel $(\mathcal{N}, \mathcal{T}^\beta \otimes Q)$ under CGPSs for the best-possible side channel Q .

The conditional athermality distillation and formation capacities of a quantum channel $\mathcal{N}$ are the optimal asymptotic rates of the distillation yield and formation cost, respectively, as the error vanishes over asymptotically many (parallel) uses of the channel $\mathcal{N}$:

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{T}^\beta) := \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Dist}^{(1,\varepsilon)}(\mathcal{N}^{\otimes n}, \mathcal{T}^{\beta \otimes n}), \quad (3)$$

$$\text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{T}^\beta) := \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Cost}^{(1,\varepsilon)}(\mathcal{N}^{\otimes n}, \mathcal{T}^{\beta \otimes n}). \quad (4)$$

A direct consequence of the resource-theoretic approach is the fact that the resource distillation capacity of a channel is never greater than its formation capacity,

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{T}^\beta) \leq \text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{T}^\beta), \quad (5)$$

and it follows from [Corollary 1](#) that the resource distillation capacity is upper bounded as

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{T}^\beta) \leq \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D^{\text{reg}}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}], \quad (6)$$

where $D^{\text{reg}}[\mathcal{N} \| \mathcal{M}] := \lim_{n \rightarrow \infty} \frac{1}{n} D[\mathcal{N}^{\otimes n} \| \mathcal{M}^{\otimes n}]$ is the regularized relative entropy between channels $\mathcal{N}, \mathcal{M}$ [21, 22].

We observe that for the trivial Hamiltonian, the resource theory of conditional athermality reduces to the resource theory of conditional purity as $\gamma_A^\beta = \pi_A$ and $\mathcal{T}_{A' \rightarrow A}^\beta = \mathcal{R}_{A' \rightarrow A}^\pi$ when $\hat{H}_A \propto \mathbb{1}_A$. For a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ with $\hat{H}_A \propto \mathbb{1}_A$, its one-shot resource distillation yield and formation cost depend on its hypothesis-testing conditional entropy $S_H^\varepsilon[A|B]_\mathcal{N}$ and ε -smoothed conditional min-entropy $S_\infty^\varepsilon[A|B]_\mathcal{N}$ respectively ([Corollary 2](#)),

$$\text{Dist}^{(1,\varepsilon)}(\mathcal{N}, \mathcal{R}^\pi) = \frac{1}{2} \left(\log |A| - S_H^{\varepsilon^2}[A|B]_\mathcal{N} \right), \quad (7)$$

$$\text{Cost}^{(1,\varepsilon)}(\mathcal{N}, \mathcal{R}^\pi) = \frac{1}{2} \left(\log |A| - S_\infty^\varepsilon[A|B]_\mathcal{N} \right). \quad (8)$$

The resource distillation and formation capacities of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, $A' \simeq A$, are lower bounded as ([Proposition 4](#) and [Proposition 5](#))

$$\frac{1}{2} \min \{ \log |A| - S^{\nearrow}[A|B]_\mathcal{N}, \log |A'| |A| - S(R_A A | R_B B)_{\Phi_\mathcal{N}} \} \leq \text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \quad (9)$$

$$\leq \text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi), \quad (10)$$

where $S^{\nearrow}[A|B]_{\mathcal{N}} := \inf_{\psi \in \text{St}(RA'B')}$ $S(A|RB)_{\mathcal{N}(\psi)}$ is the no-signaling min-entropy [4] and $\Phi_{RAAR_{BB}}^{\mathcal{N}} := \mathcal{N}(\Phi_{RAA} \otimes \Phi_{R_{BB}})$ is the Choi state of $\mathcal{N}_{A'B' \rightarrow AB}$.

We prove that the asymptotic equipartition property holds for the conditional min-entropy of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ if it is either tele-covariant [23–26] (Theorem 4) or no-signaling from $A' \rightarrow B$ [6, 27] (Theorem 7),

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n|B^n]_{\mathcal{N}^{\otimes n}} = S[A|B]_{\mathcal{N}}, \quad (11)$$

where $S[A|B]_{\mathcal{N}} := -\inf_{Q \in \text{Ch}(B', B)} D[\mathcal{N} \| \mathcal{R}^{\mathbb{1}} \otimes Q]$ is the von Neumann conditional channel entropy [4]. The asymptotic equipartition property along with Theorem 1 allows us to exactly determine the conditional purity distillation and formation capacities of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ obeying certain symmetries. If a channel $\mathcal{N}_{A'B' \rightarrow AB}$ is tele-covariant (Theorem 5) or no-signaling channel from $A' \rightarrow B$ (Theorem 6), then

$$\text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}) = \text{Cost}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}) = \frac{1}{2}(\log |A| - S[A|B]_{\mathcal{N}}), \quad (12)$$

and equivalently, the following asymptotic equipartition property holds,

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_H^{\varepsilon^2}[A^n|B^n]_{\mathcal{N}^{\otimes n}} = S[A|B]_{\mathcal{N}} = \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n|B^n]_{\mathcal{N}^{\otimes n}}. \quad (13)$$

Thus, the resource theory of conditional purity is asymptotically reversible for quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$ that are tele-covariant or no-signaling from $A' \rightarrow B$. Furthermore, we find that the superdense coding capacity [28, 29] of the Choi state $\Phi^{\mathcal{N}}$ of a tele-covariant channel $\mathcal{N}_{A'B' \rightarrow AB}$, where $A' \simeq A$, is double the conditional purity capacity of the channel, see Eq. (115),

$$\frac{1}{2} \text{Sdc}(R_A A; R_B B)_{\Phi^{\mathcal{N}}} = \text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}) = \text{Cost}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}). \quad (14)$$

We note that for a bipartite quantum channel $\mathcal{R}_{A'B' \rightarrow AB}$ that is conditional uniformly mixing channel, i.e., $\mathcal{R} = \mathcal{R}_{A' \rightarrow A}^{\pi} \otimes \mathcal{Q}_{B' \rightarrow B}$ for any side channel $\mathcal{Q}$, we have, $S_H^{\varepsilon=0}[A|B]_{\mathcal{R}} = S[A|B]_{\mathcal{R}} = S_{\infty}[A|B]_{\mathcal{R}} = \log |A|$; if $\mathcal{Q}$ is taken to be $\mathcal{R}_{B' \rightarrow B}^{\pi}$, then $\mathcal{R} = \mathcal{R}_{A' \rightarrow A}^{\pi} \otimes \mathcal{R}_{B' \rightarrow B}^{\pi}$ is both tele-covariant and no-signaling from $A' \rightarrow B$, and a free object in the resource theory of athermality for channels with trivial output Hamiltonian. We can then interpret Eq. (12) as

$$\text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}) = \text{Cost}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}) = \frac{1}{2}(S[A|B]_{\mathcal{R}^{\pi} \otimes \mathcal{Q}} - S[A|B]_{\mathcal{N}}), \quad (15)$$

for any side channel $\mathcal{Q}$. That is, the resource distillation and formation capacities of a channel $\mathcal{N}_{A'B' \rightarrow AB}$ that is tele-covariant or no-signaling from $A' \rightarrow B$, is equal to half of the difference between the von Neumann conditional entropies of a conditional uniformly mixing channel and the channel $\mathcal{N}$ itself.

Consider two quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$ and $\mathcal{M}_{C'D' \rightarrow CD}$, where $\widehat{H}_A \propto \mathbb{1}_A$ and $\widehat{H}_C \propto \mathbb{1}_C$, that are tele-covariant or no-signaling from $A' \rightarrow B$. The asymptotic optimal rate of the resource (conditional athermality or purity) gain $\Delta[\mathcal{N} \rightarrow \mathcal{M}]$ during transformation of $\mathcal{N}$ to $\mathcal{M}$ under the action of CGPSs is equal to,

$$\Delta(\mathcal{N} \rightarrow \mathcal{M}, \mathcal{R}_{A' \rightarrow A}^{\pi}) = \text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}) - \text{Cost}^{(\infty, 0)}(\mathcal{M}, \mathcal{R}^{\pi}) = \frac{1}{2} \left[\log \frac{|A|}{|C|} + S[C|D]_{\mathcal{M}} - S[A|B]_{\mathcal{N}} \right]. \quad (16)$$

For a quantum channel $\mathcal{N}_{A'B'C' \rightarrow ABC}$ that is tripartite tele-covariant [26] or no-signaling from $A' \rightarrow BC$,

$$\Delta(\mathcal{N} \rightarrow \text{tr}_C \circ \mathcal{N}, \mathcal{R}_{A' \rightarrow A}^\pi) = \text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}_{A' \rightarrow A}^\pi) - \text{Cost}^{(\infty, 0)}(\text{tr}_C \circ \mathcal{N}, \mathcal{R}_{A' \rightarrow A}^\pi) \quad (17)$$

$$= \frac{1}{2} (S[A|B]_{\mathcal{N}} - S[A|BC]_{\mathcal{N}}) \geq 0, \quad (18)$$

where $S[A|B]_{\mathcal{N}} := \inf_{Q \in \text{Ch}(B'C', B)} D[\text{tr}_C \circ \mathcal{N} \| \mathcal{T}^\beta \otimes Q]$ for a tripartite channel $\mathcal{N}_{A'B'C' \rightarrow ABC}$. Inequality (18) follows because the channel entropy satisfies the strong subadditivity property [4]: the conditional entropy $S[A|B]_{\mathcal{N}}$ of a quantum channel $\mathcal{N}_{A'B'C' \rightarrow ABC}$ is nonincreasing upon conditioning, $S[A|B]_{\mathcal{N}} \geq S[A|BC]_{\mathcal{N}}$.

FIG. 1. Summary of the signaling properties of channels and the bounds on the conditional channel min-entropy $S_\infty[A|B]_{\mathcal{N}}$ for different classes of bipartite channels $\mathcal{N}_{A'B' \rightarrow AB}$. For simplicity, we have assumed that $|A'| = |B'| = |B| = |A|$. The further the conditional entropy of a unitary channel lies to the left of $-\log |A|$, the greater the signaling from $A' \rightarrow B$ exhibited by the channel. Maximally entangling unitary channels sit at the left extremal point of $-3 \log |A|$, while the controlled unitary channels C_U are lower bounded by $-2 \log |A|$, indicating a clear gap between the signaling ability of swap-like and controlled unitary channels. $\hat{C}_U$ denotes the controlled unitary with orthogonal unitary operators. The conditional min-entropy of channels $\mathcal{N}$ in the sets C-SEP-P, C-PPT-P, and $S_{A' \nrightarrow B}$ are all lower bounded by $-\log |A|$. See Section VI for related results in generality.

The dependence of conditional athermality (and purity) distillation and formation rates on conditional channel entropies reflects an intrinsic relation between the channel's thermodynamic resource content and its underlying causal structure. We consider broad classes of channels to illustrate the interdependence between underlying causal structure and conditional entropy (Figure 1 and Section VIA). We summarize some of our main results on the conditional min-entropy of a bipartite quantum channel in Table I in blue text. In the table, we make comparison with analogous observations for conditional min-entropy of states [16]. The properties of conditional channel entropies can be of independent interest and serve as tools to analyze other informational aspects of quantum processes in quantum communication and computation, many-body quantum physics, open quantum systems, etc.

C. Related works

The resource theory of athermality of quantum states has been widely studied under various settings [20, 30, 31], along with different classes of free operations such as Gibbs-preserving channels, thermal operations, covariant thermal operations, and catalytic assistance [32–37]. The resource theory of athermality of states generalizes the resource theory of purity of states [38–40]. In parallel, the thermodynamic aspects of quantum channels have been investigated to better

understand the energetics of quantum processors, as well as their informational and computational limitations [3, 41–46].

Our work complements an alternative line of research in which the resourcefulness of athermal channels is studied under the assumption that unitaries commuting with the Hamiltonian are free operations [41, 47]. Although the identity channel trivially commutes with the Hamiltonian, preserving a quantum state in isolation from the environment incurs an energy cost. This observation motivates the need for a resource theory in which identity and noiseless quantum channels are not considered free. The resource theory of purity of quantum channels provides a step in this direction for trivial Hamiltonians [48, 49]. Recent works [2, 3, 43], including the present one, align with and further advance this ongoing effort for non-trivial Hamiltonians.

In [2, 3], thermodynamic cost of the transformation between two channels was determined and the basic thermodynamic concept of the channel free energy was introduced using both axiomatic and operational approaches. The free energy of quantum channels was shown to be dependent on different information processing capabilities of a channel like entanglement-assisted classical capacity [50] and private randomness distillation capacity [49].

We directly generalize the resource theory of athermality for single-input single-output quantum channels under the action of Gibbs-preserving superchannels (GPSs) [2, 3]. Furthermore, we introduce a resource theory of conditional athermality for bipartite quantum channels under CG-PSSs. This framework reduces to the standard resource theory of athermality for quantum channels when the bipartite channels are decoupled (i.e., tensor-product channels between the two parties). Our analysis also shows that the resource theory of athermality is asymptotically reversible under the action of GPSs, even when the input and output dimensions of the channels differ. In addition, we generalize the resource theory of purity of quantum channels to a resource theory of conditional purity for bipartite channels under conditional uniformity-preserving superchannels.

Our work provides operational interpretations of the hypothesis-testing, max-, and regularized relative entropies between quantum channels and decoupled quantum channels in thermodynamic settings. Building upon known limitations in channel discrimination tasks [5, 10, 21, 22, 51, 52], we determine asymptotic rates for the distillation and formation of conditional purity for broad families of quantum channels. Our contributions also connect to broader developments in the resource theories of quantum channels, including entanglement, asymmetry, purity, and coherence [10, 11, 26, 53–56], as well as to the thermodynamic interpretation of negative entropic quantities [37, 46, 57, 58] and the role of quantum correlations in thermodynamics [2, 44, 59–62].

The clear operational interpretation of the conditional entropy of quantum states [18], as established in [19, 63], represents a landmark result in quantum information theory. In a similar spirit, we expect that our operational characterization of conditional channel entropies will yield new insights into quantum processes relevant to quantum information processing and computation, and will prove to be broadly useful across quantum information science.

D. Outline

The paper is organized as follows. In Section II, we introduce the necessary preliminaries and notations used throughout the paper. We also review generalized divergences and their channel extensions, which form the basis of entropic quantities. In particular, we introduce the generalized entropy and conditional entropy of bipartite quantum channels, along with their smoothed variants. In Section III, we introduce the framework for the resource theory of conditional athermality for bipartite quantum channels, where the free objects are conditional absolutely thermalizing channels and the free operations are conditional Gibbs-preserving superchannels. Within this framework, we formalize the operational tasks of conditional athermality distillation and forma-

tion, and determine limitations on their one-shot and asymptotic rates. In Section IV, we prove several properties of the conditional min-entropy of quantum channels, along with its bounds and the asymptotic equipartition property. In Section V, we consider bipartite channels with trivial Hamiltonians where the resource theory of conditional athermality reduces to the resource theory of conditional purity under conditional purity-preserving superchannels. We show that the conditional distillation and formation capacities are related to conditional channel entropies, thereby providing an operational interpretation of these quantities. We prove that the resource theory of conditional purity is asymptotically reversible under conditional purity-preserving superchannels. We discuss the relation of the conditional purity capacity of a tele-covariant channel with the superdense coding capacity of its Choi state. In Section VI, we explore the implications of the causal structure of a bipartite channel on its conditional channel entropy and the conditional purity distillation and formation rates. We prove the asymptotic reversibility of the resource theory of conditional purity for semicausal channels that are no-signaling from non-conditioning input to conditioning output. We consider several examples of bipartite channels of practical interest and discuss bounds on their conditional channel min-entropies. Finally, we conclude in Section VII with a brief discussion of potential open problems.

II. PRELIMINARIES

A. Standard notations and definitions

We consider separable Hilbert spaces of finite-dimensions. Quantum states are described by positive semidefinite operators with unit trace. Quantum channels are physical transformations of quantum states and described by completely positive, trace-preserving linear maps. Quantum superchannels describe physical transformations of quantum channels and its action on a quantum channel is described by the concatenation of the channel with pre-processing and post-processing quantum channels.

A quantum system A and associated the Hilbert space $\mathcal{H}_A$ are both denoted with A for simplicity, $\dim(\mathcal{H}_A) = |A|$ and $AB := A \otimes B$. $L(A, B)$ denotes the set of all linear transformations (or operators) from $A \rightarrow B$. $L(A)$ and $L_+(A)$ denotes the set of bounded operators and positive semidefinite operators defined on A , respectively. X_A denotes $X \in L(A)$ and $\mathbb{1}_A$ is the identity operator on A . $\text{St}(A)$ denotes the set of all density operators on A ; $\text{St}_{\leq}(A)$ denotes the set of all subnormalized density operators on A . $\text{Ch}(A', A)$ denotes the set of all quantum channels from $L(A') \rightarrow L(A)$. A superoperator $\mathcal{N}_{A \rightarrow B}$ denotes a linear map from $L(A) \rightarrow L(B)$. $\text{id}_{A' \rightarrow A}$ denotes the identity channel, where $A' \simeq A$. Let $\Gamma_{RA'} := \sum_{i,j=0}^{d-1} |ii\rangle \langle jj|_{RA'}$, where $d = \min\{|R|, |A'|\}$ and $\{|i\rangle\}_{i=0}^{d-1}$ is an orthonormal set of vectors, denote the maximally entangled operator and $\Phi_{RA'} := \frac{1}{d} \Gamma_{RA'}$ is a maximally entangled state. The Choi operator of a linear map $\mathcal{N} : L(A') \rightarrow L(A)$ is given by $\Gamma_{RA}^{\mathcal{N}} := \text{id}_R \otimes \mathcal{N}_{A' \rightarrow A}(\Gamma_{RA'})$, where $R \simeq A'$. For a quantum channel $\mathcal{N}_{A' \rightarrow A}$, its Choi state is $\Phi_{RA}^{\mathcal{N}} := \text{id}_R \otimes \mathcal{N}_{A' \rightarrow A}(\Phi_{RA'})$, where $R \simeq A'$. The Choi state of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is $\Phi_{RAAB}^{\mathcal{N}} = \mathcal{N}(\Phi_{RAA'} \otimes \Phi_{RBB'})$. For a bipartite state ρ_{AB} , we use $\rho_A := \text{tr}_B(\rho_{AB})$.

An operator $U_{A' \rightarrow A}$ is unitary if $U^\dagger U = \mathbb{1}_{A'}$ and $UU^\dagger = \mathbb{1}_A$ and corresponding channel is $\mathcal{U}_{A' \rightarrow A}(\cdot) = U(\cdot)U^\dagger$, and it holds that $A' \simeq A$. An operator $V_{A' \rightarrow A}$ is isometry if $V^\dagger V = \mathbb{1}_{A'}$ and $VV^\dagger = \Pi_A$, where $|A'| \leq |A|$ and Π_A is projection on A with $\text{rank}(\Pi_A) = |A'|$; the corresponding isometry channel is $\mathcal{V}_{A' \rightarrow A}(\cdot) = V(\cdot)V^\dagger$. Let $\text{SCh}((A', A), (B', B))$ denote the set of all quantum superchannels that maps $\text{Ch}(A', A) \rightarrow \text{Ch}(B', B)$, and the action of any $\Theta \in \text{SCh}((A', A), (B', B))$ on $\mathcal{N} \in \text{Ch}(A', A)$ can be expressed as [64, 65]

$$\Theta(\mathcal{N}) = \mathcal{Q}_{CA \rightarrow B} \circ \mathcal{N}_{A' \rightarrow A} \circ \mathcal{P}_{B' \rightarrow CA'}, \quad (19)$$

where $\mathcal{P}$ is some channel that pre-processes $\mathcal{N}$ and $\mathcal{Q}$ is some channel that post-processes $\mathcal{N}$.

Let $\text{SEP}(A; B)$ denote the set of all separable states ρ_{AB} that is separable between A, B , i.e., all $\rho \in \text{St}(AB)$ of the form $\rho_{AB} = \sum_x p_X(x) \omega_A^x \otimes \tau_B^x$ for some probability distribution $\{p_X(x)\}_x$ and $\omega^x \in \text{St}(A)$ and $\tau^x \in \text{St}(B)$ for each x . Let $\text{Ent}(A; B)$ be the set of all states ρ_{AB} that is entangled (not separable) between A, B . Let $\text{PPT}(A; B)$ denote the set of all states ρ_{AB} that remains positive under the partial transposition on B , i.e., $T_B(\rho_{AB}) \geq 0$ for transposition T_B with respect to some basis on B (without loss of generality) [66]. A bipartite state ρ_{AB} is called NPT if $\rho_{AB} \notin \text{PPT}(A; B)$.

The action of a swap operator is $U^{\text{SWAP}}_{A'B' \rightarrow AB}(|i\rangle_{A'} \otimes |j\rangle_{B'}) = |j\rangle_A \otimes |i\rangle_B$ for each vectors in some orthonormal bases $\{|i\rangle_{A'}\}_i$ and $\{|j\rangle_{B'}\}_j$, and $\{|j\rangle_A\}_j$ and $\{|i\rangle_B\}_i$ are some orthonormal sets of vectors. Its Choi operator has the form $\Gamma^{S_{A:B}} = \Gamma_{R_A B} \otimes \Gamma_{R_B A} = \Gamma_{R_A A: R_B B}$. We call a unitary operation $\mathcal{U}_{A'B' \rightarrow AB}$ as maximally entangling or a swap-like operation (channel), denoted by $\mathcal{U} \in \text{SWAP}_{A;B}$, if its Choi operator $\Phi_{R_A A R_B B}^{\mathcal{U}} \in \text{Ent}(R_A A; R_B B)$ is maximally entangled of Schmidt rank $\min\{|A'| |A|, |B'| |B|\}$. Here, $\text{SWAP}(A; B)$ denotes the set of all swap-like operations from $A'B' \rightarrow AB$. A swap operation composed with pre-processing local unitaries on A', B' and post-processing local isometries on A, B is a swap-like operation.

We denote the Hamiltonian of a quantum system A with $\hat{H}_A$. $\gamma_A^\beta := \exp(-\beta \hat{H}_A) / Z_A^\beta$, where $Z_A^\beta := \text{tr}[\exp(-\beta \hat{H}_A)]$ is the partition function, denotes a thermal or Gibbs state of A associated with inverse temperature β and $\hat{H}_A$. The Hamiltonian $\hat{H}_{AB}$ of two noninteracting quantum systems A and B is given by $\hat{H}_A + \hat{H}_B := \hat{H}_A \otimes \mathbb{1}_B + \mathbb{1}_A \otimes \hat{H}_B$ as the interaction Hamiltonian is absent, $\hat{H}_{AB}^{\text{int}} = 0$. Let $\mathcal{R}_{A' \rightarrow A}^\omega$ denote the completely positive linear map that replaces the input with $\omega_{A'}$, $\mathcal{R}_{A' \rightarrow A}^\omega(X_{A'}) := \text{tr}(X_{A'}) \omega_A$. The absolutely thermal channel is defined as $\mathcal{T}_{A' \rightarrow A}^\beta(\cdot) = \mathcal{R}_{A' \rightarrow A}^{\gamma_A^\beta}(\cdot) = \text{tr}(\cdot) \gamma_A^\beta$. For a trivial Hamiltonian $\hat{H}_A \propto \mathbb{1}_A$, γ_A^β is equal to the maximally mixed state $\pi_A := \frac{1}{|A|} \mathbb{1}_A$.

$\|X\|_p := (\text{tr}[|X|^p])^{1/p}$ is the Schatten p -norm of an operator X for $p \in [1, \infty)$ (definition is also extended to $p \in (0, 1)$ but then $\|X\|_p$ is not a norm), where $\|X\|_1$ is also called the trace-norm. Fidelity between $\rho_A \in \text{St}(A)$ and $\sigma_A \in L_+(A)$ is defined as $F(\rho_A, \sigma_A) := \|\sqrt{\rho} \sqrt{\sigma}\|_1^2$, and generalized fidelity is defined as $F_\leq(\rho, \sigma) := \left[\sqrt{F(\rho, \sigma)} + \sqrt{(1 - \text{tr}(\rho))(1 - \text{tr}(\sigma))} \right]^2$ for $\rho, \sigma \in \text{St}_\leq(A)$. The generalized purified distance $P(\rho, \sigma) := \sqrt{1 - F_\leq(\rho, \sigma)}$ for $\rho, \sigma \in \text{St}_\leq(A)$.

B. Generalized divergence

The generalized state divergence $\mathbf{D} : \text{St}(A) \times \text{St}(A) \rightarrow \mathbb{R}$ is a real-valued function on a pair of states that is monotone under the action of an arbitrary quantum channel $\mathcal{N}_{A \rightarrow B}$, i.e., $\mathbf{D}(\rho \| \sigma) \geq \mathbf{D}(\mathcal{N}(\rho) \| \mathcal{N}(\sigma))$ for arbitrary $\rho, \sigma \in \text{St}(A)$ and arbitrary $\mathcal{N} \in \text{Ch}(A, B)$ [14, 21, 67]. Some examples of the generalized state divergences are hypothesis-testing relative entropy D_H^ε , quantum relative entropy D [68], sandwiched Rényi relative entropy D_α for $\alpha \in [\frac{1}{2}, 1) \cup (1, \infty)$ [69, 70], Petz-Rényi relative entropy $\bar{D}_\alpha$ for $\alpha \in [0, 1) \cup (1, 2]$, trace-distance, purified distance, etc.

For arbitrary $\rho \in L(A)$ and arbitrary $\sigma \in L_+(A)$,

- Quantum Relative Entropy:

$$D(\rho \| \sigma) := \text{tr}[\rho(\log \rho - \log \sigma)] \quad (20)$$

provided $\text{supp}(\rho) \subseteq \text{supp}(\sigma)$, and is $+\infty$ otherwise.

- Hypothesis-Testing relative entropy: For $\varepsilon \in [0, 1]$,

$$D_H^\varepsilon(\rho \| \sigma) = -\log \inf\{\text{tr}(\Lambda \sigma) : 0 \leq \Lambda \leq \mathbb{1}, \text{tr}(\Lambda \rho) \geq 1 - \varepsilon\}. \quad (21)$$

- Sandwiched Rényi relative entropy: For $\alpha \in [\frac{1}{2}, 1) \cup (1, \infty)$,

$$D_\alpha(\rho\|\sigma) = \frac{1}{\alpha-1} \log \text{tr} \left[\left(\sigma^{\frac{1-\alpha}{2\alpha}} \rho \sigma^{\frac{1-\alpha}{2\alpha}} \right)^\alpha \right], \quad (22)$$

where $D_\alpha(\rho\|\sigma) = +\infty$ for $\alpha > 1$ if $\text{supp}(\rho) \not\subseteq \text{supp}(\sigma)$.

- Petz-Rényi relative entropy: For $\alpha \in [0, 1) \cup (1, \infty)$,

$$\overline{D}_\alpha(\rho\|\sigma) = \frac{1}{\alpha-1} \log \text{tr} (\rho^\alpha \sigma^{1-\alpha}) \quad (23)$$

where $\overline{D}_\alpha(\rho\|\sigma) = +\infty$ for $\alpha > 1$ if $\text{supp}(\rho) \not\subseteq \text{supp}(\sigma)$.

- Quantum max-relative entropy:

$$D_{\max}(\rho\|\sigma) = \log \inf\{\lambda \geq 0 : \rho \leq \lambda \sigma\} \quad (24)$$

where $D_{\max}(\rho\|\sigma) = +\infty$ if $\text{supp}(\rho) \not\subseteq \text{supp}(\sigma)$.

We have $\lim_{\alpha \rightarrow 1} D_\alpha(\rho\|\sigma) = D(\rho\|\sigma) = \lim_{\alpha \rightarrow 1} \overline{D}_\alpha(\rho\|\sigma)$, $D_\infty(\rho\|\sigma) := \lim_{\alpha \rightarrow \infty} D_\alpha(\rho\|\sigma) = D_{\max}(\rho\|\sigma)$, and $\overline{D}_0(\rho\|\sigma) = D_H^{\varepsilon=0}(\rho\|\sigma)$. We consider log with respect to base 2 unless stated otherwise.

Generalized channel divergence: The generalized channel divergence $\mathbf{D} : \text{Ch}(A, B) \times \text{Ch}(A, B) \rightarrow \mathbb{R}$ is a real-valued function that is based on the generalized state divergence $\mathbf{D}(\cdot\|\cdot)$ and defined between a quantum channel $\mathcal{N}_{A \rightarrow B}$ relative to a completely-positive map $\mathcal{M}_{A \rightarrow B}$ as [71] (see also [72])

$$\mathbf{D}[\mathcal{N}\|\mathcal{M}] := \sup_{\rho \in \text{St}(RA)} \mathbf{D}(\text{id} \otimes \mathcal{N}(\rho_{RA})\|\text{id} \otimes \mathcal{M}(\rho_{RA})), \quad (25)$$

where supremum is over all possible states with arbitrary $|R|$. The generalized channel divergence between two quantum channels is monotone under the action of quantum superchannels [4, Theorem 1]. The generalized channel divergence $\mathbf{D}[\cdot\|\cdot]$ is called sandwiched Rényi relative entropy $D_\alpha[\cdot\|\cdot]$, hypothesis-testing relative entropy $D_H^\varepsilon[\cdot\|\cdot]$, quantum relative entropy $D[\cdot\|\cdot]$, purified distance $P[\cdot, \cdot]$, etc. when the associated generalized state divergence $\mathbf{D}(\cdot\|\cdot)$ is taken to be $D_\alpha(\cdot\|\cdot)$, $D_H^\varepsilon(\cdot\|\cdot)$, $D(\cdot\|\cdot)$, purified distance $P(\cdot, \cdot)$, etc., respectively. It suffices to optimize over pure input states $\rho \in \text{St}(RA)$ such that $R \simeq A$ in Eq. (25) for $D_H^\varepsilon[\cdot\|\cdot]$, $D_\alpha[\cdot\|\cdot]$ (when $\alpha \in [\frac{1}{2}) \cup (1, \infty)$), $D[\cdot\|\cdot]$, and $P[\cdot, \cdot]$. For quantum channels $\mathcal{N}, \mathcal{M} \in \text{Ch}(A, B)$, $D_\infty[\mathcal{N}\|\mathcal{M}] = D_\infty(\Gamma_{RAB}^\mathcal{N} \|\Gamma_{RAB}^\mathcal{M}) = D_\infty(\Phi_{RAB}^\mathcal{N} \|\Phi_{RAB}^\mathcal{M})$, where $R_A \simeq A$ [52].

The regularized generalized channel divergence $\mathbf{D}^{\text{reg}}[\mathcal{N}\|\mathcal{M}]$ for channels $\mathcal{N}, \mathcal{M} \in \text{Ch}(A, B)$ is defined as [22, 52]

$$\mathbf{D}^{\text{reg}}[\mathcal{N}\|\mathcal{M}] := \lim_{n \rightarrow \infty} \frac{1}{n} \mathbf{D}[\mathcal{N}^{\otimes n} \|\mathcal{M}^{\otimes n}]. \quad (26)$$

C. Entropies and conditional entropies

The generalized state and channel divergences have been used to provide a collective method to define entropic and information measures; see, for example, [4, 16, 73]. The entropy functions quantify the amount of randomness or uncertainty present in a state. The conditional entropy functions quantify the amount of randomness or uncertainty present in a state when part of the system, or memory, is accessible to the observer. See Table II, where we compare dimensional bounds for entropy and conditional entropy of random variables, states, and channels.

	Min-entropy	Conditional min-entropy
Random variables	$0 \leq H_\infty(X) \leq \log X $ [14, 16]	$0 \leq H_\infty(X Y) \leq \log X $ [14, 16]
Quantum states	$0 \leq S_\infty(A)_\rho \leq \log A $ [14]	$-\log A \leq S_\infty(A B)_\rho \leq \log A $ [15]
Quantum channels	$-\log A \leq S_\infty[A]_\mathcal{M} \leq \log A $ [74]	$-\log A' B' B \leq S_\infty[A B]_\mathcal{N} \leq \log A $

TABLE II. We compare dimensional bounds for min-entropies [14, 46] vs. conditional min-entropies [4, 16] of random variables, quantum states, and quantum channels. We have min-entropy $H(X)$ and conditional min-entropy $H(X|Y)$ for classical probability distributions, min-entropy $S_\infty(A)_\rho$ and conditional min-entropy $S_\infty(A|B)_\rho$ for quantum states, and min-entropy $S_\infty[A]_\mathcal{M}$ and conditional min-entropy $S[A|B]_\mathcal{N}$ of point-to-point channels $\mathcal{M}_{A' \rightarrow A}$ and bipartite quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$ (Proposition 2), respectively.

The generalized entropy $\mathbf{S}(A)_\rho$ of a quantum state ρ_A is defined as

$$\mathbf{S}(A)_\rho := -\mathbf{D}(\rho_A \| \mathbb{1}_A), \quad (27)$$

for $\mathbf{D}(\cdot \| \cdot)$ being quantum relative entropy, sandwiched Rényi relative entropy, hypothesis-testing relative entropy etc. The generalized entropy reduces to the von Neumann entropy $S(A)_\rho := S(\rho_A) := -\text{tr}[\rho \log \rho]$ when the associated state divergence is quantum relative entropy.

The generalized conditional entropy $\mathbf{S}(A|B)_\rho$ of a bipartite quantum state ρ_{AB} is defined as

$$\mathbf{S}(A|B)_\rho := \mathbf{S}^\dagger(A|B)_\rho := - \inf_{\sigma \in \text{St}(B)} \mathbf{D}(\rho_{AB} \| \mathbb{1}_A \otimes \sigma_B), \quad (28)$$

for $\mathbf{D}(\cdot \| \cdot)$ being quantum relative entropy, sandwiched Rényi relative entropy, hypothesis-testing relative entropy, Petz-Rényi relative entropy, etc. We can also define a related quantifier for the sandwiched Rényi conditional entropy in the following way: for $\alpha \in [\frac{1}{2}, 1) \cup (1, \infty)$ and a quantum state ρ_{AB} ,

$$S_\alpha^\dagger(A|B)_\rho := -D_\alpha(\rho_{AB} \| \mathbb{1}_A \otimes \rho_B) \leq S_\alpha(A|B)_\rho. \quad (29)$$

For the von Neumann conditional entropy of a quantum state ρ_{AB} , we have

$$S(A|B)_\rho := - \inf_{\sigma \in \text{St}(B)} D(\rho_{AB} \| \mathbb{1}_A \otimes \sigma_B) = -D(\rho_{AB} \| \mathbb{1}_A \otimes \rho_B) = S(AB)_\rho - S(B)_\rho. \quad (30)$$

Generalized conditional channel entropy: The generalized conditional channel entropy of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is defined as [4]

$$\mathbf{S}[A|B]_\mathcal{N} := - \inf_{Q \in \text{Ch}(B', B)} \mathbf{D}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^\mathbb{1} \otimes Q_{B' \rightarrow B}], \quad (31)$$

for $\mathbf{D}[\cdot \| \cdot]$ being quantum relative entropy, sandwiched Rényi relative entropy, hypothesis-testing relative entropy, etc. between completely positive maps. For a replacer channel $\mathcal{R}_{A'B' \rightarrow AB}^\omega$, i.e., $\mathcal{R}_{A'B' \rightarrow AB}^\omega(\cdot) = \text{tr}(\cdot) \omega_{AB}$ for a given $\omega \in \text{St}(AB)$, $\mathbf{S}[A|B]_\mathcal{N} = \mathbf{S}(A|B)_\omega$ whenever $\mathbf{D}(\rho \otimes \sigma \| \tau \otimes \sigma) = \mathbf{D}(\rho \| \tau)$. The generalized channel entropy $\mathbf{S}[A]_Q$ of a quantum channel $Q_{A' \rightarrow A}$ is defined as $\mathbf{S}[Q] := -\mathbf{D}[Q \| \mathcal{R}^\mathbb{1}]$.

A channel $Q_{B' \rightarrow B}$ in Eq. (31) can be considered to be a side channel in a similar spirit as a state σ_B in Eq. (28) can be considered as a side information. The entropic and conditional entropic functions are named after the generalized state or channel divergences they are based on.

Smoothed relative-entropy: The max-relative entropy function $D_{\max}(\rho \| \sigma)$ can show sensitive dependence on the tails of the spectrum of ρ , such that small changes in ρ can lead to drastic

changes in max-relative entropy. Therefore the concept of smoothened max-relative entropy is introduced which is more robust against finite errors that inevitably creep in during any operational implementation. To define smoothed relative entropy we first introduce the ε -ball $\mathcal{B}^\varepsilon(\rho)$ around the state ρ in Hilbert space A as

$$\mathcal{B}^\varepsilon(\rho) := \{\sigma \in \text{St}_\leq(A) : P(\rho, \sigma) \leq \varepsilon\}. \quad (32)$$

The smoothed max-relative entropy is given as $D_\infty^\varepsilon(\rho \| \sigma) := \inf_{\rho' \in \mathcal{B}^\varepsilon(\rho)} D_\infty(\rho' \| \sigma)$. We can similarly define a ε -ball $\mathcal{B}^\varepsilon[\mathcal{N}]$ around the channel $\mathcal{N}_{A' \rightarrow A}$ as

$$\mathcal{B}^\varepsilon[\mathcal{N}] := \{Q \in \text{Ch}(A', A) : P[\mathcal{N}, Q] \leq \varepsilon\}. \quad (33)$$

where $P[\cdot, \cdot]$ is the purified distance. The smoothed max-relative entropy defined with respect to the ε -ball defined above is given as

$$D_\infty^\varepsilon[\mathcal{N} \| \mathcal{M}] := \inf_{Q \in \mathcal{B}^\varepsilon[\mathcal{N}]} D_\infty^\varepsilon[Q \| \mathcal{M}]. \quad (34)$$

and the smoothed conditional channel min-entropy for the channel $\mathcal{N}_{A'B' \rightarrow AB}$ is given as

$$S_\infty^\varepsilon[A|B]_\mathcal{N} := \sup_{M \in \mathcal{B}^\varepsilon[\mathcal{N}]} S_\infty[A|B]_M \quad (35)$$

$$= - \inf_{Q \in \text{Ch}(B', B)} D_\infty^\varepsilon[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^\mathbb{1} \otimes Q_{B' \rightarrow B}] \quad (36)$$

III. CONDITIONAL ATHERMALITY DISTILLATION AND FORMATION

When we look around, we observe that different objects can possess different temperatures; even within a single system, one part may have thermalized while another remains far from thermal equilibrium. From a dynamical perspective, certain processes drive systems toward thermalization, whereas other coexisting processes often don't exhibit such tendency. A simplified (toy-model) representation of such naturally occurring dynamics can be described by a bipartite quantum channel of the form $\mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}$, where $\mathcal{T}^\beta$ tends to thermalize all inputs to γ_A^β . A thermal state γ_A^β is in equilibrium with a thermal bath at a temperature $\beta \in (0, \infty)$. This decomposition formalizes the idea that two processes, one strictly thermal $\mathcal{T}^\beta$ and the other described by an arbitrary channel Q , coexist and act in parallel on distinct subsystems. We are going to refer to bipartite quantum channels of the form $\mathcal{T}^\beta \otimes Q$ as partially (or conditionally) thermalizing channel. Notice that for a given $\mathcal{T}_{A' \rightarrow A}^\beta$, thermal state γ_A^β of the output gets fixed. Also for $\widehat{H}_A \propto \mathbb{1}_A$, we have $\gamma_A^\beta = \pi_A = \frac{1}{|A|} \mathbb{1}_A$.

Resource theory of conditional athermality: To formalize these intuitive observations, we introduce the resource theory of conditional athermality of bipartite quantum processes. For simplicity, we consider the conditional athermal resource theory for an arbitrary bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$. The free objects are bipartite quantum channels of the form $\mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}$. The equilibrium state γ^β corresponding to the bath at temperature β fixes the absolutely thermal channel $\mathcal{T}_{A' \rightarrow A}^\beta$ for parts A', A of the system for a given conditional athermal resource theory. That is, $\mathcal{T}^{\beta'} \otimes Q$ is not a free object but rather a resource when the bath for A is at temperature β and $\beta' \neq \beta$ [2]. The free operations are conditional Gibbs-preserving superchannels (CGPSs) Θ^β . A CGPS, $\Theta^\beta \in \text{Sch}((A'B', AB), (C'D', CD))$, is defined as a superchannel that preserves conditionally thermalizing channel $\mathcal{T}^\beta$, i.e., for an arbitrary $Q \in \text{Ch}(B', B)$ there exists some $Q' \in \text{Ch}(D', D)$ such that

$$\Theta^\beta(\mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}) = \mathcal{T}_{C' \rightarrow C}^\beta \otimes Q'_{D' \rightarrow D}. \quad (37)$$

These channels can be characterized as postprocessing with a conditional Gibbs covariant channel [37]. We discuss these properties in Appendix E. The resourceful objects are bipartite quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$ that are not partially thermalizing on A , i.e., channels that are not of the form $\mathcal{T}_{A' \rightarrow A}^\beta \otimes \mathcal{Q}_{B' \rightarrow B}$. To denote athermal resourcefulness of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ with respect to the given free object $\mathcal{T}_{A' \rightarrow A}^\beta \otimes \mathcal{Q}_{B' \rightarrow B}$, we may write $(\mathcal{N}, \mathcal{T}^\beta \otimes \mathcal{Q})$ whenever required. Two bipartite quantum channels $\mathcal{N}, \mathcal{M}$ are said to be conditional athermality equivalent if there exists some quantum channels $\mathcal{Q}, \mathcal{Q}'$ and a CGPS $\Theta_1^\beta(\mathcal{T}^\beta \otimes \mathcal{Q}) = \mathcal{T}^\beta \otimes \mathcal{Q}'$ that can convert $\mathcal{N} \rightarrow \mathcal{M}$, and similarly another CGPS $\Theta_2^\beta(\mathcal{T}^\beta \otimes \mathcal{Q}') = \mathcal{T}^\beta \otimes \mathcal{Q}$ that can convert $\mathcal{M} \rightarrow \mathcal{N}$, and we write $(\mathcal{N}, \mathcal{T}^\beta \otimes \mathcal{Q}) \sim (\mathcal{M}, \mathcal{T}^\beta \otimes \mathcal{Q}')$.

Resourcefulness: We inspect channel free energies to determine the standard resource unit. The thermal channel free energy $F_T^\beta[\mathcal{P}]$ of an arbitrary quantum channel $\mathcal{P}_{A' \rightarrow A}$ is given by $F_T^\beta[\mathcal{P}] := (-\log Z_A^\beta + D[\mathcal{P} \parallel \mathcal{T}^\beta])\beta^{-1} \ln 2$ and its resource-theoretic free energy $F^\beta[\mathcal{P}] = F_T^\beta[\mathcal{P}] - F_T^\beta[\mathcal{T}^\beta]$ [2, 3]. For a given $\mathcal{T}_{A' \rightarrow A}^\beta$, the free energy of a quantum channel $\mathcal{P}_{A' \rightarrow A}$ is maximum only if $\mathcal{P}_{A' \rightarrow A}$ is an isometry channel and they are minimum iff $\mathcal{P} = \mathcal{T}^\beta$ [2, 3] (also see Lemma 5). The resource-theoretic thermal channel free energy F^β is additive for tensor-product quantum channels with noninteracting output Hamiltonians [2]. For a bipartite quantum channel $\mathcal{P}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$, we have $F_T^\beta[\mathcal{P} \otimes \mathcal{Q}] - F_T^\beta[\mathcal{T}^\beta \otimes \mathcal{Q}] = F^\beta[\mathcal{P}] = \beta^{-1} D[\mathcal{P} \parallel \mathcal{T}^\beta] \ln 2$. This leads to the fact that among tensor-product quantum channels $\mathcal{P}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$ for a fixed channel $\mathcal{Q}$, F^β is maximum only if $\mathcal{P}$ is an isometry channel and minimum iff $\mathcal{P} = \mathcal{T}^\beta$. As Hamiltonian in general can be arbitrary, the choice of trivial Hamiltonian is made for the standard resource unit in the resource theory of athermality. The channel free energy $F^\beta[\mathcal{P}]$ of a unitary process is minimal when its output Hamiltonian is fully degenerate [2]. In the resource theory of athermality under Gibbs-preserving superchannels [2], all unitary channels $\mathcal{U}_{A' \rightarrow A}$ with trivial Hamiltonian are resource equivalent to each other. The standard resource unit of size m in the resource theory of athermality is taken to be the identity channel id_m with trivial Hamiltonian and input dimension of m , without loss of generality.

Conditional athermality resource monotones: The generalized resource-theoretic conditional thermal free energy $F^\beta[A|B]_\mathcal{N}$ of an arbitrary bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is defined with respect to conditional bath at temperature β (or conditionally thermalizing channel on A'),

$$F^\beta[A|B]_\mathcal{N} := \beta^{-1} \ln 2 \inf_{\mathcal{Q} \in \text{Ch}(B', B)} \mathbf{D}[\mathcal{N} \parallel \mathcal{T}^\beta \otimes \mathcal{Q}]. \quad (38)$$

$F^\beta[A|B]_\mathcal{N}$ is nonincreasing under the action of an arbitrary CGPS $\Theta \in \text{Sch}((A'B', AB), (C'D', CD))$. When $\mathbf{D}[\cdot \parallel \cdot]$ is channel sandwiched Rényi relative entropy $D_\alpha[\cdot \parallel \cdot]$ for $\alpha \in [\frac{1}{2}, \infty]$, where $D_\alpha = D$ at $\alpha = 1$ and $D_\alpha = D_\infty$ at $\alpha = \infty$, then $F_\alpha^\beta[A|B]_\mathcal{N} \geq 0$ for all $\mathcal{N} \in \text{Ch}(A'B', AB)$. For a tensor-product channel $\mathcal{N} = \mathcal{P}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$, the sandwiched Rényi conditional free energy reduces to the sandwiched Rényi free energy of the channel $\mathcal{P}_{A' \rightarrow A}$, $F_\alpha^\beta[A|B]_\mathcal{N} = F_{T, \alpha}^\beta[A]_{\mathcal{T}^\beta} - F_{T, \alpha}^\beta[A|B]_\mathcal{N} = F_\alpha^\beta[A]_\mathcal{P} = \beta^{-1} \ln 2 D_\alpha[\mathcal{P} \parallel \mathcal{T}^\beta]$ for all $\alpha \in [\frac{1}{2}, \infty]$. For a bipartite replacer channel $\mathcal{R}_{A'B' \rightarrow AB}^\rho$, $F_\alpha^\beta[A|B]_{\mathcal{R}^\rho} = \beta^{-1} \ln 2 \inf_{\omega \in \text{St}(B)} D_\alpha(\rho_{AB} \parallel \gamma_A^\beta \otimes \omega_B)$ for $\alpha \in [\frac{1}{2}, \infty]$. For a conditional isometry channel $\mathcal{V}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$ with $\hat{H}_A \propto \mathbb{1}_A$, where $\mathcal{V}$ is an isometry channel, $F^\beta[\mathcal{V} \otimes \mathcal{Q}] = \beta^{-1} \ln |\mathcal{V}| |A|$ (see Lemma 6).

Standard resource unit: All conditional unitary channels $\mathcal{U}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$ with trivial Hamiltonian $\hat{H}_A \propto \mathbb{1}_A$ are resource equivalent to each other. That is, $(\mathcal{U} \otimes \mathcal{Q}, \mathcal{R}^\pi \otimes \mathcal{Q}) \sim (\text{id} \otimes \mathcal{Q}, \mathcal{R}^\pi \otimes \mathcal{Q})$, where $\hat{H}_A \propto \mathbb{1}_A$, for any unitary channel $\mathcal{U}_{A' \rightarrow A}$, $\text{id}_{A' \rightarrow A}$, and some channel $\mathcal{Q}$, since CGPSs can be defined as appropriate unitary pre-processing that can take any unitary channel to any other unitary channel. As Hamiltonian in general can be arbitrary, we set our standard conditional

athermal (resource) unit with respect to trivial Hamiltonian. The standard resource unit of size m is a conditional identity channel $(\text{id}_m \otimes Q, \mathcal{R}^\pi \otimes Q)$, for the m -dimensional identity channel and some side channel $Q_{B' \rightarrow B}$.

Resource conversion: Resource conversion distance is a conditional athermality resource monotone that captures the distance between input resource channel and output resource channel under the action of CGPS. For the conversion of a resource channel $(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B})$ to another resource channel $(\mathcal{M}_{C'D' \rightarrow CD}, \mathcal{T}_{C' \rightarrow C}^\beta \otimes Q'_{D' \rightarrow D})$ under the action of CGPS Θ^β , the athermal resource conversion distance in terms of purified channel distance $P[\cdot, \cdot]$ is given by

$$d_{\text{CGPS}}((\mathcal{N}, \mathcal{T}^\beta \otimes Q) \rightarrow (\mathcal{M}, \mathcal{T}^\beta \otimes Q')) := \min_{\Theta \in \text{Sch}} \{P[\mathcal{N}, \Theta(\mathcal{M})] : \Theta(\mathcal{T}^\beta \otimes Q) = \mathcal{T}^\beta \otimes Q'\}. \quad (39)$$

Conditional athermality distillation and formation: For brevity, we at times denote the conditional identity channel $\text{id} \otimes Q$ as $\text{id}_m \otimes Q$ or id_m for m -dimensional input on id , whenever it is clear from the context. In the task of conditional athermality distillation, we want to estimate the largest possible standard conditional athermality resource unit $(\text{id}_m \otimes Q', \mathcal{R}^\pi \otimes Q')$ that a resource channel $(\mathcal{N}, \mathcal{T}^\beta \otimes Q)$ can be transformed to, under the action of some CGPS up to an error $\varepsilon \in [0, 1]$. In the task of conditional athermality dilution, we would like to form a channel $(\mathcal{N}, \mathcal{T}^\beta \otimes Q)$ using the smallest standard resource unit $(\text{id}_m \otimes Q', \mathcal{R}^\pi \otimes Q')$, under the action of CGPS up to an error $\varepsilon \in [0, 1]$. To capture these notions, we define

$$\begin{aligned} \text{Dist}^{(1, \varepsilon)}((\mathcal{N}, \mathcal{T}^\beta \otimes Q) \rightarrow (\text{id}_m \otimes Q', \mathcal{R}^\pi \otimes Q')) \\ := \sup_m \{ \log m : d_{\text{CGPS}}((\mathcal{N}, \mathcal{T}^\beta \otimes Q) \rightarrow (\text{id}_m \otimes Q', \mathcal{R}^\pi \otimes Q')) \leq \varepsilon \}. \end{aligned} \quad (40)$$

$$\begin{aligned} \text{Cost}^{(1, \varepsilon)}((\text{id}_m \otimes Q', \mathcal{R}^\pi \otimes Q') \rightarrow (\mathcal{N}, \mathcal{T}^\beta \otimes Q)) \\ := \inf_m \{ \log m : d_{\text{CGPS}}((\text{id}_m \otimes Q', \mathcal{R}^\pi \otimes Q') \rightarrow (\mathcal{N}, \mathcal{T}^\beta \otimes Q)) \leq \varepsilon \}. \end{aligned} \quad (41)$$

Definition 1 (One-shot conditional athermality distillation and formation). *The one-shot conditional athermality distillation yield and formation cost of a quantum bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ under the action of some CGPSs up to an error $\varepsilon \in [0, 1]$, are defined as*

$$\text{Dist}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) := \inf_{Q \in \text{Ch}} \text{Dist}^{(1, \varepsilon)}((\mathcal{N}, \mathcal{T}^\beta \otimes Q) \rightarrow (\text{id}_m \otimes Q', \mathcal{R}^\pi \otimes Q')), \quad (42)$$

$$\text{Cost}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) := \inf_{Q \in \text{Ch}} \text{Cost}^{(1, \varepsilon)}((\text{id}_m \otimes Q'', \mathcal{R}^\pi \otimes Q'') \rightarrow (\mathcal{N}, \mathcal{T}^\beta \otimes Q)), \quad (43)$$

for some quantum channels Q', Q'' .

$\text{Dist}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta)$ is the maximum number of conditional qubit unitary channel, with trivial output Hamiltonian, that can be extracted from a single use of a resource channel $(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B})$ through some CGPS for the worst-possible side channel Q , up to an error ε . $\text{Cost}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta)$ is the minimum number of conditional qubit unitary channel, with trivial output Hamiltonian, that is required to prepare a single copy of a resource channel $(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B})$ through some CGPS with access to the best-possible side channel Q , up to an error ε .

Definition 2 (Conditional athermality distillation and formation capacity). *The capacities of the conditional athermality distillation yield and formation cost of a quantum bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ under*

the action of some CGPSs, are defined as the optimal distillation and formation rates over asymptotically many i.i.d. uses of $\mathcal{N}$ are defined respectively as

$$\text{Dist}^{(\infty,0)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) := \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Dist}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}^{\otimes n}, \mathcal{T}_{A' \rightarrow A}^{\beta \otimes n}), \quad (44)$$

$$\text{Cost}^{(\infty,0)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) := \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Cost}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}^{\otimes n}, \mathcal{T}_{A' \rightarrow A}^{\beta \otimes n}), \quad (45)$$

where $\mathcal{T}_{A' \rightarrow A}^{\beta \otimes n} := (\mathcal{T}_{A' \rightarrow A}^\beta)^{\otimes n}$ is the tensor-product of n $\mathcal{T}_{A' \rightarrow A}^\beta$, assuming that the channel outputs $A'_1, A'_2, \dots, A'_n$ are noninteracting.

We present one of the main results in the following theorem where we determine the one-shot conditional athermality distillation and formation rates of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, see Appendix C 1 for the detailed proof.

Theorem 1 (Single-shot yield and cost). *The one-shot conditional athermality distillation yield and formation cost of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ up to an error $\varepsilon \in [0, 1]$, is given by*

$$\text{Dist}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) = \frac{1}{2} \inf_{Q \in \text{Ch}(B',B)} D_H^{\varepsilon^2}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}], \quad (46)$$

$$\text{Cost}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) = \frac{1}{2} \inf_{Q \in \text{Ch}(B',B)} D_\infty^\varepsilon[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}]. \quad (47)$$

We note that the one-shot conditional athermality distillation yield and formation cost of a resource channel $(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta)$ can also be expressed as half the resource-theoretic ε -smoothed conditional hypothesis-testing and max free energies,

$$\text{Dist}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) = \frac{\beta}{2 \ln 2} F_H^{\beta, \varepsilon^2}[A|B]_\mathcal{N}, \quad (48)$$

$$\text{Cost}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) = \frac{\beta}{2 \ln 2} F_\infty^{\beta, \varepsilon}[A|B]_\mathcal{N}, \quad (49)$$

where

$$\begin{aligned} F_H^{\beta, \varepsilon}[A|B]_\mathcal{N} &:= \beta^{-1} \ln 2 \inf_{Q \in \text{Ch}(B',B)} D_H^\varepsilon[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}], \\ F_\infty^{\beta, \varepsilon}[A|B]_\mathcal{N} &:= \beta^{-1} \ln 2 \inf_{Q \in \text{Ch}(B',B)} D_\infty^\varepsilon[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}]. \end{aligned} \quad (50)$$

We note that Theorem 1 implies that the resource theory of athermality for arbitrary single-input single-output quantum channels is asymptotically reversible under the action of Gibbs-preserving superchannels. The proof arguments in [2, 3] follow for arbitrary channel even when the input and output system dimensions are not the same. Another direct consequence of Theorem 1 is the following observation.

Corollary 1. *For a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$,*

$$\text{Dist}^{(\infty,0)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) \leq \frac{1}{2} \inf_{Q \in \text{Ch}(B',B)} D^{\text{reg}}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}], \quad (51)$$

where $D^{\text{reg}}[\cdot \| \cdot]$ is defined with channel relative entropy $D[\cdot \| \cdot]$ in Eq. (26).

Proof. It follows from the definition and [Theorem 1](#) that

$$2 \text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{T}^\beta) = \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \inf_{Q \in \text{Ch}(B'^n, B^n)} D_H^{\varepsilon^2}[\mathcal{N}^{\otimes n} \| \mathcal{T}_{A' \rightarrow A^n}^{\beta^{\otimes n}} \otimes Q] \quad (52)$$

$$\leq \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \inf_{Q \in \text{Ch}(B', B)} D_H^{\varepsilon^2}[\mathcal{N}^{\otimes n} \| \mathcal{T}_{A' \rightarrow A}^{\beta^{\otimes n}} \otimes Q^{\otimes n}]. \quad (53)$$

We know that $\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} D_H^\varepsilon[\mathcal{N}^{\otimes n} \| \mathcal{M}^{\otimes n}] = D^{\text{reg}}[\mathcal{N} \| \mathcal{M}]$ [\[51\]](#). Therefore, for an arbitrary $Q \in \text{Ch}(B', B)$,

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} D_H^{\varepsilon^2}[\mathcal{N}^{\otimes n} \| \mathcal{T}_{A' \rightarrow A}^{\beta^{\otimes n}} \otimes Q^{\otimes n}] = D^{\text{reg}}[\mathcal{N} \| \mathcal{T}^\beta \otimes Q], \quad (54)$$

and taking infimum over $Q \in \text{Ch}(B', B)$ on both sides, we arrive at the inequality [\(51\)](#). $\square$

We make an important remark here that the protocols for the conditional athermality distillation yield and formation cost of a quantum channel $\mathcal{N}$ can be laced with adaptive strategies [\[10, 21\]](#), where adaptive channels are conditional Gibbs-preserving [\[37\]](#), for many uses of $\mathcal{N}$. The non-adaptive strategy is special case of adaptive strategy. However, based on the recent results on the limitations on channel discrimination tasks [\[22, 51, 75\]](#), we can claim that $\frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D^{\text{reg}}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}]$ is an upper bound also for the asymptotic rate of the conditional athermality distillation assisted with CGPSs using adaptive strategy. One can also consider restricted class of free operations instead of CGPSs. The distillation yield won't be larger under restricted class of free operations and the formation cost won't be lesser under restricted class of free operations, when compared to the resource theory under CGPSs.

Distillation yield and formation cost relation: Let us recall the relation between $D_H^\varepsilon(\rho \| \sigma)$ and $D_\infty(\rho \| \sigma)$ for $\rho \in \text{St}(A)$, $\sigma \in \text{L}_+(A)$, and $\varepsilon \in (0, 1)$,

$$D_H^\varepsilon(\rho \| \sigma) \leq D_\infty(\rho \| \sigma) + \log \left(\frac{1}{1 - \varepsilon} \right). \quad (55)$$

Utilizing this for channel divergences based on the definitions, for quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$, $\mathcal{T}_{A' \rightarrow A}^\beta$ and $Q_{B' \rightarrow B}$, and $\varepsilon \in (0, 1)$, we have

$$D_H^\varepsilon[\mathcal{N} \| \mathcal{T}^\beta \otimes Q] \leq D_\infty[\mathcal{N} \| \mathcal{T}^\beta \otimes Q] + \log \left(\frac{1}{1 - \varepsilon} \right), \quad (56)$$

implying that asymptotically the distillation yield is never greater than the formation cost,

$$\text{Dist}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) \leq \text{Cost}^{(1,\delta=0)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) + \frac{1}{2} \log \left(\frac{1}{1 - \varepsilon^2} \right), \quad (57)$$

$$\text{Dist}^{(\infty,0)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) \leq \text{Cost}^{(\infty,0)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta). \quad (58)$$

In a proper resource theory, the resource formation capacity of an object is never lesser than the resource distillation capacity of that object when the allowed transformations are free operations. This is because if resource distillation capacity of an object was strictly more than its resource formation capacity under free operations, one could first distill resource from that object and then would form the object while gaining standard resource units for free and all this under free operations. Free operations in a proper resource theory are those that cannot generate resource units, thereby implying inequality [\(58\)](#), i.e., the conditional athermality distillation capacity of a channel is always lesser than its conditional formation capacity.

We remark that the zero-error one-shot conditional athermality distillation and formation rates of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ that is tensor-product of two local quantum channels, $\mathcal{N} = \mathcal{P}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$, are equal to the zero-error one-shot athermality distillation and formation rates of a quantum channel $\mathcal{P}$, respectively. This follows from [Theorem 1](#) and [\[4, Theorem 2\]](#).

If we consider B', B in a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ to be trivial ($B' \simeq B \simeq \mathbb{C}$), then $\mathcal{N}$ is a single-input, single-output quantum channel from $A' \rightarrow A$. Conditional athermal resource channels $(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta \otimes \mathcal{Q}_{B' \rightarrow B})$ and $(\text{id}_{A' \rightarrow A} \otimes \mathcal{Q}'_{B' \rightarrow B}, \mathcal{R}_{A' \rightarrow A}^\pi \otimes \mathcal{Q}'_{B' \rightarrow B})$ reduce to athermal resource channels $(\mathcal{N}_{A' \rightarrow A}, \mathcal{T}^\beta)$ and $(\text{id}_{A' \rightarrow A}, \mathcal{R}_{B' \rightarrow B}^\pi)$, respectively, for trivial B', B . This leads to the observation that the resource theory of conditional athermality of bipartite quantum channels provides a unifying framework to the resource theory of athermality of quantum channels [\[2, 3\]](#), the resource theory of purity of quantum channels [\[2, 48\]](#), the resource theory of athermality of quantum states [\[37, 76\]](#), and the resource theory of purity of quantum states [\[39, 77\]](#), when the set of free operations contains all free operations (see [\[2, Section IV.A.\]](#) for relevant discussions).

The causal structure of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ in general can be more intricate than a tensor-product channel $\mathcal{P}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$. There are several questions regarding the kind of causal structure a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ has: signaling or no-signaling from $A' \rightarrow B$, separability preserving, entangling, entanglement-breaking, etc. A bipartite channel $\mathcal{P}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$ is no-signaling from $A' \rightarrow B$ as well as separability preserving (non-entangling). If we consider Ash holds A', A and Bob holds B', B , then a channel $\mathcal{P}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$ represents quantum channels locally acted by Ash and Bob on their respective systems. The conditional athermality formation rate of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ allows us to estimate the amount of conditional athermality $\text{id}_m \otimes \mathcal{Q}'$ required to form the channel $\mathcal{N}$ which could have intricate causal structure. We discuss these aspects in coming sections in detail for quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$ whose $\hat{H}_A \propto \mathbb{1}_A$.

IV. CONDITIONAL CHANNEL MIN-ENTROPY

In this section, we prove some of the main properties of conditional min-entropy, such as asymptotic equipartition property for tele-covariant channels, continuity, dimensional bounds, etc. Asymptotic equipartition property of conditional min-entropy will be applied to determine the asymptotic rates of the conditional purity formation cost of tele-covariant bipartite quantum channels.

The sandwiched Rényi conditional entropy $S_\alpha[A|B]_\mathcal{N}$ of an arbitrary quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, for $\alpha \in [\frac{1}{2}, \infty]$, is defined as [\[4\]](#)

$$S_\alpha[A|B]_\mathcal{N} := - \inf_{Q \in \text{Ch}(B', B)} D_\alpha[\mathcal{N}_{A' \rightarrow A} \| \mathcal{R}_{A' \rightarrow A}^\mathbb{1} \otimes Q_{B' \rightarrow B}], \quad (59)$$

where $\mathcal{R}_{A' \rightarrow A}^\mathbb{1}(\cdot) := \text{tr}(\cdot) \mathbb{1}_A$, $\lim_{\alpha \rightarrow 1} S_\alpha[A|B]_\mathcal{N} = S[A|B]_\mathcal{N}$ is von Neumann conditional entropy, and $\lim_{\alpha \rightarrow \infty} S_\alpha[A|B]_\mathcal{N} = S_\infty[A|B]_\mathcal{N}$ is the conditional min-entropy. The sandwiched conditional entropy $S_\alpha[A|B]_\mathcal{N}$, for $\alpha \in [\frac{1}{2}, \infty]$, of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ satisfies the following properties [\[4\]](#):

1. It is nondecreasing under the actions of an arbitrary conditional uniformity preserving superchannels Θ^π ,

$$S_\alpha[A|B]_\mathcal{N} \geq S_\alpha[C|D]_{\Theta^\pi(\mathcal{N})}, \quad (60)$$

for $\Theta^\pi \in \text{SCh}((A'B', AB), (C'D', CD))$ such that $\Theta^\pi(\mathcal{R}_{A' \rightarrow A}^\pi \otimes \mathcal{Q}_{B' \rightarrow B}) = \mathcal{R}_{C' \rightarrow C}^\pi \otimes \mathcal{Q}'_{D' \rightarrow D}$ (see [Eq. \(93\)](#) and discussions around it).

2. Conditioning doesn't increase entropy,

$$S_\alpha[A|B]_\mathcal{N} \leq S_\alpha[A]_\mathcal{N}, \quad (61)$$

where $S_\alpha[A]_\mathcal{N} := S_\alpha[\text{tr}_B \circ \mathcal{N}_{A'B' \rightarrow AB}] = -D_\alpha[\text{tr}_B \circ \mathcal{N} \| \mathcal{R}_{A'B' \rightarrow A}^\mathbb{1}]$. $\text{tr}_B \circ \mathcal{N}_{A'B' \rightarrow AB}$ is a reduced channel of $\mathcal{N}$ [4] and $S_\alpha[Q] := -D_\alpha[Q_{C' \rightarrow C} \| \mathcal{R}_{C' \rightarrow C}^\mathbb{1}]$ is the sandwiched Rényi entropy of a quantum channel $Q_{C' \rightarrow C}$ [74, 78] (see also [72]).

3. For an arbitrary replacer channel $\mathcal{R}_{A'B' \rightarrow AB}^\rho$

$$S_\alpha[A|B]_{\mathcal{R}^\rho} = S_\alpha(A|B)_\rho. \quad (62)$$

4. For a tensor-product bipartite channel $\mathcal{N} = \mathcal{P}_{A' \rightarrow A} \otimes Q_{B' \rightarrow B}$, the sandwiched Rényi conditional entropy reduces to the sandwiched Rényi entropy of $\mathcal{P} \in \text{Ch}(A', A)$,

$$S_\alpha[A|B]_\mathcal{N} = S_\alpha[A]_\mathcal{P}. \quad (63)$$

5. For $\alpha_1, \alpha_2 \in [\frac{1}{2}, \infty]$ and $\alpha_1 \leq \alpha_2$, we have $S_{\alpha_1}[A|B]_\mathcal{N} \geq S_{\alpha_2}[A|B]_\mathcal{N}$. In particular, $S_\infty[A|B]_\mathcal{N} \leq S[A|B]_\mathcal{N}$.

Lemma 1. *The sandwiched Rényi conditional entropy $S_\alpha[A|B]_\mathcal{N}$, for $\alpha \in [\frac{1}{2}, \infty]$, of a bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is maximum, $S_\alpha[A|B]_\mathcal{N} = \log |A|$ iff $\mathcal{N}$ is conditional uniformly mixing channel, $\mathcal{N} = \mathcal{R}_{A' \rightarrow A}^\pi \otimes Q_{B' \rightarrow B}$ for arbitrary $Q \in \text{Ch}(B', B)$. Also, $S_\alpha[A|B]_\mathcal{N} \leq \log |A|$.*

Proof.

$$S_\alpha[A|B]_\mathcal{N} = - \inf_{Q \in \text{Ch}(B', B)} D_\alpha[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^\mathbb{1} \otimes Q_{B' \rightarrow B}] \quad (64)$$

$$= \log |A| - \inf_{Q \in \text{Ch}(B', B)} D_\alpha[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^\pi \otimes Q_{B' \rightarrow B}]. \quad (65)$$

For $\alpha \in [\frac{1}{2}, \infty]$, we know that $D_\alpha[\mathcal{N} \| \mathcal{M}] \geq 0$ for any two arbitrary channels $\mathcal{N}, \mathcal{M}$ and the inequality saturates ($= 0$) iff $\mathcal{N} = \mathcal{M}$. We can then conclude that $S_\alpha[A|B]_\mathcal{N} = \log |A|$ iff $\mathcal{N} = \mathcal{R}_{A' \rightarrow A}^\pi \otimes Q_{B' \rightarrow B}$ for some $Q \in \text{Ch}(B', B)$ and also $S_\alpha[A|B] \leq \log |A|$. $\square$

The Choi operator $\Gamma^\mathcal{N}$ of a bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is $\Gamma_{R_A A' R_B B'}^\mathcal{N} = \mathcal{N}(\Gamma_{R_A A'} \otimes \Gamma_{R_B B'})$, where $\Gamma_{R_A A'}$ denotes a maximally entangled operator. A maximally entangled operator $\Gamma_{R:A'B'}$ of $R : A'B'$ can be written as $\Gamma_{R:A'B'} = \Gamma_{R_A A'} \otimes \Gamma_{R_B B'}$, where $R = R_A R_B$ for $R \simeq A'B'$. We recall that for a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ [4] (see also [5]),

$$S_\infty[A|B]_\mathcal{N} := - \inf_{Q \in \text{Ch}(B', B)} D_\infty[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^\mathbb{1} \otimes Q_{B' \rightarrow B}] \quad (66)$$

$$= - \inf_{Q \in \text{Ch}(B', B)} D_\infty(\Gamma_{R_A A' R_B B'}^\mathcal{N} \| \mathbb{1}_{R_A A'} \otimes \Gamma_{R_B B'}^Q) \quad (67)$$

$$= - \inf_{Q \in \text{Ch}(B', B)} D_\infty(\Phi_{R_A A' R_B B'}^\mathcal{N} \| \mathbb{1}_{R_A A'} \otimes \Phi_{R_B B'}^Q) - \log |A'| \quad (68)$$

$$= - \log \inf_{Q \in \text{Ch}(B', B)} \left\| (\Gamma_{R_B B'}^Q)^{-\frac{1}{2}} \Gamma_{R_A A' R_B B'}^\mathcal{N} (\Gamma_{R_B B'}^Q)^{-\frac{1}{2}} \right\|_\infty \quad (69)$$

$$= - \log \min \left\{ \frac{\text{tr } M}{|B'|} : \Gamma_{R_A A' R_B B'}^\mathcal{N} \leq \mathbb{1}_{R_A A'} \otimes M, 0 \leq M, \text{tr}_B M = \frac{\text{tr } M}{|B'|} \mathbb{1}_{R_B} \right\}, \quad (70)$$

where $M \in \text{L}_+(R_B B)$. Eq. (70) provides semidefinite program (SDP) representation of the conditional channel min-entropy.

We first show that the conditional min-entropy of $\mathcal{N}_{A'B' \rightarrow AB}$ can be bounded by the conditional min-entropy of its Choi state $\Phi_{R_A A R_B B}^{\mathcal{N}} = \frac{1}{|A'| |B'|} \Gamma_{R_A A R_B B}^{\mathcal{N}}$. This fact is crucial in making important observations like asymptotic equipartition property of the conditional min-entropy and proving that the conditional channel min-entropy is minimum iff the channel is a swap-like operation.

Proposition 1. *The conditional min-entropy $S_{\infty}[A|B]_{\mathcal{N}}$ of an arbitrary bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, with $|A'| < +\infty$, is bounded as*

$$S_{\infty}^{\downarrow}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'| \leq S_{\infty}[A|B]_{\mathcal{N}} \leq S_{\infty}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|, \quad (71)$$

where $\mathbf{S}^{\downarrow}(A|B)_{\rho} := -\mathbf{D}(\rho_{AB} \| \mathbb{1}_A \otimes \rho_B)$ and $\mathbf{S}(A|B)_{\rho} := \inf_{\sigma \in \text{St}(B)} \mathbf{D}(\rho_{AB} \| \mathbb{1}_A \otimes \sigma_B)$.

Proof. We first prove the upper bound, using definition,

$$\begin{aligned} -S_{\infty}[A|B]_{\mathcal{N}} &= \inf_{Q \in \text{Ch}(B', B)} D_{\infty}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \pi_{R_A} \otimes \mathbb{1}_A \otimes \Phi_{R_B B}^Q) \\ &= \inf_{Q \in \text{Ch}(B', B)} D_{\infty}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \mathbb{1}_{R_A} \otimes \mathbb{1}_A \otimes \Phi_{R_B B}^Q) + \log |A'| \\ &\geq \inf_{\sigma \in \text{St}(R_B B)} D_{\infty}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \mathbb{1}_{R_A} \otimes \mathbb{1}_A \otimes \sigma_{R_B B}) + \log |A'| \\ &= -S_{\infty}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} + \log |A'|. \end{aligned} \quad (72)$$

To prove the lower bound, consider a reduced channel $\mathcal{T}_{B' \rightarrow B}^{\mathcal{N}}$ of $\mathcal{N}_{A'B' \rightarrow AB}$ defined as

$$\mathcal{T}_{B' \rightarrow B}^{\mathcal{N}}(\cdot) := \text{tr}_A \circ \mathcal{N}_{A'B' \rightarrow AB}(\pi_{A'} \otimes \cdot). \quad (73)$$

Notice that $\Phi_{R_B B}^{\mathcal{T}^{\mathcal{N}}} = \Phi_{R_B B}^{\mathcal{N}}$. Then,

$$\begin{aligned} -S_{\infty}[A|B]_{\mathcal{N}} &= \inf_{Q \in \text{Ch}(B', B)} D_{\infty}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^{\mathbb{1}} \otimes Q_{B' \rightarrow B}] \\ &\leq D_{\infty}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^{\mathbb{1}} \otimes \mathcal{T}_{B' \rightarrow B}^{\mathcal{N}}] \\ &= D_{\infty}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \mathbb{1}_{R_A} \otimes \mathbb{1}_A \otimes \Phi_{R_B B}^{\mathcal{N}}) + \log |A'| \\ &= -S_{\infty}^{\downarrow}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} + \log |A'|. \end{aligned} \quad (74)$$

That is,

$$S_{\infty}^{\downarrow}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} \leq S_{\infty}[A|B]_{\mathcal{N}} + \log |A'| \leq S_{\infty}(R_A A | R_B B)_{\Phi^{\mathcal{N}}}. \quad (75)$$

□

We have the following dimensional bound on the conditional min-entropy, which will also holds true for the conditional von Neumann entropy of a bipartite quantum channel.

Proposition 2. *The conditional min-entropy of a bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is lower bounded as*

$$\max\{-\log |B| + S_{\infty}[AB]_{\mathcal{N}}, -\log |A'| - \log \min\{\text{rank}(\Phi_{R_A A}^{\mathcal{N}}), \text{rank}(\Phi_{R_B B}^{\mathcal{N}})\}\} \leq S_{\infty}[A|B]_{\mathcal{N}}. \quad (76)$$

In terms of the dimension of the systems of $\mathcal{N}_{A'B' \rightarrow AB}$, we have

$$-\log \min\{|A'| |B'| |B|, |A'|^2 |A|\} \leq S_{\infty}[A|B]_{\mathcal{N}} \leq \log |A|. \quad (77)$$

Proof. The upper bound on $S_\infty[A|B]_\mathcal{N}$ follows directly from inequality (61) [4],

$$S_\infty[A|B]_\mathcal{N} \leq S[A|B]_\mathcal{N} \leq \log |A|. \quad (78)$$

We may also observe that $S_\infty[A|B]_\mathcal{N} \leq S_\infty(A|R_A R_B B)_{\Phi^\mathcal{N}} \leq \log |A|$.

To derive the lower bounds on $S_\infty[A|B]_\mathcal{N}$, we notice that

$$S_\infty[A|B]_\mathcal{N} \geq S_\infty^\downarrow(R_A A | R_B B)_{\Phi^\mathcal{N}} - \log |A'| \quad (79)$$

$$\geq -\log \min\{\text{rank}(\Phi_{R_A A}^\mathcal{N}), \text{rank}(\Phi_{R_B B}^\mathcal{N})\} - \log |A'| \quad (80)$$

$$\geq -\log \min\{|A'|^2 |A|, |A'| |B'| |B|\}, \quad (81)$$

where we used $S^\downarrow(A|B)_\rho \geq -\log \min\{\text{rank}(\rho_A), \text{rank}(\rho_B)\}$ [16, Lema 5.11] to arrive the second inequality. $\square$

The theorem below states that the lower bound in inequality (77) is saturated if and only if the channel is a swap-like or maximally entangling operation, that is, if the Choi state of the channel is a maximally entangled state, $\Phi_{R_A A: R_B B} \in \text{Ent}(R_A A; R_B B)$, of Schmidt rank $\min\{|A'| |A|, |B'| |B|\}$. We provide the detailed proof in Appendix C 6 where we show that the upper and lower bounds of $S_\infty[A|B]_\mathcal{N}$, as given in Proposition 1 coincide if and only if the channel is a maximally entangling operation.

Theorem 2. *The conditional min-entropy of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ achieves the minimum if and only if the channel is a maximally entangling unitary operation, i.e., $\mathcal{N} \in \text{SWAP}(A; B)$,*

$$S_\infty[A|B]_{\mathcal{N} \in \text{SWAP}(A; B)} = -\log \min\{|A'|^2 |A|, |A'| |B'| |B|\}. \quad (82)$$

The smooth conditional channel min-entropy for the swap-like operation is close to the extremal bound. In particular, we have

$$S_\infty^\epsilon[A|B]_{\mathcal{N} \in \text{SWAP}(A; B)} \leq -\log \min\{|A'|^2 |A|, |A'| |B'| |B|\} + \log \frac{1}{1 - \epsilon^2}, \quad (83)$$

where we have used the fact that $S_\infty^\epsilon[A|B]_\mathcal{N} \leq S_\infty^\epsilon(R_A A | R_B B)_{\Phi^\mathcal{N}} - \log |A'|$ (see inequality (C49)) and the following inequality from [79, Lemma 5] for a pure state ψ_{AB} ,

$$S_\infty^\epsilon(A|B)_\psi \leq -S_\infty(A)_\psi + \log \frac{1}{1 - \epsilon^2}. \quad (84)$$

Since the Choi state of a swap-like operation is maximally entangled, the inequality (83) follows.

We now prove that the conditional min-entropy satisfies asymptotic continuity.

Theorem 3 (Asymptotic continuity). *Consider two arbitrary bipartite channels $\mathcal{N}_{A'B' \rightarrow AB}$ and $\mathcal{M}_{A'B' \rightarrow AB}$. For $\frac{1}{2} \|\mathcal{N} - \mathcal{M}\|_\diamond \leq \delta \in [0, 1]$, the difference of their conditional min-entropy is bounded as*

$$|S_\infty[A|B]_\mathcal{N} - S_\infty[A|B]_\mathcal{M}| \leq \frac{1}{\ln 2} |A| \min\{|A'| |A|, |B'| |B|\} \delta. \quad (85)$$

We provide the detailed proof in Appendix C 3.

Tele-covariant channels [25, 26]: Let G and H be finite groups. Let $g \mapsto U_{A'}^{(g)}$, $h \mapsto V_{B'}^{(h)}$ be unitary representations of G and H acting on input systems A' and B' , respectively. Let $(g, h) \mapsto W_A^{(g, h)}$, $(g, h) \mapsto Z_B^{(g, h)}$ be unitary representations acting on output systems A and B , respectively. A

bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is said to be bicovariant with respect to these representations if, for all input states $\rho_{A'B'}$ and all $g \in G, h \in H$ [23, 80],

$$\mathcal{N}_{A'B' \rightarrow AB} \left(\mathcal{U}_{A'}^{(g)} \otimes \mathcal{V}_{B'}^{(h)} (\rho_{A'B'}) \right) = \mathcal{W}_A^{(g,h)} \otimes \mathcal{Z}_B^{(g,h)} (\mathcal{N}_{A'B' \rightarrow AB} (\rho_{A'B'})), \quad (86)$$

where $\mathcal{U}^{(g)}(\cdot) := U^{(g)}(\cdot)U^{(g)\dagger}$, $\mathcal{V}^{(h)}(\cdot) := V^{(h)}(\cdot)V^{(h)\dagger}$, $\mathcal{W}^{(g,h)}(\cdot) := W^{(g,h)}(\cdot)W^{(g,h)\dagger}$, $\mathcal{Z}^{(g,h)}(\cdot) := Z^{(g,h)}(\cdot)Z^{(g,h)\dagger}$. The channel $\mathcal{N}$ is called tele-covariant if it is bicovariant such that the input representations form unitary one-designs, i.e.,

$$\frac{1}{|G|} \sum_{g \in G} U_{A'}(g) \rho_{A'} U_{A'}(g)^\dagger = \pi_{A'}, \quad \frac{1}{|H|} \sum_{h \in H} V_{B'}(h) \rho_{B'} V_{B'}(h)^\dagger = \pi_{B'}, \quad (87)$$

for all states $\rho_{A'}$ and $\rho_{B'}$. We refer the readers to [26, Section V.C.] for the definition and relevant results on multipartite tele-covariant channels, which generalize the concept of covariance to multipartite quantum channels with respect to the input representations forming unitary one-designs.

In general, for an arbitrary quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, it holds that [4]

$$S[A|B]_{\mathcal{N}} \leq S(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|, \quad (88)$$

and the inequality is known to be saturated, $S[A|B]_{\mathcal{N}} = S(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|$, if $\mathcal{N}$ is tele-covariant [4, Theorem 4].

We now prove that the conditional channel min-entropy exhibits asymptotic equipartition property: on an average, the conditional min-entropy of the asymptotically many uses of a tele-covariant channel approaches its von Neumann conditional channel entropy.

Theorem 4 (Asymptotic equipartition property). *For $\varepsilon \in (0, 1)$ and asymptotically many i.i.d. uses of an bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$, the smoothed conditional channel min-entropy satisfies the following bounds in terms of the conditional von Neumann entropy of the Choi state $\Phi^{\mathcal{N}}$,*

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n | B^n]_{\mathcal{N}^{\otimes n}} \leq S(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|. \quad (89)$$

If $\mathcal{N}_{A'B' \rightarrow AB}$ is tele-covariant, then

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n | B^n]_{\mathcal{N}^{\otimes n}} \leq S[A|B]_{\mathcal{N}}, \quad (90)$$

$$\lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n | B^n]_{\mathcal{N}^{\otimes n}} \geq S[A|B]_{\mathcal{N}}. \quad (91)$$

We provide the detailed proof in Appendix C 4. The following identity follows from the above theorem and [4, Theorem 4], for a tele-covariant quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$,

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n | B^n]_{\mathcal{N}^{\otimes n}} = S[A|B]_{\mathcal{N}} = S(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|. \quad (92)$$

The asymptotic equipartition property also holds for quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$ that are no-signaling from $A' \rightarrow B$ (see Theorem 7). We discuss some consequences of the asymptotic equipartition property of the conditional channel min-entropy for tele-covariant channels in the following section and for no-signaling channels in section VI.

V. CONDITIONAL PURITY DISTILLATION AND FORMATION CAPACITY

If a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ has output A with fully degenerate Hamiltonian $\hat{H}_A \propto \mathbb{1}_A$ then the resource theory of conditional athermality reduces to the resource theory of conditional purity, given $\gamma_A^\beta = \pi_A$. The free operations are conditional uniformity preserving superchannels (CUPS) Θ^π . A CUPS $\Theta^\pi \in \text{Sch}((A'B', AB), (C'D', CD))$ is defined as a superchannel that preserves conditional uniformly mixing channel $\mathcal{R}^\pi$, i.e., for an arbitrary $Q \in \text{Ch}(B', B)$ there exists some $Q' \in \text{Ch}(D', D)$ such that

$$\Theta^\pi(\mathcal{R}_{A' \rightarrow A}^\pi \otimes Q_{B' \rightarrow B}) = \mathcal{R}_{C' \rightarrow C}^\pi \otimes Q'_{D' \rightarrow D}. \quad (93)$$

We observe that a conditional athermal resource channel $(\mathcal{N}, \mathcal{T}^\beta \otimes Q)$ becomes $(\mathcal{N}, \mathcal{R}^\pi \otimes Q)$ when $\hat{H}_A \propto \mathbb{1}_A$, which is also a conditional purity resource channel. The conditional identity channel $\text{id}_{A' \rightarrow A} \otimes Q_{B' \rightarrow B}$ is conditional purity resource equivalent to all conditional unitary channels $\mathcal{U}_{A' \rightarrow A} \otimes Q_{B' \rightarrow B}$ and can be deemed as the standard resource unit for the conditional purity. Following Theorem 1, we have the following corollary that determines the one-shot conditional purity distillation and formation.

Corollary 2 (One-shot conditional purity distillation and cost). *The one-shot conditional purity distillation yield $\text{Dist}^{(1, \varepsilon)}(\mathcal{N}, \mathcal{R}^\pi)$ and formation cost $\text{Cost}^{(1, \varepsilon)}(\mathcal{N}, \mathcal{R}^\pi)$ of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ are given as*

$$\text{Dist}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{R}_{A' \rightarrow A}^\pi) = \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D_H^{\varepsilon^2}[\mathcal{N} \| \mathcal{R}^\pi \otimes Q] = \frac{1}{2} (\log |A| - S_H^{\varepsilon^2}[A|B]_{\mathcal{N}}), \quad (94)$$

$$\text{Cost}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{R}_{A' \rightarrow A}^\pi) = \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D_\infty^\varepsilon[\mathcal{N} \| \mathcal{R}^\pi \otimes Q] = \frac{1}{2} (\log |A| - S_\infty^\varepsilon[A|B]_{\mathcal{N}}), \quad (95)$$

where for a bipartite channel $\mathcal{M}_{A'B' \rightarrow AB}$, $S_H^\varepsilon[A|B]_{\mathcal{M}}$ is the hypothesis-testing conditional entropy obtained by taking the generalized channel divergence in Eq. (31) to be hypothesis-testing relative entropy and $S_\infty^\varepsilon[A|B]_{\mathcal{M}}$ is the ε -smoothed conditional min-entropy (Eq. (35)).

Thus, we have operational meaning of $S_H^\varepsilon[A|B]_{\mathcal{N}}$ and $S_\infty^\varepsilon[A|B]_{\mathcal{N}}$ for a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, as for $\varepsilon \in [0, 1]$

$$\begin{aligned} S_H^\varepsilon[A|B]_{\mathcal{N}} &= \log |A| - 2 \text{Dist}^{(1, \sqrt{\varepsilon})}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{R}_{A' \rightarrow A}^\pi), \\ S_\infty^\varepsilon[A|B]_{\mathcal{N}} &= \log |A| - 2 \text{Cost}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{R}_{A' \rightarrow A}^\pi). \end{aligned} \quad (96)$$

We determine the exact optimal asymptotic rate (capacity) of the conditional purity formation cost of a tele-covariant quantum channel in Corollary 3.

We define the conditional purity distillation capacity $\text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^\pi)$ of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ as the optimal asymptotic rate of the conditional purity distillation yield of the channel $\mathcal{N}$.

Proposition 3 (Conditional purity distillation capacity (Converse bound)). *The conditional purity distillation capacity of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is upper bounded as*

$$\text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^\pi) := \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Dist}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}^{\otimes n}, \mathcal{R}_{A' \rightarrow A}^{\pi^n}) \leq \frac{1}{2} (\log |A| - S^{\text{reg}}[A|B]_{\mathcal{N}}), \quad (97)$$

where $S^{\text{reg}}[A|B]_{\mathcal{M}}$ is the regularized von Neumann conditional channel entropy of an arbitrary $\mathcal{M} \in \text{Ch}(A'B', AB)$ based on the regularized relative entropy (Eq. (26))

$$S^{\text{reg}}[A|B]_{\mathcal{N}} := - \inf_{Q \in \text{Ch}(B', B)} D^{\text{reg}}[\mathcal{N} \| \mathcal{R}^\pi \otimes Q]. \quad (98)$$

Proof. It follows from [Corollary 1](#),

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \leq \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D^{\text{reg}}[\mathcal{N} \| \mathcal{R}^\pi \otimes Q] \quad (99)$$

$$= \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} (\log |A| + D^{\text{reg}}[\mathcal{N} \| \mathcal{R}^1 \otimes Q]) \quad (100)$$

$$= \frac{1}{2} (\log |A| - S^{\text{reg}}[A|B]_{\mathcal{N}}). \quad (101)$$

□

Proposition 4 (Conditional purity distillation capacity (achievability)). *The conditional purity distillation capacity of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is lower bounded as*

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \geq \frac{1}{2} [\log |A'| |A| - S(R_A A | R_B B)_{\Phi^{\mathcal{N}}}] . \quad (102)$$

Proof. Consider $\varepsilon \in (0, 1)$ and $\alpha \in (0, 1)$, and let $f(\alpha, \varepsilon) := \frac{\alpha}{1-\alpha} \log \frac{1}{\varepsilon^2}$. For an arbitrary quantum channel $Q \in \text{Ch}(B^m, B^n)$,

$$D_H^{\varepsilon^2}[\mathcal{N}^{\otimes n} \| \mathcal{R}_{A'^n \rightarrow A^n}^\pi \otimes Q_{B'^n \rightarrow B^n}] \geq D_H^{\varepsilon^2}(\Phi_{R_A^n A^n R_B^n B^n}^{\mathcal{N}^{\otimes n}} \| \Phi_{R_A^n A^n}^{\mathcal{R}^{\pi \otimes n}} \otimes \Phi_{R_B^n B^n}^Q) \quad (103)$$

$$\geq \bar{D}_\alpha(\Phi_{R_A^n A^n R_B^n B^n}^{\mathcal{N}^{\otimes n}} \| \Phi_{R_A^n A^n}^{\mathcal{R}^{\pi \otimes n}} \otimes \Phi_{R_B^n B^n}^Q) - f(\alpha, \varepsilon) \quad (104)$$

$$\geq \inf_{\sigma \in \text{St}(R_B^n B^n)} \bar{D}_\alpha(\Phi_{R_A^n A^n R_B^n B^n}^{\mathcal{N}^{\otimes n}} \| \Phi_{R_A^n A^n}^{\mathcal{R}^{\pi \otimes n}} \otimes \sigma_{R_B^n B^n}) - f(\alpha, \varepsilon) \quad (105)$$

$$= n(\log |A'| |A| - \bar{S}_\alpha(R_A A | R_B B)_{\Phi^{\mathcal{N}}}) - f(\alpha, \varepsilon), \quad (106)$$

where the last equality holds because the Petz-Rényi conditional entropy is additive for tensor-product states (see [\[81, Lemma 7\]](#)). Therefore, the following holds for all $\alpha \in (0, 1)$,

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) := \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Dist}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}^{\otimes n}, \mathcal{R}_{A'^n \rightarrow A^n}^\pi) \quad (107)$$

$$\geq \frac{1}{2} \left[\log |A'| |A| - \bar{S}_\alpha(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \frac{\alpha}{1-\alpha} \log \frac{1}{\varepsilon^2} \right] \quad (108)$$

$$= \frac{1}{2} \left[\log |A'| |A| - \bar{S}_\alpha(R_A A | R_B B)_{\Phi^{\mathcal{N}}} \right]. \quad (109)$$

Taking limit $\alpha \rightarrow 1^-$, we arrive at $\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \geq \frac{1}{2} [\log |A'| |A| - S(R_A A | R_B B)_{\Phi^{\mathcal{N}}}]$. □

We define the conditional purity formation capacity $\text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi)$ of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ as the optimal asymptotic rate of the conditional purity formation cost of the channel $\mathcal{N}$. An application of [Theorem 4](#) and [Corollary 2](#) is the following corollary which determines $\text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi)$ exactly when $\mathcal{N}$ is tele-covariant and a single-letter lower bound for arbitrary $\mathcal{N}$ in terms of its Choi state.

Corollary 3 (Conditional purity formation capacity). *The conditional purity formation capacity of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is lower bounded as*

$$\text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) := \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Cost}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}^{\otimes n}, \mathcal{R}_{A'^n \rightarrow A^n}^\pi) \geq \frac{1}{2} [\log |A'| |A| - S(R_A A | R_B B)_{\Phi^{\mathcal{N}}}] . \quad (110)$$

We now state one of the main results that showcases the asymptotic reversibility of the conditional purity for tele-covariant quantum channels $\mathcal{N}_{A'B' \rightarrow AB}$.

Theorem 5 (Purity capacity of tele-covariant channels). *The conditional purity distillation and formation capacities of an arbitrary tele-covariant quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ are the same and exactly determined in terms of its conditional entropy,*

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) = \text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) = \frac{1}{2} (\log |A| - S[A|B]_{\mathcal{N}}) = \frac{1}{2} [\log |A'| |A| - S(R_A A | R_B B)_{\Phi^{\mathcal{N}}}] . \quad (111)$$

That is, the resource theory of conditional purity for tele-covariant channels under the action of CUPs is asymptotically reversible.

Proof. Let $\mathcal{N}_{A'B' \rightarrow AB}$ be a tele-covariant channel. Asymptotic equipartition property (Theorem 4) of the conditional channel min-entropy implies that

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n | B^n]_{\mathcal{N}} = S[A|B]_{\mathcal{N}} = S(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|, \quad (112)$$

and from Corollary 2,

$$\text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) = \frac{1}{2} (\log |A| - S[A|B]_{\mathcal{N}}) = \frac{1}{2} [\log |A'| |A| - S(R_A A | R_B B)_{\Phi^{\mathcal{N}}}] . \quad (113)$$

Whereas, from Proposition 4, we have

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \geq \frac{1}{2} (\log |A'| |A| - S(R_A A | R_B B)_{\Phi^{\mathcal{N}}}) . \quad (114)$$

Observing that $\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \leq \text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi)$ always holds, we conclude the proof. $\square$

Superdense coding: Let Ash and Bob be connected through a tele-covariant quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, where A', A are held by Ash and B', B are held by Bob and we assume $|A'| = |A| = d$. Ash and Bob use this channel to share its Choi state $\Phi_{R_A A R_B B}^{\mathcal{N}}$ among them, where $R_A A$ is with Ash and $R_B B$ is with Bob. Ash and Bob carry out superdense coding protocol [29, 82], Ash performs the unitary operations $\mathcal{U}_i^{\mathcal{N}}$ on $R_A A$ with probability p_i , following which she can send her system $R_A A$ to Bob through a noiseless channel. The superdense coding capacity $\text{Sdc}(\Phi^{\mathcal{N}})$ captures the maximum amount of classical information that can be transmitted from Ash to Bob by sending quantum systems, utilizing pre-shared entanglement ($\Phi^{\mathcal{N}}$). For a two-qudit quantum state ρ_{AB} , where $|A| = d$, its superdense coding capacity $\text{Sdc}(A; B)_{\rho} = \log d - S(A|B)_{\rho}$ [29]; this shows quantum advantage over classical protocol only when $S(A|B)_{\rho} < 0$. Using this and Corollary 3, we find that the superdense coding capacity $\text{Sdc}(\Phi^{\mathcal{N}})$ of the Choi state $\Phi_{R_A A R_B B}^{\mathcal{N}}$ of a tele-covariant $\mathcal{N}$, with $|A'| = |A|$, is

$$\begin{aligned} \text{Sdc}(R_A A; R_B B)_{\Phi^{\mathcal{N}}} &= \log |A'| |A| - S(R_A A | R_B B)_{\Phi^{\mathcal{N}}} \\ &= \log |A| - S[A|B]_{\mathcal{N}} \\ &= 2 \text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) = 2 \text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) . \end{aligned} \quad (115)$$

That is, the superdense coding capacity of the Choi state of a tele-covariant channel $\mathcal{N}$ is exactly the double of the conditional purity capacity of $\mathcal{N}$.

VI. CAUSAL STRUCTURE AND CONDITIONAL CHANNEL ENTROPY

We now examine relations between the causal structure of a bipartite channel and its conditional entropies, and in turn will provide insights for its conditional athermality formation cost.

Semicausal channels: A quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is called semicausal from $A' \rightarrow B$ (or no signaling from $A' \rightarrow B$) if operations on A' cannot influence output B . Let $S_{A' \nrightarrow B}$, where $S_{A' \nrightarrow B} \subset \text{Ch}(A'B', AB)$, denote the set of all bipartite channels $\mathcal{N}_{A'B' \rightarrow AB}$ that is semicausal (no-signaling) from $A' \rightarrow B$. For a bipartite quantum channel $\mathcal{N} \in S_{A' \nrightarrow B}$, we have a reduced channel $\mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}}$ derived from $\mathcal{N}$ such that [6, 27]

$$\text{tr}_A \circ \mathcal{N}_{A'B' \rightarrow AB} = \text{tr}_{A'} \otimes \mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}} \quad (116)$$

where $\mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}}(\cdot) = \text{tr}_A \circ \mathcal{N}(\rho_{A'} \otimes \cdot)$ holds true for all $\rho \in \text{St}(A')$. All semicausal channels have the semilocalizable structure [83]: each $\mathcal{N} \in S_{A' \nrightarrow B}$ can be written as a composition of some quantum channels in $\text{Ch}(B', BC)$ and $\text{Ch}(A'C, A)$,

$$\mathcal{N}_{A'B' \rightarrow AB} = (\tilde{\mathcal{N}}_{A'C \rightarrow A} \otimes \text{id}_B) \circ (\text{id}_{A'} \otimes \tilde{\mathcal{N}}_{B' \rightarrow BC}). \quad (117)$$

For all $\rho \in \text{St}(A')$, we have $\text{tr}_C \circ \tilde{\mathcal{N}}_{B' \rightarrow BC} = \text{tr}_A \circ \mathcal{N}(\rho_{A'} \otimes \cdot) = \mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}}$. We can write following equivalent condition for Eq. (116): For an arbitrary $\mathcal{N} \in S_{A' \nrightarrow B}$,

$$\mathcal{R}_{A \rightarrow A}^{\omega} \circ \mathcal{N}_{A'B' \rightarrow AB} = \mathcal{R}_{A' \rightarrow A}^{\omega} \otimes \mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}} \quad (118)$$

where $\mathcal{R}^{\omega}$ denotes a replacer channel.

NS conditional channel entropy: The sandwiched Rényi NS conditional channel entropy $S_{\alpha}^{\nrightarrow}$ of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, for $\alpha \in [\frac{1}{2}, \infty]$, is defined as [4]

$$S_{\alpha}^{\nrightarrow}[A|B]_{\mathcal{N}} := -D_{\alpha}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A \rightarrow A}^1 \circ \mathcal{N}_{A'B' \rightarrow AB}]. \quad (119)$$

The von Neumann NS conditional entropy $S^{\nrightarrow}[A|B]_{\mathcal{N}}$ (in $\lim \alpha \rightarrow 1$ in Eq. (119)) of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ satisfies [4]

$$S^{\nrightarrow}[A|B]_{\mathcal{N}} = \inf_{\psi \in \text{St}(RA'B')} S(A|RB)_{\mathcal{N}(\psi)}, \quad (120)$$

$$S^{\nrightarrow}[A|B]_{\mathcal{N}} \geq S[A|B]_{\mathcal{N}}. \quad (121)$$

where it suffices to optimize over pure states $\psi_{RA'B'}$, $R \simeq A'B'$, in Eq. (121). The inequality (121) is saturated, i.e., $S^{\nrightarrow}[A|B]_{\mathcal{N}} = S[A|B]_{\mathcal{N}}$ iff $\mathcal{N} \in S_{A' \nrightarrow B}$ [4, Theorem 5]. $S^{\nrightarrow}[A|B]_{\mathcal{N}}$ and related entropic quantities are also studied in the context of entropy accumulation theorem and cryptography in [84, 85] and conditional channel merging in [4].

Proposition 5. *For an arbitrary quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ its conditional purity distillation and formation capacities under CUPSs are bounded from below as*

$$\frac{1}{2} \left(\log |A| - S^{\nrightarrow}[A|B]_{\mathcal{N}} \right) \leq \text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}) \leq \text{Cost}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^{\pi}). \quad (122)$$

Proof. To prove the lower bound, consider $\varepsilon \in (0, 1)$ and $\alpha \in (0, 1)$, and let $f(\alpha, \varepsilon) := \frac{\alpha}{1-\alpha} \log \frac{1}{\varepsilon^2}$.

For an arbitrary quantum channel $Q \in \text{Ch}(B'^n, B^n)$,

$$D_H^{\varepsilon^2}[\mathcal{N}^{\otimes n} \| \mathcal{R}_{A'^n \rightarrow A^n}^\pi \otimes Q_{B'^n \rightarrow B^n}] \geq \sup_{\psi \in \text{St}(RA'B')} D_H^{\varepsilon^2}((\mathcal{N}(\psi_{RA'B'}))^{\otimes n} \| \pi_A^{\otimes n} \otimes Q(\psi_{RB'}^{\otimes n})) \quad (123)$$

$$\geq \sup_{\psi \in \text{St}(RA'B')} \bar{D}_\alpha((\mathcal{N}(\psi_{RA'B'}))^{\otimes n} \| \pi_A^{\otimes n} \otimes Q(\psi_{RB'}^{\otimes n})) - f(\alpha, \varepsilon) \quad (124)$$

$$\geq \inf_{\sigma \in \text{St}(R_B^n B^n)} \sup_{\psi \in \text{St}(RA'B')} \bar{D}_\alpha((\mathcal{N}(\psi_{RA'B'}))^{\otimes n} \| \pi_A^{\otimes n} \otimes \sigma_{R^n B^n}) - f(\alpha, \varepsilon) \quad (125)$$

$$= n \left(\log |A| - \inf_{\psi \in \text{St}(RA'B')} \bar{S}_\alpha(A|RB)_{\mathcal{N}(\psi)} \right) - f(\alpha, \varepsilon), \quad (126)$$

where the last equality holds because the Petz-Rényi conditional entropy is additive for tensor-product states. Therefore, the following holds for all $\alpha \in (0, 1)$,

$$\text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^\pi) = \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \text{Dist}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}^{\otimes n}, \mathcal{R}_{A'^n \rightarrow A^n}^\pi) \quad (127)$$

$$\geq \frac{1}{2} \left(\log |A| - \inf_{\psi \in \text{St}(RA'B')} \bar{S}_\alpha(A|RB)_{\mathcal{N}(\psi)} - \lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} \frac{\alpha}{1 - \alpha} \log \frac{1}{\varepsilon^2} \right) \quad (128)$$

$$= \frac{1}{2} \left(\log |A| - \inf_{\psi \in \text{St}(RA'B')} \bar{S}_\alpha(A|RB)_{\mathcal{N}(\psi)} \right). \quad (129)$$

Taking limit $\alpha \rightarrow 1^-$, $\text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^\pi) \geq \frac{1}{2} \left(\log |A| - \inf_{\psi \in \text{St}(RA'B')} S(A|RB)_{\mathcal{N}(\psi)} \right) = \frac{1}{2} (\log |A| - S^\nearrow[A|B]_{\mathcal{N}})$. The other inequality follows from Eq. (58). $\square$

Theorem 6. For an arbitrary quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, $A' \simeq A$, that is no-signaling from $A' \rightarrow B$ ($\mathcal{N} \in \mathcal{S}_{A' \nrightarrow B}$), its conditional purity distillation and formation capacities are the same and exactly determined in terms of its conditional entropy,

$$\text{Dist}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^\pi) = \text{Cost}^{(\infty, 0)}(\mathcal{N}, \mathcal{R}^\pi) = \frac{1}{2} (\log |A| - S[A|B]_{\mathcal{N}}) = \frac{1}{2} (\log |A| - S^\nearrow[A|B]_{\mathcal{N}}). \quad (130)$$

That is, the resource theory of conditional purity for no-signaling quantum channels under the action of CGPSs is asymptotically reversible.

We provide detailed proof of Theorem 6 in Appendix C 5. We write the asymptotic equipartition property of the conditional channel min-entropy for no-signaling quantum channels as a theorem below, proof of which follows from the proof arguments of Theorem 6.

Theorem 7 (Asymptotic equipartition property). For $\varepsilon \in (0, 1)$ and asymptotically many i.i.d. uses of an arbitrary bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$, the smoothed conditional channel min-entropy satisfies the following bounds,

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n|B^n]_{\mathcal{N}^{\otimes n}} \leq S^\nearrow[A|B]_{\mathcal{N}} = \inf_{\psi \in \text{St}(RA'B')} S(A|RB)_{\mathcal{N}(\psi)}. \quad (131)$$

If $\mathcal{N}_{A'B' \rightarrow AB}$ is no-signaling, $\mathcal{N} \in \mathcal{S}_{A' \nrightarrow B}$, then

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n|B^n]_{\mathcal{N}^{\otimes n}} \leq S[A|B]_{\mathcal{N}}, \quad (132)$$

$$\lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n|B^n]_{\mathcal{N}^{\otimes n}} \geq S[A|B]_{\mathcal{N}}. \quad (133)$$

A consequence of [Theorem 6](#) for $\mathcal{N} \in \mathcal{S}_{A' \nrightarrow B}$ is that

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n|B^n]_{\mathcal{N}^{\otimes n}} = S[A|B]_{\mathcal{N}} = S^\nabla[A|B]_{\mathcal{N}} = \inf_{\psi \in \text{St}(RA'B')} S(A|RB)_{\mathcal{N}(\psi)}. \quad (134)$$

We now inspect the relations between the causal structure of a quantum channel and its conditional min-entropy.

Proposition 6. *For an arbitrary bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$, its NS conditional min-entropy satisfies*

$$S_\infty^\nabla[A|B]_{\mathcal{N}} = S_\infty^\downarrow(A|R_AR_BB)_{\Phi^{\mathcal{N}}}. \quad (135)$$

Proof. Note that for any channel $\mathcal{N}_{A'B' \rightarrow AB}$, we have $\mathcal{R}_{A \rightarrow A}^\mathbb{1} \circ \mathcal{N}(\cdot) = \mathbb{1}_A \otimes \text{tr}_A \circ \mathcal{N}(\cdot)$, and therefore, $\Phi^{\mathcal{R}_{A \rightarrow A}^\mathbb{1} \circ \mathcal{N}} = \mathbb{1}_A \otimes \text{tr}_A \Phi^{\mathcal{N}}$. From the definition of NS conditional min-entropy, we get

$$S_\infty^\nabla[A|B]_{\mathcal{N}} = -D_\infty[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A \rightarrow A}^\mathbb{1} \circ \mathcal{N}_{A'B' \rightarrow AB}] \quad (136)$$

$$= -D_\infty(\Phi_{R_AR_BB}^{\mathcal{N}} \| \mathbb{1}_A \otimes \Phi_{R_AR_BB}^{\mathcal{N}}) \quad (137)$$

$$= S_\infty^\downarrow(A|R_AR_BB)_{\Phi^{\mathcal{N}}}. \quad (138)$$

□

In the following lemma we show that for a bipartite semicausal causal channel, its NS conditional min-entropy lower bounds its conditional min-entropy.

Lemma 2. *For an arbitrary bipartite semicausal channel $\mathcal{N}_{A'B' \rightarrow AB} \in \mathcal{S}_{A' \nrightarrow B}$, we have*

$$S_\infty^\downarrow(R_AA|R_BB)_{\Phi^{\mathcal{N}}} - \log |A'| = S_\infty^\nabla[A|B]_{\mathcal{N}} \leq S_\infty[A|B]_{\mathcal{N}}. \quad (139)$$

Proof. For a bipartite channel $\mathcal{N}_{A'B' \rightarrow AB} \in \mathcal{S}_{A' \nrightarrow B}$, there exists a quantum channel $\mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}}$ such that $\mathcal{R}_{A \rightarrow A}^\mathbb{1} \circ \mathcal{N} = \mathcal{R}_{A' \rightarrow A}^\mathbb{1} \otimes \mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}}$. This implies $\Phi_{R_BB}^{\mathcal{Q}^{\mathcal{N}}} = \Phi_{R_BB}^{\mathcal{N}}$ and

$$S_\infty^\nabla[A|B]_{\mathcal{N}} = -D_\infty[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A \rightarrow A}^\mathbb{1} \circ \mathcal{N}_{A'B' \rightarrow AB}] \quad (140)$$

$$= -D_\infty[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^\mathbb{1} \otimes \mathcal{Q}_{B' \rightarrow B}^{\mathcal{N}}] \quad (141)$$

$$= -D_\infty(\Phi^{\mathcal{N}} \| \mathbb{1}_{R_AA} \otimes \Phi_{R_BB}^{\mathcal{N}}) - \log |A'| \quad (142)$$

$$= S_\infty^\downarrow(R_AA|R_BB)_{\Phi^{\mathcal{N}}} - \log |A'| \quad (143)$$

$$\leq S_\infty[A|B], \quad (144)$$

where the last inequality follows from [Proposition 1](#). □

A direct consequence of the above two results, [Lemma 2](#) and [Proposition 6](#), is the fundamental lower bound on the conditional min-entropy of a semicausal bipartite channel.

Proposition 7. *For an arbitrary semicausal bipartite channel, its conditional min-entropy is always lower bounded by the negative logarithm of the dimension of the non-conditioning output system. That is, for each $\mathcal{N}_{A'B' \rightarrow AB} \in \mathcal{S}_{A' \nrightarrow B}$, we always have $S_\infty[A|B]_{\mathcal{N}} \geq -\log |A|$.*

Proof. From [Lemma 2](#) and [Proposition 6](#), we have

$$S_\infty[A|B]_{\mathcal{N}} \geq S_\infty^\nabla[A|B]_{\mathcal{N}} \quad (145)$$

$$= S_\infty^\downarrow(A|R_AR_BB)_{\Phi^{\mathcal{N}}} \quad (146)$$

$$\geq -\log \text{rank}(\Phi_A^{\mathcal{N}}) \geq -\log |A|. \quad (147)$$

□

Now we inspect the relations between entangling capabilities [10] of a bipartite quantum channel with its conditional entropies.

Completely PPT-preserving channels: A bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is called completely PPT-preserving [86] if it completely preserves positivity of states under partial transposition, i.e., $\text{id}_{R_A R_B} \otimes \mathcal{N}_{A'B' \rightarrow AB}(\rho_{R_A A' R_B B'}) \in \text{PPT}(R_A A; R_B B)$ for all $\rho_{R_A A' R_B B'} \in \text{PPT}(R_A A'; R_B B')$, where $R_A \simeq A'$, $R_B \simeq B'$. A bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is completely PPT-preserving iff its Choi state $\Phi^{\mathcal{N}} \in \text{PPT}(R_A A'; R_B B')$ [87]. These channels do not generate distillable entanglement [10, 25] and appears as free operations in the resource theory of entanglement of bipartite quantum channels [11, 88, 89]. In Appendix C2, we provide proof of the following proposition that provides lower bound on the conditional min-entropy a completely PPT-preserving channel $\mathcal{N}_{A'B' \rightarrow AB}$.

Proposition 8. *The conditional min-entropy of a completely PPT-preserving bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is always lower bounded by the negative of logarithm of its non-conditioning input system,*

$$S_{\infty}[A|B]_{\mathcal{N}} \geq -\log |A'|. \quad (148)$$

Entangling and separable channels: A subclass of completely PPT-preserving channels are completely separability-preserving channels. A bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is called completely separability-preserving if its operator-sum representation is given by [90]

$$\mathcal{N}(\rho_{A'B'}) = \sum_i (K_{A'}^i \otimes M_{B'}^i) \rho_{A'B'} (K_{A'}^i \otimes M_{B'}^i)^{\dagger}, \quad (149)$$

such that for each i , $K_{A'}^i \in L(A', A)$ and $M_{B'}^i \in L(B', B)$, and $\sum_i (K_{A'}^i \otimes M_{B'}^i)^{\dagger} (K_{A'}^i \otimes M_{B'}^i) = \mathbb{1}_{A'B'}$. That is, Kraus operators of a completely separability-preserving channel $\mathcal{N}_{A'B' \rightarrow AB}$ can be written as tensor-product of operators on $A' \rightarrow A$ and $B' \rightarrow B$. These channels preserve the set of separable states, and in fact they form the largest set of completely entanglement non-generating channels [91]. The Choi state $\Phi_{R_A A' R_B B'}^{\mathcal{N}} \in \text{SEP}(R_A A; R_B B)$ of a bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ iff the channel is completely separability-preserving. Any bipartite channel that is not completely separability-preserving is called entangling. The Choi state $\Phi_{R_A A' R_B B'}^{\mathcal{N}}$ of an entangling channel $\mathcal{N}_{A'B' \rightarrow AB}$ is entangled $\Phi_{R_A A' R_B B'}^{\mathcal{N}} \in \text{Ent}(R_A A; R_B B)$. A quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ is said to be NPT entangling if its Choi state $\Phi_{R_A A' R_B B'}^{\mathcal{N}} \notin \text{PPT}(R_A A; R_B B)$.

A related observation below follows directly from Proposition 8.

Corollary 4. *For any completely separability-preserving channel $\mathcal{N}_{A'B' \rightarrow AB}$, $S_{\infty}[A|B]_{\mathcal{N}} \geq -\log |A'|$ always holds. $S_{\infty}[A|B]_{\mathcal{N}} < -\log |A'|$ implies that the channel $\mathcal{N}_{A'B' \rightarrow AB}$ is NPT entangling.*

A direct consequence of the above observation is that for any local quantum operations and classical communication (LOCC) channel [24] $\mathcal{L}_{A'B' \rightarrow AB}$, its conditional min-entropy is lower bounded as $S_{\infty}[A|B]_{\mathcal{L}} \geq -\log |A'|$. This follows because $\text{LOCC} \subset \text{C-SEP-P} \subset \text{C-PPT-P}$, where LOCC is the set of all LOCC channels, C-SEP-P is the set of all completely separability-preserving channels, and C-PPT-P is the set of all completely PPT-preserving channels.

Corollary 5. *Given a bipartite unitary channel $\mathcal{U}_{A'B' \rightarrow AB}$, $S[A|B]_{\mathcal{U}} < -\log |A'|$ if and only if $\mathcal{U}_{A'B' \rightarrow AB}$ is an entangling channel.*

Proof. Note that $S[A|B]_{\mathcal{U}} \leq S(R_A A | R_B B)_{\Phi^{\mathcal{U}}} - \log |A'|$, and given a pure state ψ , $S(A|B)_{\psi} < 0$ if and only if ψ is entangled. Therefore, $S[A|B]_{\mathcal{U}} < -\log |A'|$ if and only if $\Phi^{\mathcal{U}}$ is entangled, equivalently, if and only if $\mathcal{U}$ is entangling. $\square$

A. Examples: Bipartite unitary channels

In this section, we determine the conditional entropies either analytically or numerically for a broad class of bipartite unitaries, as well as for noisy unitary channels of practical interest in quantum information processing [10, 23, 25, 64, 92, 93].

Before we begin with our results, let us recall that for a pure state ψ_{AB} , its conditional min-entropy satisfies $S_\infty(A|B)_\psi = -2 \log \text{tr}(\sqrt{\psi_B})$ [15], where $\psi_B := \text{tr}_A \psi_{AB}$. For a pure state ψ_{AB} , the optimal conditional state on B for $S(A|B)_\psi$ is $(\text{tr} \sqrt{\psi_B})^{-1} \sqrt{\psi_B}$. That is, for pure state ψ_{AB} ,

$$S_\infty(A|B)_\psi = - \inf_{\sigma \in \text{St}(B)} D_\infty(\psi_{AB} \| \mathbb{1}_A \otimes \sigma_B) = -D_\infty(\psi_{AB} \| \mathbb{1}_A \otimes (\text{tr} \sqrt{\psi_B})^{-1} \sqrt{\psi_B}) \quad (150)$$

$$= -\log \text{tr}(\sqrt{\psi_B}) - D_\infty(\psi_{AB} \| \mathbb{1}_A \otimes \sqrt{\psi_B}). \quad (151)$$

The conditional min-entropy $S_\infty^\downarrow(A|B)_\psi$ of a pure state ψ_{AB} can also be calculated from the duality relations [16]: $S_\infty^\downarrow(A|B)_\psi = -S_\infty(A)_\psi = -\log \text{rank}(\psi_A)$. For a pure state ψ_{AB} , its Schmidt rank is equal to the rank of the reduced states, $\text{rank}(\psi_A) = \text{rank}(\psi_B)$.

Bipartite unitary channels: For an arbitrary unitary channel $\mathcal{U}_{A'B' \rightarrow AB}$ corresponding to a unitary operator $U_{A'B' \rightarrow AB}$, its Choi state $\Phi^{\mathcal{U}}$ is also a pure state, given by $\Phi^{\mathcal{U}} = |U\rangle\rangle\langle\langle U|$, where $|U\rangle\rangle = \sum_i \mathbb{1}_{R_B} \otimes U |ii\rangle$ is the vectorization of the operator U . The conditional min-entropy of its Choi state is given by

$$S_\infty(R_A A | R_B B)_{\Phi^{\mathcal{U}}} = -2 \log \text{tr} \sqrt{\Phi_{BR_B}^{\mathcal{U}}}. \quad (152)$$

Consider a class of unitary channels $\mathcal{U}_{AB \rightarrow AB}$ called the controlled unitary channels and denoted as $\mathcal{C}_{\mathcal{U}}$, with control on A and unitary operations on B . The corresponding unitary operator is given by $C_{\mathcal{U}} = \sum_j |j\rangle\langle j|_A \otimes U_j$, where $\{|j\rangle\rangle_j$ are orthonormal basis in A and $\{U_j\}_j$ are unitary operators on B . When the operators $\{U_i\}_i$ form a complete set of mutually orthonormal unitary operators, we denote such channels as $\widehat{\mathcal{C}}_{\mathcal{U}}$. For such channels conditional min-entropy of the Choi state has a relatively simple form, as we show in the following.

Lemma 3. *Given an arbitrary controlled unitary channel $\mathcal{C}_{\mathcal{U}}$, we have*

$$S_\infty^\downarrow(AR_A | BR_B)_{\Phi^{\mathcal{C}_{\mathcal{U}}}} = -\log |\text{span}\{|U_j\rangle\rangle\}|. \quad (153)$$

Proof. The Choi state of the controlled unitary defined above is given by

$$\Phi^{\mathcal{C}_{\mathcal{U}}} = \frac{1}{|A|} \left[\sum_j |jj\rangle\langle jj| \otimes \Phi^{\mathcal{U}_j} + \sum_{i \neq k} |ii\rangle\langle kk| \otimes |U_i\rangle\rangle\langle\langle U_k| \right]. \quad (154)$$

The reduced state of $\Phi^{\mathcal{C}_{\mathcal{U}}}$ is given by $\Phi_{R_B B}^{\mathcal{C}_{\mathcal{U}}} = \frac{\sum_j \Phi^{\mathcal{U}_j}}{|A|}$. Therefore,

$$S_\infty^\downarrow(AR_A | BR_B)_{\Phi^{\mathcal{C}_{\mathcal{U}}}} = -D_\infty(\Phi^{\mathcal{C}_{\mathcal{U}}} \| \mathbb{1}_{R_A A} \otimes \frac{\sum_j \Phi^{\mathcal{U}_j}}{|A|}) \quad (155)$$

$$= -\log \text{rank}(\sum_j \Phi^{\mathcal{U}_j}) \quad (156)$$

$$= -\log |\text{span}\{|U_j\rangle\rangle\}|. \quad (157)$$

□

As an example, consider the case where $\{U_j\}_j$ is an irreducible set of unitary operators (they do not have a non-trivial invariant subspace), then $|\text{span}\{|U_j\rangle\rangle\}| = |A|$. As a simple corollary of the above Lemma, if the control space is 2-dimensional with the controlled unitary operator $C_U = |0\rangle\langle 0|_A \otimes \mathbb{1}_B + |1\rangle\langle 1|_A \otimes U_B$, the min-entropy is $S_\infty^\downarrow(AR_A|BR_B)_{\Phi^{C_U}} = -1$ with the obvious assumption that $U_B \neq \mathbb{1}_B$.

Proposition 9. *Let C_U be a controlled unitary channel, such that the corresponding unitary operators are $C_U = \sum_j |j\rangle\langle j|_A \otimes U_j$ where $\{|j\rangle\rangle_j$ are orthonormal basis in A and $\{U_j\}_j$ are unitary operators on B . We have*

$$S_\infty[A|B]_{C_U} \geq -2 \log |A|. \quad (158)$$

The inequality saturates for $\widehat{C}_U$, i.e., when $\{|U_j\rangle\rangle_j$ is an orthonormal set, $S_\infty[A|B]_{\widehat{C}_U} = -2 \log |A|$.

Proof. From Lemma 3 and the bounds on channel min-entropy from Proposition 1, we have $S_\infty[A|B]_{C_U} \geq -2 \log |A|$ for all controlled unitary channels since $|\text{span}\{|U_j\rangle\rangle\}| \leq |A|$. The inverse relations follows for channels $\widehat{C}_U$ since $\{|U_i\rangle\rangle_i$ form an orthonormal basis for system A . From Equation (152) we have

$$S_\infty(AR_A|BR_B)_{\Phi^{\widehat{C}_U}} = -2 \log \text{tr} \sqrt{\frac{\sum_i \Phi^{\mathcal{U}_i}}{|A|}} \quad (159)$$

$$= -\log |A|. \quad (160)$$

Again using Proposition 1, we get $S_\infty[A|B]_{\widehat{C}_U} = -2 \log |A|$. This proves the proposition. $\square$

This bound also holds for von Neumann conditional entropy of $\widehat{C}_U$ as we show below

Corollary 6. *Given the controlled unitary channel $\widehat{C}_U$, the von Neumann conditional entropy is $S[A|B]_{\widehat{C}_U} = -2 \log |A|$.*

Proof. Note that $S[A|B]_{\widehat{C}_U} \leq S(R_A A|R_B B)_{\Phi^{\widehat{C}_U}} - \log |A|$. Since $\Phi^{\widehat{C}_U}$ is a pure state, we have

$$S(R_A A|R_B B)_{\Phi^{\widehat{C}_U}} = -S(\Phi_{R_A A}^{\widehat{C}_U}) \quad (161)$$

$$= -S\left(\frac{1}{|A|} \Pi_A\right) \quad (162)$$

$$= -\log |A|. \quad (163)$$

Therefore, $S[A|B]_{\widehat{C}_U} \leq -2 \log |A|$. Since $S[A|B]_{\widehat{C}_U} \geq S_\infty[A|B]_{\widehat{C}_U} = -2 \log |A|$, we have $S[A|B]_{\widehat{C}_U} = -2 \log |A|$. $\square$

Corollary 7. *Given the controlled unitary channel $\widehat{C}_U$, we have $S_\infty[B|A]_{\widehat{C}_U} = -2 \log |A|$.*

Proof. Note that $\Phi_{R_A A}^{\widehat{C}_U} = \frac{\sum_{i=1}^{|A|} |i\rangle\langle i|}{|A|}$, and the following the steps in Lemma 3 we see that $S_\infty^\downarrow(R_B B|R_A A)_{\widehat{C}_U} = -\log |A|$. Similarly, we have $S_\infty(R_B B|R_A A)_{\widehat{C}_U} = -\log |A|$, which proves the assertion that $S_\infty[B|A]_{\widehat{C}_U} = -2 \log |A|$. Using the arguments similar to Corollary 6 we can also conclude that $S[A|B]_{\widehat{C}_U} = -2 \log |A|$. $\square$

As a result, for controlled unitary channels $\widehat{C}_{\mathcal{U}}$, we see that the conditional entropy of A conditioned on B is equal to the conditional entropy of B conditioned on A ,

$$S_{\infty}[A|B]_{\widehat{C}_{\mathcal{U}}} = S_{\infty}[B|A]_{\widehat{C}_{\mathcal{U}}}, \quad (164)$$

indicating that such channels have similar signaling power in both directions.

The NS conditional min-entropy of a unitary channel $\mathcal{U}_{A'B' \rightarrow AB}$ is completely characterized by $|A|$. Using the unitality of $\mathcal{U}$ we have $\Phi_{AB}^{\mathcal{U}} = \frac{1}{|A'||B'|} \mathbb{1}_{AB}$, therefore $\Phi_A^{\mathcal{U}} = \frac{|B|}{|A'||B'|} \mathbb{1}_A$. Since $|A'||B'| = |A||B|$, we have $\Phi_A^{\mathcal{U}} = \pi_A$. Using Proposition 6, we have $S_{\infty}^{\nearrow}[A|B]_{\mathcal{N}} = -\log |A|$.

For no-signaling channel $\mathcal{N}_{A'B' \rightarrow AB} \in S_{A' \nrightarrow B}$, we have the inequality $S_{\infty}[A|B]_{\mathcal{N}} \geq S_{\infty}^{\nearrow}[A|B]_{\mathcal{N}}$ (Lemma 2). For no-signaling unitary channels $\mathcal{U}_{A'B' \rightarrow AB} \in S_{A' \nrightarrow B}$, we have $S_{\infty}[A|B]_{\mathcal{U}} \geq -\log |A|$. If we restrict dimensional condition on the unitary channels $\mathcal{U}$ to $|A'| = |A|$, then that puts constrain also on B , $|B'| = |B|$. The unitary channels $\mathcal{U} \in S_{A' \nrightarrow B}$ with $A' \simeq A$ are tensor-product of local unitaries, $\mathcal{U} = \mathcal{U}_{A' \rightarrow A} \otimes \mathcal{U}_{B' \rightarrow B}$, and

$$S_{\infty}[A|B]_{\mathcal{U}_{A' \rightarrow A} \otimes \mathcal{U}_{B' \rightarrow B}} = S_{\infty}^{\nearrow}[A|B]_{\mathcal{U}_{A' \rightarrow A} \otimes \mathcal{U}_{B' \rightarrow B}} = S_{\infty}[A]_{\mathcal{U}} = -\log |A'|. \quad (165)$$

For all conditional isometry channels $\mathcal{V}_{A' \rightarrow A} \otimes \mathcal{Q}_{B' \rightarrow B}$, where $\mathcal{V}_{A' \rightarrow A}$ is an isometry and $\mathcal{Q} \in \text{Ch}(B', B)$, we have $S_{\infty}[A|B]_{\mathcal{V} \otimes \mathcal{Q}} = S_{\infty}[A]_{\mathcal{V}} = -\log |A'|$. All entangling unitaries are capable of generating distillable entanglement [66, 88] and non-entangling unitaries are tensor-product of local unitaries which cannot generate any kind of entanglement.

We now show that for the special case of two-qubit unitary channels, the conditional min-entropy always saturates its upper limit, and hence, completely determined by its Choi state.

Proposition 10. *For an arbitrary two-qubit unitary channel $\mathcal{U}_{A'B' \rightarrow AB}$, we have*

$$S_{\infty}[A|B]_{\mathcal{U}} = S_{\infty}(R_A A | R_B B)_{\Phi^{\mathcal{U}}} - \log |A'|. \quad (166)$$

Proof. From Equation (150), we see that the optimal state for the relative min-entropy of the Choi state is given by the state $(\text{tr} \sqrt{\Phi_{R_B B}^{\mathcal{U}}})^{-1} \sqrt{\Phi_{R_B B}^{\mathcal{U}}}$.

$$S_{\infty}(R_A A | R_B B)_{\Phi^{\mathcal{U}}} = -\inf_{\sigma} D_{\infty}(\Phi^{\mathcal{U}} | \mathbb{1}_{R_A A} \otimes \sigma) \quad (167)$$

$$= -D_{\infty}(\Phi^{\mathcal{U}} | \mathbb{1}_{R_A A} \otimes (\text{tr} \sqrt{\Phi_{R_B B}^{\mathcal{U}}})^{-1} \sqrt{\Phi_{R_B B}^{\mathcal{U}}}). \quad (168)$$

Due to Lemma 9 presented in Appendix D, we see that this state is also a Choi state of a CPTP map. Therefore, we have

$$\inf_{M \in \text{Ch}(B', B)} D_{\infty}(\Phi^{\mathcal{U}} | \mathbb{1}_{R_A A} \otimes \Phi^M) = \inf_{\sigma} D_{\infty}(\Phi^{\mathcal{U}} | \mathbb{1}_{R_A A} \otimes \sigma) \quad (169)$$

$$= S_{\infty}(R_A A | R_B B)_{\Phi^{\mathcal{U}}}. \quad (170)$$

Since $S_{\infty}[A|B]_{\mathcal{N}} = -\inf_{M \in \text{Ch}(B', B)} D_{\infty}(\Phi^{\mathcal{U}} | \mathbb{1}_{R_A A} \otimes \Phi^M) - \log |A'|$, the above identities prove the proposition. $\square$

Based on our numerical calculations, we observe that Proposition 10 also holds for a broad class of two-qubit unitaries $\mathcal{U}_{A'B' \rightarrow AB}$ with added white noise: let $\mathcal{N}_p := p\mathcal{R}^{\pi} + (1-p)\mathcal{U}$ for $p \in [0, 1]$, then $S_{\infty}[A|B]_{\mathcal{N}_p} = S_{\infty}(R_A A | R_B B)_{\Phi^{\mathcal{N}_p}} - \log |A'|$. We plot these instances for some special two-qubit unitaries in Figure 2. We conjecture that Proposition 10 holds true for all two-qubit unitaries with added white noise. We leave this as an open problem.

FIG. 2. Plot showing the conditional min-entropy $S_\infty[A|B]_N$ along with the upper and lower bounds $S_\infty(AR_A|BR_B)_{\Phi^N} - 1$ and $S_\infty^\dagger(AR_A|BR_B)_{\Phi^N} - 1$ for two-qubit channels parametrized as $N_p := pR^\pi + (1-p)N$ for $p \in [0, 1]$, where N is chosen to be CNOT, SWAP, id. We see that the conditional channel min-entropy coincides with the upper bound. For the case of a noisy two-qubit swap channel, both the upper and lower bounds coincide for all values of p .

VII. DISCUSSIONS

The fundamental information-theoretic notions of conditional entropy and conditional information for quantum states have enabled substantial conceptual and technological advances in quantum information science. These quantities also provide a unifying framework connecting computational, informational, and thermodynamic aspects of quantum systems. A particularly striking feature is that the conditional entropy of quantum states can be negative, which is impossible for classical joint probability distributions [18, 63]. This counterintuitive property is now well understood as a signature of entanglement [18]. Another cornerstone result is the strong subadditivity of quantum entropy [94], which establishes that conditional entropy does not increase under further conditioning.

In this work, we determine the operational meanings of conditional channel entropies in the context of channel transformation under thermodynamic constraints. Too negative conditional channel min-entropy implies that the channel is signaling from non-conditioning input to conditioning output. It also reflects that the channel is able to generate distillable entanglement. We provide framework and tools to study energetics of quantum information processing. More broadly, our results highlight a fundamental connection between thermodynamic resources, causal structure, and the quantum correlations generating abilities in quantum processes.

There are several open questions emerging from our study here. One direction is to consider the conditional athermality and purity distillation and formation under physically motivated free operations that would be subset of CGPSs. It is also of interest to determine the exact optimal rates for other broad classes of bipartite channels and shed light on the asymptotic reversibility (or irreversibility) of the conditional athermality under CGPSs. We leave further study of the properties of conditional channel free energy for future work. The properties of the conditional

channel entropies and the strong subadditivity of the channel entropy has potential to provide novel insight and tools for the study of quantum communication and computation, quantum error correction, open quantum systems, and many-body quantum systems, where quantum processes and their causal structure play critical role [3, 26, 65, 95–102].

APPENDIX

In Appendix A, we briefly discuss some properties of the generalized conditional channel entropies. We discuss some results on the channel free energies of single-input, single-output quantum channels in Appendix B. We provide detailed proofs of the results in the main content in Appendix C: The proof of Theorem 1 is in Appendix C1, the proof of Proposition 8 is in Appendix C2, the proof of Theorem 3 is in Appendix C3, the proof of Theorem 4 is in Appendix C4, the proof of Theorem 6 is in Appendix C5, and the proof of Theorem 2 is in Appendix C6. In Appendix D, we discuss a relevant result on the Choi states of two-qubit unitary channels. In Appendix E, we discuss the form of conditional Gibbs-preserving superchannels.

Appendix A: Generalized conditional channel entropies

Let us denote $\mathbb{D}(\cdot\|\cdot)$ denote the generalized divergence for families of Petz-Rényi relative entropy $\overline{D}_\alpha(\cdot\|\cdot)$ for $\alpha \in [0, 2]$ and sandwiched Rényi relative entropy $D_\alpha(\cdot\|\cdot)$ for $\alpha \in [\frac{1}{2}, \infty]$, where $\alpha = 1$ means $\lim_{\alpha \rightarrow 1}$, i.e., $\overline{D}_1(\cdot\|\cdot) = D_1(\cdot\|\cdot) = D(\cdot\|\cdot)$, and $\alpha = \infty$ means $\lim_{\alpha \rightarrow \infty}$. For an arbitrary quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, the conditional channel entropy $\mathbb{S}[A|B]_{\mathcal{N}}$ is [4]

$$\mathbb{S}[A|B]_{\mathcal{N}} = - \inf_{Q \in \text{Ch}(B', B)} \mathbb{D}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^1 \otimes Q_{B' \rightarrow B}]. \quad (\text{A1})$$

and the NS conditional channel entropy $\mathbb{S}^\nearrow[A|B]_{\mathcal{N}}$ is [4]

$$\mathbb{S}^\nearrow[A|B]_{\mathcal{N}} := \mathbb{D}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A \rightarrow A}^1 \circ \mathcal{N}_{A'B' \rightarrow AB}]. \quad (\text{A2})$$

Lemma 4. For a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$,

$$\mathbb{S}[A|B]_{\mathcal{N}} \leq \mathbb{S}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|, \quad (\text{A3})$$

where $\mathbb{S}^\downarrow(R_A A | R_B B)_{\Phi^{\mathcal{N}}} := - \inf_{\sigma \in \text{St}(R_B B)} \mathbb{D}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \mathbb{1}_{R_A A} \otimes \sigma_{R_B B})$. Furthermore, if $\mathcal{N}_{A'B' \rightarrow AB}$ is tele-covariant, then

$$\mathbb{S}^\downarrow(R_A A | R_B B)_{\Phi^{\mathcal{N}}} - \log |A'| \leq \mathbb{S}[A|B]_{\mathcal{N}} \quad (\text{A4})$$

Proof. The proof argument is similar to the proof of bounds in [Proposition 1](#). We arrive at the upper bound observing that

$$\begin{aligned}
-\mathbb{S}[A|B]_{\mathcal{N}} &= \inf_{Q \in \text{Ch}(B', B)} \mathbb{D}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A} \otimes Q_{B' \rightarrow B}] \\
&\geq \mathbb{D}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \mathbb{1}_{R_A A} \otimes \Phi_{R_B B}^Q) - \log |A'| \\
&\geq \inf_{\sigma \in \text{St}(R_B B)} \mathbb{D}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \mathbb{1}_{R_A A} \otimes \Phi_{R_B B}^Q) - \log |A'| \\
&= -\mathbb{S}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} + \log |A'|.
\end{aligned} \tag{A5}$$

To arrive at the lower bound, we now consider that $\mathcal{N}$ is tele-covariant. Let a reduced channel $\mathcal{T}_{B' \rightarrow B}^{\mathcal{N}}$ of $\mathcal{N}_{A'B' \rightarrow AB}$ defined as

$$\mathcal{T}_{B' \rightarrow B}^{\mathcal{N}}(\cdot) := \text{tr}_A \circ \mathcal{N}_{A'B' \rightarrow AB}(\pi_{A'} \otimes \cdot). \tag{A7}$$

Notice that $\Phi_{R_B B}^{\mathcal{T}^{\mathcal{N}}} = \Phi_{R_B B}^{\mathcal{N}}$. Then,

$$\begin{aligned}
-\mathbb{S}[A|B]_{\mathcal{N}} &= \inf_{Q \in \text{Ch}(B', B)} \mathbb{D}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^{\mathbb{1}} \otimes Q_{B' \rightarrow B}] \\
&\leq \mathbb{D}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{R}_{A' \rightarrow A}^{\mathbb{1}} \otimes \mathcal{T}_{B' \rightarrow B}^{\mathcal{N}}] \\
&= \mathbb{D}(\Phi_{R_A A R_B B}^{\mathcal{N}} \| \mathbb{1}_{R_A} \otimes \mathbb{1}_A \otimes \Phi_{R_B B}^{\mathcal{N}}) + \log |A'| \\
&= -\mathbb{S}^{\downarrow}(R_A A | R_B B)_{\Phi^{\mathcal{N}}} + \log |A'|,
\end{aligned} \tag{A8}$$

where the second equality holds because a maximally entangled state is an optimal input state for the generalized channel divergence between two jointly tele-covariant channels [\[71\]](#) (see also [\[103\]](#)). $\square$

Proposition 11. For a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, the dimensional lower bound is achieved,

$$\mathbb{S}[A|B]_{\mathcal{N}} = -\log \min\{|A'| |B'| |B|, |A'|^2 |A|\}, \tag{A9}$$

iff $\mathcal{N}$ is a maximally entangling (swap-like) operation.

Proof. For arbitrary $\rho, \sigma \in \text{St}(A)$, we have $\overline{D}_{\alpha_1}(\rho \| \sigma) \leq \overline{D}_{\alpha_2}(\rho \| \sigma)$ and $D_{\alpha_1}(\cdot \| \cdot) \leq D_{\alpha_2}(\rho \| \sigma)$ whenever $\alpha_1 \leq \alpha_2$ [\[16\]](#). Also, in limit $\alpha \rightarrow \infty$, $\overline{D}_{\alpha}(\rho \| \sigma) = D_{\infty}(\rho \| \sigma)$. For an arbitrary channel $\mathcal{N}_{A'B' \rightarrow AB}$,

$$S_{\infty}[A|B]_{\mathcal{N}} \leq \mathbb{S}[A|B]_{\mathcal{N}}. \tag{A10}$$

Swap is a tele-covariant channel and its Choi state is $\Phi_{R_A B} \otimes \Phi_{R_B A}$. We also have $\mathbb{S}^{\downarrow}(A|B)_{\rho} = -\log \min\{|A|, |B|\} = \mathbb{S}(A|B)_{\rho}$ if and only if ρ_{AB} is maximally entangled. From [Theorem 2](#) and [Lemma 4](#), we conclude that $\mathbb{S}[A|B]_{\mathcal{N}} = -\log \min\{|A'| |B'| |B|, |A'|^2 |A|\}$ iff $\mathcal{N}$ is a swap operation $\text{SWAP}_{A:B}$. $\square$

We remark that the conditional channel min-entropy can, in general, lie strictly between the bounds in [Proposition 1](#); see [Figure 3](#) for an example.

FIG. 3. Plot showing the conditional min-entropy $S_\infty[A|B]_N$ along with the upper and lower bounds $S_\infty(AR_A|BR_B)_{\Phi^N} - 1$ and $S_\infty(AR_A|BR_B)_{\Phi^N} - 1$ for two-qubit channels parametrized as $\mathcal{N}_p := p\mathcal{R}^\pi + (1-p)\mathcal{N}$ for $p \in [0, 1]$, where $\mathcal{N}$ is a numerically generated random channel using Quantinf package [104]. There is a clear separation between conditional min-entropy and its bounds in Proposition 1.

Appendix B: Channel free energy

The channel free energy $F^\beta[\mathcal{P}] = \beta^{-1}D[\mathcal{P}||\mathcal{T}^\beta]\ln 2$ of an arbitrary quantum channel $\mathcal{P}_{A' \rightarrow A}$ can be expressed as [2, 3]

$$\frac{\beta}{\ln 2}F^\beta[\mathcal{P}] = D[\mathcal{P}||\mathcal{T}^\beta] = \sup_{\psi \in \text{St}(RA')} D(\mathcal{P}(\psi_{RA'})||\mathcal{T}^\beta(\psi_{RA'})) \quad (\text{B1})$$

$$= \sup_{\psi \in \text{St}(RA')} D(\mathcal{P}(\psi_{RA'})||\psi_R \otimes \gamma_A^\beta) \quad (\text{B2})$$

$$= \sup_{|\psi\rangle\langle\psi| \in \text{St}(RA')} \left[I(R; A)_{\mathcal{P}(\psi)} + D(\mathcal{P}(\psi_{A'})||\gamma_A^\beta) \right], \quad (\text{B3})$$

where it suffices to optimize over pure states $\psi \in \text{St}(RA')$ with $R \simeq A'$ in Eq. (B1).

Lemma 5 ([2]). *The resource-theoretic thermal channel free energy $F^\beta[\mathcal{P}] := \beta^{-1}D[\mathcal{P}||\mathcal{T}^\beta]\ln 2$ of an arbitrary quantum channel $\mathcal{P}_{A' \rightarrow A}$ is maximum if it is an isometry channel.*

Proof. Notice that it suffices to optimize over pure states $\psi_{RA'} = |\psi\rangle\langle\psi|_{RA'}$ with $R \simeq A'$ in the RHS of Eq. (B1). Due to joint-convexity (quasi-convexity suffices) of relative entropy between states, maximum value of the state relative entropy $D(\rho||\sigma)$ for a fixed state σ is achieved only if ρ is a pure state [105]. This implies that the maximum value for $D[\mathcal{P}||\mathcal{T}^\beta]$ can be achieved only if the channel $\mathcal{P}$ is an isometry channel. $\square$

Lemma 6. *Consider an isometry channel $\mathcal{V}_{A' \rightarrow A}$ with $\mathcal{V}(\cdot) := V(\cdot)V^\dagger$ and let β be finite. The channel free energy of $\mathcal{V}_{A' \rightarrow A}$ is $F_\infty^\beta[\mathcal{V}] = \beta^{-1} \ln \text{tr}[\Pi_A^\mathcal{V}(\gamma_A^\beta)^{-1}]$, where $\Pi_A^\mathcal{V} := VV^\dagger$ is a projector on A and $\text{rank}(\Pi_A^\mathcal{V}) = |A'|$.*

Proof. Given a pure state ψ , we have $D_\infty(\psi\|\sigma) = \log \langle \psi | \sigma^{-1} | \psi \rangle$ for a positive operator σ . Using this, we have

$$\beta F_\infty^\beta[\mathcal{V}] = D_\infty(\Phi^\mathcal{V} \|\Phi^\mathcal{T}) \ln 2 \quad (\text{B4})$$

$$= \ln \left(\frac{1}{|A'|} \sum_j \langle j | \otimes \langle j | V^\dagger \left(\frac{1}{|A'|} \mathbb{1}_R \otimes \gamma_A^\beta \right)^{-1} \sum_i (|i\rangle \otimes V |i\rangle) \right) \quad (\text{B5})$$

$$= \ln \left(\sum_{i,j} \delta_{ji} \langle j | V^\dagger (\gamma_A^\beta)^{-1} V |i\rangle \right) \quad (\text{B6})$$

$$= \ln \left(\text{tr} \left[\gamma_\beta^{-1} V V^\dagger \right] \right). \quad (\text{B7})$$

□

A direct consequence of the above lemma is the following corollary.

Corollary 8. For an isometry channel $\mathcal{V}_{A' \rightarrow A}$ with $\widehat{H}_A \propto \mathbb{1}_A$, we have $F^\beta[\mathcal{V}] = F_\infty^\beta[\mathcal{V}] = \beta^{-1} \ln(|A'| |A|)$.

Proof. For the trivial Hamiltonian, we have $(\gamma_A^\beta)^{-1} = \mathbb{1}_A |A|$ and $\text{tr} \left[(\gamma_A^\beta)^{-1} \Pi_A^\mathcal{V} \right] = \text{tr}(|A| \Pi_A^\mathcal{V}) = |A'| |A|$ which proves $F_\infty^\beta[\mathcal{V}] = \beta^{-1} \ln(|A'| |A|)$. We also know,

$$F_\infty^\beta[\mathcal{V}] \geq F^\beta[\mathcal{V}] \geq \beta^{-1} D[\Phi^\mathcal{V} \|\mathbb{1}_R \otimes \pi_A] \ln 2 \quad (\text{B8})$$

$$= \beta^{-1} \ln |A'| |A|, \quad (\text{B9})$$

which concludes the proof. □

Our Lemma 6 also provides an upper bound on the free energy of a quantum channel $\mathcal{P}_{A' \rightarrow A}$,

$$F^\beta[\mathcal{P}] \leq F_\infty^\beta[\mathcal{P}] \leq F_\infty^\beta[\mathcal{V}] \leq \beta^{-1} \ln \text{tr}[(\gamma_A^\beta)^{-1}]. \quad (\text{B10})$$

We note that the above bound can also be derived from [44, Theorem A5] due to the relation between the robustness of athermality and channel max-free energy [2].

Appendix C: Proofs

1. Proof of Theorem 1

Theorem. The one-shot conditional athermality distillation yield and formation cost of a quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$, up to an error $\varepsilon \in [0, 1]$, is given by

$$\text{Dist}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) = \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D_H^{\varepsilon^2}[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}], \quad (\text{C1})$$

$$\text{Cost}^{(1,\varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \mathcal{T}_{A' \rightarrow A}^\beta) = \frac{1}{2} \inf_{Q \in \text{Ch}(B', B)} D_\infty^\varepsilon[\mathcal{N}_{A'B' \rightarrow AB} \| \mathcal{T}_{A' \rightarrow A}^\beta \otimes Q_{B' \rightarrow B}]. \quad (\text{C2})$$

Proof. Before we begin the proof, let us denote the uniformly mixing channel $\mathcal{R}_{C' \rightarrow C}^\pi$ as $\mathcal{R}_m^\pi$ whenever $|C'| = |C| = m$. We can decompose a uniformly mixing channel $\mathcal{R}_m^\pi$ by taking a uniform mixture of Weyl unitary channels $\mathcal{W}^i(\cdot) = W^i(\cdot)W^{i\dagger}$,

$$\mathcal{R}_m^\pi(\cdot) = \frac{1}{m^2} \sum_{i=0}^{m^2-1} W^i(\cdot)W^{i\dagger}, \quad (\text{C3})$$

where $\{W^i\}_{i=0}^{m^2-1}$ is the set (group) of Weyl unitaries that form the complete orthonormal basis for the space of all linear operators acting on m -dimensional Hilbert space. Let $W^0 = \text{id}_m$ be the identity operation and $\text{id}_m^\perp := \sum_{i=1}^{m^2-1} W^i$, then

$$\mathcal{R}_m^\pi = \frac{1}{m^2} \text{id}_m + \frac{1}{m^2} \sum_{i=1}^{m^2-1} W^i = \frac{1}{m^2} (\text{id}_m + \text{id}_m^\perp). \quad (\text{C4})$$

The single-shot distillation cost of the resource $(\mathcal{N}_{A'B' \rightarrow AB}, \Gamma_{A' \rightarrow A}^\beta \otimes \mathcal{Q}_{B' \rightarrow B})$ is given by

$$\begin{aligned} & \text{Dist}^{(1, \varepsilon)}(\mathcal{N}_{A'B' \rightarrow AB}, \Gamma_{A' \rightarrow A}^\beta \otimes \mathcal{Q}_{B' \rightarrow B}) \\ &:= \sup \left\{ \log m : d_{\text{CGPS}}((\mathcal{N}, \Gamma^\beta \otimes \mathcal{Q}) \rightarrow (\text{id}_m \otimes \mathcal{Q}', \mathcal{R}_m^\pi \otimes \mathcal{Q}')) \leq \varepsilon \right\} \end{aligned} \quad (\text{C5})$$

$$= \sup \left\{ \log m : P[\text{id}_m \otimes \mathcal{Q}', \Theta(\mathcal{N})] \leq \varepsilon, \Theta(\Gamma^\beta \otimes \mathcal{Q}) = \mathcal{R}_m^\pi \otimes \mathcal{Q}' \right\}. \quad (\text{C6})$$

A resource distillation process is effectively a measure and prepare channel where an object is processed with a free operation and then a free measurement is performed; the optimal distillation rate is when the processing with free operation and measurement is optimized for maximal distillation of the resource unit. A conditional athermality distillation process from $(\mathcal{N}_{A'B' \rightarrow AB}, \Gamma_{A' \rightarrow A}^\beta \otimes \mathcal{Q}_{B' \rightarrow B})$ under the action of a conditional Gibbs-preserving superchannel Θ_ψ^Λ , where $\psi_{RA'B'}$ is a state and Λ_{RAB} is an effect operator, s.t. $0 \leq \Lambda \leq \mathbb{1}$, can be described as

$$\Theta_\psi^\Lambda(\mathcal{N}) = \text{tr}(\Lambda \Theta(\mathcal{N})(\psi)) \text{id}_m \otimes \mathcal{Q}' + \text{tr}((\mathbb{1} - \Lambda) \Theta(\mathcal{N})(\psi)) \frac{\text{id}_m^\perp \otimes \mathcal{Q}'}{m^2 - 1}, \quad (\text{C7})$$

where Θ is a conditional Gibbs-preserving superchannel. The conditional Gibbs-preserving condition $\Theta_\psi^\Lambda(\Gamma^\beta \otimes \mathcal{Q}) = \mathcal{R}_m^\pi \otimes \mathcal{Q}'$ implies

$$\text{tr}(\Lambda \Theta(\Gamma^\beta \otimes \mathcal{Q})(\psi)) = \frac{1}{m^2}. \quad (\text{C8})$$

Furthermore, the generalized purified distance of the standard resource unit with respect to output of this superchannel is given by $P[\text{id}_m \otimes \mathcal{Q}', \Theta_\psi^\Lambda(\mathcal{N})] = \sqrt{1 - \text{tr}(\Lambda \Theta(\mathcal{N})(\psi))}$. Hence the conversion distance under such operations can be written as

$$d_{\text{CGPS}}((\mathcal{N}, \Gamma^\beta \otimes \mathcal{Q}), (\text{id}_m \otimes \mathcal{Q}', \mathcal{R}_m^\pi \otimes \mathcal{Q}')) = \min_{\Theta, \Lambda, \psi} \left\{ \sqrt{1 - \text{tr}(\Lambda \Theta(\mathcal{N})(\psi))} : \text{tr}(\Lambda \Theta(\Gamma^\beta \otimes \mathcal{Q})(\psi)) = \frac{1}{m^2} \right\}. \quad (\text{C9})$$

Using this expression in Eq. (C5), we have for a conditional Gibbs-preserving superchannel

$\Theta \in \text{CGPS}$,

$$\text{Dist}^{(1,\varepsilon)}(\mathcal{N}, \Gamma^\beta \otimes \mathcal{Q}) = \sup \left\{ \log m : \sqrt{1 - \text{tr}(\Lambda \Theta(\mathcal{N})(\psi))} \leq \varepsilon, \text{tr}(\Lambda \Theta(\Gamma^\beta \otimes \mathcal{Q})(\psi)) = \frac{1}{m^2} \right\} \quad (\text{C10})$$

$$= \sup_{\Theta \in \text{CGPS}, \Lambda, \psi} \left\{ -\frac{1}{2} \log \text{tr}(\Lambda \Theta(\Gamma^\beta \otimes \mathcal{Q})(\psi)) : 1 - \text{tr}(\Lambda \Theta(\mathcal{N})(\psi)) \leq \varepsilon^2 \right\} \quad (\text{C11})$$

$$= \frac{1}{2} \sup_{\Theta \in \text{CGPS}} \sup_{\psi} \sup_{\Lambda} \left\{ -\log \text{tr}((\Gamma^\beta \otimes \mathcal{Q})(\psi) \Lambda) : 1 - \text{tr}(\mathcal{N}(\psi) \Lambda) \leq \varepsilon^2 \right\} \quad (\text{C12})$$

$$= \frac{1}{2} \sup_{\Theta \in \text{CGPS}} \sup_{\psi} D_{\text{H}}^{\varepsilon^2}(\Theta(\mathcal{N})(\psi) \parallel \Theta(\Gamma^\beta \otimes \mathcal{Q})(\psi)) \quad (\text{C13})$$

$$= \frac{1}{2} D_{\text{H}}^{\varepsilon^2}[\mathcal{N} \parallel \Gamma^\beta \otimes \mathcal{Q}]. \quad (\text{C14})$$

The one-shot cost of preparation of a channel resource $(\mathcal{N}_{A'B' \rightarrow AB}, \Gamma_{A' \rightarrow A}^\beta \otimes \mathcal{Q}_{B' \rightarrow B})$ under the free operation is defined as

$$\text{Cost}^{(1,\varepsilon)}(\mathcal{N}, \Gamma^\beta \otimes \mathcal{Q}) = \inf_m \left\{ \log m : d_{\text{CGPS}}((\text{id}_m \otimes \mathcal{Q}', \mathcal{R}^\pi \otimes \mathcal{Q}') \rightarrow (\mathcal{N}, \Gamma^\beta \otimes \mathcal{Q})) \leq \varepsilon \right\}.$$

Following the definition of conversion distance in Eq. (39) and using the decomposition of $\mathcal{R}_m^\pi$ from Eq. (C4), we have

$$\Theta(\mathcal{R}_m^\pi \otimes \mathcal{Q}') = \frac{1}{m^2} \Theta(\text{id}_m \otimes \mathcal{Q}') + \frac{1}{m^2} \Theta(\text{id}_m^\perp \otimes \mathcal{Q}') \quad (\text{C15})$$

$$= \Gamma^\beta \otimes \mathcal{Q} \quad (\text{C16})$$

This yields the bound $m^2 \Gamma^\beta \otimes \mathcal{Q} \geq \Theta(\text{id}_m \otimes \mathcal{Q}')$. Replacing $\mathcal{E} = \Theta(\text{id}_m \otimes \mathcal{Q}')$, we have

$$d_{\text{CGPS}}((\text{id} \otimes \mathcal{Q}', \mathcal{R}^\pi \otimes \mathcal{Q}') \rightarrow (\mathcal{N}, \Gamma^\beta \otimes \mathcal{Q})) = \min_{\mathcal{E}} \left\{ P[\mathcal{N}, \mathcal{E}] : m^2 \Gamma^\beta \otimes \mathcal{Q} \geq \mathcal{E} \right\} \quad (\text{C17})$$

$$= \min_{\mathcal{E}} \left\{ P[\mathcal{N}, \mathcal{E}] : 2 \log m \geq D_\infty[\mathcal{E} \parallel \Gamma^\beta \otimes \mathcal{Q}] \right\}. \quad (\text{C18})$$

The conversion cost can now be written as

$$\text{Cost}^{(1,\varepsilon)}(\mathcal{N}, \Gamma^\beta \otimes \mathcal{Q}) = \inf \left\{ \log m : P(\mathcal{N}, \mathcal{E}) \leq \varepsilon, \log m \geq \frac{1}{2} D_\infty(\mathcal{E} \parallel \Gamma^\beta \otimes \mathcal{Q}) \right\} \quad (\text{C19})$$

$$= \inf \left\{ \frac{1}{2} D_\infty(\mathcal{E} \parallel \Gamma^\beta \otimes \mathcal{Q}) : P(\mathcal{N}, \mathcal{E}) \leq \varepsilon \right\} \quad (\text{C20})$$

$$= \frac{1}{2} D_\infty^\varepsilon[\mathcal{N} \parallel \Gamma^\beta \otimes \mathcal{Q}]. \quad (\text{C21})$$

The statements for the optimal distillation and preparation cost follow from their definitions. $\square$

2. Proof of Proposition 8

Proposition. *The conditional min-entropy of a completely PPT-preserving bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$ is always lower bounded by the negative of logarithm of its non-conditioning input system,*

$$S_\infty[A|B]_{\mathcal{N}} \geq -\log |A'|. \quad (\text{C22})$$

As we will show, the proof of the proposition is a straightforward consequence of the following Lemma.

Lemma 7. *Given a bipartite PPT state ρ_{AB} , we have*

$$S_{\infty}^{\downarrow}(A|B)_{\rho} \geq 0. \quad (\text{C23})$$

Proof. A bipartite PPT state ρ_{AB} satisfies the following reduction criteria [106],

$$\mathbb{1}_A \otimes \rho_B \geq \rho_{AB}. \quad (\text{C24})$$

From the primal problem for $S_{\infty}^{\downarrow}(A|B)_{\rho}$ given by

$$2^{-S_{\infty}^{\downarrow}(A|B)_{\rho}} = \inf\{\lambda; \lambda \mathbb{1}_A \otimes \rho_B \geq \rho, \lambda > 0\}, \quad (\text{C25})$$

we see that for PPT states, the optimal value satisfies $\lambda^* \leq 1$, or $S_{\infty}^{\downarrow}(A|B)_{\rho} \geq 0$. $\square$

Given a completely PPT-preserving channel $\mathcal{N}_{A'B' \rightarrow AB}$, the corresponding Choi state $\phi_{R_A A R_B B}^{\mathcal{N}}$ is a PPT state such that $S_{\infty}^{\downarrow}(R_A A | R_B B)_{\phi^{\mathcal{N}}} \geq 0$. Using Proposition 1, we have

$$S_{\infty}[A|B]_{\mathcal{N}} \geq S_{\infty}^{\downarrow}(R_A A | R_B B)_{\phi^{\mathcal{N}}} - \log |A'| \quad (\text{C26})$$

$$\geq -\log |A'|. \quad (\text{C27})$$

3. Proof of Theorem 3

Theorem. *Consider two arbitrary bipartite channels $\mathcal{N}_{A'B' \rightarrow AB}$ and $\mathcal{M}_{A'B' \rightarrow AB}$. For $\frac{1}{2}\|\mathcal{N} - \mathcal{M}\|_{\diamond} \leq \delta \in [0, 1]$, the difference of their conditional min-entropy is bounded as*

$$|S_{\infty}[A|B]_{\mathcal{N}} - S_{\infty}[A|B]_{\mathcal{M}}| \leq \frac{1}{\ln 2} |A| \min\{|A'| |A|, |B'| |B|\} \delta. \quad (\text{C28})$$

Proof. Consider the functional $\mathcal{E} : \text{Ch}(A'B', AB) \rightarrow \mathbb{R}^+$ given by $\mathcal{E}(\mathcal{N}) := |A'|^{-1} 2^{-S_{\infty}[A|B]_{\mathcal{N}}}$, or equivalently

$$\mathcal{E}(\mathcal{N}) = \inf_{\mathcal{M} \in \text{Ch}(B', B)} \{\lambda, \lambda(\mathbb{1}_{AA'} \otimes \Phi^{\mathcal{M}}) \geq \Phi^{\mathcal{N}}\}. \quad (\text{C29})$$

One can extend this functional to the space of Hermiticity preserving maps,

$$\tilde{\mathcal{E}}(\mathcal{N}) = \inf_{\mathcal{M} \in \text{HPTP}(B', B)} \{\lambda, \lambda(\mathbb{1}_{AA'} \otimes \Phi^{\mathcal{M}}) \geq \Phi^{\mathcal{N}}\}. \quad (\text{C30})$$

Note that we can equate $\tilde{\mathcal{E}}(\mathcal{N}) = \widehat{\mathcal{E}}(\Phi^{\mathcal{N}})$ as a map on the Choi matrices of the Hermiticity preserving maps $\mathcal{N}$. The map $\tilde{\mathcal{E}}(\mathcal{N})$ satisfies the following properties:

1. $\tilde{\mathcal{E}}(a\mathcal{N}) = a\tilde{\mathcal{E}}(\mathcal{N}) \forall a \in \mathbb{R}^+$, since, $\Phi^{(a\mathcal{N})} = a\Phi^{\mathcal{N}}$.
2. $\Phi^{\mathcal{N}} \geq \Phi^{\mathcal{M}} \implies \tilde{\mathcal{E}}(\mathcal{N}) \geq \tilde{\mathcal{E}}(\mathcal{M})$.
3. $\tilde{\mathcal{E}}(\mathcal{N} + \mathcal{M}) \leq \tilde{\mathcal{E}}(\mathcal{N}) + \tilde{\mathcal{E}}(\mathcal{M})$.

4. $\tilde{\mathcal{E}}(\mathcal{N}) \leq \min\{|AA'|, |BB'|\} \text{tr}(\Phi^{\mathcal{N}} P^+)$. Here, $\text{tr}(XP^+)$ is the sum of the positive eigenvalues of X . To show this, we note that for any Hermiticity preserving map $\mathcal{N}$, we have the spectral decomposition of its Choi matrix as $\Phi^{\mathcal{N}} = \sum_i \lambda_i \Phi^{\mathcal{K}_i}$ where $\{\mathcal{K}_i\}_i$ are rank 1 CP maps. This is because every bipartite pure state can be written as a Choi matrix of a CP map. Using the property 1 and 3, we have the convexity of $\tilde{\mathcal{E}}(\mathcal{N})$, such that,

$$\tilde{\mathcal{E}}(\mathcal{N}) \leq \sum_i \lambda_i \tilde{\mathcal{E}}(\mathcal{K}_i) \quad (\text{C31})$$

$$\leq \sum_{\lambda_i \geq 0} \lambda_i \tilde{\mathcal{E}}(\mathcal{K}_i) \quad (\text{C32})$$

We have

$$\tilde{\mathcal{E}}(\mathcal{K}_i) = \inf_{\mathcal{M} \in \text{HPTP}(B', B)} \{\lambda, \lambda(\mathbb{1}_{A'A} \otimes \Phi^{\mathcal{M}}) \geq \Phi^{\mathcal{K}_i}\} \quad (\text{C33})$$

$$\leq \inf \{\lambda, \lambda(\mathbb{1}_{A'A} \otimes \Phi^{\mathcal{M}_i}) \geq \Phi^{\mathcal{K}_i}\} \quad (\text{C34})$$

$$= 2^{-S_{\infty}^{\downarrow}(R_A A | R_B B)_{\Phi^{\mathcal{K}_i}}} \quad (\text{C35})$$

$$\leq \min\{|A'| |A|, |B'| |B|\}. \quad (\text{C36})$$

Here $\mathcal{M}_i(\cdot) = \text{tr}_A \circ \mathcal{K}_i(\mathbb{1}_A \otimes \cdot)$ is the reduced CP map and $\Phi^{\mathcal{M}_i} = \text{tr}_{A'A}(\Phi^{\mathcal{K}_i})$. In the last inequality, we have used the lower bound on the min-conditional entropy: $S_{\infty}^{\downarrow}(A|B)_{\rho} \geq -\log \min\{|A|, |B|\}$. Furthermore, the sum of the positive part of the spectrum of the state $\Phi^{\mathcal{N}}$ is given by $\sum_{\lambda_i \geq 0} \lambda_i = \text{tr}(\Phi^{\mathcal{N}} P^+)$, which gives us the required bound.

The diamond norm between two maps is given as

$$\|\mathcal{N} - \mathcal{M}\|_{\diamond} = \max_{\rho} \|\text{id} \otimes \mathcal{N}(\rho) - \text{id} \otimes \mathcal{M}(\rho)\|_1 \geq \|\Phi^{\mathcal{N}} - \Phi^{\mathcal{M}}\|_1. \quad (\text{C37})$$

Therefore, $\frac{1}{2}\|\mathcal{N} - \mathcal{M}\|_{\diamond} \leq \delta$ implies $\frac{1}{2}\|1\|_1 \geq \|\Phi^{\mathcal{N}} - \Phi^{\mathcal{M}}\|_1 \leq \delta$. Using the properties of the functional $\tilde{\mathcal{E}}$, we have the following for two arbitrary CPTP map $\mathcal{N}$ and $\mathcal{M} \in \text{Ch}(A'B', AB)$

$$\tilde{\mathcal{E}}(\mathcal{N}) \leq \tilde{\mathcal{E}}(\mathcal{M}) + \tilde{\mathcal{E}}(\mathcal{N} - \mathcal{M}) \quad (\text{C38})$$

$$\leq \tilde{\mathcal{E}}(\mathcal{M}) + \min\{|AA'|, |BB'|\} \text{tr}((\Phi^{\mathcal{N}} - \Phi^{\mathcal{M}})P^+) \quad (\text{C39})$$

$$= \tilde{\mathcal{E}}(\mathcal{M}) + \min\{|AA'|, |BB'|\} \|\Phi^{\mathcal{N}} - \Phi^{\mathcal{M}}\|_1 \quad (\text{C40})$$

$$\leq \tilde{\mathcal{E}}(\mathcal{M}) + \min\{|AA'|, |BB'|\} \delta \quad (\text{C41})$$

Here we have used equality $\text{tr}(XP^+) = \frac{1}{2}(\|X\|_1 + \text{tr}(X))$. Consequently, if $\mathcal{N}$ and $\mathcal{M}$ are quantum channels, $\text{tr}((\Phi^{\mathcal{N}} - \Phi^{\mathcal{M}})P^+) = \frac{\|\Phi^{\mathcal{N}} - \Phi^{\mathcal{M}}\|_1}{2}$. Using $\ln(a+x) - \ln(a) \leq \frac{x}{a}$ and substituting $a+x = \tilde{\mathcal{E}}(\mathcal{N})$, and $a = \tilde{\mathcal{E}}(\mathcal{M})$, we have

$$\tilde{\mathcal{E}}(\mathcal{N}) - \tilde{\mathcal{E}}(\mathcal{M}) \leq \min\{|AA'|, |BB'|\} \delta \quad (\text{C42})$$

$$\Rightarrow \frac{2^{-S_{\infty}[A|B]_{\mathcal{N}}} - 2^{-S_{\infty}[A|B]_{\mathcal{M}}}}{2^{-S_{\infty}[A|B]_{\mathcal{N}}}} \leq \frac{\delta}{2^{-S_{\infty}[A|B]_{\mathcal{N}}}} \min\{|AA'|, |BB'|\} \quad (\text{C43})$$

$$\Rightarrow S_{\infty}[A|B]_{\mathcal{N}} - S_{\infty}[A|B]_{\mathcal{M}} \leq \frac{|A| \min\{|AA'|, |BB'|\} \delta}{\text{tr}(\Phi^{\mathcal{M}}) \ln 2} \quad (\text{C44})$$

In the last step, we have used the inequality $2^{-S_{\infty}[A|B]_{\mathcal{N}}} \geq \frac{\text{tr}(\Phi^{\mathcal{N}})}{|A|}$. □

4. Proof of Theorem 4

Theorem. For $\varepsilon \in (0, 1)$ and asymptotically many i.i.d. uses of a bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$, the smoothed conditional channel min-entropy satisfies the following bounds in terms of the conditional von Neumann entropy of the Choi state $\Phi^{\mathcal{N}}$,

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n|B^n]_{\mathcal{N}^{\otimes n}} \leq S(R_A A|R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|. \quad (\text{C45})$$

If $\mathcal{N}$ is tele-covariant, then

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n|B^n]_{\mathcal{N}^{\otimes n}} \leq S[A|B]_{\mathcal{N}}, \quad (\text{C46})$$

$$\lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n|B^n]_{\mathcal{N}^{\otimes n}} \geq S[A|B]_{\mathcal{N}}. \quad (\text{C47})$$

Proof. For an arbitrary channel $\mathcal{N}_{A'B' \rightarrow AB}$, using the upper bound on conditional channel min-entropy from Proposition 1, we get

$$S_{\infty}^{\varepsilon}[A|B]_{\mathcal{N}} \leq \sup_{\mathcal{M} \in \mathcal{B}^{\varepsilon}[\mathcal{N}]} S_{\infty}(R_A A|R_B B)_{\Phi^{\mathcal{M}}} - \log |A'|, \quad (\text{C48})$$

Note that

$$\sup_{\mathcal{M} \in \mathcal{B}^{\varepsilon}[\mathcal{N}]} S_{\infty}(R_A A|R_B B)_{\Phi^{\mathcal{M}}} \leq \sup_{\Phi^{\mathcal{M}} \in \mathcal{B}^{\varepsilon}(\Phi^{\mathcal{N}})} S_{\infty}(R_A A|R_B B)_{\Phi^{\mathcal{M}}} \quad (\text{C49})$$

$$\leq \sup_{\rho \in \mathcal{B}^{\varepsilon}(\Phi^{\mathcal{N}})} S_{\infty}(R_A A|R_B B)_{\Phi^{\mathcal{M}}} \quad (\text{C50})$$

$$= S_{\infty}^{\varepsilon}(R_A A|R_B B)_{\Phi^{\mathcal{N}}}, \quad (\text{C51})$$

where the smoothed conditional min-entropy is defined for $\varepsilon \in [0, 1]$ as

$$S_{\infty}^{\varepsilon}(A|B)_{\rho} := \sup_{\tilde{\rho} \in \mathcal{B}^{\varepsilon}(\rho)} S_{\infty}(R_A A|R_B B)_{\tilde{\rho}}, \quad (\text{C52})$$

$$\text{and, } S_{\infty}^{\downarrow, \varepsilon}(A|B)_{\rho} := - \inf_{\tilde{\rho} \in \mathcal{B}^{\varepsilon}(\rho)} D_{\infty}(\tilde{\rho} \| \mathbb{1}_A \otimes \rho_B). \quad (\text{C53})$$

We now use the asymptotic convergence of the conditional min-entropy to prove the first inequality of the theorem. For $\varepsilon \in (0, 1)$, the smoothed conditional min-entropy functions follows the asymptotic equipartition property [17, Theroem 1],

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}(A^n|B^n)_{\rho^{\otimes n}} = S(A|B)_{\rho}. \quad (\text{C54})$$

Noting $\Phi^{\mathcal{N}^{\otimes n}} = (\Phi^{\mathcal{N}})^{\otimes n}$, we get

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_{\infty}^{\varepsilon}[A^n|B^n]_{\mathcal{N}^{\otimes n}} \leq S(R_A A|R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|, \quad (\text{C55})$$

which concludes the proof of inequality (C45).

Inequality (C46) follows from inequality (C45) and the fact that for a tele-covariant channel $\mathcal{N}$,

$$S[A|B]_{\mathcal{N}} = S(R_A A|R_B B)_{\Phi^{\mathcal{N}}} - \log |A'|. \quad (\text{C56})$$

To show the inequality (C47), we adapt the techniques used in the proof argument of [74, Theorem 21]. Let $\mathcal{M}_{A'^n B'^n \rightarrow A^n B^n}$ be a channel in ε -neighborhood of $\mathcal{N}^{\otimes n}$, then

$$\sup_{\mathcal{M} \in \mathcal{B}^\varepsilon[\mathcal{N}^{\otimes n}]} S_\infty[A|B]_{\mathcal{M}} = \sup_{\mathcal{M} \in \mathcal{B}^\varepsilon[\mathcal{N}^{\otimes n}]} -\inf_{\mathcal{P}} D_\infty[\mathcal{M} \| \mathcal{R}_{A'^n \rightarrow A^n}^{\mathbb{1}} \otimes \mathcal{P}_{B'^n \rightarrow B^n}] \quad (\text{C57})$$

Consider the following choice of the channel $\mathcal{P}_{B'^n \rightarrow B^n} = \mathcal{K}_{B' \rightarrow B}^{\otimes n}$ defined as

$$\mathcal{K}_{B' \rightarrow B}(\cdot) := \text{tr}_A \circ \mathcal{N}_{A'B' \rightarrow AB}(\pi_{A'} \otimes \cdot). \quad (\text{C58})$$

A de Finetti state $\omega_{R^n A'^n B'^n}$, where $R \cong A'B'$, is a state of a multipartite system that is invariant under any permutation of its subsystems. It can be decomposed as

$$\omega_{R^n A'^n B'^n} = \int d\mu(\sigma) \sigma_{RA'B'}^{\otimes n} \quad (\text{C59})$$

where $\sigma_{RA'B'}$ are pure states and $d\mu(\sigma)$ is the Haar measure on the space of pure states. Let $\text{Perm}(A'^n, A^n)$ denote the set of permutation covariant channels from $A'^n \rightarrow A^n$. Action of such channels on de Finetti states would leave them permutation invariant.

$$\sup_{\mathcal{M} \in \mathcal{B}^\varepsilon[\mathcal{N}^{\otimes n}]} S_\infty[A|B]_{\mathcal{M}} \geq \sup_{\mathcal{M} \in \mathcal{B}^\varepsilon[\mathcal{N}^{\otimes n}]} -D_\infty[\mathcal{M} \| \mathcal{R}_{A'^n \rightarrow A^n}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n}] \quad (\text{C60})$$

$$\geq \sup_{\mathcal{M} \in \mathcal{B}^\varepsilon[\mathcal{N}^{\otimes n}], \mathcal{M} \in \text{Perm}((A'B')^n, (AB)^n)} -D_\infty[\mathcal{M} \| \mathcal{R}_{A'^n \rightarrow A^n}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n}] \quad (\text{C61})$$

$$= \sup_{\mathcal{M} \in \mathcal{B}^\varepsilon[\mathcal{N}^{\otimes n}], \mathcal{M} \in \text{Perm}((A'B')^n, (AB)^n)} -D_\infty(\mathcal{M}(\omega) \| \mathcal{R}_{A'^n \rightarrow A^n}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n}(\omega)), \quad (\text{C62})$$

where $\omega_{R'R^n A'^n B'^n}$ is the purification of the de Finetti state $\omega_{R^n A'^n B'^n}$. The equality holds since $\omega_{A'^n B'^n}$ is a full rank state. From [107], we note that if $\mathcal{M} \in \text{Perm}((A'B')^n, (AB)^n)$ such that $\mathcal{M} \in \mathcal{B}^\varepsilon[\mathcal{N}^{\otimes n}]$, then $\mathcal{M}(\omega) \in \mathcal{B}^{\varepsilon'}(\mathcal{N}^{\otimes n}(\omega))$ where $\varepsilon' = \varepsilon(n+1)^{2(|A|^2-1)}$. We have the final expression on the RHS satisfy the following

$$(\text{C62}) \geq \sup_{\mathcal{M}(\omega) \in \mathcal{B}^{\varepsilon'}(\mathcal{N}^{\otimes n}(\omega)), \mathcal{M} \in \text{Perm}((A'B')^n, (AB)^n)} -D_\infty(\mathcal{M}(\omega) \| \mathcal{R}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n}(\omega)) \quad (\text{C63})$$

$$= \sup_{\sigma \in \mathcal{B}^{\varepsilon'}(\mathcal{N}^{\otimes n}(\omega)), \sigma_{RR'^n} = \omega_{RR'^n}} -D_\infty(\sigma \| \mathcal{R}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n}(\omega)) \quad (\text{C64})$$

This equality can be shown as follows: clearly, (C63) $\leq$ (C64) since the reduced state of $\mathcal{M}(\omega)$ is $\omega_{R'R}$. (C63) $\geq$ (C64) follows because $\mathcal{N}^{\otimes n}$ is invariant under the action of the superchannel $\Theta(\mathcal{M}) = \frac{1}{n!} \pi_{(AB)^n} \circ \mathcal{M} \circ \pi_{(A'B')^n} \in \text{Perm}((A'B')^n, (AB)^n)$ and

$$\mathcal{M}(\omega) \in \mathcal{B}^{\varepsilon'}(\mathcal{N}^{\otimes n}(\omega)) \implies \Theta(\mathcal{M})(\omega) \in \mathcal{B}^{\varepsilon'}(\mathcal{N}^{\otimes n}(\omega)). \quad (\text{C65})$$

Let σ be the state that optimizes the expression in Eq. (C64). From the [108, Lemma 10], there exists a CPTP map $\widetilde{\mathcal{M}}$ s.t. $\sigma = \widetilde{\mathcal{M}}(\omega) \in \mathcal{B}^\varepsilon(\mathcal{N}^{\otimes n}(\omega))$. Due to the Θ -invariance of $\mathcal{N}^{\otimes n}$, we can show that $\Theta(\widetilde{\mathcal{M}})(\omega) \in \mathcal{B}^\varepsilon(\mathcal{N}^{\otimes n}(\omega))$ and since $\Theta(\widetilde{\mathcal{M}}) \in \text{Perm}((A'B')^n, (AB)^n)$, we have

$$(\text{C63}) \geq -D_\infty(\Theta(\widetilde{\mathcal{M}})(\omega) \| \mathcal{R}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n}(\omega)) \quad (\text{C66})$$

$$= -D_\infty(\Theta(\widetilde{\mathcal{M}})(\omega) \| \Theta(\mathcal{R}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n})(\omega)) \quad (\text{C67})$$

$$\geq -D_\infty(\widetilde{\mathcal{M}}(\omega) \| \mathcal{R}^{\mathbb{1}} \otimes \mathcal{K}^{\otimes n}(\omega)) = (\text{C64}). \quad (\text{C68})$$

The equality follows since the channel $\mathcal{R}_{A^n}^\pi \otimes \mathcal{K}^{\otimes n}$ is invariant under Θ . This shows (C63)=(C64). Using [109, Theorem 3], for $\varepsilon'/2 - \delta \leq 1$ and $\delta \geq 0$, we get

$$(C64) = \sup_{\sigma \in \mathcal{B}^{\varepsilon'/2-\delta}(\mathcal{N}^{\otimes n}(\omega))} -D_\infty(\sigma \| \mathcal{R}_{A^n \rightarrow A^n}^\pi \otimes \mathcal{K}^{\otimes n}(\omega)) - \log \frac{8 + \delta^2}{\delta^2} \quad (C69)$$

$$\begin{aligned} &\geq -D_\alpha(\mathcal{N}^{\otimes n}(\omega) \| \mathcal{R}_{A^n \rightarrow A^n}^\pi \otimes \mathcal{K}^{\otimes n}(\omega)) \\ &\quad - \log \frac{8 + \delta^2}{\delta^2} - \frac{1}{\alpha - 1} \log \frac{1}{(\varepsilon'/2 - \delta)^2} - \log \frac{1}{1 - (\varepsilon'/2 - \delta)^2} \end{aligned} \quad (C70)$$

$$\geq -nD_\alpha[\mathcal{N} \| \mathcal{R}_{A \rightarrow A}^\pi \otimes \mathcal{K}] + f(\varepsilon', \delta), \quad (C71)$$

where $\alpha > 1$ and we have used the results from [110, Theorem 3]. Then, for $\alpha > 1$, we have

$$S_\infty^\varepsilon[A^n | B^n]_{\mathcal{N}^{\otimes n}} \geq -nD_\alpha[\mathcal{N} \| \mathcal{R}_{A \rightarrow A}^\pi \otimes \mathcal{K}] + f(\varepsilon', \delta), \quad (C72)$$

$$\frac{1}{n} S_\infty^\varepsilon[A^n | B^n]_{\mathcal{N}^{\otimes n}} \geq -D_\alpha[\mathcal{N} \| \mathcal{R}_{A \rightarrow A}^\pi \otimes \mathcal{K}] + \frac{1}{n} f(\varepsilon', \delta). \quad (C73)$$

Taking the limit $n \rightarrow \infty$, then $\lim \alpha \rightarrow 1^+$ and noting that $\Phi^K = \text{tr}_{R_A A} \Phi^\mathcal{N}$ for a tele-covariant channel $\mathcal{N}$, we get

$$\lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n | B^n]_{\mathcal{N}^{\otimes n}} \geq S(R_A A | R_B B)_{\Phi^\mathcal{N}} - \log |A'| = S[A | B]_\mathcal{N}. \quad (C74)$$

□

5. Proof of Theorem 6

Theorem (Asymptotic equipartition property). *For $\varepsilon \in (0, 1)$ and asymptotically many i.i.d. uses of an arbitrary bipartite channel $\mathcal{N}_{A'B' \rightarrow AB}$, the smoothed conditional channel min-entropy satisfies the following bounds,*

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n | B^n]_{\mathcal{N}^{\otimes n}} \leq S^\nearrow[A | B]_\mathcal{N} = \inf_{\psi \in \text{St}(R_A A' B')} S(A | RB)_{\mathcal{N}(\psi)}. \quad (C75)$$

If $\mathcal{N}_{A'B' \rightarrow AB}$ is no-signaling, $\mathcal{N} \in S_{A' \nrightarrow B}$, then

$$\lim_{\varepsilon \rightarrow 0^+} \lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n | B^n]_{\mathcal{N}^{\otimes n}} \leq S[A | B]_\mathcal{N}, \quad (C76)$$

$$\lim_{n \rightarrow \infty} \frac{1}{n} S_\infty^\varepsilon[A^n | B^n]_{\mathcal{N}^{\otimes n}} \geq S[A | B]_\mathcal{N}. \quad (C77)$$

Proof. We prove Eq. (130) in parts. Let us observe that $S^{\text{reg}}[A | B]_\mathcal{N}$ for a channel $\mathcal{N} \in S_{A' \nrightarrow B}$ is additive. It follows because, for any quantum channel $\mathcal{M}_{C'_i \rightarrow A_i B_i}$, $i \in \{1, \dots, n\}$, we have for $\alpha \geq 1$ [84]

$$\inf_{\rho \in \text{St}(R C^m)} S_\alpha(A^n | R B^n)_{\mathcal{M}^{\otimes n}(\rho)} = \sum_i \inf_{\rho \in \text{St}(R_i C'_i)} S_\alpha(A_i | R_i B_i)_{\mathcal{M}(\rho)}. \quad (C78)$$

That makes $S^\nearrow[A | B]_\mathcal{N}$ to be additive under tensor-product of bipartite quantum channels which in turn makes $S[A | B]_\mathcal{N}$ to be additive under tensor-product of bipartite quantum channels that are

no-signaling from $A' \rightarrow B$. In particular, for quantum channels $\mathcal{N}_{A'_i B'_i \rightarrow A_i B_i}^i$, such that $\mathcal{N}^i \in \mathcal{S}_{A'_i \rightarrow B_i}$ for $i \in \{1, \dots, n\}$, then

$$S[A^n|B^n]_{\otimes_i \mathcal{N}^i} = S^{\nearrow}[A^n|B^n]_{\otimes_i \mathcal{N}^i} = \sum_{i=1}^n S^{\nearrow}[A_i|B_i]_{\mathcal{N}^i} = \sum_{i=1}^n \inf_{\psi \in \text{St}(R_i A'_i B'_i)} S(A_i|R_i B_i)_{\mathcal{N}^i}. \quad (\text{C79})$$

Therefore, for $\mathcal{N} \in \mathcal{S}_{A' \rightarrow B}$, we have

$$\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \leq \frac{1}{2} \left(\log |A| - \lim_{n \rightarrow \infty} \frac{1}{n} S[A^n|B^n]_{\mathcal{N}^{\otimes n}} \right) \quad (\text{C80})$$

$$= \frac{1}{2} \left(\log |A| - \lim_{n \rightarrow \infty} \frac{1}{n} S[A|B]_{\mathcal{N}} \right) \quad (\text{C81})$$

$$= \frac{1}{2} (\log |A| - S[A|B]_{\mathcal{N}}) = \frac{1}{2} (\log |A| - S^{\nearrow}[A|B]_{\mathcal{N}}), \quad (\text{C82})$$

which concludes the proof for the conditional distillation capacity because $\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \geq \frac{1}{2} (\log |A| - S^{\nearrow}[A|B]_{\mathcal{N}})$ holds for arbitrary $\mathcal{N}$.

For an arbitrary quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ and its reduced channel $\mathcal{Q}_{B' \rightarrow B}$, where for all states $\rho_{A'}$,

$$\mathcal{Q}_{B' \rightarrow B}(\cdot) = \text{tr}_A \circ \mathcal{N}_{A'B' \rightarrow AB} \circ \mathcal{R}_{A' \rightarrow A}^\pi(\rho_{A'} \otimes \cdot), \quad (\text{C83})$$

we have from Eq. (51), for $\alpha > 1$,

$$\frac{1}{n} S_\infty^\varepsilon[A^n|B^n]_{\mathcal{N}^{\otimes n}} \geq -D_\alpha[\mathcal{N} \| \mathcal{R}_{A' \rightarrow A}^\pi \otimes \mathcal{Q}] + \frac{1}{n} f(\varepsilon', \delta). \quad (\text{C84})$$

We note that $\text{tr}_{RA}(\mathcal{N}(\psi_{RA'B'})) = \mathcal{Q}(\psi_{RB'})$, for all input states $\psi_{RA'B'}$ and $\psi_{RB'} = \text{tr}_{A'}(\psi_{RA'B'})$, if $\mathcal{N} \in \mathcal{S}_{A' \rightarrow B}$. For $\mathcal{N} \in \mathcal{S}_{A' \rightarrow B}$, taking the limit $n \rightarrow \infty$ and then $\lim \alpha \rightarrow 1^+$ in Eq. (C84), we get

$$\frac{1}{n} S_\infty^\varepsilon[A^n|B^n]_{\mathcal{N}^{\otimes n}} \geq S[A|B]_{\mathcal{N}} = \inf_{\psi \in \text{St}(R A' B')} S(A|RB)_{\mathcal{N}(\psi)}. \quad (\text{C85})$$

That is, for $\mathcal{N} \in \mathcal{S}_{A' \rightarrow B}$,

$$\text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \leq \frac{1}{2} (\log |A| - S^{\nearrow}[A|B]_{\mathcal{N}}), \quad (\text{C86})$$

concluding the proof as $\text{Dist}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi) \leq \text{Cost}^{(\infty,0)}(\mathcal{N}, \mathcal{R}^\pi)$. $\square$

6. Proof of Theorem 2

The swap operation on a bipartite system simply exchanges the subsystems, such that the action of the corresponding unitary is given by $U_{A'B' \rightarrow AB}^{\text{SWAP}}(|i\rangle_{A'} |j\rangle_{B'}) = |j\rangle_A |i\rangle_B$. The Choi state of the swap operation is maximally entangled across the $R_A A : R_B B$ partition. We refer to any channel as a swap-like or maximally entangling channel whose Choi state is equivalent to $\Phi_{R_A A : R_B B}$. Below we provide the dimensional constraints between the input and output systems under any isometry that maps two maximally entangled states.

Lemma 8. *Given two maximally entangled states $\Phi_{A:B}$ and $\Phi_{A:C}$, there exists $\mathcal{E}_{B \rightarrow C} \in \text{Ch}(B, C)$ such that $\mathcal{E}_{B \rightarrow C}(\Phi_{A:B}) = \Phi_{A:C}$, only if either $|A| \leq |B| \leq |C|$, or $|A| \geq |B| = |C|$.*

Proof. Since the Choi state of the map $\mathcal{E}_{B \rightarrow C}$ is a pure state, it must be an isometry, and hence $|B| \leq |C|$. Let $\{a_i\}_i$, $\{b_j\}_j$ and $\{c_k\}_k$ be orthonormal basis of the Hilbert spaces A , B and C respectively. We can write the maximally entangled in AB state $\Phi_{A:B} = \frac{1}{d} \sum_{i,j} |a_i, b_i\rangle \langle a_j, b_j|$, where $d = \min\{|A|, |B|\}$. Let $\mathcal{E}_{B \rightarrow C}$ be a channel that maps $\Phi_{A:B}$ to $\Phi_{A:C}$, that is

$$\mathcal{E}_{B \rightarrow C} \left(\frac{1}{d} \sum_{i,j} |a_i, b_i\rangle \langle a_j, b_j| \right) = \frac{1}{d'} \sum_{k,l} |a_k, c_k\rangle \langle a_l, c_l|, \quad (\text{C87})$$

where, $d' = \min\{|A|, |C|\}$. Since a local map cannot increase the Schmidt rank of a state, we must have $d \geq d'$. Combining this with the observation $|B| \leq |C|$, if $|A| \geq |B|$, we must have $|C| = |B|$, else we must have $|A| \leq |B|$. $\square$

Now we proceed to prove the main theorem.

Theorem. *The conditional min-entropy of a bipartite quantum channel $\mathcal{N}_{A'B' \rightarrow AB}$ achieves the minimum if and only if the channel is a maximally entangling unitary operation. For a quantum channel $\mathcal{N}_{A'B' \rightarrow AB} \in \text{SWAP}(A; B)$, we have*

$$S_\infty[A|B]_{\mathcal{N} \in \text{SWAP}(A; B)} = -\log \min\{|A'|^2|A|, |A'| |B'| |B|\}. \quad (\text{C88})$$

Proof. We will first show that the upper and lower bound of $S_\infty[A|B]_{\mathcal{N}}$ as given in [Proposition 1](#) coincide at Φ^N if it is a maximally entangled state, that is

$$\min_{\mathcal{N}} S_\infty^\downarrow(R_A A | R_B B)_{\Phi^N} = \min_{\mathcal{N}} S_\infty(R_A A | R_B B)_{\Phi^N} = S_\infty^\downarrow(R_A A | R_B B)_{\Phi^{\text{SWAP}_{A:B}}} \quad (\text{C89})$$

Consider the SDP for $S_\infty(A|B)_{\rho_{AB}}$ which can be written as [\[15\]](#)

$$S_\infty(A|B)_{\rho_{AB}} = -\log \sup_{X_{AB}} \{ \text{tr}(\rho_{AB} X_{AB}) : \text{tr}_A(X_{AB}) = \mathbb{1}_B, X_{AB} \geq 0 \}. \quad (\text{C90})$$

We can write $X_{AB} = \mathcal{E}_{B' \rightarrow A}(\Gamma_{BB'})$ as a Choi matrix of a channel $\mathcal{E}_{B' \rightarrow A}$, which gives us

$$S_\infty(A|B)_{\rho_{AB}} = -\log |d| - \log \sup_{\mathcal{E}_{B' \rightarrow A}} \{ \text{tr}(\rho_{AB} \mathcal{E}_{B' \rightarrow A}(\Phi_{BB'})) : \mathcal{E}_{B' \rightarrow A} \in \text{Ch}(B', A) \} \quad (\text{C91})$$

Here $d = \min\{|B|, |B'|\}$. Note that for density matrices ρ and σ , $\text{tr}(\rho\sigma) \leq 1$ and it is maximum iff $\rho = \sigma = |\psi\rangle \langle \psi|$. Therefore, we have

$$S_\infty(A|B)_{\rho_{AB}} \geq -\log d, \quad (\text{C92})$$

and the bound is achieved iff $\rho_{AB} = \mathcal{E}_{B' \rightarrow A}(\Phi_{BB'}) = \Phi_{AB}$. From [Lemma 8](#) we see that this is possible in two cases: case 1: $|B| \leq |B'| \leq |A|$, which implies $d = |B|$ and case 2: $|B| \geq |B'| = |A|$, which implies $d = |A|$. Hence,

$$\min_{\rho_{AB}} S_\infty(A|B)_{\rho_{AB}} = -\log d = \begin{cases} -\log |B| & \text{if } |B| \leq |A| \\ -\log |A| & \text{if } |A| \leq |B| \end{cases} \quad (\text{C93})$$

Equivalently,

$$\min_{\rho_{AB}} S_\infty(A|B)_{\rho_{AB}} = S_\infty(A|B)_{\Phi_{AB}} = -\log \min\{|A|, |B|\}. \quad (\text{C94})$$

For $S_\infty^\downarrow(A|B)_\rho$, the SDP can be written as

$$S_\infty^\downarrow(A|B)_{\rho_{AB}} = -\log \sup_{X_{AB}} \{ \text{tr}(\rho_{AB} X_{AB}) : \text{tr}((\mathbb{1}_A \otimes \rho_B) X_{AB}) = 1, X_{AB} \geq 0 \}. \quad (\text{C95})$$

Here, X_{AB} being a positive operator, can be written as a Choi matrix of a CP map: $X_{AB} = \mathcal{E}_{A' \rightarrow B}(\Gamma_{AA'})$. This makes the dual map $\mathcal{E}_{B \rightarrow A'}^*$, a CP map such that $\mathcal{E}_{B \rightarrow A'}^*(\rho_B)$ is a density matrix. This also implies that $\mathcal{E}_{B \rightarrow A'}^*(\rho_{AB})$ is also a density matrix. We have

$$\begin{aligned} \min_{\rho_{AB}} S_\infty^\downarrow(A|B)_{\rho_{AB}} &= -\log \sup_{\rho_{AB}} \{ |d| \text{tr}(\mathcal{E}_{A \rightarrow B'}^*(\rho_{AB}) \Phi_{AA'}) \} \\ &= S_\infty^\downarrow(A|B)_{\Phi_{AB}} \\ &= -\log \min\{|A|, |B|\}. \end{aligned} \quad (\text{C96})$$

From Theorem 1 we have the identity

$$S_\infty^\downarrow(R_A A | R_B B)_{\Phi^\mathcal{N}} - \log |A'| \leq S_\infty[A|B]_\mathcal{N} \leq S_\infty(R_A A | R_B B)_{\Phi^\mathcal{N}} - \log |A'|. \quad (\text{C97})$$

using the above results, we have

$$\begin{aligned} \min_{\mathcal{N}} S_\infty^\downarrow(R_A A | R_B B)_{\Phi^\mathcal{N}} &\leq S_\infty^\downarrow(R_A A | R_B B)_{\Phi^{\text{SWAP}_{A:B}}} \\ &= S_\infty^\downarrow(R_A A | R_B B)_{\Phi_{R_A A : R_B B}} \\ &= -\log \min\{|A'| |A|, |B'| |B|\} \\ &\leq \min_{\mathcal{N}} S_\infty^\downarrow(R_A A | R_B B)_{\Phi^\mathcal{N}} \end{aligned} \quad (\text{C98})$$

Therefore, for swap-like operations $\mathcal{N} = \text{SWAP}_{A:B}$, where $\Phi^\mathcal{N} = \Phi_{R_A A : R_B B}$, we have

$$\inf_{\mathcal{N}} S_\infty^\downarrow(R_A A | R_B B)_{\Phi^\mathcal{N}} = -\log \min\{|A'| |A|, |B'| |B|\} \quad (\text{C99})$$

and similarly

$$\inf_{\mathcal{N}} S_\infty(R_A A | R_B B)_{\Phi^\mathcal{N}} = -\log \min\{|A'| |A|, |B'| |B|\} \quad (\text{C100})$$

Since the upper and lower bounds meet, we have the following relation

$$\inf_{\mathcal{N}} S_\infty[A|B]_\mathcal{N} = S_\infty[A|B]_{\text{SWAP}_{A:B}} = -\log |A'| - \log \min\{|A'| |A|, |B'| |B|\}. \quad (\text{C101})$$

The uniqueness follows since $S_\infty^\downarrow(R_A A | R_B B)_{\Phi^\mathcal{N}} = -\log \min\{|A'| |A|, |B'| |B|\}$ if and only if $\Phi^\mathcal{N} = \Phi_{R_A A : R_B B}$. $\square$

Appendix D: Some results on two-qubit channels

Lemma 9. Given a two-qubit unitary channel $\mathcal{U}_{A'B' \rightarrow AB}$, with the Choi state $\Phi^\mathcal{U}$, the state $\rho_{R_B B} := \frac{1}{\text{tr} \sqrt{\Phi_{R_B B}^\mathcal{U}}} \sqrt{\Phi_{R_B B}^\mathcal{U}}$ is a Choi state of a unital qubit channel.

Proof. Since $\Phi^{\mathcal{U}}$ is a Choi state of a unital CP map, we have $\Phi_{R_A R_B}^{\mathcal{U}} = \Phi_{AB}^{\mathcal{U}} = \frac{1}{4} \mathbb{1}_4$. As a consequence, the state $\Phi_{R_B B}^{\mathcal{U}} \in \mathbb{C}^2 \otimes \mathbb{C}^2$, is a Choi matrix of a unital qubit channel, since $\text{tr}_{R_B} \Phi_{R_B B}^{\mathcal{U}} = \frac{1}{2} \mathbb{1}_2$ and $\text{tr}_B \Phi_{R_B B}^{\mathcal{U}} = \frac{1}{2} \mathbb{1}_2$. In fact $\Phi_{R_B B}^{\mathcal{U}} \in \mathbb{C}^2 \otimes \mathbb{C}^2$ is a Choi state of a unistochastic channel [111]. These conditions also imply that the state $\Phi_{R_B B}^{\mathcal{U}}$ can be written as a locally maximally mixed (LMM) state as follows

$$\Phi_{R_B B}^{\mathcal{U}} = \frac{1}{4} \left(\mathbb{1}_4 + \sum_{i,j=1}^3 R_{ij} \sigma_i \otimes \sigma_j \right). \quad (\text{D1})$$

We know that [112, 113] a locally maximally mixed state on $\mathbb{C}^4$ is equivalent to a Bell-diagonal state up to local unitary. Consequently, we have

$$\sigma_{R_B B} := \mathcal{U}_{R_B} \otimes \mathcal{U}_B (\Phi_{R_B B}^{\mathcal{U}}) = \frac{1}{4} (\mathbb{1}_4 + \sum_{i=1}^3 S_{ii} \sigma_i \otimes \sigma_i). \quad (\text{D2})$$

Clearly, the square root $\sqrt{\sigma_{R_B B}}$ is also diagonal in the Bell basis. Since marginals of a Bell-diagonal operator are proportional to the Identity, we have

$$\frac{1}{\text{tr} \sqrt{\sigma_{R_B B}}} \text{tr}_{R_B} \sqrt{\sigma_{R_B B}} = \frac{1}{2} \mathbb{1}_2, \quad (\text{D3})$$

$$\text{and, } \frac{1}{\text{tr} \sqrt{\sigma_{R_B B}}} \text{tr}_B \sqrt{\sigma_{R_B B}} = \frac{1}{2} \mathbb{1}_2. \quad (\text{D4})$$

The Choi state condition for the state $\rho_{R_B B} = \frac{1}{\text{tr} \sqrt{\Phi_{R_B B}^{\mathcal{U}}}} \sqrt{\Phi_{R_B B}^{\mathcal{U}}}$ follows since

$$\sqrt{\Phi_{R_B B}^{\mathcal{U}}} = \mathcal{U}_{R_B}^{\dagger} \otimes \mathcal{U}_B^{\dagger} (\sqrt{\sigma_{R_B B}}), \quad (\text{D5})$$

$$\text{which implies } \frac{1}{\text{tr} \sqrt{\Phi_{R_B B}^{\mathcal{U}}}} \text{tr}_B \sqrt{\Phi_{R_B B}^{\mathcal{U}}} = \mathcal{U}_{R_B}^{\dagger} \left(\frac{1}{\text{tr} \sqrt{\sigma_{R_B B}}} \text{tr}_B \sqrt{\sigma_{R_B B}} \right) \quad (\text{D6})$$

$$= \frac{1}{2} \mathbb{1}_2. \quad (\text{D7})$$

Similarly, we can show that $\text{tr}_{R_B} \rho_{R_B B} = \frac{1}{2} \mathbb{1}_2$, proving the unitality of the qubit channel. This proves that the state $\rho_{R_B B} = \frac{1}{\text{tr} \sqrt{\Phi_{R_B B}^{\mathcal{U}}}} \sqrt{\Phi_{R_B B}^{\mathcal{U}}}$ is a Choi state of a unital qubit map. $\square$

Since a convex combination of LMM states is an LMM state, we have the following corollary of the above Lemma.

Corollary 9. *Given a two-qubit channel $\mathcal{N}_{A'B' \rightarrow AB}$ that can be expressed as a convex combination of two-qubit unitary channels $\mathcal{U}_{A'B' \rightarrow AB}$, the state $\rho_{R_B B} := \frac{1}{\text{tr} \sqrt{\Phi_{R_B B}^{\mathcal{N}}}} \sqrt{\Phi_{R_B B}^{\mathcal{N}}}$ is the Choi state of a unital qubit channel.*

Lemma 10. [2, Lemma 10] *Given a state with spectral decomposition $\rho = \sum_i p_i |\psi_i\rangle\langle\psi_i|$, the max-relative entropy $D_{\infty}(\rho\|\sigma)$ where $\sigma \geq 0$, is bounded as follows*

$$\log \left(\max_i p_i \langle \psi_i | \sigma^{-1} | \psi_i \rangle \right) \leq D_{\infty}(\rho\|\sigma) \leq \log \left(\sum_i p_i \langle \psi_i | \sigma^{-1} | \psi_i \rangle \right). \quad (\text{D8})$$

Corollary 10. *The max-relative entropy $D_\infty(\rho\|\sigma)$ for a fixed operator $\sigma \geq 0$ maximizes when the state ρ is a pure state. That is,*

$$\max_{\rho} D_\infty(\rho\|\sigma) = \max_{|\psi\rangle\langle\psi|} D_\infty(|\psi\rangle\langle\psi|\|\sigma), \quad (\text{D9})$$

where $|\psi\rangle\langle\psi|$ are pure states.

Proof. Since pure states are a subset of the set of states, we naturally have $\max_{\rho} D_\infty(\rho\|\sigma) \geq \max_{\psi} D_\infty(\psi\|\sigma)$. To show the converse relation, let us have a Hermitian operator Λ with spectral decomposition $\Lambda = \sum_i \lambda_i |\lambda_i\rangle\langle\lambda_i|$, and $\lambda_{\max} := \max_i \lambda_i$. Then, for every density operator ρ , $\text{tr}(\Lambda\rho) \leq \text{tr}(\Lambda|\lambda_{\max}\rangle\langle\lambda_{\max}|)$. As a consequence, since σ^{-1} is a Hermitian operator, we have the following relation

$$\max_{\{p_i, \psi_i\}} \sum_i p_i \langle\psi_i|\sigma^{-1}|\psi_i\rangle = \max_{\varphi} \langle\varphi|\sigma^{-1}|\varphi\rangle \quad (\text{D10})$$

where $\{p_i\}_i$ forms a probability distribution and $\{\psi_i\}_i$ forms an orthonormal basis. From [Lemma 10](#) we see that the upper and lower bounds for $D_\infty(\rho\|\sigma)$ coincide when ρ is a pure state.

$$\max_{\rho} D_\infty(\rho\|\sigma) \leq \max_{\{p_i, \psi_i\}} \log \sum_i p_i \langle\psi_i|\sigma^{-1}|\psi_i\rangle \quad (\text{D11})$$

$$= \max_{\varphi} \log \langle\varphi|\sigma^{-1}|\varphi\rangle \quad (\text{D12})$$

$$= \max_{|\psi\rangle\langle\psi|} D_\infty(|\psi\rangle\langle\psi|\|\sigma). \quad (\text{D13})$$

□

Appendix E: The conditional Gibbs-preserving superchannels

Since the action of any superchannel Θ on a channel $\mathcal{N}$ can be written as a pre-processing and post-processing of $\mathcal{N}$, the conditional Gibbs-preserving superchannel Θ^β can be characterized by any superchannel where the post-processing is conditional Gibbs covariant as we see below,

$$\Theta^\beta(\mathcal{T}_{A'\rightarrow A}^\beta \otimes \mathcal{Q}_{B'\rightarrow B}) = \mathcal{T}_{C'\rightarrow C}^\beta \otimes \mathcal{Q}_{D'\rightarrow D} \quad (\text{E1})$$

$$\text{or, } \mathcal{A}_{AB\rightarrow CD} \circ (\mathcal{T}_{A'\rightarrow A}^\beta \otimes \mathcal{Q}_{B'\rightarrow B}) \circ \mathcal{B}_{C'D'\rightarrow A'B'} = \mathcal{T}_{C'\rightarrow C}^\beta \otimes \mathcal{Q}_{D'\rightarrow D} \quad (\text{E2})$$

$$\text{equivalently, } \mathcal{A}_{AB\rightarrow CD} \circ (\mathcal{T}_{C''\rightarrow A}^\beta \otimes \mathcal{Q}_{D''\rightarrow B}) = \mathcal{T}_{C'\rightarrow C}^\beta \otimes \mathcal{Q}_{D'\rightarrow D} \quad (\text{E3})$$

such that $C''D'' \cong C'D'$. Action of channel $\mathcal{A}_{AB\rightarrow CD}$ is therefore governed by the constraint

$$\mathcal{A}_{AB\rightarrow CD}(\gamma_A^\beta \otimes \rho_B) = \gamma_C^\beta \otimes \sigma_D. \quad (\text{E4})$$

for arbitrary states ρ_B and σ_D . These are exactly the free operations in the resource theory of conditional athermality as defined in [\[37, Proposition 3\]](#). Such channel are no-signaling from A to D and are conditionally covariant with respect to the absolutely thermal channel: $\mathcal{T}_{C\rightarrow C}^\beta \circ \mathcal{A}_{AB\rightarrow CD} = \mathcal{A}_{AB\rightarrow CD} \circ \mathcal{T}_{A\rightarrow A}^\beta$.

Abstract. Erasing a quantum memory costs work, but correlations with a remote system can reduce this cost. We introduce assisted quantum erasure and ask when low-cost erasure is exclusive to a designated helper. In the device-dependent setting, exclusivity is characterized by an entanglement-of-formation gap between the helper and any adversary. With only Bob’s device trusted, random dephasing and conditional erasure yield an entropic uncertainty benchmark: beating it certifies steering and exclusive thermodynamic control. Finally, Bell nonlocality and self-testing provide a route to fully device-independent erasure bounds, making work cost an operational witness of secure control.

Keywords: quantum erasure, Landauer principle, quantum thermodynamics, entanglement, steering, Bell nonlocality, device independence

1 Introduction

Erasing information is a fundamental physical operation. By Landauer’s principle, resetting a memory to a fixed pure state requires thermodynamic work proportional to the entropy of the memory. In quantum information processing, however, memories are often correlated with remote systems. These correlations can be used operationally: a helper who measures a correlated system and sends a classical message can reduce the work cost of erasing the memory.

We introduce *assisted quantum erasure* (Fig.1) and use it to formulate a notion of *exclusive control*. The question is not only whether a party can reduce Bob’s erasure cost, but whether this ability is exclusive to a designated helper Alice. Given a work budget $W_{\max}$, Alice has exclusive erasure if

$$W_{A \rightarrow B} \leq W_{\max} < W_{E \rightarrow B}, \quad (1)$$

where $W_{A \rightarrow B}$ is Bob’s assisted erasure cost with Alice’s help, while $W_{E \rightarrow B}$ is the corresponding cost achievable by an adversary Eve. Thus, “who can erase” becomes an operational and thermodynamic access-control question.

2 Device-dependent exclusive erasure

We first consider the device-dependent setting, where the state and all operations are trusted. If Alice performs a measurement $A_M = \{\Pi_k\}$ and announces the outcome k , Bob’s optimal assisted erasure cost is

$$W_{A \rightarrow B} = \min_{A_M} \sum_k p_k S(\rho_{B|\Pi_k}) = S(B) - J_0(B|A), \quad (2)$$

where $J_0(B|A)$ is the one-way classical correlation from Alice to Bob.

Figure 1: Illustration of assisted erasure with competing parties. Bob’s system begins in a high-entropy state, ρ_B (red). Alice and Eve each hold systems correlated with Bob’s, and perform local measurements (A_M and E_M) to assist in erasure. The resulting conditional states $\rho_{B|A_M}$ and $\rho_{B|E_M}$ show reduced entropy (blue and purple), reflecting Alice’s and Eve’s influence. Although both parties are correlated with Bob, only Alice achieves complete erasure, indicating a stronger correlation than Eve. The thermometer encodes the residual entropy of Bob’s memory, visually distinguishing exclusive thermodynamic control.

*federico.centrone@icfo.eu

Classical correlations are insufficient for exclusivity: if ρ_{AB} is separable, any advantage obtained by Alice can be reproduced by an adversary holding the relevant classical side information. Hence, entanglement is necessary for exclusive erasure.

Our main device-dependent result is a complete characterization in terms of entanglement of formation. For any extension ρ_{ABE} of ρ_{AB} , Alice achieves a strictly lower erasure cost than Eve if and only if

$$E_f(A:B)_{\rho_{AB}} > E_f(E:B)_{\rho_{EB}}. \quad (3)$$

Thus, in the trusted setting, exclusive thermodynamic control is governed by an entanglement-of-formation gap. Entanglement is not merely a witness of nonclassicality; it quantifies privileged thermodynamic access to Bob's memory.

3 One-sided semi-device-independent protocol

We then relax the assumptions on Alice's device while keeping Bob's operations trusted. Bob randomly dephases his memory in one of two incompatible bases, $R = \{|r_i\rangle\}$ or $S = \{|s_j\rangle\}$, and announces the basis. Alice's untrusted device returns a classical outcome, which Bob uses to perform a conditional erasure operation under a fixed work budget.

The random dephasing turns Bob's quantum memory into a classical register whose uncertainty is constrained by the Maassen–Uffink relation. For any local-hidden-state model, Alice's announcements cannot predict both dephased registers better than the complementarity of the bases allows. Consequently, the assisted work cost satisfies

$$\widetilde{W}_{A \rightarrow B} \geq \frac{1}{2} C(R, S), \quad C(R, S) = \min_{i,j} \log \frac{1}{|\langle r_i | s_j \rangle|^2}. \quad (4)$$

If the observed assisted erasure cost violates this bound,

$$\widetilde{W}_{A \rightarrow B} < \frac{1}{2} C(R, S), \quad (5)$$

then the correlations are steerable and Alice has an exclusive advantage over any adversary:

$$\widetilde{W}_{A \rightarrow B} < \widetilde{W}_{E \rightarrow B}. \quad (6)$$

Thus, in the one-sided semi-device-independent setting, steering is the resource enabling exclusive erasure.

4 Recoverability and device-independent outlook

Exclusive erasure also provides a robustness guarantee against adversarial intervention. By applying an authentication routine on a vanishing test fraction of many i.i.d. copies, Bob can distinguish honest assistance from adversarial behaviour before irreversibly erasing the data block. Asymptotically, either the authentication test fails

and Bob preserves the untouched data block, or the accepted evolution is indistinguishable from honest Alice-assisted erasure. Hence, no adversary respecting the same work cap can induce additional irrecoverable loss beyond Bob's deliberate erasure and the vanishing sacrificial test fraction.

Finally, we outline a fully device-independent extension. In a Bell scenario, Alice and Bob estimate nonlocal correlations from classical input-output data. Standard device-independent techniques bound conditional entropies such as $H(Z_B|E)$ and $H(Z_B|Z_A)$, which translate into lower bounds on the erasure cost achievable by an adversary and an honest helper, respectively. Bell nonlocality can therefore certify a positive gap between authorized and unauthorized erasure assistance. Near-maximal violations, together with robust self-testing, identify explicit low-cost honest strategies while preserving lower bounds on any adversary's erasure capability.

5 Conclusion

Our results establish erasure work as an operational witness of secure control over quantum memory. In the device-dependent setting, exclusive erasure is characterized by entanglement of formation; in the one-sided semi-device-independent setting, it is certified by steering through an entropic uncertainty benchmark; and in the fully device-independent direction, Bell nonlocality provides a route to adversary-independent erasure bounds. This gives a thermodynamic interpretation of the hierarchy of quantum correlations: entanglement, steering, and Bell nonlocality determine who can make erasure cheap under different levels of trust.

Abstract. Quantum random number generators aim to exploit the inherent indeterminism of quantum measurements to generate random numbers. However, justifying that the outputs of a real device have a quantum origin remains a significant challenge. Here we introduce two semi-device-independent randomness expansion protocols in a prepare-and-measure setting, using the device-independent aspects to justify the non-classical nature of the generation process. In our protocols, the source and measurement devices are treated as uncharacterised and we assume trust only in a testing device, which could be implemented using a photodiode. One protocol achieves expansion by recycling the input randomness, while the other uses a biased input distribution to achieve expansion in settings where recycling is not possible. The protocols are proven secure against quantum side information. Our results show that high randomness rates are achievable under experimentally realistic conditions, with expansion obtained in as few as 10^5 to 10^6 rounds with the recycling protocol and reasonable error parameters.

Keywords: Semi Device Independent, Device Independent, Randomness Expansion, Entropy Accumulation

Introduction

Random numbers have numerous applications, including cryptography, gambling, and scientific experiments. To enable use in all such applications, we use two key requirements: the numbers in the output should be uniformly distributed, and no third party should be able to get information about them.

The standard quantum way to generate random numbers relies on having a detailed physical model of the devices used in the protocol. Security is proved based on the model and if the real world device deviates from it, the security proof may no longer apply. To address this, device-independent (DI) randomness expansion protocols [3, 4, 5] were introduced. These protocols achieve randomness expansion without relying on any assumptions about the inner workings of the devices used in the protocol, removing the need for a detailed device model and hence protecting against modelling errors and device imperfections. However, implementing DI protocols experimentally poses significant challenges, primarily due to the need for robust entanglement distribution and detection [16].

Semi-device-independent protocols aim to bridge this gap by making physically well-motivated as-

sumptions about the experimental setup, in order to significantly simplify the implementation. Since entanglement distribution is a primary bottleneck in DI protocols, most semi-DI protocols use prepare-and-measure setups [6, 7].

In this work, we propose semi-DI randomness expansion protocols based on the prepare-and-measure framework [1], which has since been studied for randomness certification tasks in semi-DI settings [2, 8, 9, 10, 11, 12, 13]. Unlike certification protocols, which aim to verify the unpredictability of a given string, our focus is on randomness expansion, that is, generating an output string whose length exceeds the amount of initial randomness consumed. This task becomes particularly relevant in scenarios where the input randomness is a private bit string and cannot be treated as a free resource.

Many existing semi-device-independent randomness expansion protocols, such as source-device-independent and measurement-device-independent schemes [7], rely on partial characterisation of either the source or the measurement device. In contrast, our assumption model is weaker: we do not characterise *either* the source or the measurement device, and instead require trust in a testing device, which could be implemented using a photodiode. This testing device acts as a binary on/off

detector, making it easier to model and verify in practice compared to a power meter that would be required to justify energy-based assumptions as in [2, 1]. All the quantities needed in our analysis are inferred directly from the *in-protocol* detection statistics, rather than imposed as external assumptions that would require running a separate composable protocol for their certification [14], which would be resource-intensive[15].

We establish security using the Entropy Accumulation Theorem (EAT) [17], which provides security against adversaries holding quantum side information and avoids any i.i.d. assumption in the protocol, in contrast to many existing semi-DI randomness certification or expansion protocols. Our protocol achieves randomness expansion by recycling input randomness: part or all of the seed is recycled in the extraction step. This substantially reduces the seed requirement while preserving composable security, and, as we show, enables high expansion rates even with relatively few rounds.

Given the minimal physical assumptions in our framework, one might expect a significant loss in performance. However, our results show that this is not the case. The recycling protocol achieves strong asymptotic expansion rates under realistic experimental parameters, and its performance is particularly notable in the finite-size regime. Positive expansion can be obtained with as few as 10^5 rounds in favourable experimental conditions, and with approximately 10^6 rounds under realistic imperfections. These results demonstrate that, despite operating under weaker assumptions than existing semi-DI approaches, our protocol delivers both high certified rates and practical finite-size efficiency.

Protocol overview

To generate raw random bits, we carry out the protocol over many rounds. In each round, the source prepares a state depending on an input $X \in \{0, 1\}$, and a switch routes the signal depending on a second input T .

If $T = 0$, the signal is sent to the measurement device, which outputs a bit Y . If $T = 1$, the signal is sent to the trusted testing device, which performs a two-outcome projective trusted measurement and generates a bit $Z \in \{0, 1\}$.

From the observed data, we estimate two quantities:

- the **score** ω , defined as the (appropriately) weighted frequency with which the measurement device correctly outputs the input, and
- the **overlap** Θ , defined as the (appropriately weighted) frequency of measuring $Z = 0$ in the testing rounds.

Importantly, while generating raw randomness, we do not assume identical behaviour across rounds. The source and measurement device may exhibit memory and need not behave identically from one round to the next. We assume that the source and measurement device do not share entanglement during the protocol. This is an assumption that we would ideally like to avoid, but it is currently required for the security proof. However, we allow the source to be arbitrarily entangled with the adversary, and permit arbitrary classical correlations between the source, measurement device, and adversary.

Figure 2: Finite-size randomness expansion rates for Protocol that recycles input randomness as a function of the number of rounds n (log scale) when $\Theta = 0.9$. Figure (i) corresponds to testing probability $\gamma = 0.1$. Figure (ii) corresponds to testing probability $\gamma = 0.01$. We have chosen the completeness error $\epsilon_C = 10^{-3}$ and soundness error to be $\epsilon_S = 10^{-6}$ to generate the curves.

To achieve randomness expansion, during randomness extraction step, we consider two protocols based on this raw randomness generation setup:

1. **Recycling protocol:** The input randomness used to choose the inputs X and T is not treated as a consumed resource. Instead, it is combined with the outputs and used as input to a quantum-proof extractor [19].
2. **Biased-input protocol:** We also consider a protocol based on a highly biased input distribution. This reduces the amount of input randomness required and is useful in settings where the input randomness cannot be recycled or may be public.

Results

Our results demonstrate strong randomness expansion under experimentally realistic conditions. In particular, the following can be achieved:

- Positive randomness expansion can be achieved with as few as 10^5 rounds under favourable conditions.
- Around 10^6 rounds are sufficient even in the presence of realistic imperfections.
- The recycling protocol achieves high asymptotic rates. A key reason for this is our method to directly bound von-Neumann entropy in the semi-DI setting.

- The rates remain robust even under moderate detection inefficiencies.
- All of the above is achieved while going beyond randomness certification to genuine randomness expansion, under minimal assumptions: no i.i.d. assumption, uncharacterised source and measurement devices, and security against a quantum adversary holding side information.

Lower bounds for adiabatic quantum algorithms by quantum speed limits

Jyong-Hao Chen 

Instituut-Lorentz, Universiteit Leiden, P.O. Box 9506, 2300 RA Leiden, The Netherlands

(Received 27 July 2022; accepted 13 June 2023; published 8 September 2023)

We introduce a simple framework for estimating lower bounds on the runtime of a broad class of adiabatic quantum algorithms. The central formula consists of calculating the variance of the final Hamiltonian with respect to the initial state. After examining adiabatic versions of certain keystone circuit-based quantum algorithms, this technique is applied to adiabatic quantum algorithms with undetermined speedup. In particular, we analytically obtain lower bounds on adiabatic algorithms for finding k -clique in random graphs. Additionally, for a particular class of Hamiltonian, it is straightforward to prove the equivalence between our framework and the conventional approach based on spectral gap analysis.

DOI: [10.1103/PhysRevResearch.5.033175](https://doi.org/10.1103/PhysRevResearch.5.033175)

I. INTRODUCTION

Adiabatic approximation in quantum mechanics has found applications in many fields since it was initially developed in the 1920s [1,2]. Nonetheless, the idea that adiabatic approximation may serve as a basis for quantum computing did not arise until the last two decades [3,4]. It has been proved [5,6] that adiabatic quantum computation is computationally equivalent to the standard circuit-based quantum computation [7,8].

An adiabatic quantum algorithm (AQA) consists of three components [9,10]: (i) a *problem* (or *final*) Hamiltonian H_1 whose ground state encodes solutions to the problem; (ii) a *driver* (or *initial*) Hamiltonian H_0 who does not commute with the final Hamiltonian H_1 and whose ground state is known; and (iii) a timing *schedule* $\lambda(t) \in [0, 1]$, a time-dependent strictly increasing function that interpolates between the initial Hamiltonian and the final Hamiltonian. The full time-dependent Hamiltonian $H_{\lambda(t)}$ of an AQA is then defined as

$$H_{\lambda(t)} := (1 - \lambda(t))H_0 + \lambda(t)H_1, \quad (1)$$

with boundary conditions $\lambda(0) = 0$ and $\lambda(T) = 1$, where T is the runtime of the algorithm.

An AQA is executed by preparing a quantum system at the ground state of the initial Hamiltonian H_0 and then letting it evolve. The adiabatic theorem [1,2,11,12] guarantees that the final state of time evolution remains close to the instantaneous ground state of the problem Hamiltonian H_1 , provided that the system evolves slowly enough, or, equivalently, the runtime must be long enough. A typical sufficient condition for the runtime T is that it must scale polynomially with an inverse of the minimum spectral gap (the difference between the

two smallest energy eigenvalues) of the full Hamiltonian H_{λ} [10,12,13]. Nevertheless, analytical calculation of spectral gap is possible only for relatively simple Hamiltonians, whereas performing numerical calculations is limited to small system size.

The main contribution of this work is to present a more elementary, alternative method to the conventional spectral gap analysis for estimating the runtime of adiabatic quantum algorithms. In contrast to the well-known gap conditions [10,12,13], which provide *sufficient* conditions for runtime, our formula provides a lower bound (or *necessary* condition). More significantly, our technique can be exploited to analytically obtain a lower bound on runtime for an adiabatic quantum algorithm with undetermined speedup, i.e., the adiabatic algorithm of Childs *et al.* [14] for finding k -clique in random graphs, where the conventional method based on spectral gap is unable to do so.

This paper is organized as follows. In Sec. II, we derive the main formula for estimating a *necessary* runtime using the quantum uncertainty of the final Hamiltonian with respect to the initial state. We shall clarify the condition for which the obtained necessary runtime can be interpreted as a *lower bound* (in the sense of computational complexity) on the runtime of AQAs. After examining our formula with adiabatic versions [4,15–18] of certain keystone quantum algorithms [19–23] in Sec. III and Sec. IV, our technique is applied in Sec. V to analytically obtain lower bounds for adiabatic algorithms of finding k -clique in random graphs. Section VI compares our approach to conventional spectral gap analysis and relevant prior works. Finally, conclusions are presented in Sec. VII.

II. FORMALISM

Consider a quantum system characterized by a time-dependent Hamiltonian H_{λ} with $\lambda = \lambda(t)$ being a function of time t . For each λ , the instantaneous ground state $|\Phi_{\lambda}\rangle$ is the solution to the eigenvalue problem $H_{\lambda}|\Phi_{\lambda}\rangle = E_{\text{GS},\lambda}|\Phi_{\lambda}\rangle$, where $E_{\text{GS},\lambda}$ is the ground state energy. On the other hand, the actual dynamics of the quantum system is described by the

physical (or time-evolved) state $|\Psi_\lambda\rangle$, which is the solution to the scaled time-dependent Schrödinger equation $i\Gamma\partial_\lambda|\Psi_\lambda\rangle = H_\lambda|\Psi_\lambda\rangle$ with initial condition $|\Psi_0\rangle = |\Phi_0\rangle$, where $\Gamma := \partial_t\lambda(t)$ is the driving rate. Mathematically, adiabaticity can be quantified by the fidelity between the physical state $|\Psi_\lambda\rangle$ and the instantaneous ground state $|\Phi_\lambda\rangle$, namely, the *adiabatic fidelity* $\mathcal{F}(\lambda) := |\langle\Phi_\lambda|\Psi_\lambda\rangle|^2$. In essence, the quantum adiabatic theorem [1,2,11,12] ensures the following condition

$$1 - \mathcal{F}(\lambda) \leq \epsilon, \quad (2)$$

provided that the driving rate Γ is small enough for any given allowance $\epsilon \in [0, 1]$.

Building upon the seminal work of Ref. [24], one of the main results of Ref. [25] is the following inequality that ties the adiabatic fidelity $\mathcal{F}(\lambda)$, the overlap of instantaneous ground states $\mathcal{C}(\lambda) := |\langle\Phi_\lambda|\Phi_0\rangle|^2$, and the Bures angle for physical states $\theta(\lambda) := \arccos(|\langle\Psi_\lambda|\Psi_0\rangle|)$ through

$$|\mathcal{F}(\lambda) - \mathcal{C}(\lambda)| \leq \sin\theta(\lambda) \leq \sin\tilde{\mathcal{R}}(\lambda), \quad (3)$$

where $\tilde{\mathcal{R}}(\lambda) := \min(\mathcal{R}(\lambda), \frac{\pi}{2})$,

$$\mathcal{R}(\lambda) := \int_0^\lambda \frac{d\lambda'}{|\Gamma(\lambda')|} \delta E_0(\lambda'), \quad (4a)$$

$$\delta E_0(\lambda) = \sqrt{\langle H_\lambda^2 \rangle_0 - \langle H_\lambda \rangle_0^2}. \quad (4b)$$

Here, $\langle \cdots \rangle_0 := \langle \Psi_0 | \cdots | \Psi_0 \rangle$. The second inequality in Eq. (3), i.e., $\theta(\lambda) \leq \tilde{\mathcal{R}}(\lambda)$, sets an upper bound on the Bures angle of physical states and is dubbed as *quantum speed limit* [26–32]. This name is suggested by the fact that since the Bures angle $\theta(\lambda) \in [0, \pi/2]$ is a measure of distance, the quantum uncertainty $\delta E_0(\lambda)$ signifies speed.

In this work, we explore a union of the adiabatic condition [Eq. (2)] and the inequality of adiabatic fidelity [Eq. (3)] at the end of the time evolution of AQAs, $t = T$ [i.e., when $\lambda(t = T) = 1$]. Combining Eq. (2) with Eq. (3) leads to the following inequality that must be satisfied by the runtime T :

$$T \geq \frac{\arcsin(\max(1 - \epsilon - \mathcal{C}(1), 0))}{\mathcal{R}(1)/T}. \quad (5)$$

This inequality may be interpreted as a *necessary condition* obeyed by the runtime T of adiabatic quantum evolution.

Proof. We begin with rewriting the inequality [Eq. (3)] into the following form:

$$\mathcal{C}(\lambda) - \sin\tilde{\mathcal{R}}(\lambda) \leq \mathcal{F}(\lambda) \leq \mathcal{C}(\lambda) + \sin\tilde{\mathcal{R}}(\lambda). \quad (6)$$

This together with Eq. (2) yields $1 - \epsilon \leq \mathcal{F}(\lambda) \leq \mathcal{C}(\lambda) + \sin\tilde{\mathcal{R}}(\lambda)$, which can be expressed as

$$\max(1 - \epsilon - \mathcal{C}(\lambda), 0) \leq \sin\tilde{\mathcal{R}}(\lambda), \quad (7)$$

since $\sin\tilde{\mathcal{R}}(\lambda) \geq 0$ by definition. Now, because $\sin x$ is a monotonically increasing function for $x \in [0, \pi/2]$, the inequality above can be inverted to obtain

$$\arcsin(\max(1 - \epsilon - \mathcal{C}(\lambda), 0)) \leq \tilde{\mathcal{R}}(\lambda) \leq \mathcal{R}(\lambda), \quad (8)$$

where we have used $\tilde{\mathcal{R}}(\lambda) \leq \mathcal{R}(\lambda)$ to obtain the last inequality. Upon taking $\lambda(t = T) = 1$, the proof of Eq. (5) is therefore complete. ■

Notice that inequality Eq. (5) is applicable to Hamiltonians of any given form. Next, we shall specifically utilize inequality Eq. (5) for AQAs having a full Hamiltonian $H_{\lambda(t)}$ defined in Eq. (1). If so, the function $\mathcal{R}(\lambda(t))$ per Eqs. (4) and (1) reads

$$\mathcal{R}(\lambda(t)) = t \overline{\lambda(t)} \delta V_n, \quad (9a)$$

$$\delta V_n := \sqrt{\langle H_1^2 \rangle_0 - \langle H_1 \rangle_0^2}. \quad (9b)$$

Here, δV_n is the quantum uncertainty of the final Hamiltonian H_1 with respect to the initial ground state $|\Phi_0\rangle$, and $\overline{\lambda(t)} := t^{-1} \int_0^t dt' \lambda(t')$ is the time average of the schedule function $\lambda(t)$. The subscript n emphasizes that the quantum uncertainty δV_n often varies with the problem size (or number of qubits) n . Hence, with the help of Eq. (9), inequality Eq. (5) can be written as

$$T \geq \frac{\arcsin(\max(1 - \epsilon - \mathcal{C}(1), 0))}{\overline{\lambda(T)} \delta V_n}. \quad (10)$$

Now, since the numerator $\arcsin(\max(1 - \epsilon - \mathcal{C}(1), 0))$ is $\mathcal{O}(1)$,¹ and because $0 < \overline{\lambda(T)} \leq 1$ (as a consequence of $\lambda(t) \in [0, 1]$ by definition), we shall just concentrate on the asymptotic behavior of δV_n [Eq. (9b)] for the purpose of performing asymptotic analysis using Eq. (10):

$$T \geq T_{\text{inf}}, \quad T_{\text{inf}} := \mathcal{O}(1/\delta V_n). \quad (11)$$

Observe that estimating a necessary runtime T_{inf} using Eq. (11) requires only two ingredients, i.e., the initial state $|\Phi_0\rangle$ and the final Hamiltonian H_1 . Although the schedule function $\lambda(t)$ is one of the three ingredients for specifying an AQA, our formula [Eq. (11)] for determining a necessary runtime does not depend on any particular form of $\lambda(t)$. This is unlike the conventional approach of spectral gap analysis [13] where an explicit form of $\lambda(t)$ must be specified; given an initial Hamiltonian and a final Hamiltonian, different forms of $\lambda(t)$ could result in different estimations of asymptotic forms of runtime. However, it is not possible for those runtime estimates using spectral gap analysis to be smaller than the necessary runtime determined by Eq. (11). In other words, for an AQA specified by an initial state and a final Hamiltonian, one can use Eq. (11) to obtain a necessary runtime. This necessary runtime might be saturated by choosing a particular schedule function or a different initial Hamiltonian.

Although the inequality Eq. (11) is established as a universal necessary condition for the runtime of any AQA, interpreting the necessary runtime T_{inf} [Eq. (11)] as a *lower bound* on time complexity only applies to those AQAs whose quantum uncertainty δV_n does not diverge when n goes to infinity, namely, if

$$\lim_{n \rightarrow \infty} 1/\delta V_n \neq 0. \quad (12)$$

Otherwise, one would incorrectly deduce that the required runtime decreases as the input size n increases. The asymptotic property [Eq. (12)] can be fulfilled by a wide class of

¹Throughout this paper, we use $\mathcal{O}(\cdot)$ to indicate “order of.”

final Hamiltonians H_1 that meets the following condition² (up to a redefinition³ of H_1):

$$\langle H_1^2 \rangle_0 \stackrel{!}{=} \langle H_1 \rangle_0. \quad (13)$$

To see this, imposing the *moments condition* [Eq. (13)] on the definition of quantum uncertainty δV_n [Eq. (9b)] yields $\delta V_n = \sqrt{\langle H_1 \rangle_0(1 - \langle H_1 \rangle_0)}$. This quantum uncertainty satisfies the desired asymptotic property [Eq. (12)] since the expectation value $\langle H_1 \rangle_0$ is bounded, $0 \leq \langle H_1 \rangle_0 \leq 1$, which is a consequence of the moments condition [Eq. (13)] together with the Cauchy-Schwarz inequality. If the moments condition [Eq. (13)] holds, the corresponding lower bound on runtime [Eq. (11)] reads

$$T_{\text{inf}} = \mathcal{O}(1/\delta V_n), \quad \delta V_n = \sqrt{\langle H_1 \rangle_0(1 - \langle H_1 \rangle_0)}. \quad (14)$$

A stronger condition than the moments condition [Eq. (13)] is when the final Hamiltonian is a projector, namely, if $H_1^2 \stackrel{!}{=} H_1$. As we shall see shortly, the adiabatic version of Deutsch-Jozsa algorithm [15,16], Bernstein-Vazirani algorithm [17], and Grover search [4,18] all can be implemented using a projector final Hamiltonian. A representative final Hamiltonian that does not satisfy the asymptotic property [Eq. (12)] is the one containing Ising terms, whose quantum uncertainty scales as $\delta V_n \propto \sqrt{n}$ (see Appendix A).

In what follows, we shall focus on AQAs that satisfy the moments condition [Eq. (13)], and apply formula Eq. (14) to obtain a lower bound on runtime. For this purpose, we need to specify what kind of initial state $|\Phi_0\rangle$ and final Hamiltonian H_1 we wish to use. For an AQA consisting of n qubits, the initial state $|\Phi_0\rangle$ can often be chosen as the uniform superposition of all basis states of the 2^n -dimensional Hilbert space in the computational basis

$$|\Phi_0\rangle = \frac{1}{\sqrt{2^n}} \sum_{z \in \{0,1\}^n} |z\rangle = |+\rangle^{\otimes n}. \quad (15)$$

Here, $|z\rangle = |z_0\rangle \otimes |z_1\rangle \otimes \cdots \otimes |z_{n-1}\rangle$ with each $z_i \in \{0,1\}$, $\{0,1\}^n$ is the set of 2^n possible n -bit binary strings, and $|\pm\rangle = (|0\rangle \pm |1\rangle)/\sqrt{2}$. As for the final Hamiltonian H_1 , the following two types of final Hamiltonian satisfying Eq. (13) will be discussed in detail:

- (i) Final Hamiltonian with orthogonal projection.
- (ii) A special class of optimization problems.

III. FINAL HAMILTONIAN OF TYPE-I

Let Π_{Φ_1} be a projector that projects onto the eigenspace of the final state $|\Phi_1\rangle$. In certain AQAs, their final Hamiltonian H_1 can be implemented by a complementary projector of Π_{Φ_1}

$$H_1 = \mathbb{I} - \Pi_{\Phi_1}, \quad (16)$$

where $\mathbb{I}$ is an identity operator. Adiabatic Deutsch-Jozsa algorithm [15,16] and adiabatic Bernstein-Vazirani algorithm [17]

are two examples of AQAs whose final Hamiltonian has the form shown in Eq. (16).

A. Example: Adiabatic Deutsch-Jozsa algorithm

Recall that in the problem of Deutsch-Jozsa [19], we are given a Boolean function $f : \{0,1\}^n \rightarrow \{0,1\}$. The task is to determine whether f is constant or balanced (i.e., equal number of output of 0's and 1's). In the AQA proposed by Ref. [15], the final state is chosen as (here, $N \equiv 2^n$)

$$|\Phi_1\rangle = \mu_f |0\rangle + \frac{1 - \mu_f}{\sqrt{N}} \sum_{i=1}^{N-1} |i\rangle, \quad (17)$$

where $\mu_f := N^{-1} |\sum_{z \in \{0,1\}^n} (-1)^{f(z)}|$. If f is constant (respectively, balanced), then $\mu_f = 1$ (respectively, $\mu_f = 0$). The corresponding final Hamiltonian can be constructed as a projector shown in Eq. (16) with $\Pi_{\Phi_1} = |\Phi_1\rangle\langle\Phi_1|$. The initial state is chosen as an equal weight superposition of all basis states [Eq. (15)]. In Ref. [15], using conventional spectral gap analysis yields the scaling of runtime $T \sim \mathcal{O}(N)$ for $\lambda(t) = \frac{t}{T}$ and $T \sim \mathcal{O}(\sqrt{N})$ for a local adiabatic evolution. These results do not reach the well-known [19] optimal runtime, i.e., $\mathcal{O}(1)$. Nevertheless, we shall demonstrate that using the formula Eq. (14) enables us to obtain the lowest runtime found in Ref. [15]. We compute the overlap $|\langle\Phi_1|\Phi_0\rangle|^2$ using Eqs. (15) and (17) as

$$|\langle\Phi_1|\Phi_0\rangle|^2 = \frac{1}{N} (\mu_f + (1 - \mu_f)\sqrt{N-1})^2, \quad (18)$$

and apply it to Eq. (14) to obtain $T_{\text{inf}} = \mathcal{O}(\sqrt{N})$, which is consistent with the result obtained by Ref. [15] as mentioned above.

From the general expression of T_{inf} [Eq. (14)], it is clear that in order to reproduce the correct optimal runtime of the Deutsch-Jozsa algorithm, the overlap $|\langle\Phi_1|\Phi_0\rangle|^2$ should be independent of N . In light of this, the final state [Eq. (17)] should be modified. Exactly this modification has been carried out in Ref. [16] by replacing the final state of Eq. (17) with the one which is more symmetric in amplitudes:

$$|\Phi_1\rangle = \frac{\mu_f}{\sqrt{N/2}} \sum_{i=0}^{N/2-1} |2i\rangle + \frac{1 - \mu_f}{\sqrt{N/2}} \sum_{i=0}^{N/2-1} |2i+1\rangle. \quad (19)$$

Upon using Eqs. (15) and (19), the overlap $|\langle\Phi_1|\Phi_0\rangle|^2$ reads

$$|\langle\Phi_1|\Phi_0\rangle|^2 = \frac{1}{N} \frac{1}{N/2} \left(\mu_f \frac{N}{2} + (1 - \mu_f) \frac{N}{2} \right)^2 = \frac{1}{2}. \quad (20)$$

This result should be compared with that of Eq. (18). Bringing Eq. (20) to Eq. (14) yields $T_{\text{inf}} = \mathcal{O}(1)$. Therefore, the optimal runtime for the Deutsch-Jozsa problem is attained. In contrast to the usual approach of estimating runtime via spectral gap as done in Refs. [15,16], our formalism clearly illustrates why the algorithm of Ref. [16] is superior to that of Ref. [15].

B. Example: Adiabatic Bernstein-Vazirani algorithm

As the second example for the final Hamiltonian of Type-I [Eq. (16)], we consider an adiabatic algorithm solving the Bernstein-Vazirani problem. Recall that in the

²Throughout this paper, the notation “ $\stackrel{!}{=}$ ” is used to indicate the case where both sides of an equation are posited to be equal.

³For instance, if $H_1^2 = -H_1$, one can define a new Hamiltonian $H'_1 = \mathbb{I} + H_1$ so that $H_1'^2 = H'_1$ holds.

Bernstein-Vazirani problem [20,21], one is given an oracle that evaluates the function $f_\lambda : \{0, 1\}^n \mapsto \{0, 1\}$ with $f_\lambda(z) = \sum_{i=0}^{n-1} z_i s_i \bmod 2$. The task is to find the unknown n -bit binary string $s \in \{0, 1\}^n$ using as few queries of the function f_λ as possible. The adiabatic algorithm proposed by Ref. [17] is the following. First, notice that the oracle function f_λ can be encoded in a projector final Hamiltonian as shown in Eq. (16) and acting on two subsystems, A and B, comprising n qubits and 1 qubit, respectively,

$$H_1 = \mathbb{I}_A \otimes \mathbb{I}_B - \Pi_{\Phi_1},$$

$$\Pi_{\Phi_1} = \sum_{z \in \{0,1\}^n} |z\rangle_A \langle z| \otimes |f_\lambda(z)\rangle_B \langle f_\lambda(z)|. \quad (21)$$

The ground state of H_1 is $|\Phi_1\rangle = \frac{1}{\sqrt{2^n}} \sum_{z \in \{0,1\}^n} |z\rangle_A \otimes |f_\lambda(z)\rangle_B$ with eigenvalue 0. The initial state is again the uniform superposition state [Eq. (15)] $|\Phi_0\rangle = |+\rangle_A^{\otimes n} \otimes |+\rangle_B$. We refer to Refs. [10,17] for further details on the mechanism behind this adiabatic algorithm. For our purpose, we proceed to use the formula Eq. (14) to obtain a lower bound on the runtime. We first note that H_1 defined in Eq. (21) is apparently a projector, $H_1^2 = H_1$. The remaining task is to compute $\langle \Phi_0 | H_1 | \Phi_0 \rangle$:

$$\begin{aligned} \langle \Phi_0 | H_1 | \Phi_0 \rangle &= 1 - \frac{1}{2^n} \sum_{z \in \{0,1\}^n} |\langle + | f_\lambda(z) \rangle|^2 \\ &\stackrel{(*)}{=} 1 - \frac{1}{2^n} \sum_{z \in \{0,1\}^n} \left(\frac{1}{\sqrt{2}} \right)^2 = \frac{1}{2}, \end{aligned} \quad (22)$$

where in (*) we have used the following identity $|f_\lambda(z)\rangle_B = \frac{1}{\sqrt{2}}(|+\rangle_B + (-1)^{f_\lambda(z)}|-\rangle_B)$. Finally, it follows from Eq. (14) that $T_{\text{inf}} = \mathcal{O}(1)$ as expected.

IV. FINAL HAMILTONIAN OF TYPE-II

For optimization problems with a cost function $h : \{0, 1\}^n \rightarrow \mathbb{R}$, we seek a minimum of h . In the framework of adiabatic quantum computation [3,4], a final Hamiltonian can be defined to be diagonal in the computational basis, with cost function h being the diagonal element

$$H_1 = \sum_{z \in \{0,1\}^n} h(z) |z\rangle \langle z|. \quad (23)$$

If the uniform superposition of all basis states [Eq. (15)] is chosen as the initial state, the quantum uncertainty [Eq. (9b)] reads $\delta V_n = (\bar{h}^2 - \bar{h}^2)^{1/2}$, with the arithmetic average $\bar{h} := 2^{-n} \sum_z h(z)$ and $\bar{h}^2 := 2^{-n} \sum_z h^2(z)$. Furthermore, if we impose the moments condition [Eq. (13)], which amounts to requiring

$$\bar{h}^2 \stackrel{!}{=} \bar{h}, \quad (24)$$

then the lower bound T_{inf} [Eq. (14)]

$$T_{\text{inf}} = \mathcal{O}(1/\delta V_n) \quad \text{with} \quad \delta V_n = \sqrt{\bar{h}(1-\bar{h})} \quad (25)$$

is completely determined by the arithmetic average of the cost function, i.e., $\bar{h}$. Note that $0 \leq \bar{h} \leq 1$ as a result of Cauchy-Schwarz together with the moments condition

[Eq. (24)]. Note also that the moments condition [Eq. (24)] can be expressed using matrix analysis terminology [33,34] as $\|H_1\|_F^2 \stackrel{!}{=} \text{tr} H_1$, where $\|\cdot\|_F$ denotes the Frobenius norm (or Hilbert-Schmidt norm). If it is further assumed that the cost function h is non-negative, the moments condition [Eq. (24)] can alternatively be written as $\|H_1\|_F^2 \stackrel{!}{=} \|H_1\|_{\text{tr}}$, where $\|\cdot\|_{\text{tr}}$ represents the trace norm (or nuclear norm).

Example: Adiabatic Grover search

Taking the unstructured search problem of Grover [22,23] as an example, it can be formulated as a combinatorial optimization problem with the following cost function [4,35]: $h(z) = 0$ for M marked items and $h(z) = 1$ otherwise. For this case, one immediately finds $\bar{h}^2 = \bar{h} = 1 - M/N$ (here, $N \equiv 2^n$). It then follows from Eq. (25) that a lower bound $T_{\text{inf}} = \mathcal{O}(\sqrt{N/M})$, as expected [18,36,37]. We note that the final Hamiltonian of adiabatic Grover search can be equivalently written as $H_1 = \mathbb{I} - \sum_{z \in \mathcal{M}} |z\rangle \langle z|$, where $\mathcal{M}$ is the space of solution (of size M). Hence, this final Hamiltonian also belongs to the type-I final Hamiltonian [see Eq. (16)]. It is with this expression of projector final Hamiltonian that Ref. [38] used a formula similar to Eq. (10) to obtain the optimal runtime for adiabatic Grover search. For completeness, we present a similar calculation using our formula in Appendix B.

Thus far, three adiabatic versions of keystone quantum algorithms have been examined. We shall now apply our technique to the adiabatic algorithm proposed by Childs *et al.* [14] for finding k -clique in random graphs.

V. ADIABATIC ALGORITHM FOR FINDING K -CLIQUE

Consider a random graph G where every pair of vertices is connected or disconnected with a probability of $1/2$. A *clique* is a subgraph of G in which every pair of vertices is connected by an edge. The problem of finding cliques of k vertices (called *k-clique*) in a random graph of n vertices is an NP-complete problem if both n and k are treated as inputs [39,40].

In the algorithm proposed by Ref. [14], each vertex is associated with a qubit. Hence, there are n qubits for a graph of n vertices. As before, each qubit state is represented by $|z_i\rangle$ with $z_i \in \{0, 1\}$ for $i \in \{0, \dots, n-1\}$. A vertex i is included into a subgraph of k vertices only if $z_i = 1$.

Although the full Hilbert space is 2^n -dimensional, we can focus only on the subspace spanned by quantum states with Hamming weight k since we are only interested in those quantum states that represent cliques of k vertices. For notational convenience, we denote the set of n -bit binary strings of Hamming weight k as $\mathcal{S}_k := \{z \in \{0, 1\}^n : |z| = k\}$, where $|z| = \sum_{i=0}^{n-1} z_i$ is the Hamming weight of the n -bit binary string z . The size of $\mathcal{S}_k$ is $\binom{n}{k} \equiv C(n, k)$. In the subspace generated by binary strings from $\mathcal{S}_k$, the initial state can be chosen as a Dicke state [41–43]

$$|\Phi_0\rangle := \frac{1}{\sqrt{C(n, k)}} \sum_{z \in \mathcal{S}_k} |z\rangle. \quad (26)$$

In Ref. [14], the final Hamiltonian is of the form shown in Eq. (23) with the cost function

$$h_C(z) := \sum_{i,j=0}^{n-1} (1 - G_{ij}) z_i z_j, \quad (27)$$

where G_{ij} with $i, j \in \{0, \dots, n-1\}$ is the matrix element of the adjacency matrix for a graph G . As usual, $G_{ij} = 1$ if the vertices i and j are connected by an edge; otherwise, $G_{ij} = 0$. Observe that the cost function $h_C(z)$ takes values in $\{0, 1, \dots, L_k\}$, where $L_k = C(k, 2)$ is the total number of edges for a graph of k vertices.

We proceed to obtain a lower bound on runtime using Eq. (11) for the algorithm defined above. Since each $G_{ij} \in \{0, 1\}$ is a random variable, an exact computation for the arithmetic average $\overline{h_C}$ and $\overline{h_C^2}$ is not possible without knowing an explicit instance of G_{ij} . We attempt to consider a “mean-field” (or “randomized”) approach by replacing G_{ij} with its (classical) expectation value $\mathbb{E}[G_{ij}] = 1/2$, and obtain (see Appendix C) $\mathbb{E}[\overline{h_C}] = L_k/2$ and $\mathbb{E}[\overline{h_C^2}] = (L_k + 1)L_k/4$. It follows from Eq. (11) that a lower bound on runtime $T_{\text{rand,inf}}$ reads $T_{\text{rand,inf}} = \mathcal{O}(\sqrt{1/L_k})$, which is independent of n . It is likely that this n -independent lower bound is considerably lower than the sufficient runtime obtained using the spectral gap analysis (though it is not available). We also notice that the moments condition [Eq. (24)] is not met for the cost function defined in Eq. (27). Nevertheless, we note that the k dependence in $T_{\text{rand,inf}}$ seems consistent with the numerical data found in Ref. [14], saying that the median runtime for finding cliques of $k = 5$ is longer than that for finding cliques of $k = 6$. Specifically, $T_{\text{med}}(k = 5)/T_{\text{med}}(k = 6) = 30.87/18.56 \approx 1.66$ found in Ref. [14], whereas our result indicates $T_{\text{rand,inf}}(k = 5)/T_{\text{rand,inf}}(k = 6) = \sqrt{15/10} \approx 1.22$.

To make better use of our formula Eq. (25), we propose the following deformed cost function

$$h(z) := \frac{1}{2}(1 + h_C(z) - |1 - h_C(z)|). \quad (28)$$

This amounts to introduce $h(z) = \min(h_C(z), 1)$, where $h_C(z)$ is defined in Eq. (27). In other words, those $h_C(z) > 1$ are mapped to $h(z) = 1$. Therefore, the deformed cost function is Boolean-valued $h(z) \in \{0, 1\}$. This deformed cost function is similar to that of adiabatic Grover search discussed previously. One finds that the cost function defined in Eq. (28) along with the initial state defined in Eq. (26) satisfies the moments condition [Eq. (24)]. Explicitly, $\overline{h} = \overline{h^2} = (1 - M/C(n, k))$, which renders a lower bound from Eq. (25)

$$T_{\text{inf}} = \mathcal{O}(\sqrt{C(n, k)/M}), \quad (29)$$

where M is the number of cliques of k vertices. The result [Eq. (29)] is consistent with that of a circuit-based algorithm of Ref. [44] in which the time complexity is related to the number of Grover iterations. For the special case of $n \gg k$, Eq. (29) simplifies $T_{\text{inf}} = \mathcal{O}(n^{k/2})$ for $n \gg k$. A well-studied case is $k = 3$, i.e., the so-called *3-clique problem* (or *triangle-finding problem*); the resulting lower bound is $T_{\text{inf}} = \mathcal{O}(n^{3/2})$. The exponent, $3/2$, agrees with that found in a quantum algorithm [45] for the triangle-finding problem using a plain Grover search.

VI. DISCUSSIONS

A. Connection to spectral gap analysis

We shall now attempt to connect our approach with conventional spectral gap analysis. An equivalence between the two approaches can be directly shown for a particular class of Hamiltonians where both the initial and final Hamiltonians are of the projector form $H_0 = \mathbb{I} - |\Phi_0\rangle\langle\Phi_0|$ and $H_1 = \mathbb{I} - |\Phi_1\rangle\langle\Phi_1|$. It was then proved in Ref. [46] that the spectral gap of the full Hamiltonian H_λ [Eq. (1)], denoted as $g(H_\lambda)$, is bounded from below: $g(H_\lambda) \geq |\langle\Phi_1|\Phi_0\rangle| \equiv g_{\min}$, where $g_{\min} = \min_{\lambda \in [0, 1]} g(H_\lambda)$ is the minimal spectral gap. If the schedule function $\lambda(t)$ is chosen simply as $\lambda(t) = t/T$, spectral gap analysis [13, 18] yields the scaling of runtime $T_{\text{gap}} \sim \mathcal{O}(1/g_{\min}^2)$. Furthermore, it is possible to improve [13, 18] the error dependence on the minimal gap by adopting a nonlinear schedule function; if so, one obtains $T'_{\text{gap}} \sim \mathcal{O}(1/g_{\min})$. On the other hand, using our formalism, we directly obtain $\langle H_1 \rangle_0 = \langle H_1^2 \rangle_0 = 1 - |\langle\Phi_1|\Phi_0\rangle|^2 = 1 - g_{\min}^2$. Consequently, a lower bound on runtime follows from Eq. (14): $T_{\text{inf}} = \mathcal{O}(1/g_{\min})$.

If the minimal gap $g_{\min} = |\langle\Phi_1|\Phi_0\rangle|$ is independent of n , then the two estimates T_{gap} and T_{inf} are equal: $T_{\text{gap}} = T_{\text{inf}} = \mathcal{O}(1)$. This is the case for the adiabatic Deutsch-Jozsa algorithm and the adiabatic Bernstein-Vazirani algorithm discussed previously. For the case of adiabatic Grover search, the optimal runtime obtained from the spectral gap analysis along with a nonlinear schedule function yields [18] $T'_{\text{gap}} = \mathcal{O}(1/g_{\min})$, which again agrees with our lower bound $T_{\text{inf}} = \mathcal{O}(1/g_{\min})$.

B. Comparison with prior works

The performance of adiabatic quantum algorithms has been extensively investigated in a variety of settings. Among the existing research on this topic, three groups of studies that utilize quantum speed limits are particularly relevant to our current work. (i) A new class of quantum speed limits is presented in Refs. [47, 48] and applied to adiabatic searches. A lower bound on runtime is defined there as the minimum time it takes for the physical state to be orthogonal to the initial state. This definition is, however, too restrictive.⁴ Additionally, it is unclear whether the results obtained in Refs. [47, 48] are applicable beyond adiabatic searches.

(ii) While the main result of Ref. [38] is an inequality similar to Eq. (10), the present work makes several significant advances. Our method for estimating lower bounds is more systematic and rigorous, and we carefully clarified the applicability of Eq. (10). In particular, we highlighted the importance of the asymptotic property [Eq. (12)] and the irrelevance of the schedule function $\lambda(t)$ in asymptotic analysis. Furthermore, we explored a wider range of adiabatic quantum algorithms, including the adiabatic Grover algorithm examined in Ref. [38] as well as several additional adiabatic algorithms. Notably, we obtained an analytical result on lower

⁴Indeed, the final state of most adiabatic quantum algorithms is never orthogonal to the initial state, even though the overlap between the two is typically very small.

bounds for the adiabatic algorithm of Childs *et al.* [14] for finding k -clique in random graphs, which is an algorithm with undetermined quantum speedup.

(iii) It is also worth noting that quantum speed limits and the formalism of shortcuts to adiabaticity [49–56] are combined in Ref. [57] to investigate the performance of adiabatic quantum computation. However, the purpose and scope of Ref. [57] is significantly different from ours.

VII. CONCLUDING REMARKS

We have shown that for a wide class of adiabatic quantum algorithms (AQAs) in which the asymptotic property presented in Eq. (12) holds, nontrivial lower bounds on the runtime of adiabatic algorithms can be estimated by calculating the quantum uncertainty of the final Hamiltonian with respect to the initial state [see Eq. (11)]. A runtime estimation obtained by conventional spectral gap analysis is by no means smaller than the necessary runtime derived using our method. The reason is that our formula provides a necessary condition that must be obeyed by the runtime of adiabatic quantum evolution. Choosing a specific schedule function or initial Hamiltonian may cause the necessary runtime to be saturated.

Our findings may shed new light on the design of new adiabatic quantum algorithms. For instance, if a potential quantum speedup of an adiabatic quantum algorithm is undetermined, one may attempt a deformation of the original adiabatic algorithm to fulfill the moments condition [Eq. (13)] and then apply Eq. (14) to obtain a lower bound on runtime.

The runtime of the deformed algorithm thus obtained may be utilized to estimate the spectral gap (and hence, a sufficient runtime) of the original algorithm by means of matrix inequalities such as Weyl's inequalities [33,34]. For optimization problems, it is important to emphasize that the lower bound formula [Eq. (25)] is not valid for every optimization problem but only for those in which the cost function meets the moments condition [Eq. (24)]. Therefore, it would be interesting to investigate further the implications of the moments condition on general Boolean functions using techniques from Boolean function analysis [58]. Another future direction would be to derive bounds on the runtime of adiabatic quantum algorithms in open quantum systems.

APPENDIX A: QUANTUM UNCERTAINTY OF ISING TERMS

Consider a final Hamiltonian H_1 that consists of Ising terms $H_1 = -\sum_{i=0}^{n-1} Z_i Z_{i+1}$, where Z_i is the third Pauli matrix acting on the i th qubit. Recall that $Z|+\rangle = |+\rangle$ and $Z|-\rangle = -|-\rangle$. Choosing the initial state $|\Phi_0\rangle$ as the uniform superposition state [Eq. (15)]. We first compute

$$|\tilde{\Phi}\rangle := H_1|\Phi_0\rangle = -\sum_{i=0}^{n-1} Z_i Z_{i+1} |+\rangle^{\otimes n} = -\sum_{i=0}^{n-1} (|-\rangle_i \otimes |-\rangle_{i+1} \otimes |+\rangle^{\otimes n-2}). \quad (\text{A1})$$

We then find

$$\begin{aligned} \langle \Phi_0 | H_1 | \Phi_0 \rangle &= \langle \Phi_0 | \tilde{\Phi} \rangle = \langle + |^{\otimes n} \left(-\sum_{i=0}^{n-1} (|-\rangle_i \otimes |-\rangle_{i+1} \otimes |+\rangle^{\otimes n-2}) \right) = 0, \\ \langle \Phi_0 | H_1^2 | \Phi_0 \rangle &= \langle \tilde{\Phi} | \tilde{\Phi} \rangle = \sum_{i,j=0}^{n-1} (\langle - |_i \otimes \langle - |_{i+1} \otimes \langle + |^{\otimes n-2}) (| - \rangle_j \otimes | - \rangle_{j+1} \otimes | + \rangle^{\otimes n-2}) = \sum_{i,j=0}^{n-1} \delta_{ij} = n. \end{aligned} \quad (\text{A2})$$

It then follows from Eq. (9b) that the quantum uncertainty reads $\delta V_n = \sqrt{n}$.

APPENDIX B: DETAIL CALCULATION FOR ADIABATIC GROVER SEARCH

Consider a set of N items among which $M < N$ items are marked, the goal being to find marked items in minimum time. We use n qubits to encode the N items. Hence, the Hilbert space is of dimension $N = 2^n$. In this space, the basis states can be written as $|i\rangle$ with $i \in \{0, \dots, N-1\}$. The desired final state is $|\Phi_1\rangle = \frac{1}{\sqrt{M}} \sum_{m \in \mathcal{M}} |m\rangle$, and the corresponding final Hamiltonian can be chosen as a projector $H_1 = \mathbb{I} - \sum_{m \in \mathcal{M}} |m\rangle \langle m|$, where $\mathcal{M}$ is the space of solution (of size M). One can easily see

that the ground state of H_1 is $|\Phi_1\rangle$ with eigenenergy zero.

The remaining task is to calculate the quantum uncertainty δV_n [Eq. (9b)] with $|\Phi_0\rangle$ given by the uniform superposition state [Eq. (15)]. First, we calculate the overlap $|\langle \Phi_1 | \Phi_0 \rangle|^2$:

$$\begin{aligned} |\langle \Phi_1 | \Phi_0 \rangle|^2 &= \left| \left(\frac{1}{\sqrt{M}} \sum_{m \in \mathcal{M}} \langle m | \right) \left(\frac{1}{\sqrt{N}} \sum_{i=0}^{N-1} |i\rangle \right) \right|^2 \\ &= \frac{1}{MN} \left| \sum_{m \in \mathcal{M}} \sum_{i=0}^{N-1} \langle m | i \rangle \right|^2 = \frac{M}{N}. \end{aligned} \quad (\text{B1})$$

We then obtain $\langle \Phi_0 | H_1 | \Phi_0 \rangle = 1 - |\langle \Phi_1 | \Phi_0 \rangle|^2 = 1 - \frac{M}{N}$. Bringing this result to Eq. (14) yields $T_{\text{inf}} = \mathcal{O}(\sqrt{N/M})$.

APPENDIX C: DETAIL CALCULATION FOR ADIABATIC ALGORITHM OF FINDING k-CLIQUE IN RANDOM GRAPHS

We want to calculate $\langle \Phi_0 | H_1 | \Phi_0 \rangle =: \overline{h_C}$ and $\langle \Phi_0 | H_1^2 | \Phi_0 \rangle =: \overline{h_C^2}$, where

$$\begin{aligned}\overline{h_C} &= \frac{1}{C(n, k)} \sum_{z \in \{0,1\}^n: |z|=k} h_C(z), \\ \overline{h_C^2} &= \frac{1}{C(n, k)} \sum_{z \in \{0,1\}^n: |z|=k} h_C^2(z),\end{aligned}\quad (C1)$$

with the cost function $h_C(z) = \sum_{i>j} (1 - G_{ij}) z_i z_j$ as defined in Eq. (27). To conduct the calculation, one encounters terms like $\sum_{i>j} G_{ij}$, which cannot be done generically without knowing the explicit form of G_{ij} . We attempt a “mean-field” approach by considering the “average property” of G_{ij} since each pair of vertices has probability p to be connected and probability $(1 - p)$ otherwise. Note that the value of p is $1/2$ in the main text.

1. Mean-field approach

We shall approximate G_{ij} by its expected value, $\mathbb{E}[G_{ij}]$. Specifically, since each $G_{ij} = 1$ with probability p and $G_{ij} = 0$ with probability $1 - p$, we obtain

$$\mathbb{E}[G_{ij}] = p. \quad (C2)$$

We now compute $\overline{h_C}$ (C1):

$$\begin{aligned}\overline{h_C} &= \frac{1}{C(n, k)} \sum_{z \in \{0,1\}^n: |z|=k} \sum_{i>j} (1 - G_{ij}) z_i z_j \\ &\approx \mathbb{E}[\overline{h_C}] \\ &= \frac{1}{C(n, k)} \sum_{z \in \{0,1\}^n: |z|=k} \sum_{i>j} (1 - \mathbb{E}[G_{ij}]) z_i z_j.\end{aligned}\quad (C3)$$

There are $C(n, k)$ states $|z\rangle$ satisfy $|z| = k$ that we have to consider. For each such state, there are k 's z_i for which $z_i = 1$. Therefore, the first term in the parenthesis of Eq. (C3) is simply

$$\begin{aligned}\sum_{z \in \{0,1\}^n: |z|=k} \sum_{i>j} z_i z_j &= \sum_{z \in \{0,1\}^n: |z|=k} C(k, 2) \\ &= C(n, k) C(k, 2) = C(n, k) L_k.\end{aligned}\quad (C4)$$

Here, for notational convenience, we define $L_k \equiv C(k, 2)$. The second term in the parenthesis of Eq. (C3) can be calculated with the help of Eq. (C2)

$$\sum_{z \in \{0,1\}^n: |z|=k} \sum_{i>j} \mathbb{E}[G_{ij}] z_i z_j = p C(n, k) L_k. \quad (C5)$$

Bringing Eqs. (C4) and (C5) back to Eq. (C3) yields

$$\mathbb{E}[\overline{h_C}] = (1 - p) L_k. \quad (C6)$$

Next, we compute $\overline{h_C^2}$ (C1):

$$\begin{aligned}\overline{h_C^2} &= \frac{1}{C(n, k)} \sum_{z \in \{0,1\}^n: |z|=k} \sum_{i'>j'} \sum_{i>j} (1 - 2G_{ij} + G_{i'j'} G_{ij}) z_{i'} z_{j'} z_i z_j \\ &\approx \mathbb{E}[\overline{h_C^2}] \\ &= \frac{1}{C(n, k)} \sum_{z \in \{0,1\}^n: |z|=k} \sum_{i'>j'} \sum_{i>j} (1 - 2\mathbb{E}[G_{ij}] + \mathbb{E}[G_{i'j'} G_{ij}]) z_{i'} z_{j'} z_i z_j.\end{aligned}\quad (C7)$$

There are three terms in the parenthesis of Eq. (C7). The first term is deterministic,

$$\sum_{z \in \{0,1\}^n: |z|=k} \sum_{i'>j'} \sum_{i>j} z_{i'} z_{j'} z_i z_j = \sum_{z \in \{0,1\}^n: |z|=k} \left(\sum_{i'>j'} z_{i'} z_{j'} \right) \left(\sum_{i>j} z_i z_j \right) = \sum_{z \in \{0,1\}^n: |z|=k} L_k L_k = C(n, k) L_k^2. \quad (C8)$$

The second term in the parenthesis of Eq. (C7) reads

$$\begin{aligned}\sum_{z \in \{0,1\}^n: |z|=k} \sum_{i'>j'} \sum_{i>j} (-2\mathbb{E}[G_{ij}]) z_{i'} z_{j'} z_i z_j &= -2 \sum_{z \in \{0,1\}^n: |z|=k} \left(\sum_{i'>j'} z_{i'} z_{j'} \right) \left(\sum_{i>j} \mathbb{E}[G_{ij}] z_i z_j \right) \\ &\stackrel{(C2)}{=} -2 \sum_{z \in \{0,1\}^n: |z|=k} \left(\sum_{i'>j'} z_{i'} z_{j'} \right) \left(\sum_{i>j} p z_i z_j \right) = -2p C(n, k) L_k^2.\end{aligned}\quad (C9)$$

Before proceeding to calculate the third term in the parenthesis of Eq. (C7), we notice the following decomposition property

$$\begin{aligned}\sum_{i'>j'} \sum_{i>j} \mathbb{E}[G_{i'j'} G_{ij}] &= \sum_{i>j} \mathbb{E}[G_{ij} G_{ij}] + \sum_{i'>j', i>j: i \neq i', j \neq j'} \mathbb{E}[G_{i'j'} G_{ij}] = \sum_{i>j} \mathbb{E}[G_{ij}^2] + \sum_{i'>j', i>j: i \neq i', j \neq j'} \mathbb{E}[G_{i'j'}] \mathbb{E}[G_{ij}] \\ &= \sum_{i>j} p + \sum_{i'>j', i>j: i \neq i', j \neq j'} p^2 = L_k p + (L_k^2 - L_k) p^2.\end{aligned}\quad (C10)$$

Finally, the third term in the parenthesis of Eq. (C7) is

$$\sum_{z \in \{0,1\}^n: |z|=k} \left(\sum_{i' > j'} \sum_{i > j} \mathbb{E}[G_{i'j'} G_{ij}] z_{i'} z_{j'} z_i z_j \right) \stackrel{(C10)}{=} pC(n, k) L_k^2 \left(p + \frac{(1-p)}{L_k} \right). \quad (C11)$$

Upon using the above results, Eq. (C7) reads

$$\mathbb{E}[\overline{h_C^2}] = \left(1 - 2p + p \left(p + \frac{1-p}{L_k} \right) \right) L_k^2 = (1-p)^2 L_k^2 + p(1-p) L_k. \quad (C12)$$

Hence, the quantum uncertainty reads $\delta V_n = \sqrt{p(1-p)L_k}$. It then follows from Eq. (11) a lower bound on runtime

$$T_{\text{inf}} = \mathcal{O}(\sqrt{1/L_k}), \quad (C13)$$

which is independent of n . Note that if the cost function $h_C(z)$ is rescaled as $h_C(z) \rightarrow h_C(z)/L_k$, one should find $T_{\text{inf}} = \mathcal{O}(\sqrt{L_k})$.

2. Combinatorial approach

In this section, we use an explicit combinatorial method to reproduce the same result as we found in Eq. (C13). The following observation is crucial: If a binary string z of Hamming weight k represents a graph that is a k -clique after adding α connected edges, then $h_C(z) = \alpha$, where $\alpha \in \{0, 1, \dots, C(k, 2)\}$.

To simplify the notation, let us define $L_k \equiv C(k, 2)$ for convenience. Now the question is what is the multiplicity m_α

for each possible value of cost function $h_C(z) = \alpha$. Since each of the L_k edges has probability p to be present when random graphs are generated uniformly, we expect

$$m_\alpha = p^{L_k - \alpha} (1-p)^\alpha C(L_k, \alpha) C(n, k), \quad (C14)$$

for $\alpha \in \{0, 1, \dots, L_k\}$. One verifies that the sum of all multiplicity equals $C(n, k)$, i.e., the number of binary strings of Hamming weight k

$$\sum_{\alpha=0}^{L_k} m_\alpha = C(n, k) \sum_{\alpha=0}^{L_k} \underbrace{p^{L_k - \alpha} (1-p)^\alpha C(L_k, \alpha)}_{=(p+1-p)^{L_k}} = C(n, k). \quad (C15)$$

We proceed to compute $\mathbb{E}[\overline{h_C}]$:

$$\mathbb{E}[\overline{h_C}] = \frac{1}{C(n, k)} \sum_{\alpha=0}^{L_k} m_\alpha \alpha = \sum_{\alpha=0}^{L_k} p^{L_k - \alpha} (1-p)^\alpha C(L_k, \alpha) \alpha = (1-p) L_k, \quad (C16)$$

which is the same as Eq. (C6). We then compute $\mathbb{E}[\overline{h_C^2}]$:

$$\mathbb{E}[\overline{h_C^2}] = \frac{1}{C(n, k)} \sum_{\alpha=0}^{L_k} m_\alpha \alpha^2 = \sum_{\alpha=0}^{L_k} p^{L_k - \alpha} (1-p)^\alpha C(L_k, \alpha) \alpha^2 = (1-p)^2 L_k^2 + p(1-p) L_k, \quad (C17)$$

which is identical to Eq. (C12).

Abstract. Storage and retrieval of quantum channels encodes an unknown channel into a program state for later use. While classical estimation-based strategies are optimal for unitary channels, we show that this optimality fails for isometry channels. For an isometry with input dimension d , output dimension D , and n queries, we prove that the optimal estimation fidelity is $F = 1 - d(D - d)/n + O(n^{-2})$, implying that classical storage requires $n = \Theta(\epsilon^{-1})$ to achieve diamond-norm error ϵ . We then propose a quantum strategy based on port-based teleportation requiring only $n = \Theta(1/\sqrt{\epsilon})$, yielding a quadratic improvement and extending to general quantum channels. The technical manuscript of this work is available at Ref. [1].

1 Introduction

Universal programming is the task to store the action of a quantum channel Λ to a quantum state called the program state ϕ_Λ [2]. It is aimed to establish a quantum analogue of a classical program, where bit strings represent channels on bit strings. The size of the program state is called *program cost*, and the no-programming theorem prohibits deterministic and exact implementation of universal programming using a finite program cost [2]. To circumvent this no-go theorem, researchers developed probabilistic or approximate protocols [2–21] with generalization to measurements [22–38], infinite-dimensional systems [39], and generalized probabilistic theory [40]. Previous works construct storage-and-retrieval (SAR) protocols, where the program state ϕ_Λ is prepared using multiple queries to Λ , and the number of queries is called *query complexity*. There are two strategies for the implementation of SAR: *classical* and *quantum* strategies (Fig. 1).

The classical strategy is proposed for the deterministic SAR (dSAR) of unitary channels, based on unitary estimation [41], and also called the *estimation-based* strategy. It is classical in the sense that the strategy involves extracting the matrix representation of the unitary channel, which can be stored in a classical register. Unitary estimation is the task to estimate an unknown unitary channel $\mathcal{U}(\cdot) := U \cdot U^\dagger$ corresponding to $U \in \text{SU}(d)$. To do this, one first prepares a quantum state $|\phi_U\rangle$ using multiple queries to $\mathcal{U}$ and measures $|\phi_U\rangle$ to obtain the estimate $\hat{U} \in \text{SU}(d)$ corresponding to the unitary channel $\hat{\mathcal{U}}(\cdot) := \hat{U} \cdot \hat{U}^\dagger$. The quantum state $|\phi_U\rangle$ can be used as the program state for dSAR and the retrieval of $\mathcal{U}$ is done by applying the estimated unitary channel

$\hat{\mathcal{U}}$ [Fig. 1 (a)]. The optimal query complexity and program cost are achieved by the estimation-based strategy for dSAR of unitary channels [17, 42]. The construction in Ref. [17] is based on the unitary estimation protocol achieving the Heisenberg limit (HL) [17, 43–46].

The quantum strategy is based on port-based teleportation (PBT), and is also called the *PBT-based* strategy. This strategy directly retrieves the stored channel without extracting its classical description. The PBT-based strategy is proposed for the probabilistic SAR (pSAR) and dSAR of a general quantum channel Λ . PBT is a variant of quantum teleportation, which uses a $2n$ -qudit entangled state $|\phi_{\text{PBT}}\rangle$ between the sender (Alice) and receiver (Bob), and Bob chooses a port based on the measurement outcome [12, 13]. The quantum state $(\mathbb{1}_{\mathcal{L}(\mathbb{C}^d)}^{\otimes n} \otimes \Lambda^{\otimes n})(|\phi_{\text{PBT}}\rangle\langle\phi_{\text{PBT}}|)$ can be used as a program state, and the teleportation protocol retrieves the quantum channel Λ [Fig. 1 (b)]. The optimal success probability of pSAR of unitary channels is shown to be achieved by the optimal probabilistic PBT [14, 47].

Despite the progress on SAR of unitary channels, less is known for SAR beyond unitary channels. One of the important classes of quantum channels is the set of *isometry channels*, which is defined by $\mathcal{V}(\cdot) := V \cdot V^\dagger$ for $V : \mathbb{C}^d \rightarrow \mathbb{C}^D$ satisfying $V^\dagger V = \mathbb{1}_d$, where $\mathbb{1}_d$ is the identity operator on $\mathbb{C}^d$. The isometry channel represents encoding of quantum information, used in various quantum information processing tasks such as quantum error correction and quantum communication [48]. It also represents a general quantum channel via the Stinespring dilation [49, 50]. However, less is known about an isometry channel compared to a unitary channel, e.g., the optimal estimation of an isometry channel is not known. Since isometry channel can be considered as the unitary channel where the input space is restricted to a subspace, it is not trivial whether the optimal estimation error obeys the

Figure 1: (a) Classical (estimation-based) strategy for dSAR of isometry channels $\mathcal{V}(\cdot) := V \cdot V^\dagger$. One first prepare a quantum state $|\phi_V\rangle$ with multiple queries to $\mathcal{V}$, and measure $|\phi_V\rangle$ to obtain the estimate $\hat{V}$ corresponding to the isometry channel $\hat{\mathcal{V}}(\cdot) := \hat{V} \cdot \hat{V}^\dagger$ as the measurement outcome. The quantum state $|\phi_V\rangle$ can be used as the program state, and the isometry channel can be retrieved by applying the estimated isometry channel $\hat{\mathcal{V}}$ on an input quantum state $|\psi\rangle$.

(b) Quantum (PBT-based) strategy for dSAR of isometry channels. The sender (Alice) and the receiver (Bob) share a $2n$ -qudit entangled state ϕ_{PBT} . PBT is the task to send an unknown quantum state $|\psi\rangle$, where Alice and Bob share a $2n$ -qudit entangled state $|\phi_{\text{PBT}}\rangle$. Alice applies a joint measurement on $|\psi\rangle$ and her share of $|\phi_{\text{PBT}}\rangle$, sends the measurement outcome a to Bob, and Bob chooses the port a on his share of $|\phi_{\text{PBT}}\rangle$ to obtain an input quantum state $|\psi\rangle$. The quantum state $(\mathbb{1}_d^{\otimes n} \otimes V^{\otimes n}) |\phi_{\text{PBT}}\rangle$ can be used as a program state for dSAR of an isometry channel $\mathcal{V}$.

Figure 2: Quantum state estimation obeys the SQL, where the estimation fidelity F_{est} is given by $F_{\text{est}} = 1 - \Theta(n^{-1})$ for a query complexity n , while unitary estimation achieves the HL, where $F_{\text{est}} = 1 - \Theta(n^{-2})$ holds. This work shows that estimation of isometry $V \in \mathbb{V}_{\text{iso}}(d, D)$ obeys the SQL for all $d < D$ (Thm. 1).

HL (true for unitary estimation [17, 44–46]) or the standard quantum limit (SQL; true for state estimation [51]).

This work investigates SAR and estimation of isometry channels. We define the task *isometry estimation* as a generalization of unitary estimation and compare the classical (estimation-based) strategy and the quantum (PBT-based) strategy for dSAR of isometry channels. We show that the isometry estimation obeys the SQL, which leads to showing the inefficiency of the estimation-based strategy in terms of the query complexity (Fig. 2). The query complexity of the PBT-based strategy is shown to be optimal, and the program cost of the PBT-based strategy is less than that of the estimation-based strategy, which presents a quadratic quantum advantage in the sense of Refs. [52–54]. We also show the universal programming of general quantum channels as an application, whose program cost is smaller than the protocol shown in Ref. [19].

2 Definitions of the tasks

For a set of quantum channels $\mathbb{S}$, *universal programming* of $\mathbb{S}$ is the task to retrieve a quantum channel $\Lambda \in \mathbb{S}$ by using a quantum state $\phi_\Lambda \in \mathcal{L}(\mathcal{P})$ called the program state, that encodes the information of Λ , where $\mathcal{L}(\mathcal{P})$ represents the set of linear operators on a Hilbert space $\mathcal{P}$. The retrieval is done by applying a quantum channel Φ , which is independent of Λ , on an input quantum state ρ and the quantum state ϕ_Λ . The retrieved channel $\mathcal{R}_\Lambda$ is given by $\mathcal{R}_\Lambda(\rho) := \Phi(\rho \otimes \phi_\Lambda)$. The size of the program state is called the *program cost*, defined by $c_P := \log \dim \mathcal{P}$. The approximation error ϵ of the retrieved channel is called the *retrieval error*, which is given by the worst-case diamond-norm error: $\epsilon := \frac{1}{2} \sup_{\Lambda \in \mathbb{S}} \|\mathcal{R}_\Lambda - \Lambda\|_\diamond$. When the program state ϕ_Λ is prepared by n queries of Λ , the task is called *storage and retrieval* of $\mathbb{S}$, and the number of queries is called the *query complexity* of the protocol. In this work, we consider two classes of the set $\mathbb{S}$:

- Isometry channels: $\mathbb{S} = \mathbb{S}_{\text{isometry}}^{(d,D)} := \{\mathcal{V}(\cdot) := V \cdot V^\dagger \mid V \in \mathbb{V}_{\text{iso}}(d, D) := \{V : \mathbb{C}^d \rightarrow \mathbb{C}^D \mid V^\dagger V = \mathbb{1}_d\}\}$.
- General quantum channels: $\mathbb{S} = \mathbb{S}_{\text{CTP}}^{(d,D)} := \{\Lambda : \mathcal{L}(\mathbb{C}^d) \rightarrow \mathcal{L}(\mathbb{C}^D) \mid \Lambda \text{ is a CPTP map}\}$.

Isometry estimation is the task defined as follows. An unknown isometry operator $V \in \mathbb{V}_{\text{iso}}(d, D)$ is drawn from the Haar measure of $\mathbb{V}_{\text{iso}}(d, D)$ [55, 56], and the task is to estimate the corresponding isometry channel $\mathcal{V}(\cdot) := V \cdot V^\dagger$ with n queries to $\mathcal{V}$. One can first prepare a quantum state ϕ_V using n queries to $\mathcal{V}$, and measure ϕ_V to obtain the estimate $\hat{V}$ as the measurement outcome with the probability distribution

denoted by $p(\hat{V}|V)d\hat{V}$. The accuracy of the estimation is evaluated by the *estimation fidelity*, defined by $F_{\text{est}} := \int dV \int d\hat{V} p(\hat{V}|V) F_{\text{ch}}(V, \hat{V})$, where dV and $d\hat{V}$ are the Haar measure of $\mathbb{V}_{\text{iso}}(d, D)$ and $F_{\text{ch}}(V, \hat{V})$ is the channel fidelity [57] between isometry channels $\mathcal{V}, \hat{\mathcal{V}}$ defined by $F_{\text{ch}}(V, \hat{V}) := \frac{1}{d^2} \left| \text{Tr} \left(V^\dagger \hat{V} \right) \right|^2$. The task of isometry estimation covers unitary estimation and state estimation as the special cases ($D = d$ for unitary estimation and $d = 1$ for state estimation). We denote the optimal fidelity of isometry estimation by $F_{\text{est}}(n, d, D)$. The optimal retrieval error in the estimation-based strategy for dSAR of $\mathbb{S}_{\text{Isometry}}^{(d, D)}$ is given by $\epsilon = 1 - F_{\text{est}}(n, d, D)$.

3 Summary of the main results.

Our contributions are summarized as follows.

1. **Optimal isometry estimation.**— We show the optimal fidelity of isometry estimation as follows.

Theorem 1 *The optimal fidelity of isometry estimation is given by $F_{\text{est}}(n, d, D) = 1 - \frac{d(D-d)}{n} + O(n^{-2})$, which is achieved by calling the isometry channels in parallel.*

This theorem shows that, as long as $D > d$ holds, the fidelity of isometry estimation obeys the SQL $F_{\text{est}} = 1 - \Theta(n^{-1})$ similarly to the state estimation [Fig. 2]. This is in contrast with the unitary estimation corresponding to the case of $D = d$, which obeys the HL $F_{\text{est}} = 1 - \Theta(n^{-2})$. This theorem also shows the exact coefficient of the leading term in n , which is unknown for the case of unitary channels except for $d = 2, 3$ [46, 58].

2. **Proof of quantum advantage.**— We construct the asymptotically optimal protocol for SAR of isometry channels to show the advantage over the classical strategy.

Theorem 2 *The optimal query complexity for dSAR of $\mathbb{S}_{\text{Isometry}}^{(d, D)}$ with the retrieval error ϵ is given by $n = \frac{\Theta(d^2)}{\sqrt{\epsilon}}$, which is achieved by the PBT-based strategy.*

Since Thm. 2 shows that the estimation-based strategy requires $n = \Theta(\epsilon^{-1})$ to achieve the diamond-norm error ϵ , we find that the PBT-based strategy offers a quadratic improvement in query complexity.

3. **Conjecture on optimal program cost for universal programming.**— We optimize the program cost based on the estimation-based and PBT strategies, which leads to the following Corollary and Theorem [59].

Corollary 3 *The program cost of the universal programming of isometry channels with the estimation-based strategy is given by $c_P \leq \frac{2Dd-d^2-1}{2} \log \Theta(\epsilon^{-1})$.*

Theorem 4 *There exists a protocol for universal programming of $\mathbb{S}_{\text{Isometry}}^{(d, D)}$ with the program cost given by $c_P \leq \frac{Dd-1}{2} \log \Theta(\epsilon^{-1})$, which is achieved by the PBT-based strategy.*

From these observations, we extend the conjecture on optimal program cost raised in Ref. [17], which states that the optimal program cost of unitary operators with ν real parameters is given by $c_P^{(\text{conj})} = \frac{\nu}{2} \log \Theta(\epsilon^{-1})$, as follows.

Conjecture 1 *The optimal program cost of estimation-based universal programming of an isometry channel with ν parameters is given by $c_P^{(\text{est})} = \frac{\nu}{2} \log \Theta(\epsilon^{-1})$.*

4. **Application: Universal programming of CPTP maps.**— As an application of SAR of isometry channels, we show a universal programming protocol of CPTP maps using the Stinespring dilation.

Theorem 5 *There exists a universal programming of $\mathbb{S}_{\text{CPTP}}^{(d, D)}$ with the program cost $c_P \leq \frac{Dd^2-1}{2} \log \Theta(\epsilon^{-1})$.*

This program cost is improved over that shown in Ref. [19] achieving the program cost $c_P \leq 2Dd^2 \log \Theta(\epsilon^{-1})$.

Consequently, we show a quadratic advantage of the quantum strategy over the classical one, which highlights the importance of the PBT in quantum information processing. The analysis on isometry estimation has its own interest which unifies the state estimation and unitary estimation. The developed isometry estimation protocol also finds applications in the transformation of isometry channels [60, 61]. In particular, the optimal estimation fidelity provides an approximation error of the measure-and-prepare strategy for such a transformation, which serves as a starting point for optimizing such transformation protocols.

Quantum Circuit Optimization by Graph Coloring

Hochang Lee¹

Abstract. Depth optimization of a circuit consisting of commuting operations is shown to be polynomial time reducible (in the number of operations) to solving the vertex coloring problem in graph theory. The opposite direction is also proven to hold, meaning that the two problems are equivalent. The reduction implies *any algorithm* for the vertex coloring can be utilized to optimize a commuting circuit. The idea is validated numerically and applied to finite field multiplications and additions by quantum Fourier transform. The full version of the paper is available in Quantum 10, 1996 (2026).

Keywords: quantum circuit, optimization, graph coloring

1 Motivation and idea

Quantum circuits composed of finitely many unitary operations that mutually commute arise in several computational settings. Throughout this work, we refer to such circuits as commuting circuits. Because the underlying unitary operations mutually commute, such circuits are naturally amenable to parallelization, i.e., certain operations can be executed in parallel whenever the hardware supports it. Hardware-dependent constraints therefore determine which operations can be executed concurrently, and consequently lead to the notion of *depth* of a circuit. (Definition of the depth is given below.)

In circuit synthesis, a function can generally be implemented by multiple constructions, and selecting one that minimizes resource usage is a central consideration in circuit design [14]. Under a fixed number of qubits, a design with smaller depth is typically preferred, as it reflects better utilization of the available parallelism. For this reason, among others, optimizing the depth of a circuit is an active area of research [14, 13, 3, 8, 2].

This study establishes a formal connection between depth optimization of commuting circuits and a well-known NP-hard problem in graph theory. The main idea is that parallel scheduling can be expressed as a coloring constraint. Concretely, fix the hardware concurrency model, i.e., specify which operations are allowed to run simultaneously. From the list of commuting operations, build a graph whose vertices correspond to operations, and edges correspond to constraints which operations cannot be executed in parallel.

Definition 1 (Depth of a circuit) *Given a hardware system, operations are parallelizable if and only if they can be simultaneously executed on the system. A layer is the maximal set of operations such that the operations are parallelizable. Depth of a circuit is the number of consecutive layers to run the circuit.*

A depth- d implementation of a commuting circuit is a partition of the operations into d -layers, where every layer contains only mutually compatible operations. In the graph picture, each layer is an independent set (no edges inside the layer), so assigning layers is precisely a

proper vertex coloring: operations in the same layer share a color, and edges enforce different colors. Minimizing the depth therefore becomes minimizing the number of colors, and the minimum depth of a circuit is equal to the *chromatic number* of the corresponding graph. An approximate solution of the depth minimization also translates into that of the vertex coloring with appropriate care.

2 On the hardness of circuit optimization

The optimization of a logic circuit has long been studied. The minimum circuit size problem asks if a Boolean function is computable by a circuit of limited size, and several papers of evidence suggest that the problem might be NP-hard [11, 1, 6, 9, 7]. In quantum computing, recent works show that optimizing a quantum circuit in some occasions is NP-hard [16, 15], and specifically in the paper by Wetering and Amy [15], wide range of optimization targets have been considered including T -count, T -depth, Toffoli-count, Toffoli-depth, CNOT-count and so on, proving that the quantum circuit optimization is generally hard. Along the line of study, one of the conclusions drawn from this work is that the depth optimization of a commuting quantum circuit is NP-hard, implying that this small class of quantum circuits is already hard to optimize.

3 Circuit optimization strategy

The fact that gate ordering is reduced to graph coloring results in a way to optimize the depth of a commuting circuit. A simple strategy is to utilize any (approximate) coloring solver. An abstract form of the algorithm is as follows:

Algorithm 1 OptimizeCircuit

Input: v ▷ input circuit
Output: v' ▷ output circuit

```
1:  $G \leftarrow \text{ConstructGraph}(v)$ 
2:  $\tilde{G} \leftarrow \text{ColoringSolver}(G)$ 
3:  $v' \leftarrow \text{BackToCircuit}(\tilde{G})$ 
4: return  $v'$ 
```

Since graph theory has been studied extensively over

*pansics@nsr.re.kr

history, one may expect the strategy to be effective on some occasions. Computational complexity and the depth of the resulting circuit are determined by the algorithm for graph coloring. Validity of the strategy and applications to known circuits from literature are examined in the full paper.

4 Discussion

One limitation of the reduction strategy is that it only works on commuting circuits. Two workarounds can be further investigated. One direction is to transform a noncommuting circuit into one such that a portion of commuting parts is large. The other way is to divide a noncommuting circuit into many commuting parts and then applying the method where available. For example, LU decomposition is employed in optimizing linear circuits [10, 12], where we see a potential application of the coloring method.

We want to point out that the strategy developed in this work is capable of finding the optimal depth of a commuting circuit corresponding to a perfect graph [4], since there exists a polynomial time algorithm for graph coloring of a perfect graph [5]. The next question is then whether it is possible to find such a circuit that has practical uses while its optimal depth is not yet known. We have not formally proved yet, but considering that the perfect graphs do not have odd ring of length ≥ 5 , a circuit consisting of commuting CNOT gates seems to correspond to a perfect graph.¹ However, we were not able to take advantage of such a fact for a useful application.

During the journal review process, we were asked to address two nontrivial points. One is that if the reduction idea can be generalized to account for hardware restrictions such as qubit connectivity and gate set, and the other is if the vertex coloring approach is advantageous over the edge coloring of a hypergraph. We briefly discuss the issues in the full paper.

Logical gates on Floquet codes via folds and twists

Alexandra E. Moylett¹ *

Bhargavi Jonnadula¹ †

¹ *Nu Quantum Ltd., Cambridge, United Kingdom*

Abstract. Floquet codes are a new family of error-correcting codes, with a central open question being how to implement logical operations on these codes. We extend two techniques from static quantum error-correcting codes to Floquet codes: fold-transversal operations for logical Hadamard and S gates; and Dehn twists for logical CNOT gates. Through numerical benchmarking of the logical operations on the CCS Honeycomb code, we establish a logical-gate threshold of 0.25-0.35% and verify exponential error suppression below threshold, with comparable performance to a quantum memory on the same code.

A full technical manuscript is available at [1].

Keywords: Quantum error correction, logical gates, Floquet codes

1 Introduction

Quantum error correction (“QEC”) has developed significantly in both theory and practice over recent years [2, 3]. One area of particular interest has been in identifying what logical gates can be implemented, for which a variety of techniques have been developed [4, 5, 6].

There has been a shift towards thinking of quantum error correction as a dynamic process since the introduction of Floquet codes [7]. Traditional QEC codes keep logical information static during the duration of the code, while Floquet codes enable it to evolve dynamically without sacrificing error protection. Floquet codes also have desirable hardware properties due to measurements being between pairs of qubits, making them suitable for both hardware distributed across a quantum network [8] and with native two-qubit measurements [9].

The question of what logical gates can be implemented on Floquet codes has prompted some interest. In Hastings and Haah [7], it was shown that the process of measuring the stabilisers in the original Floquet code induces a logical operation similar to the Hadamard gate. This in turn led to the development of dynamic automorphism codes [10], which can implement the full Clifford group across k logical qubits, but require these logical qubits to be arranged as a vertical stack of $k + 1$ layers of qubits. It has also been shown that some techniques from static codes can be extended to Floquet codes, such as lattice surgery [11] and twist defects [12].

In Higgott and Breuckmann [13], it was suggested that two further techniques from the study of logical gates on static codes could be adapted to Floquet codes. The first is fold-transversal gates [14, 4], which utilise symmetries between the Z and X stabilisers. And the second is Dehn twists [15], which distort the lattice of a code to implement logical CNOT gates. Higgott and Breuckmann leave the details of revising these methods to Floquet codes as an open question. Adapting these techniques from static to Floquet codes is challenging. While a Floquet code embeds a static code at each moment, using this for logical gates raises technical issues—such as ensuring the embedded code enables effective logical gates

Figure 1: Logical-gate techniques adapted to Floquet codes. (a) We identify time-dependent ZX-dualities and utilise them to implement logical Hadamard and S gates. (b) We distort the underlying lattice to implement logical CNOT gates via Dehn twists, using the *edge exchange gadget* shown in Figure 2.

and mapping the embedded code back to the Floquet code fault-tolerantly.

In this work, we introduce novel techniques for fault-tolerantly implementing both fold-transversal logical gates and Dehn twists on Floquet codes. Our techniques are general and can be applied to a variety of Floquet codes with different lattices and measurement schedules, details of which can be found in the full paper [1]. We also study how to implement logical gates on Floquet codes by identifying logical gates on the embedded codes.

2 Fold-transversal gates

Fold-transversal gates were originally developed for the surface code [14] and later extended to more general CSS codes [4]. The implementation of a fold-transversal logical gate requires a ZX-duality [4]. A ZX-duality τ is an isomorphism of the physical qubits which exchanges X and Z stabilisers in the code. Given τ , one can implement a logical gate by, for example, applying a Hadamard gate to each physical qubit and then applying SWAP gates between pairs of qubits i and j such that $i < j$ and $\tau(i) = j$. The specific logical gate implemented by this process will depend on the choice of code and ZX-duality.

On Floquet codes, we utilise ZX-dualities which appear over time to implement logical gates. For example, in the honeycomb Floquet code shown in Figure 1a, if we finish

*alex.moylett@nu-quantum.com

†bhargavi.jonnadula@nu-quantum.com

measuring qubits connected by blue edges in the ZZ basis and are about to measure qubits connected by red edges in the XX basis, the stabilisers on the red, green, and blue plaquettes are X, Y and Z, respectively. At this point in time a ZX-duality can be identified by the white dashed line, with qubits on the line being mapped to themselves and qubits on either side of the line mapping to the qubit on the reflected side. It is a valid ZX-duality since X (resp. Z) stabilisers on the red (resp. blue) plaquettes are mapped to Z (resp. X) stabilisers on the blue (resp. red) plaquettes, and Y stabilisers on green plaquettes are mapped to Y stabilisers on other green plaquettes.

From this time-dependent ZX-duality, we are able to define logical gates using the same physical gate sequences as for static codes [4]. For example, applying Hadamard gates to each physical qubit and SWAP gates to pairs of qubits across the fold shown in Figure 1a gives us a logical $H_0 \otimes H_1$ gate. We also show in the full paper how to extend this technique to Floquet codes using different measurement schedules and defined on different lattices.

3 Dehn twists

Dehn twists were previously studied in static topological codes and implement a logical CNOT by distorting the lattice around a non-trivial loop [16, 15]. On a Floquet code, we first identify a non-trivial loop where the edge colours alternate between green edges and blue/red edges. Part of such a loop is shown in Figure 2a. In Figure 2b we present a sequence of CNOT gates which, if applied between measuring blue edges in the ZZ basis and red edges in the XX basis, have the effect of swapping the order of a red and blue edge in a loop, as shown in Figure 2c. Figure 1b shows that an instantaneous Dehn twist can be performed by applying the gadget in parallel at multiple locations on the lattice, deforming the entire lattice at once. Alternatively, deforming only part of the lattice at a time implements a Dehn twist in linear time. Both approaches are equivalent to a logical CNOT, with the only difference being the time overhead.

4 Benchmarking

4.1 Protocol

To understand how the aforementioned logical gates perform, we have developed logical circuits to implement the fold-transversal $H_0 \otimes H_1$ gate and the instantaneous Dehn twist on the CSS Honeycomb Floquet code. We present a summary of our protocol in Figure 3. We assume perfect logical state preparation and measurement, with d noisy rounds of quantum memory before and after the logical gate. We use circuit-level noise in the bulk of the circuit, with two-qubit measurements implemented using an in-place measurement circuit [17]. We also developed quantum memory circuits of the same number of QEC rounds as as a comparison. We simulated these circuits using Stim [18] and decoded them using PyMatching [19]. In the full paper we also present simulations for linear-time Dehn twists and fold-transversal $S_0 \otimes S_1$

Figure 2: (a) A sequence of four qubits connected in a chain of edges coloured $g \rightarrow r \rightarrow g \rightarrow b \rightarrow g$ from top to bottom. (b) The edge exchange gadget consists of applying four CNOT gates across pairs of qubits in this chain, with the two control qubits (a and b) connected by a red edge, and the two target qubits (c and d) connected by a blue edge. (c) The transformation of the stabilisers due to this gadget. The sequence of edge colours is now $g \rightarrow b \rightarrow g \rightarrow r \rightarrow g$.

Figure 3: The protocol followed when benchmarking logical gates. $\text{QEC}(d, \epsilon)$ indicates d QEC rounds with physical error probability ϵ , with $\epsilon = 0$ indicating a noiseless QEC round. $U(\epsilon)$ indicates a logical gate U followed by a single QEC round, with physical error probability ϵ . P and Q are X or Z bases, with P' and Q' chosen such that the logical information is preserved.

gate, along with comparable quantum memory simulations. Example Stim circuits generated when performing the simulations are available in [20].

4.2 Thresholds

We began by studying the thresholds of these techniques, which we present in Figure 4. In all three cases we find a threshold of approximately 0.32%, suggesting that the threshold is largely unaffected by these logical gates.

4.3 Sub-threshold performance

We also studied the performance of these techniques at sub-threshold error rates of 0.1% and 0.05%. The results are presented in Figure 5, where we find that the fold-transversal Hadamard gate has near-identical performance to that of a quantum memory. The instantaneous Dehn twist has slightly worse performance, but is still able to exponentially suppress errors. The linear Dehn twist performs similarly and is therefore omitted from Figures 4 and 5 for clarity.

Note that in the full paper we also benchmark a fold-transversal $S_0 \otimes S_1$ gate, which shows some error suppression but flattens out at higher code distances [1]. We attribute this to a limitation of the decoder: the fold-transversal $S_0 \otimes S_1$ gate introduces non-graph-

Figure 4: Threshold estimates for (a) a $(2d+1)$ -round quantum memory experiment, (b) a logical $H_0 \otimes H_1$ gate, and an instantaneous Dehn twist.

Figure 5: Sub-threshold performance of the CSS Honeycomb Floquet code for a $(2d+1)$ -round quantum memory experiment (solid), a fold-transversal $H_0 \otimes H_1$ gate (dotted), and an instantaneous Dehn twist (dashed).

like errors, meaning that PyMatching cannot be used as a decoder. Instead we used Belief Propagation and zeroth-order Localised Statistics Decoding (“BP+LSD-0”) [21, 22], which is able to decode more general errors but suffers from sub-optimal performance for large codes [23, 24]. We verify this in the full paper by showing that a $(2d+1)$ -round quantum memory experiment decoded with BP+LSD-0 also exhibits this limitation.

5 Logical gates via embedded codes

After each measurement sub-round, the Floquet code embeds an instantaneous stabiliser code [25]. In this section, we discuss how to perform logical gates via these embedded codes.

Consider the CSS honeycomb Floquet code. After each sub-round, the code embeds a toric code tessellated with hexagons and triangles. Each parity measurement between two qubits, which can be thought of as a $[[2, 1, 1]]$

Figure 6: Embedding in the honeycomb Floquet code. Honeycomb Floquet code, along with a choice of logicals, is shown in (a). Figure (b) highlights the instantaneous toric code on the 3.6.3.6 lattice that the Floquet code embeds after the **rXX** sub-round.

repetition code, yields an effective single qubit that lies at the vertices of the instantaneous code. For example, after the **rXX** sub-round, the instantaneous toric code is demonstrated in Figure 6b. Note that there is no ZX-duality in the instantaneous code due to X and Z checks having different weights. Hence, fold-transversal gates are not possible via the embedded code. Nevertheless, logical gates through Dehn twists are still possible. The CNOT operations during the Dehn twist on the embedded code can be perceived as transversal CNOT gates between two $[[2, 1, 1]]$ repetition codes. Maintaining the 3-colourability of the code during the application of Dehn twists is essential for retrieving the Floquet code from its embedding. Furthermore, stabilisers change during Dehn twists and fold-transversal gate implementations, and should therefore be appropriately compared when performing QEC rounds. In the full paper we show that Dehn twists on this embedded code can fulfil these requirements [1].

6 Conclusion

In this work we have extended two possible techniques fault-tolerant logical gates from static codes to Floquet codes. Through benchmarking, we showed that these methods still yield an exponential error suppression. We also investigate logical gates which can be implemented via the embedded code. Further work is required in understanding what other logical gates can be implemented on Floquet codes, as well as the architecture requirements for implementing these logical gates on real hardware.

Code availability

Example Stim circuits generated for the simulations presented in this paper are available in [20].

Abstract. Quantum information processing is, in practice, restricted to efficiently implementable operations. Motivated by this, we study quantum divergences that retain their operational meaning while faithfully capturing these computational constraints. We introduce two computational divergences, i.e., a computational max-divergence and computational measured Rényi divergences, both defined through efficient binary measurements and suited to computational state discrimination. We prove that the infinite-order limit of the latter equals the former, as in the information-theoretic setting. Moreover, in the many-copy regime, we show that regularized versions yield a one-sided computational Stein bound. We lastly analyze induced computational resource measures and derive continuity bounds, study their applications for computational resource theories, as well as derive separations from information-theoretic analogues.

Keywords: computational quantum information theory, complexity constraints, complexity-bounded observers, computational resource theory

Quantum divergences can quantify how well quantum states are distinguishable from each other and therefore play a central role in, e.g., hypothesis testing [1, 2], quantum resource theories [3, 4], and quantum thermodynamics [5, 6]. Yet, as defined, they are agnostic to certain practical limitations. Quantum information processing is complexity-constrained in practice: as systems scale, transformations and measurements that are information-theoretically allowed become infeasible under realistic time and gate constraints [7–9]. Information-theoretic quantum divergences do not take these constraints into account and their operational meaning may therefore be lost in real-world settings.

To account for such computational limitations, several recent works, e.g. [10–16], have aimed at building a solid foundation for a computational quantum information theory. A main focus of these works lies in defining new computational entropies which incorporate computational constraints while retaining the operational meaning of the underlying information-theoretic quantity. This approach has been especially fruitful in cryptography, where there exist multiple valid, but inequivalent, computational quantum entropies from which pseudorandomness can be extracted; see e.g. [10–12].

Of particular interest is also the *complexity entropy* and underlying computational divergence termed *complexity relative entropy*, which were introduced in [13, 14]. The complexity relative entropy serves as the computational analogue to the hypothesis-testing relative entropy [17–21] and can therefore express the optimal rate of data compression and decoupling under computational constraints, where the latter only holds under an additional unproven assumption [14]. One additional benefit of this computational divergence is that it can also be used to quantify the optimal asymmetric hypothesis-

testing error exponent under computational constraints.

Nevertheless, even with all of this progress, computational quantum information theory still lags far behind its information-theoretic counterpart. In this work, we help lessen this gap by developing a principled, cohesive mathematical approach towards defining operational divergences under computational constraints. Specifically, we introduce two new types of computational divergences: the *computational max-divergence* and *computational measured Rényi divergences*. We expect these computational quantities to be similarly useful to their information-theoretic counterparts. To highlight this, we prove several key properties, including an equivalence relation between the two divergences that mirrors a known information-theoretic result, and consider two applications.

Our contributions

Our first contribution lies in the construction of a conic structure that incorporates computational constraints. Similar conical structures arise naturally in quantum information theory [22–24]. We extend this perspective to the computational setting, where one is restricted to efficient measurements. Informally summarized, we take the natural approach of saying that an effect operator $E \in \{E \mid 0 \leq E \leq \mathbb{1}\}$ which acts on n qudits is efficient if one can implement the corresponding binary POVM $M = \{E, \mathbb{1} - E\}$ with at most a polynomial number $p(n)$ of gates from a prior fixed gate set. For any n , we denote the set of all *polynomially generated set of effect operators* as $\mathbf{E}_n^{\text{eff}}$ and the set of all associated efficient binary POVMs as $\mathbf{M}_n^{\text{eff}} := \{M = \{E, \mathbb{1} - E\} \mid E \in \mathbf{E}_n^{\text{eff}}\}$. Moreover, we show that arbitrary convex combinations of such efficient effect operators admit a poly-time efficient approximation up to inverse-poly-accuracy (see also Cor. 3.11).

*alvaro.yanguez@lip6.fr

Figure 1: (a) Represents the family of cones that is induced by the set of efficiently generated quantum effect operators $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$. (b) A family of states $\{\rho_n\}_{n \in \mathbb{N}}$ with growing system size. (c) Measurement maps $\mathcal{M}_n^{\text{eff}}$ acting on ρ_n (e.g., $p = \text{Tr}[E \rho_n]$ for $E \in \mathbf{E}_n^{\text{eff}}$); distances and divergences are defined by optimizing over these maps.

Proposition (Polynomial Effect Approximation (Informal, Prop. 3.10)). *For any E in the convex envelope of $\mathbf{E}_n^{\text{eff}}$, there exist $\{E_1, \dots, E_k\} \in \mathbf{E}_n^{\text{eff}}$ and $k = \text{poly}(n)$ such that*

$$\left\| E - \frac{1}{k} \sum_{i=1}^k E_i \right\|_{\infty} \leq \frac{1}{\text{poly}(n)}.$$

We choose $\mathcal{C}_n^{\mathbf{E}_{\text{eff}}}$ to be the smallest convex cone that contains all these efficient operators $\mathbf{E}_n^{\text{eff}}$ (see Figure (a)). This cone induces a partial order “ $\leq_{\mathcal{C}_n^{\mathbf{E}_{\text{eff}}}}$ ” on the space of n -qudit states (see Figure (b)). Effectively, $\rho \leq_{\mathcal{C}_n^{\mathbf{E}_{\text{eff}}}} \sigma$ if, for every efficient binary measurement, $\mathcal{M}_M(\rho) \leq \mathcal{M}_M(\sigma)$, where

$$\begin{aligned} \mathcal{M}_M(\rho) &:= \sum_{i=0}^1 \text{Tr}[E^{i+1} \rho] |i\rangle\langle i| \\ &= \text{Tr}[E \rho] |0\rangle\langle 0| + \text{Tr}[(\mathbb{1} - E) \rho] |1\rangle\langle 1|. \end{aligned} \quad (1)$$

This computationally motivated partial order allows us to define our computational max-divergence.

New Divergences: Computational Max- and Measured Rényi Divergences

Definition (Computational Max-Divergence (Informal)). Given two positive semi-definite operators ρ, σ on n qudits, we define the *computational max-divergence* as

$$\hat{D}_{\max}(\rho \| \sigma) := \log \inf \{ \lambda \in \mathbb{R} \mid \rho \leq_{\mathcal{C}_n^{\mathbf{E}_{\text{eff}}}} \lambda \sigma \}. \quad (2)$$

This definition naturally mirrors and lower bounds its information-theoretic counterpart. As one relaxes the polynomial computational constraints (i.e. $p(n) \rightarrow \infty$ for all n), the computational max-divergence converges to the max-divergence:

$$\begin{aligned} \forall \rho, \sigma \geq 0 : \quad & \hat{D}_{\max}(\rho \| \sigma) \leq D_{\max}(\rho \| \sigma), \\ \lim_{p \rightarrow \infty} \hat{D}_{\max}(\rho \| \sigma) &= D_{\max}(\rho \| \sigma). \end{aligned}$$

The computational max-divergence can be related to a computational notion trace distance, $\hat{\Delta}$. In particular, it satisfies the following relations.

Lemma (Trace Distance Relations (Informal, Lem. 4.6 & Cor. 4.24)). *Given two quantum states ρ and σ on n qudits, it holds that*

$$\begin{aligned} \hat{D}_{\max}(\rho \| \sigma) &\geq \log \left(1 + \hat{\Delta}(\rho, \sigma) \right) \\ \hat{D}_{\max}(\rho \| \sigma) &\geq -\log \left(1 - \left(\hat{\Delta}(\rho, \sigma) \right)^2 \right). \end{aligned}$$

For $\hat{\Delta}(\rho, \sigma) \approx 0$, the first bound is tighter. Conversely, for $\hat{\Delta}(\rho, \sigma) \approx 1$, we find that the latter provides a substantially improved bound.

Moreover, the computational max-divergence is super-additive on tensor-powers of input states and we show that if the input states can be constructed efficiently, it is approximately sub-additive on those as well.

Lemma (Approximate Additivity (Informal, Lem. 4.3 & Lem. 4.4)). *Given two positive semi-definite operators $\rho = \rho_1 \otimes \rho_2$ and $\sigma = \sigma_1 \otimes \sigma_2$,*

$$\hat{D}_{\max}(\rho \| \sigma) \geq \hat{D}_{\max}(\rho_1 \| \sigma_1) + \hat{D}_{\max}(\rho_2 \| \sigma_2).$$

Furthermore, if ρ, σ are efficiently preparable quantum states, then it additionally holds that

$$\hat{D}_{\max}(\rho \| \sigma) \lesssim \hat{D}_{\max}(\rho_1 \| \sigma_1) + \hat{D}_{\max}(\rho_2 \| \sigma_2).$$

Definition (Computational Measured Rényi divergences (Informal)). Given two positive semi-definite operators ρ, σ on n qudits, we define the *computational measured Rényi divergence* for $\alpha \in (0, \infty)$ as

$$\hat{D}_{\alpha}^{\mathbf{M}_{\text{eff}}}(\rho \| \sigma) := \sup_{M \in \mathbf{M}_n^{\text{eff}}} D_{\alpha}(\mathcal{M}_M(\rho) \| \mathcal{M}_M(\sigma)),$$

where $D_\alpha(\rho\|\sigma)$ is the sandwiched Rényi divergence. For $\alpha = 1$, we omit the Rényi parameter.

As we show in Sec. 4.5, the gap between these computational divergences and their information-theoretic counterparts can be significant. Indeed, for $\alpha \in (0, \frac{1}{2})$, we show that the pseudoentanglement construction from [25] can generate quantum states for which

$$\mathring{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho, \sigma) \leq -\log(1 - \text{negl}(n)) ,$$

whereas the information-theoretic analogue scales as $\Theta(1)$. Moreover, the gap can be polynomially amplified via the approach of [25].

Following [24], the computational measured Rényi divergences satisfy various desirable properties, including data processing, joint (quasi-) convexity, and a computational Pinsker inequality (see Lem. 4.10 and Lem. 4.11). We additionally show, as one of our main results, that the max-divergence is equal to the computational measured Rényi divergence in the limit $\alpha \rightarrow \infty$.

Theorem (Max-Divergence Equivalence (Informal, Thm. 4.12)). *For any two positive semi-definite operators ρ, σ on n qudits,*

$$\mathring{D}_{\max}(\rho\|\sigma) = \lim_{\alpha \rightarrow \infty} \mathring{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma) .$$

This establishes a consistency between the conic and measured divergence formulations. Moreover, it mirrors the corresponding identity in the information-theoretic setting [26], which states there exists a binary measurement that leaves the max-divergence invariant.

Applications

Computational Hypothesis Testing

Our first application is a one-sided computational Stein's lemma, which upper bounds the hypothesis-testing error exponent. We note that this result was proven concurrently and independently in [27]. The following theorem relates the (regularized) computational measured relative entropy (i.e., $\alpha = 1$) to hypothesis testing, thus giving it an operational meaning.

Theorem (One-sided computational Stein's Lemma (Informal, Thm. 5.2)). *Let $\{\rho_k\}_{k \in \mathbb{N}}, \{\sigma_k\}_{k \in \mathbb{N}}$ be two families of quantum states. For any $0 < \varepsilon < 1$, the optimal type II error exponent $\xi^{\text{eff}}(\rho_k\|\sigma_k)$ for testing $H_0 : \sigma^{\otimes m(k)}$ against $H_1 : \rho^{\otimes m(k)}$, with $m(k) = \mathcal{O}(\text{poly}(k))$, using efficient measurements satisfies:*

$$\xi^{\text{eff}}(\rho_k\|\sigma_k) \leq \limsup_{k \rightarrow \infty} \frac{1}{m(k)} \mathring{D}_{k \cdot m(k)}^{\mathbf{M}_{k \cdot m(k)}^{\text{eff}}}(\rho_k^{\otimes m(k)}\|\sigma_k^{\otimes m(k)}) .$$

Computational Resource Theory

Our second application relates to a computational resource theory. Given an n -qudit state ρ and a set of n -qudit free states $\mathcal{F}_n$, one can naturally define the following computational measured relative entropy of resource:

$$\mathring{D}_{\mathcal{F}_n}(\rho) := \min_{\sigma \in \mathcal{F}_n} \mathring{D}_{\mathbf{M}_n}^{\text{eff}}(\rho\|\sigma) .$$

If the set of free states is closed, then this quantity satisfies both *faithfulness* and *monotonicity*; two properties which are crucial for resource monotones (see Lem. 5.6). We additionally show that this quantity satisfies an asymptotic continuity bound.

Theorem (Asymptotic continuity bound of the computational entropy of resource (Informal, Thm. 5.7)). *Let ρ, ρ' be ϵ -computationally indistinguishable, i.e. $\frac{1}{2}\|\rho - \rho'\|_{\mathbf{M}_n^{\text{eff}}} \leq \varepsilon$, then*

$$\begin{aligned} |\mathring{D}_{\mathcal{F}_n}(\rho) - \mathring{D}_{\mathcal{F}_n}(\rho')| &\leq (1 + \varepsilon)h\left(\frac{\varepsilon}{1 + \varepsilon}\right) \\ &\quad + \varepsilon\left(\kappa + \log\left(\frac{2}{\varepsilon}\right)\right) , \end{aligned}$$

where $h(\cdot)$ is the binary entropy and $\kappa := -\log(\lambda_{\min}(\sigma^*))$ is determined by the smallest eigenvalue of a full-rank state $\sigma^* \in \mathcal{F}_n$ in the set of free states $\mathcal{F}_n$.

This result can be viewed as a special case of [28, Corollary 14]; however, our work contains a novel and self-contained proof. Furthermore, the continuity bound is a computational analogue of [29, 30], and it can be used to show *computational faithfulness*: two computationally indistinguishable families of states have negligibly different computational measured relative entropies of resource. Lastly, we focus on the resource of entanglement ($\mathcal{F}_n = \text{SEP}_n$), showing that our computational entanglement measure is comparable with previously defined notions from [15]. The following results naturally mirror the information-theoretic hierarchy of entanglement monotones and extend them to the computational setting.

Lemma (Informal, Lem 5.15). *Given that the maximally entangled state is efficiently preparable, for any family of bipartite states $\{\rho_{AB}^n\}_{n \in \mathbb{N}}$, it follows that*

$$\begin{aligned} \hat{E}_D^\varepsilon(\rho_{AB}^n) - g(\sqrt{\varepsilon(n)}, n) &\leq \mathring{D}_{\text{SEP}_n}(\rho_{AB}^n) \\ &\leq \hat{E}_C^\varepsilon(\rho_{AB}^n) + g(\sqrt{\varepsilon(n)}, n) , \end{aligned}$$

where $\hat{E}_D^\varepsilon(\rho_{AB}^n)$ and $\hat{E}_C^\varepsilon(\rho_{AB}^n)$ are, respectively, the computational distillable entanglement and the computational entanglement cost of [15], and $g(\delta, n) = \mathcal{O}(\delta(n - \log \delta))$.

Up to a continuity term, this newly defined entanglement monotone is thus sandwiched between the computational distillable entanglement and the computational entanglement cost.

Abstract

Quantum information processing is limited, in practice, to efficiently implementable operations. This motivates the study of quantum divergences that preserve their operational meaning while faithfully capturing these computational constraints. Using geometric, computational, and information theoretic tools, we define two new types of computational divergences, which we term *computational max-divergence* and *computational measured Rényi divergences*. Both are constrained by a family of efficient binary measurements, and thus useful for state discrimination tasks in the computational setting. We prove that, in the infinite-order limit, the computational measured Rényi divergence coincides with the computational max-divergence, mirroring the corresponding relation in the unconstrained information-theoretic setting. For the many-copy regime, we introduce regularized versions and establish a one-sided computational Stein bound on achievable hypothesis-testing exponents under efficient measurements, giving the regularized computational measured relative entropy an operational meaning. We further define resource measures induced by our computational divergences and prove an asymptotic continuity bound for the computational measured relative entropy of resource. Focusing on entanglement, we relate our results to previously proposed computational entanglement measures and provide explicit separations from the information-theoretic setting. Together, these results provide a principled, cohesive approach towards state discrimination tasks and resource quantification under computational constraints.

1 Introduction

The success of quantum information theory lies, in part, in its ability to reduce the study of a wide range of processes, e.g., hypothesis testing [ON00, ACMT⁺07], resource theories [BaG15, CG19], quantum thermodynamics [BHN⁺15, ECP10, CRF21], and quantum cryptography [Ren05, DW05, Wol21, VW23], to robust primitive measures such as quantum divergences and entropies. Yet, as currently defined, these measures are agnostic to certain practical limitations. Quantum information processing is complexity-constrained in practice: as systems scale, transformations and measurements that are information-theoretically allowed sometimes become infeasible under realistic time and gate constraints. A simple counting argument shows that almost all states — and likewise most measurements — require exponential-size circuits to be implemented [Kni95, Aar16, JW23]. Under such efficiency constraints, a stark gap emerges between information-theoretic and feasible operations, obscuring the direct operational meaning of standard divergences and entropies in real-world settings.

This gap has led to a rich study of quantum states and transformations under computational constraints [ABF⁺23, ABV23, GE24, LREJ25, HBK24, BMB⁺24, GY25, MKH⁺25], showing that highly nonclassical states can be *indistinguishable* from simpler ones by any polynomial-time measurement. Similarly, many useful information-theoretic tools can often no longer be applied as they require inefficient operations.¹ This includes, e.g., Uhlmann’s theorem [Uhl76, BEM⁺23, MY23, BMY25], optimal data compression rates [BEM⁺23, Yao82, HMS23], and optimal quantum error correction rates [IP13, VAW⁺19, DKLP02, Ber09, McE78].

The latter two examples highlight the need for studying computationally efficient quantum information protocols. Closely related to quantum error correction, the works [ABV23, LREJ25] consider efficient quantum entanglement distillation.² In particular, [LREJ25] provides an efficient distillation protocol that can distill entanglement at a non-zero rate from a specific class of states. Similarly, [YHKH⁺22, MKH⁺25] considers efficient data compression (amongst other tasks), and manages to relate them to a new complexity relative entropy, which we discuss further below.

Efforts have been made to build a solid foundation for a *computational quantum information theory*, which can accommodate for these practical constraints. Of particular interest are computational entropies, which capture how random data is perceived to be for a computationally bounded observer. In [CCL⁺17, AA25, AHRA25], the authors define new computational quantum entropies which incorporate computational constraints while retaining the operational meaning of the underlying information-theoretic quantities, with a particular focus on cryptography.

Particularly relevant to our setting is the complexity entropy introduced in [YHKH⁺22], and its underlying computational divergence, termed the complexity relative entropy [MKH⁺25]. This latter quantity is the computational analogue to the hypothesis-testing relative entropy.

With this connection in mind, the authors of that work further show how one can relate these quantities to the optimal rates for efficient data compression, and decoupling.³ Moreover, it can be

¹This is assuming certain computational hardness assumptions [Kre21, KQST23].

²The work [ABV23, LREJ25] also considers the closely related concept of computational entanglement cost.

³For the latter, they consider a restricted kind of decoupling which traces out part of the system and relies on a conjectured chain rule.

Figure 1: (a) Represents the family of cones that is induced by the set of efficiently generated quantum effect operators $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$. (b) A family of states $\{\rho_n\}_{n \in \mathbb{N}}$ with growing system size. (c) Measurement maps $\mathcal{M}_n^{\text{eff}}$ acting on ρ_n (e.g., $p = \text{Tr}[E \rho_n]$ for $E \in \mathbf{E}_n^{\text{eff}}$); distances and divergences are defined by optimizing over these maps.

used to express the optimal error coefficient for quantum hypothesis testing under computational constraints.

Nevertheless, even with all of this progress, computational quantum information theory still lags far behind its information-theoretic counterpart. In this work, we help lessen this gap by developing a principled, cohesive mathematical approach towards defining operational divergences under computational constraints. Specifically, we introduce two new types of computational divergences: the *computational max-divergence* and *computational measured Rényi divergences*. We impose a practical restriction — access only to efficient binary measurements, the basic primitive for state discrimination — and incorporate it directly into the standard max-divergence and measured Rényi definitions.

For measured Rényi divergences, this is relatively straightforward. Informally speaking, given two quantum states, ρ and σ , and any Rényi divergence⁴ D_α , we aim to find the efficient (binary) measurement $\mathcal{M}$ that maximizes the quantity $D_\alpha(\mathcal{M}(\rho), \mathcal{M}(\sigma))$. If one views Rényi divergences as a kind of distinguishing measure [Tom16, HP91, ON00], this quantity essentially describes the optimal distinguishing power achievable via access only to efficient binary measurements.

To incorporate these constraints into the max-divergence, we adopt the geometric approach from [RKW11, GC24]. Concretely, we replace the standard Löwner order “ $\leq$ ” on positive semidefinite operators with a computationally motivated partial order “ $\leq_{\mathcal{C}_n^{\text{eff}}}$ ”. This partial order is induced by a cone generated via a set of efficiently implementable *effect operators*⁵ (each corresponding to a two-outcome POVM $(E, \mathbb{1} - E)$); see Figure 1. In other words, it turns out that $\rho \leq_{\mathcal{C}_n^{\text{eff}}} \sigma$ if $\mathcal{M}(\rho) \leq \mathcal{M}(\sigma)$ for every efficient measurement. We then use this computational partial order to define a computational max-divergence, analogous to the information-theoretic case. Naturally, $\rho \leq \sigma$

⁴Since the measurement outcomes are classical, all quantum extensions of the classical Rényi divergence collapse to the same expression.

⁵We refer to an *effect operator* as an element $E \in \mathcal{B}(\mathcal{H})$ that satisfies $0 \leq E \leq \mathbb{1}$.

implies $\rho \leq_{C_n^{\text{eff}}} \sigma$. However, the converse is not generally true. In such cases where the converse does not hold, one should view the computational partial order as stating that even though $\sigma - \rho$ is not positive semidefinite, it appears to be when restricted to efficient binary measurements.

In addition to defining these computational divergences, our main contributions are as follows. We first show that the computational max-divergence is equal to the $\alpha = \infty$ computational measured Rényi divergence in Theorem 4.12. This establishes a consistency between the conic and measured divergence formulations, and mirrors the corresponding identity in the information-theoretic (unconstrained) setting which states there exists a binary measurement that leaves the max-divergence invariant [MH23, Eq. III.65]. It also demonstrates the usefulness of conic theory to computational quantum information. We further link these quantities to computational analogs of the *trace distance* and *fidelity*, which are related by a computational Fuchs–van de Graaf inequality, Lemma 4.22, and derive a computational Pinsker inequality, Lemma 4.11. These bounds allow us to show an explicit example in which our computational measures differ from their information-theoretic counterparts: by using the pseudoentanglement construction of [GE24], we instantiate families of states whose computational fidelity and measured Rényi divergences for $\alpha \in (0, 1/2)$ are negligible while their information-theoretic counterparts remain $\Theta(1)$, establishing a concrete separation.

We also demonstrate the reach of our approach through two applications. First, in the poly-copy efficient-measurement regime, we prove a computational Stein’s lemma which upper-bounds the asymmetric hypothesis-testing error exponent that is achievable via efficient binary measurements by the regularized computationally measured relative entropy (i.e. the $\alpha = 1$ regularized computational measured Rényi divergence), see Theorem 5.2. This gives the latter an operational interpretation and relates this regularized quantity to the complexity relative entropy within the context of hypothesis testing. Second, we define computationally-constrained resource measures induced by our divergences and establish in Theorem 5.7 an asymptotic continuity bound for the computational measured relative entropy. This inequality allows one to essentially bound the change in the computational measured relative entropy that occurs when replacing a given state ρ with ρ' in terms of their corresponding computational trace distance. This bound implies *computational faithfulness* of our quantities: if two families of states are computationally indistinguishable, then the gap in their computational measured relative entropy of resource is negligible. Lastly, in the entanglement setting, we (i) exhibit an explicit separation—there exists a family of states for which the *computational measured relative entropy of entanglement* is negligible in n while its information-theoretic counterpart is maximal—and (ii) show that, under efficient LOCC operations, this computational measure approximately lies between the computational entanglement cost and the computational distillable entanglement of [ABV23], thereby mirroring the information-theoretic hierarchy in the computational setting.

Relation to prior and concurrent work. Our work sits at the intersection between measured Rényi divergences which consider restricted sets of measurements and complexity-aware information theory. With regard to the first point, [RSB24, MH23] derive many properties for measured Rényi divergences. In particular, [RSB24] introduces *locally-measured Rényi divergences*, and optimizes classical Rényi divergences over locality-constrained POVMs. They additionally derive vari-

ational formulae that are directly related to the conic formulations which appear when defining max-divergences in a conic framework, and calculate Stein/strong-converse exponents for symmetric data-hiding families. We essentially replace the locality constraints on the measurements with *efficiency* constraints. So while the measurements that are considered differ, many operational implications remain the same. Similarly, [BaHLP14] prove a quantum Stein’s lemma for several classes of *restricted* measurements via an adversarial reduction; our “computational Stein’s lemma” is a converse bound in the poly-copy, efficient-measurement regime and incorporates complexity constraints rather than locality/separability constraints.

For the computational max-divergence, our cone-geometric approach is inspired by [RKW11, GC24, RSB24]. Here, they incorporate locality (or other entanglement-related constraints) restrictions on the measurements or states directly into the underlying conic structure. Similar to our approach for the computational measured Rényi divergences, we apply this framework to the computational setting.

As mentioned above, our computational divergences are close in spirit to the complexity entropy and complexity relative entropy introduced in [YHKH⁺22, MKH⁺25]. Both our work and theirs consider efficient binary measurements and both can be related to efficient hypothesis testing, which is one of the applications we consider in this work. The main difference of course is that while they wanted to define a computational hypothesis-testing relative entropy, our goal is to define computational versions of the max-divergence and measured Rényi divergences, whose information-theoretic (unrestricted) counterparts have proven to be instrumental and found a plethora of applications in information theory [Tom16, RSB24]. We expect this to extend to the computational setting as well.

Since we study a slightly different setting, it is not immediately clear if and how our computational max-divergence can be related to the quantum computational entropies defined in [CCL⁺17, AA25, AHRA25]. In particular, a direct comparison to the quantum unpredictability entropy [AA25] and computational min-entropy [AHRA25] is hard to make. They require multi-output measurements that are constrained to act solely on quantum registers to which an adversary has access to, whereas we consider binary measurements that can act on the entire state. Nevertheless, we believe it should be possible to slightly extend or adapt our definitions to incorporate these measurement constraints.

Note: During the preparation of this manuscript, we became aware of the concurrent work [MRR⁺25] by Meyer et al. While there are some overlaps and they also consider computationally restricted hypothesis testing, many of their results complement ours and vice versa.

Structure of the paper. In Section 2, we review preliminary material on quantum information theory and conic geometry. In Section 3, we construct our sets of efficient measurements (Section 3.1) and the associated cones of efficient operators used to define the computational max-divergence (Section 3.2). We also provide definitions for the complexity-constrained trace norm and trace distance, and show how these typical notions from quantum cryptography can be related to our formalism (Section 3.3). In Section 4 we introduce the computational quantum divergences: first the computational max-divergence (Section 4.1), then the computational measured Rényi divergences (Section 4.2), showing that they coincide with the former in the limit $\alpha \rightarrow \infty$. This yields a notion of

computational fidelity (Section 4.4); combined with computational Fuchs–van de Graaf–type bounds, it leads to an explicit cryptographic separation between the computational divergences and their information-theoretic counterparts (Section 4.5). In Section 5 we present applications. We show that the Stein exponent is upper bounded by the regularized computational measured relative entropy, giving it an operational interpretation (Section 5.1). We then develop computational quantum resource measures (Section 5.2) and establish an asymptotic continuity bound for the computational measured relative entropy of a resource. Finally, focusing specifically on entanglement (Section 5.3), we introduce the computational measured relative entropy of entanglement and relate it to previously defined computational entanglement measures.

2 Preliminaries

2.1 Notation

In this work we assume all Hilbert spaces to be finite dimensional. Hilbert spaces will be denoted by $\mathcal{H}$. Given a Hilbert space $\mathcal{H}$, we denote the set of positive semidefinite operators acting on $\mathcal{H}$ by $\text{Pos}(\mathcal{H})$. An operator $\rho \in \text{Pos}(\mathcal{H})$ is called a *quantum state* if we have $\text{Tr}[\rho] = 1$. The set of quantum states on $\mathcal{H}$ is denoted by $\mathcal{S}(\mathcal{H})$. The set of bounded operators on $\mathcal{H}$ is given by $\mathcal{B}(\mathcal{H})$ and the corresponding (sub)set of Hermitian operators is denoted by $\mathcal{B}^\dagger(\mathcal{H})$. The Hilbert-Schmidt inner product on $\mathcal{B}(\mathcal{H})$ is given by $\langle a, b \rangle := \text{Tr}[a^*b]$, where $*$ denotes the Hilbert-Schmidt adjoint. We will also denote the adjoint of a quantum channel $\Phi : \mathcal{B}(\mathcal{H}_1) \rightarrow \mathcal{B}(\mathcal{H}_2)$ by $\Phi^* : \mathcal{B}(\mathcal{H}_2) \rightarrow \mathcal{B}(\mathcal{H}_1)$. For two operators $\rho, \sigma \in \text{Pos}(\mathcal{H})$ we write $\rho \ll \sigma$ if $\ker \sigma \subseteq \ker \rho$, where $\ker \tau := \{|v\rangle : \tau|v\rangle = 0\}$. Further, we say the state ρ is orthogonal to the state σ , denoted by $\rho \perp \sigma$, if $\text{Tr}[\rho\sigma] = 0$.

In Landau notation, given two functions $f(n)$ and $g(n)$, we write $f(n) = o(g(n))$ if $\lim_{n \rightarrow \infty} f(n)/g(n) = 0$. In the same way, $f(n) = \omega(g(n))$ if $\lim_{n \rightarrow \infty} f(n)/g(n) = \infty$. $f(n) = O(g(n))$ if there exists a constant $C > 0$ such that $\lim_{n \rightarrow \infty} f(n)/g(n) \leq C$. Similarly, $f(n) = \Omega(g(n))$ if there exists a constant $C > 0$ such that $\lim_{n \rightarrow \infty} f(n)/g(n) \geq C$. Lastly, $f(n) = \Theta(g(n))$ if both $f(n) = O(g(n))$ and $f(n) = \Omega(g(n))$. A function $f(n)$ is $\text{negl}(n)$, i.e., negligible, if, for every fixed c , $f(n) = o(1/n^c)$.

With $\log$ we denote the logarithm to base 2 and with $\ln$ the logarithm to base e .

2.2 Information-Theoretic Concepts

Definition 2.1 (Sandwiched Rényi Divergence [MLDS⁺13, WWY14]). Given any two positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H})$ with $\text{Tr}[\rho] > 0$, and $\alpha \in (0, 1) \cup (1, \infty)$, the *sandwiched Rényi divergence* between ρ, σ is given by:

$$D_\alpha(\rho \parallel \sigma) := \begin{cases} \frac{1}{\alpha-1} \log \frac{\left\| \sigma^{\frac{1-\alpha}{2\alpha}} \rho \sigma^{\frac{1-\alpha}{2\alpha}} \right\|_\alpha^\alpha}{\text{Tr}[\rho]} & \text{if } (\alpha < 1 \wedge \rho \not\ll \sigma) \vee \rho \ll \sigma \\ +\infty & \text{else} \end{cases} \quad (2.1)$$

In this work, the divergence of interest is the sandwiched Rényi divergence. For $\alpha \geq \frac{1}{2}$, it

satisfies the data-processing inequality (DPI) and, for $0 \leq \alpha \leq \beta$, it is monotonic in α , i.e. $D_\alpha(\rho\|\sigma) \leq D_\beta(\rho\|\sigma)$. Moreover, we use Q_α to denote

$$Q_\alpha := \left\| \sigma^{\frac{1-\alpha}{2\alpha}} \rho \sigma^{\frac{1-\alpha}{2\alpha}} \right\|_\alpha^\alpha. \quad (2.2)$$

Definition 2.2 (Relative Entropy & Max-divergence [Dat09b]). Given any two positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H})$ with $\text{Tr}[\rho] > 0$ and $\rho \ll \sigma$, the (Umegaki) *relative entropy* and *max-divergence* between ρ, σ are, respectively, given by:

$$D(\rho\|\sigma) := \frac{\text{Tr}[\rho(\log \rho - \log \sigma)]}{\text{Tr}[\rho]}, \quad (2.3)$$

$$D_{\max}(\rho\|\sigma) := \log \inf\{\lambda \in \mathbb{R} \mid \rho \leq \lambda \sigma\}. \quad (2.4)$$

Definition 2.3 (Fidelity). Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H})$, the *fidelity* between ρ, σ is given by:

$$F(\rho, \sigma) := \|\sqrt{\rho}\sqrt{\sigma}\|_1^2. \quad (2.5)$$

We are particularly interested in the sandwiched Rényi divergences for $\alpha \in \{\frac{1}{2}, 1, \infty\}$. These three cases are of particular use and one retrieves that

$$\begin{aligned} \lim_{\alpha \rightarrow 1} D_\alpha(\rho\|\sigma) &= D(\rho\|\sigma), \\ \lim_{\alpha \nearrow \infty} D_\alpha(\rho\|\sigma) &= D_{\max}(\rho\|\sigma), \\ D_{\frac{1}{2}}(\rho\|\sigma) &= -\log F(\rho, \sigma). \end{aligned}$$

A closely related divergence is the measured Rényi divergence. To properly define them, we require POVM operators which are defined as follows.

Definition 2.4 (POVM). A *positive operator-valued measure* (POVM) is given by a tuple of positive semidefinite operators $M = (E_1, \dots, E_m)$ (for some $m \in \mathbb{N}$) such that $\sum_{k=1}^m E_k = \mathbf{1}$. Moreover, if $E_i E_j = \delta_{ij} E_i$ for all $i, j \in \{1, \dots, m\}$, we call this a *projection-valued measure* (PVM). The operators E_i of a POVM are called *effect operators* or *POVM elements*.

Equally one can associate to any m -outcome POVM $M = (E_1, \dots, E_m)$ a channel that maps quantum states to classical distributions over $\{0, \dots, m-1\}$, via

$$\mathcal{M}_M : \rho \mapsto \sum_{i=0}^{m-1} \text{Tr}[\rho E_{i+1}] |i\rangle\langle i|. \quad (2.6)$$

We will sometimes drop the subscript M , when the POVM to which this measurement map corresponds is clear from context.

Definition 2.5 (Measured Divergence). Let $\mathbf{M}$ be a set of POVMs. Given any two positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H})$ with $\text{Tr}[\rho] > 0$, for any divergence $\mathbb{D}$, the corresponding *measured*

divergence between ρ, σ is given by:

$$\mathbb{D}^{\mathbf{M}}(\rho\|\sigma) = \sup_{M \in \mathbf{M}} \mathbb{D}(\mathcal{M}_M(\rho)\|\mathcal{M}_M(\sigma)). \quad (2.7)$$

We note that the RHS of Eq. (2.7) is evaluated on classical states. If $\mathbb{D} = D_\alpha$, then we call $D_\alpha^{\mathbf{M}}(\rho\|\sigma)$ a *measured Rényi divergence*, and the RHS reduces to the classical Rényi divergence. As such, it is not strictly necessary to consider the sandwiched Rényi divergence; the Petz-Rényi divergence, see [Tom16] for a formal definition, would, e.g., also yield the same definition. Nevertheless, it seems somewhat natural to consider the sandwiched Rényi divergence for the following reason. For any $\alpha \geq \frac{1}{2}$ and $\rho, \sigma \in \text{Pos}(\mathcal{H})$, if $\mathbf{M}_n = \mathbf{M}_{n, \text{ALL}}$, where $\mathbf{M}_{n, \text{ALL}}$ denotes the set of all POVMs that can act on $\rho^{\otimes n}$ (or $\sigma^{\otimes n}$), then (see, e.g., [MO14])

$$D_\alpha(\rho\|\sigma) = \lim_{n \rightarrow \infty} \frac{1}{n} D_\alpha^{\mathbf{M}_n}(\rho^{\otimes n}\|\sigma^{\otimes n}).$$

This naturally leads to the question of how one generally defines the regularization of measured divergences.

Definition 2.6 (Regularized Measured Divergence [RSB24, MH23]). Let $\widetilde{\mathbf{M}} = (\mathbf{M}_1, \mathbf{M}_2, \dots)$ be a family of POVM sets. Given any two positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H})$ with $\text{Tr}[\rho] > 0$, for any divergence $\mathbb{D}$, the corresponding *regularized measured divergence* between ρ, σ is given by:

$$\mathbb{D}^{\widetilde{\mathbf{M}}, \infty}(\rho\|\sigma) := \limsup_{n \rightarrow \infty} \frac{1}{n} \mathbb{D}^{\mathbf{M}_n}(\rho^{\otimes n}\|\sigma^{\otimes n}). \quad (2.8)$$

If the corresponding measured divergence satisfies super-additivity, i.e.,

$$\mathbb{D}^{\mathbf{M}_{k+l}}(\rho^{\otimes k+l}\|\sigma^{\otimes k+l}) \geq \mathbb{D}^{\mathbf{M}_k}(\rho^{\otimes k}\|\sigma^{\otimes k}) + \mathbb{D}^{\mathbf{M}_l}(\rho^{\otimes l}\|\sigma^{\otimes l})$$

for any $k, l \in \mathbb{N}$, then it follows from, e.g. [RSB24, Lemma 4], that

$$\mathbb{D}^{\widetilde{\mathbf{M}}, \infty}(\rho\|\sigma) = \lim_{n \rightarrow \infty} \frac{1}{n} \mathbb{D}^{\mathbf{M}_n}(\rho^{\otimes n}\|\sigma^{\otimes n}) = \sup_{n \rightarrow \infty} \frac{1}{n} \mathbb{D}^{\mathbf{M}_n}(\rho^{\otimes n}\|\sigma^{\otimes n}).$$

In this work we are primarily interested in 2-output POVMs or measurements. These are sometimes called *test-measured divergences*, see e.g. [MH23]. Moreover, while we provide general definitions for quantum divergences, we almost exclusively consider divergences between two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H})$.

2.3 Theoretic Background on Cones

In this section we summarize some basic notions and results related to cones [Bus73a, Bus73b, Eve95, RKW11, GC24].

Definition 2.7 (Convex Cone). Let $\mathcal{V}$ be a finite-dimensional real vector space with inner product

$\langle \cdot, \cdot \rangle$. A *convex cone* $\mathcal{C} \subset \mathcal{V}$ is a subset s.t.

$$a, b \in \mathcal{C} \implies \lambda a + \mu b \in \mathcal{C} \quad \forall \lambda, \mu \geq 0.$$

Moreover, for any $K \subset \mathcal{V}$, we denote by $\text{cone}(K) := \text{conv}(\bigcup_{\lambda \geq 0} \lambda K)$ the smallest (convex) cone that contains K .

A cone is called *closed* if it is closed with respect to the norm topology induced by the inner product of $\mathcal{V}$, and, as a consequence, includes its boundary. Following the notation of [RKW11] we further call a cone *pointed* if $\mathcal{C} \cap (-\mathcal{C}) = \{0\}$, where the elements of $-\mathcal{C}$ are given by

$$a \in -\mathcal{C} :\iff -a \in \mathcal{C}.$$

Similarly, a cone is *solid* if $\text{span}(\mathcal{C}) = \mathcal{V}$. In finite-dimensional $\mathcal{V}$ this is equivalent to $\mathcal{C}$ having a non-empty interior $\text{int}(\mathcal{C}) \neq \emptyset$.

Definition 2.8 (Proper Cone). A convex, closed, pointed, and solid cone is called a *proper cone*.

Definition 2.9 (Cone Base). Given some convex cone $\mathcal{C}$, a convex set B is called a *base of the cone* $\mathcal{C}$ if $\mathcal{C} = \bigcup_{\lambda \geq 0} \lambda B$ and if every $c \in \mathcal{C} \setminus \{0\}$ has a unique representation $c = \lambda b$ for some $b \in B, \lambda > 0$. If $\mathcal{C}$ is in addition closed and with non-empty interior, then B is the *base of a proper cone*.

One can also assign to each cone a dual cone.

Definition 2.10 (Dual Cone). Given a cone $\mathcal{C}$, its *dual cone* $\mathcal{C}^*$ is given by

$$\mathcal{C}^* := \{x \in \mathcal{V}^* \mid \langle x, c \rangle \geq 0, \forall c \in \mathcal{C}\}.$$

One natural consequence of this definition is that if $\mathcal{C}_1 \subset \mathcal{C}_2$, then $\mathcal{C}_2^* \subset \mathcal{C}_1^*$. We additionally note that the dual cone is also closed and convex. Moreover, if $\mathcal{C}$ is a proper cone, then so is $\mathcal{C}^*$. Lastly, in finite-dimensional vector spaces, closed convex cones are their own bi-dual cones, meaning that the corresponding dual cone is also its pre-dual cone, i.e. $(\mathcal{C}^*)^* = \mathcal{C}$. Given a real vector space $\mathcal{V}$ and a proper cone $\mathcal{C} \subset \mathcal{V}$, one can define a natural partial order on $\mathcal{V}$.

Definition 2.11 (Partial Order). Let $\mathcal{V}$ be a finite-dimensional real vector space and $\mathcal{C} \subset \mathcal{V}$ be a proper cone. We say that $a \geq_{\mathcal{C}} b$ if and only if $a - b \in \mathcal{C}$.

In the following, we will take $\mathcal{V}$ to be a vector space of Hermitian matrices $\mathcal{B}^\dagger(\mathcal{H})$, over some Hilbert space $\mathcal{H}$. This vector space is isomorphic to $\mathbb{R}^{d^2}$, where $d = \dim(\mathcal{H})$. Over the space of Hermitian matrices, one of the most common examples of (proper) cones in quantum information theory is the cone of *positive semidefinite* operators in $\mathcal{B}^\dagger(\mathcal{H})$, i.e.

$$\text{Pos}(\mathcal{H}) := \{a \in \mathcal{B}^\dagger(\mathcal{H}) \mid a \geq 0\}. \quad (2.9)$$

Notably, this cone is self-dual in $\mathcal{V}$ and we denote its induced (positive operator) partial order simply by $\geq$. This particular partial order is relevant for the definition of the max-divergence [Dat09b,

[RKW11](#)], which satisfies

$$\begin{aligned} D_{\max}(a||b) &= \log \inf\{\lambda \in \mathbb{R} | a \leq \lambda b\} \\ &= \log \sup_{v \in \text{Pos}(\mathcal{H})} \frac{\langle v, a \rangle}{\langle v, b \rangle} . \end{aligned}$$

Remark 2.12. *Note that in the above optimization one should interpret the v as being an effect operator living in the (pre-)dual of cone of $\text{Pos}(\mathcal{H})$, in which a, b live, rather than that cone itself. However, since $\text{Pos}(\mathcal{H})$ is self-dual with respect to the Hilbert-Schmidt inner product these cones are the same. This differentiation will become important for arbitrary cones in Definition 2.13.*

If one considers other proper cones inside of $\mathcal{B}^+(\mathcal{H})$, then one can use this relation between the max-divergence and the conic structure of $\text{Pos}(\mathcal{H})$ to derive a more general notion of max-divergences.

Definition 2.13 ($\mathcal{C}$ -Max-divergence [[RKW11](#), [GC24](#)]). Let $\mathcal{C}$ be a proper cone. For any $a, b \in \mathcal{C} \setminus \{0\}$, the $\mathcal{C}$ -max-divergence between a, b is given by

$$D_{\max}^{\mathcal{C}}(a||b) := \log \inf\{\lambda \in \mathbb{R} | a \leq_{\mathcal{C}} \lambda b\} . \quad (2.10)$$

If no $\lambda \in \mathbb{R}$ exists such that $\lambda b - a \in \mathcal{C}$, i.e. the infimum is over an empty set, then we set $D_{\max}^{\mathcal{C}}(a||b) = \infty$.

We note that sometimes the notation $\sup(a/b)$ is used instead of $\exp(D_{\max}(a||b))$, see e.g. [[RKW11](#)]. Moreover, there exists a dual formulation of the $\mathcal{C}$ -max-divergence.

Lemma 2.14 (Dual Expression [[RKW11](#), [GC24](#)]). *Let $\mathcal{C}$ be a proper cone. Then*

$$D_{\max}^{\mathcal{C}}(a||b) := \log \inf\{\lambda \in \mathbb{R} | a \leq_{\mathcal{C}} \lambda b\} = \log \sup_{v \in \mathcal{C}^*} \frac{\langle v, a \rangle}{\langle v, b \rangle} . \quad (2.11)$$

With these quantities, one can also additionally define a *Hilbert's projective metric* [[Bus73a](#), [Eve95](#)] on a proper cone $\mathcal{C}$ as $d_{\text{H}}^{\mathcal{C}}(a, b) := D_{\max}^{\mathcal{C}}(a||b) + D_{\max}^{\mathcal{C}}(b||a)$. For the applications we are considering in this work, it will be natural to consider the following setup. Let $\mathbb{M} \subset \mathcal{V}^*$ be a closed, convex, and pointed set with a non-empty interior in the dual space, which contains an element $e \in \mathbb{M}$ such that

$$E \in \mathbb{M} \implies e - E \in \mathbb{M} \quad \forall E \in \mathbb{M} . \quad (2.12)$$

In particular, this ensures that $\mathbb{M}$ generates a proper cone $\mathcal{C}_{\mathbb{M}}^*$.

Definition 2.15 (Distinguishability Norm). Let $\mathbb{M} \subset \mathcal{V}^*$ be a closed, convex, and pointed set with a non-empty interior. Moreover let $\mathbb{M}$ contain an element $e \in \mathbb{M}$ for which Eq. (2.12) holds. For any

element $v \in \mathcal{V}$, we denote the *distinguishability norm* of v by

$$\|v\|_{(\mathbb{M})} := \sup_{E \in \mathbb{M}} \langle 2E - e, v \rangle . \quad (2.13)$$

In particular, it is known that the distinguishability norm defines a norm on $\mathcal{V}$ [RKW11].

Remark 2.16. *In quantum information theory, this norm is simply the trace norm. Here, one chooses $\mathbb{M}$ to be the set of all effect operators, i.e., $E \in \mathbb{M}$ if and only if $0 \leq E \leq \mathbb{1}$. The operational interpretation of the trace norm is given by the task of distinguishing two equiprobable quantum states ρ and σ . In this case, one chooses $v = \rho - \sigma$ and $e = \mathbb{1}$, retrieving*

$$\begin{aligned} \|\rho - \sigma\|_{(\mathbb{M})} &= 2 \sup_{E \in \mathbb{M}} \text{Tr}[E(\rho - \sigma)] - \text{Tr}[\rho - \sigma] \\ &= 2 \sup_{E \in \mathbb{M}} \text{Tr}[E(\rho - \sigma)] \\ &= \|\rho - \sigma\|_1 . \end{aligned}$$

If one additionally chooses $\mathbb{M}$ to be a subset of all effect operators, then $\mathbb{M}$ can be related to a set of binary (POVM) measurements. The corresponding *minimal error probability* for discriminating between two equiprobable states ρ and σ is given by

$$\mathcal{P}_{err}^{\mathbb{M}}(\rho, \sigma) = \frac{1}{2} - \sup_{E \in \mathbb{M}} \frac{1}{2} |\text{Tr}[(\rho - \sigma)E]| = \frac{1}{2} - \frac{1}{4} \|\rho - \sigma\|_{\mathbb{M}} . \quad (2.14)$$

3 Cone of Efficient Binary Measurements

We first study in Section 3.1 the consequences of complexity constraints for quantum measurements, defining sets of efficient two-output measurements. We then show in Section 3.2 that one can naturally associate to these sets a proper cone inside of $\mathcal{B}^+(\mathcal{H})$; this is our main contribution for this section. As we then discuss in Section 4, this allows us to define a computational max-divergence via Definition 2.13. Moreover, we also discuss relations between our sets of efficient measurements and corresponding notions of a *computational trace norm* and *computational trace distance* in Section 3.3, and relate this connection to cryptographic constructions.

3.1 Complexity-Constrained POVMs

When we consider (generic) two-output measurements, we refer to POVMs $M = (E_1, E_2)$. It is known that any two-output POVM on $\mathcal{H}$ is implemented by appending ancillas to the quantum system, applying a quantum circuit on the entire system, applying a projective measurement on a *single* qubit in the computational basis, and tracing out the remaining subsystems. The formal way to express one specific implementation of M is typically via Naimark's dilation theorem, see e.g. [Hol11, Theorem 2.5.1], which we include below for completeness and holds for arbitrary m -outcome POVMs.

Theorem 3.1 (Naimark’s Dilation Theorem in Finite Dimensions). *Any POVM $M = (E_i)_{i=1}^m$ on $\mathcal{H}$ can be implemented via an isometry and a projective measurement on ancilla systems. In particular, there exists an isometry $V : \mathcal{B}^\dagger(\mathcal{H}) \rightarrow \mathcal{B}^\dagger(\mathcal{H} \otimes \mathcal{H}_K)$, where $\mathcal{H}_K$ denotes a Hilbert space of dimension m , such that*

$$E_k = V^* \left(\mathbb{1}_{\mathcal{H}} \otimes |k\rangle\langle k|_{\mathcal{H}_K} \right) V \quad \forall k \in [m]. \quad (3.1)$$

Remark 3.2. *One can alternatively view V as a unitary, U , on the space $\mathcal{B}^\dagger(\mathcal{H} \otimes \mathcal{H}_K)$ which acts on states of the form $\rho \otimes |0\rangle\langle 0|_{\mathcal{H}_K}$. A simple consequence of Theorem 3.1 is that for any state ρ ,*

$$\text{Tr}[E_k \rho] = \text{Tr} \left[\left(\mathbb{1}_{\mathcal{H}} \otimes |k\rangle\langle k|_{\mathcal{H}_K} \right) \left(U (\rho \otimes |0\rangle\langle 0|_{\mathcal{H}_K}) U^* \right) \right]. \quad (3.2)$$

Since only the ancillary system is being measured, one can trace out $\mathcal{H}$, thus retrieving the aforementioned interpretation of Naimark’s dilation.

Remark 3.3 (Gate complexity of the POVM). *When we refer to the complexity of a POVM, we are referring to the complexity of the (unitary) quantum circuit U that was necessary to implement it. We adopt the approach from, e.g., [AA25, AHRA25], where, in other words, one considers the process of adding ancillas, tracing out subsystems, and measuring in the computational basis, to be ‘free’ operations. To characterize the complexity of a quantum circuit, U , one first chooses an approximately universal gate set $\mathcal{G}$ consisting of $|\mathcal{G}|$ unique gates. The complexity of U is equal to the minimal number of gates that are necessary to generate U .*

For binary measurements, there exists a bijection between POVMs $M = (E, \mathbb{1} - E)$ and effect operators E . We take advantage of this bijection for the remainder of this section and will in abuse of notation sometimes refer to both effect operators and POVMs as measurements, depending on context. In particular, whenever we consider the complexity of an effect operator E , we are referring to the complexity of the associated POVM M .

Definition 3.4 (Polynomially Generated Sets of Effect Operators). *Given an approximate universal quantum gate set $\mathcal{G}$ of fixed size $|\mathcal{G}| < \infty$, a polynomially generated set of effect operators is a family of sets of effect operators*

$$\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}, \quad \mathbf{E}_n^{\text{eff}} \subseteq \{E \in \text{Pos}(\mathcal{H}^{\otimes n}) : E \leq \mathbb{1}\} \quad (3.3)$$

such that there exists a polynomial p with the property that any element of $E \in \mathbf{E}_n^{\text{eff}}$ can be implemented using at most $p(n)$ elementary gates in the sense of Remark 3.3. We will further impose that if $E \in \mathbf{E}_n^{\text{eff}}$, then so is $\mathbb{1} - E \in \mathbf{E}_n^{\text{eff}}$. Lastly, given $E_1 \in \mathbf{E}_{n_1}^{\text{eff}}$ and $E_2 \in \mathbf{E}_{n_2}^{\text{eff}}$, then $E_1 \otimes E_2 \in \mathbf{E}_{n_1+n_2}^{\text{eff}}$, if the gate complexities of E_i , say c_i , are such that $c_1 + c_2 < p(n_1 + n_2)$.

If each $\mathbf{E}_n^{\text{eff}}$ is informationally complete, i.e. it holds that $\text{span}(\mathbf{E}_n^{\text{eff}}) = \mathcal{B}(\mathcal{H}^{\otimes n})$, then we further call this family an *informationally complete polynomially generated set of effect operators*.

One should think of polynomially generated effect operators informally as ‘efficiently’ implementable measurement operators. To better understand this definition, a couple of observations

and remarks are in order. Observe that we (almost) trivially have that $0, \mathbb{1} \in \mathbf{E}_n^{\text{eff}}$, since these measurements corresponds to trivially outputting 0, 1, respectively, regardless of input. A way to implement this is to generate an ancilla qubit in the state $|0\rangle$ (for 1 one additionally applies an X gate) and subsequently measuring it in the computational basis, which we assume to be free operations. We will usually assume that the polynomial p in the definition is strictly super-additive, satisfying $p(n + m) \geq p(n) + p(m) + 1$, unless otherwise mentioned.

Remark 3.5 (Efficient effect operators, classical post-processing, and information completeness). *Implicit in this definition is that we assume that polynomial classical post-processing with NOT and OR operations is also efficient. To motivate that $E \in \mathbf{E}_n^{\text{eff}} \implies \mathbb{1} - E \in \mathbf{E}_n^{\text{eff}}$, we highlight that the POVMs, which are the physical implementation of the effect operators, $M_1 = (E, \mathbb{1} - E)$ and $M_2 = (\mathbb{1} - E, E)$ differ only by a single classical NOT post-processing step. As such, if M_1 is ‘efficient’, then M_2 should also be considered efficient, which we enforce with this condition.*

Likewise, the stability under tensor product condition (assuming the polynomial p grows fast enough, which is the case if it is super-additive) is motivated by our implicit assumption that polynomially many classical OR post-processing operations are also assumed to be efficient. For example, for two efficient effect operators E_1, E_2 the corresponding binary measurements are $M_1 = (E_1, \mathbb{1} - E_1)$ and $M_2 = (E_2, \mathbb{1} - E_2)$, and $M_3 = (E_1 \otimes E_2, \mathbb{1} - E_1 \otimes E_2)$ corresponds to the tensor product measurement $E_1 \otimes E_2$. It is implementable by implementing M_1, M_2 in parallel using at most $p(n_1) + p(n_2)$ gates and mapping the output ‘00’ to 0 and the other three outcomes to 1. This corresponds to a logical OR gate so is only polynomial classical post processing.

We point out that one way to ensure that the set of effect operators is informationally complete is if for every n ,

$$U |k\rangle\langle k| U^* \in \mathbf{E}_n^{\text{eff}} \quad \forall k \in [\dim(\mathcal{H})^n] \quad \forall U \in \mathcal{U} ,$$

where $\mathcal{U}$ is the set of Weyl operators on $\mathcal{H}^{\otimes n}$ [Wat18, Section 4.1.2] and $|k\rangle\langle k|$ is the computational basis. For the case that $\dim(\mathcal{H}) = 2$, this can be reduced to the Pauli group. Therefore, it corresponds to first applying (for all $i \in \mathbb{N}$) a unitary $U_i \in \{X, Y, Z\}$ on the i -th qubit. Then one has to apply a measurement from some set, where the corresponding effect operators are of the form

$$|1^{i_1} \dots 1^{i_n}\rangle\langle 1^{i_1} \dots 1^{i_n}| .$$

One way to generate the corresponding measurement would be to first apply the gate $X^{i_1} \otimes \dots \otimes X^{i_n}$. Subsequently, one applies a computational measurement on all n qubits. Since we are only considering binary measurements, one has to then map the outcome $0 \dots 0$ to 0 and all other outcomes to 1. This ‘ 2^n -output measurement + post-processing step’ is generally efficient, and can be implemented by an efficient quantum circuit and a computational measurement on a single qubit. So in effect, the informationally complete condition means that the polynomial $p(n)$ cannot be too small.

Unless specified otherwise, we will for the following always assume that the polynomially generated set of effect operators is informationally complete. Using the bijection between effect operators E and binary POVMs $(E, \mathbb{1} - E)$, we consequently get the following definition.

Definition 3.6 (Polynomially Generated Sets of Binary POVMs). Let $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ be an (informationally complete) polynomially generated set of effect operators. The family

$$\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}, \quad \text{where} \quad \mathbf{M}_n^{\text{eff}} := \{(E, \mathbb{1} - E) \mid E \in \mathbf{E}_n^{\text{eff}}\}, \quad (3.4)$$

is the associated (*informationally complete*) *polynomially generated set of binary POVMs*.

We recall that directly from the properties of Definition 3.4 it follows that if $M = (E, \mathbb{1} - E) \in \mathbf{M}_n^{\text{eff}}$, then so is $M' = (\mathbb{1} - E, E)$ and if $M_i = (E_i, \mathbb{1} - E_i) \in \mathbf{M}_{n_i}^{\text{eff}}$ for $i = 1, 2$, then $(E_1 \otimes E_2, \mathbb{1} - E_1 \otimes E_2) \in \mathbf{M}_{n_1+n_2}^{\text{eff}}$, if the polynomial implicit in the definition of the family $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ grows sufficiently fast.

Remark 3.7. *Our definition of efficiently generated measurements encapsulates non-uniform quantum poly time generated POVMs, which have found applications in cryptography due to their ability to model an adversary with quantum advice [AD13]. Moreover, it closely mirrors, e.g., the circuit complexity definition used in [AA25, AHRA25] to define computational entropies that are useful for cryptography. As such, any divergences we define in Section 4 via $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ may similarly be relevant for cryptographic applications.*

3.2 The Proper Cone of Efficient Measurements

Given any family $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ as defined above, for each value $n \in \mathbb{N}$ one can naturally define the smallest convex set that contains all corresponding effect operators. The same also holds true for the corresponding family $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ of binary POVMs.

Definition 3.8 (Polynomially Generated Convex Sets of Effect Operators and Binary POVMs). Let $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ denote a (informationally complete) polynomially generated set of effect operators. The corresponding (*informationally complete*) *polynomially generated convex set of effect operators* is given by the family

$$\{\overline{\mathbf{E}}_n^{\text{eff}}\}_{n \in \mathbb{N}}, \quad \text{where} \quad \overline{\mathbf{E}}_n^{\text{eff}} := \text{conv}(\mathbf{E}_n^{\text{eff}}) = \left\{ \sum_{i=1}^k \lambda_i E_n^i \mid k \in \mathbb{N}, \lambda_i \geq 0, \sum_{i=1}^k \lambda_i = 1, E_n^i \in \mathbf{E}_n^{\text{eff}} \right\}. \quad (3.5)$$

Similarly, for the corresponding polynomially generated set of binary POVMs $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, we define the (*informationally complete*) *polynomially generated convex set of binary POVMs* as

$$\{\overline{\mathbf{M}}_n^{\text{eff}}\}_{n \in \mathbb{N}}, \quad \text{where} \quad \overline{\mathbf{M}}_n^{\text{eff}} := \{(E, \mathbb{1} - E) \mid E \in \overline{\mathbf{E}}_n^{\text{eff}}\}. \quad (3.6)$$

Remark 3.9. *Note that the convex sets $\overline{\mathbf{E}}_n^{\text{eff}}$ and $\overline{\mathbf{M}}_n^{\text{eff}}$ are closed $\forall n \in \mathbb{N}$. This is due to the fact that both $\mathbf{E}_n^{\text{eff}}$ and $\mathbf{M}_n^{\text{eff}}$ are finite sets in a finite-dimensional vector space. As such, their convex hulls are simplexes and therefore closed.*

One key property of these sets is that every measurement in $\overline{\mathbf{M}}_n^{\text{eff}}$ can be efficiently approximated. This ensures that one can also view $\overline{\mathbf{M}}_n^{\text{eff}}$ as a set of efficiently approximable measurements. To prove

this property, we require the following proposition. The proof is partly based on the techniques used in [Bar15].

Proposition 3.10. *For every effect operator $E \in \overline{\mathbf{E}}_n^{\text{eff}}$, there exists a subset of $k = \frac{5(n \ln \dim(\mathcal{H})+1)}{\varepsilon^2}$ effect operators $\{E_{j_1}, \dots, E_{j_k}\} \subset \mathbf{E}_n^{\text{eff}}$ such that*

$$\left\| E - \frac{1}{k} \sum_{i=1}^k E_{j_i} \right\|_{\infty} \leq \varepsilon. \quad (3.7)$$

Proof. Let $m = |\mathbf{E}_n^{\text{eff}}|$ denote the cardinality of $\mathbf{E}_n^{\text{eff}}$ and let $E_1, \dots, E_m$ denote the elements of $\mathbf{E}_n^{\text{eff}}$. By construction, there exist weights $\alpha_1, \dots, \alpha_m \geq 0$ such that

$$\sum_{i=1}^m \alpha_i E_i = E \quad \text{and} \quad \sum_{i=1}^m \alpha_i = 1.$$

Let X be a self-adjoint random matrix valued variable which with probability α_i satisfies

$$X = E - E_i$$

Notably, this random variable satisfies

$$\mathbb{E}[X] = 0 \quad \text{and} \quad \|\mathbb{E}[X^2]\|_{\infty} \leq 1.$$

Consequently, for $X_1, X_2, \dots, X_k$, k IID copies of X , the variance satisfies

$$\sigma^2 := \left\| \sum_{i=1}^k \mathbb{E}[X_i^2] \right\|_{\infty} \leq k.$$

Applying the matrix Bernstein inequality [MJC⁺14, Cor. 5.2] for any $0 \leq \varepsilon \leq 1$, it holds that

$$\begin{aligned} \Pr \left[\lambda_{\max} \left(\frac{1}{k} \sum_{j=1}^k X_j \right) \geq \varepsilon \right] &= \Pr \left[\lambda_{\max} \left(\sum_{j=1}^k X_j \right) \geq k\varepsilon \right] \\ &\leq (\dim(\mathcal{H})^n) \exp \left(-\frac{k^2 \varepsilon^2}{3k + 2k\varepsilon} \right) \\ &\leq (\dim(\mathcal{H})^n) \exp \left(-\frac{k^2 \varepsilon^2}{5k} \right) \\ &= (\dim(\mathcal{H})^n) \exp \left(-\frac{k\varepsilon^2}{5} \right) \\ &= \exp \left(n \ln \dim(\mathcal{H}) - \frac{k\varepsilon^2}{5} \right), \end{aligned}$$

where $\lambda_{\max} \left(\frac{1}{k} \sum_{j=1}^k X_j \right)$ denotes the largest eigenvalue of $\frac{1}{k} \sum_{j=1}^k X_j$. Setting $k = \frac{5(n \ln \dim(\mathcal{H})+1)}{\varepsilon^2}$

hence ensures that

$$\Pr \left[\lambda_{\max} \left(\frac{1}{k} \sum_{j=1}^k X_j \right) \geq \varepsilon \right] \leq e^{-1} < \frac{1}{2} .$$

By the same argument for $-X_i$ it holds that, for the same value k , we have

$$\Pr \left[\lambda_{\min} \left(\frac{1}{k} \sum_{j=1}^k X_j \right) \leq -\varepsilon \right] \leq e^{-1} < \frac{1}{2} ,$$

where $\lambda_{\min} \left(\frac{1}{k} \sum_{j=1}^k X_j \right)$ denotes the smallest eigenvalue of $\frac{1}{k} \sum_{j=1}^k X_j$. Using a union bound argument, it follows from these two inequalities that

$$\Pr \left[\lambda_{\min} \left(\frac{1}{k} \sum_{j=1}^k X_j \right) \geq -\varepsilon \wedge \lambda_{\max} \left(\frac{1}{k} \sum_{j=1}^k X_j \right) \leq \varepsilon \right] \geq 1 - \frac{2}{e} > 0 .$$

As such, there must exist values for $X_1, \dots, X_k$ such that the maximal eigenvalue of $|\frac{1}{k} \sum_{j=1}^k X_j|$ is less than or equal to ε . For these specific values of X_i , we know that there exists $\{E_{j_i}\}_{i=1}^k \subset \mathbf{E}_n^{\text{eff}}$ such that

$$X_i = E - E_{j_i} .$$

By construction, it must hold for these effect operators that

$$\left\| E - \frac{1}{k} \sum_{i=1}^k E_{j_i} \right\|_{\infty} \leq \varepsilon ,$$

thus concluding the proof. $\square$

We now discuss two consequences that follow from Proposition 3.10. First, even if one chooses $\varepsilon = \frac{1}{\text{poly}(n)}$, i.e. the allowed error to scale inverse polynomially in n , one can approximate any $E \in \overline{\mathbf{E}}_n^{\text{eff}}$ using an (in general non-unique and non-degenerate) polynomial subset of effect operators $\{E_{j_i}\}_{i=1}^k \subset \mathbf{E}_n^{\text{eff}}$. Secondly, our bound on the size of this set holds true for every effect operator $E \in \overline{\mathbf{E}}_n^{\text{eff}}$. This allows one to efficiently approximate every binary POVM $M \in \overline{\mathbf{M}}_n^{\text{eff}}$ to inverse-polynomial accuracy. Note that this in particular applies to αE for some $E \in \mathbf{E}_n^{\text{eff}}$ and $0 \leq \alpha \leq 1$, as $0 \in \mathbf{E}_n^{\text{eff}}$. This consequence is formally stated in Corollary 3.11.

Corollary 3.11. *Every $M \in \overline{\mathbf{M}}_n^{\text{eff}}$ can be implemented in poly-time up to inverse-polynomial accuracy.*

Proof. It suffices to show that any $E \in \overline{\mathbf{E}}_n^{\text{eff}}$ is polynomially preparable up to inverse polynomial error. For any $\tilde{E} = \frac{1}{k} \sum_{i=1}^k E_{j_i}$, with $E_{j_i} \in \mathbf{E}_n^{\text{eff}}$ and $k = \text{poly}(n)$, we can define a circuit D_n :

1. Given a control register, prepare a control state $|\lambda'\rangle_C = \sum_{i=1}^k \frac{1}{k} |i\rangle_C$, which requires $\mathcal{O}(\log k)$

gates.

2. Apply the multiplexed unitary $\sum_{i=1}^k |i\rangle\langle i|_C \otimes U_i$, where each U_i corresponds to the unitary operator that implements E_{j_i} . This circuit can be implemented by $\mathcal{O}(\text{poly}(n) \cdot k \cdot \log(k))$ gates and $\mathcal{O}(\log(k))$ ancillas [SBM06, dCBdV⁺24].
3. Trace out the control registers, along with all other registers that will not be measured.
4. Measure the remaining qubit register.

Since the unitary operators corresponding to the effects are generated in poly-time by assumption and $k = \text{poly}(n)$ by Proposition 3.10, any $E \in \overline{\mathbf{E}}_n^{\text{eff}}$ can be approximated up to inverse polynomial precision in polynomial time. $\square$

While Proposition 3.10 provides an upper bound on the Schatten ∞ -norm, also known as the operator norm, this can straightforwardly be translated into an upper bound on the difference between the corresponding measurement channels in the diamond norm, see e.g. [KW20, Definition 6.18]. As discussed in Section 2.2, one should view any binary POVM $M = (E_1, E_2)$ as a channel

$$\mathcal{M}_M : \mathcal{B}(\mathcal{H}^{\otimes n}) \rightarrow \mathcal{B}(\mathbb{C}^2), \quad \rho \mapsto \sum_{i=0}^1 \text{Tr}[E_{i+1}\rho] |i\rangle\langle i|, \quad (3.8)$$

where $\mathbb{C}^2$ is a two-dimensional Hilbert space.

Corollary 3.12. *For every binary POVM $M \in \overline{\mathbf{M}}_n^{\text{eff}}$, there exists a subset of $k = \frac{5(n \ln \dim(\mathcal{H}) + 1)}{\varepsilon^2}$ effect operators $\{E_{j_i}\}_{i=1}^k \subset \mathbf{E}_n^{\text{eff}}$ such that the measurement maps $\mathcal{M}$ corresponding to M and $\mathcal{M}'$ to and $M' = (\frac{1}{k} \sum_{i=1}^k E_{j_i}, \mathbb{1} - \frac{1}{k} \sum_{i=1}^k E_{j_i})$ respectively, satisfy*

$$\|\mathcal{M} - \mathcal{M}'\|_{\diamond} \leq 2\varepsilon. \quad (3.9)$$

The proof of this is standard and can be found in Section A.1. With these tools, we are now in a position to define the cone related to our sets of efficient effect operators.

Definition 3.13 (Cones of Polynomially Generated Effect Operators). Given an (informationally complete) polynomially generated convex set of effect operators $\{\overline{\mathbf{E}}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, the family of cones of (informationally complete) polynomially generated effect operators is given by

$$\{\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}\}_{n \in \mathbb{N}}, \quad \text{where} \quad \mathcal{C}_n^{\mathbf{E}^{\text{eff}}} = \bigcup_{\lambda \geq 0} \lambda \overline{\mathbf{E}}_n^{\text{eff}} = \text{cone}(\mathbf{E}_n^{\text{eff}}). \quad (3.10)$$

Remark 3.14. We note that this cone is the computational analog to the cones used in, e.g., [RSB24, RKW11, GC24]. Apart from constraining the measurements to be efficiently generated, the main difference is that we consider binary measurements. Their work considers general m -output POVMs. In principle, we could define computational analogs to their sets of POVMs provided in [RSB24, Eq. (4.1)] or [RKW11, Eq. (76)]. In their setting, $E_1, \dots, E_m \in \mathbf{E}_n^{\text{eff}}$ if there exists an efficiently implementable measurement given by $M = (E_1, \dots, E_m)$. Elements in $\overline{\mathbf{E}}_n^{\text{eff}}$ would still correspond to

convex mixtures of elements in $\mathbf{E}_n^{\text{eff}}$. However, as there is no more 1-to-1 correspondence between the set of efficient effect operators $\mathbf{E}_n^{\text{eff}}$ and the set of efficient measurements $\mathbf{M}_n^{\text{eff}}$, Proposition 3.10 would no longer suffice to ensure that every measurement in $\overline{\mathbf{M}}_n^{\text{eff}}$ is efficiently preparable. This issue becomes particularly exacerbated when m is exponential in n , which is, e.g., the case when measuring n qubits in the computational basis. Finding techniques to generalize our theory to the case for m -output measurements while adequately capturing the computational constraints thus remains an interesting open question.

Lemma 3.15. *The family of cones of informationally complete polynomially generated effect operators $\{\mathcal{C}_n^{\text{Eeff}}\}_{n \in \mathbb{N}}$ is a family of proper cones.*

Proof. The cones are convex and closed because their generating sets $\overline{\mathbf{E}}_n^{\text{eff}}$ are convex and closed. To see that the cones must be pointed, first note that every element $E \in \mathcal{C}_n^{\text{Eeff}}$ is positive semidefinite. As such, if $F \in \mathcal{C}_n^{\text{Eeff}}$ and $-F \in \mathcal{C}_n^{\text{Eeff}}$, it follows that $F = 0$. Thus, every cone $\mathcal{C}_n^{\text{Eeff}}$ is pointed. Lastly, solidness, i.e. having a non-empty interior, follows from the information completeness condition imposed on $\overline{\mathbf{E}}_n^{\text{eff}}$. To see this one can show, using a standard counter argument, e.g., [BV04, Section 2.1.3], that closed convex sets with empty interior cannot span the whole space. $\square$

To each $\mathcal{C}_n^{\text{Eeff}}$, one can generate its dual cone. This corresponding family of dual cones is defined below.

Definition 3.16 (Family of Dual Cones). The family of *dual cones* of $\{\mathcal{C}_n^{\text{Eeff}}\}_{n \in \mathbb{N}}$ is denoted by

$$\{\mathcal{C}_n^{\text{Seff}}\}_{n \in \mathbb{N}} := \{\mathcal{C}_n^{\text{Eeff}}^*\}_{n \in \mathbb{N}} = \left\{ Y \in \mathcal{B}(\mathcal{H}^{\otimes n}) \mid \text{Tr}(Y^* X) \geq 0 \ \forall X \in \mathcal{C}_n^{\text{Eeff}} \right\}_{n \in \mathbb{N}}. \quad (3.11)$$

Remark 3.17. *Since we work in finite dimensional vector spaces the dual cone is also the pre-dual cone, so its elements should be thought of as all ‘states’ which are positive w.r.t. the partial order $\leq_{\mathcal{C}_n^{\text{Seff}}}$ induced by measurements in $\mathbf{E}_n^{\text{eff}}$. It is easy to see that the family of dual cones $\{\mathcal{C}_n^{\text{Seff}}\}_{n \in \mathbb{N}}$ contains the family of cones of all positive semidefinite operators, i.e., $\text{Pos}(\mathcal{H}^{\otimes n}) \subseteq \mathcal{C}_n^{\text{Seff}}$, so in particular contains all quantum states.*

One interesting question that arises is whether all valid (binary) POVMs with effect operators in $\mathcal{C}_n^{\text{Eeff}}$ can be efficiently approximated. Since we can efficiently approximate convex mixtures of efficiently implementable effect operators, including $0, \mathbb{1}$, it follows that for any $0 \leq \alpha \leq 1$ one can approximate αE for any $E \in \mathbf{E}_n^{\text{eff}}$, as mentioned above. The question now is, whether this also holds for αE when $\alpha > 1$, if αE is part of some POVM, i.e. $E \in \overline{\mathbf{E}}_n^{\text{eff}}$ and $\alpha E \leq \mathbb{1}$. We will now argue that for certain cases one should not expect this to be true.

As is discussed in, e.g., [Gol08], one cannot efficiently implement all functions of the form

$$f : \{0, 1\}^n \rightarrow \{0, 1\}.$$

As such, one binary measurement that would generally be inefficient is, given a (uniformly) random function f , to first measure n qubits in the computational basis and then map the output $x \in \{0, 1\}^n$ to $f(x) \in \{0, 1\}$. However, as we discussed in Remark 3.5, there exists a setting, i.e. a polynomial

and approximately universal gate-set, in which the effect operators

$$|x\rangle\langle x| := |1^{x_1} \dots 1^{x_n}\rangle\langle 1^{x_1} \dots 1^{x_n}| \in \mathbf{E}_n^{\text{eff}}$$

are efficiently implementable. As such, the effect operator doing just that is

$$E_f = \sum_{x: f(x)=0} |x\rangle\langle x| \in \mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$$

and lies in the cone $\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$, but would correspond to a binary measurement which is not efficient. Let us consider such a computationally inefficient function f with $|\{x : f(x) = 0\}| = \exp(O(n))$. We highlight that the corresponding effect operators $E_f \notin \overline{\mathbf{E}}_n^{\text{eff}}$ as they are not convex mixtures of efficient effect operators. However, there exists an $E' \in \overline{\mathbf{E}}_n^{\text{eff}}$ such that $E_f = \alpha E'$ and $\alpha = |\{x : f(x) = 0\}|$, by construction of $\overline{\mathbf{E}}_n^{\text{eff}}$. In this case, since the average size of $|\{x : f(x) = 0\}|$ scales exponentially in n , the eigenvalues of E' scale inverse exponentially and it is due to this scaling that E' becomes efficiently implementable.

Remark 3.18 (Inefficient measurements vs. $\{\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}\}_{n \in \mathbb{N}}$). *Our efficient cone of effect operators is non-uniform, in the sense that its elements are prepared by families of polynomial-size circuits without a uniform generation requirement. Many natural effects and measurements nevertheless lie outside this cone due to computational hardness. Next we give explicit non-membership examples.*

Since $\mathbf{E}_n^{\text{eff}}$ is finite for each n , the cone $\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$ is generated by finitely many rays. A rank-one projector $P_\psi := |\psi\rangle\langle\psi|$ can belong to $\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$ only if one of these generators is proportional to P_ψ . Hence, for all but finitely many ψ , $P_\psi \notin \mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$. In addition, by a standard counting argument, with overwhelming probability a Haar-random rank-one projector P_ψ requires exponential circuit size to implement [NC00, Gol08]. Moreover, [JW23] construct explicit families of states with exponential circuit lower bounds; thus the corresponding rank-one projectors are, eventually, not in $\mathbf{E}_n^{\text{eff}}$ (even up to inverse-polynomial approximation).

For QMA-complete local Hamiltonians, if one could (given the instance description) efficiently compile a polynomial-size circuit that implements a projector onto the ground space to constant precision, this would yield a BQP algorithm for a QMA-complete promise problem, implying $\text{QMA} \subseteq \text{BQP}$, which is considered unlikely [KKR05]. Finally, under standard pseudorandomness assumptions (against non-uniform quantum distinguishers), any measurement that separates pseudorandom states or unitaries from Haar-random distributions with non-negligible bias cannot be efficient—otherwise one could break the initial assumptions [JLS18, MPSY24, ABF⁺23].

3.3 Computational Trace Norm and Trace Distance

Having constructed our bases and cones of efficiently implementable measurements one straightforwardly via Definition 2.15 gets corresponding distinguishability norms, which also appear in the computational quantum cryptographic setting, see e.g. [JLS18, ABF⁺23, BCQ23].

Without computational constraints, where every measurement is implementable, the best possible distinguishability advantage between two quantum states ρ and σ is related to the trace distance

$\|\rho - \sigma\|_1$. However, if the measurements are instead constrained to be implementable with poly-size quantum operations, the information-theoretic trace distance loses its operational meaning. In such cases, one instead considers the *computational distance*. This distance can essentially be recovered by a suitable *distinguishability norm*, see Definition 2.15, which in this context we call a *computational trace norm*.

Let us recall that the convex hull of efficient effect operators $\{\overline{\mathbf{E}}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ is a closed, convex, and informationally complete set, which additionally contains the trivial measurement $\mathbf{1} \in \overline{\mathbf{E}}_n^{\text{eff}}$ and satisfies the condition

$$E \in \overline{\mathbf{E}}_n^{\text{eff}} \implies \mathbf{1} - E \in \overline{\mathbf{E}}_n^{\text{eff}} \quad \forall E \in \overline{\mathbf{E}}_n^{\text{eff}} \quad (3.12)$$

for all $n \in \mathbb{N}$. For such sets, it follows from [RKW11, Section V] that

$$\|v\|_{\overline{\mathbf{M}}_n^{\text{eff}}} := \sup_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \langle 2E - \mathbf{1}, v \rangle \quad (3.13)$$

defines a norm on the vector space of Hermitian operators $v \in \mathcal{B}^\dagger(\mathcal{H}^{\otimes n})$ for any $n \in \mathbb{N}$. This naturally allows one to define a *computational trace norm*, where $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, $v = \rho - \sigma$, and $\text{Tr}[v] = 0$.

Definition 3.19 (Computational Trace Norm). Given any two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$ and a family of informationally complete polynomially generated convex set of binary POVMs $\{\overline{\mathbf{M}}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, the *computational trace norm* between these states is given by

$$\|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} := 2 \sup_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] . \quad (3.14)$$

For general $\rho, \sigma \in \text{Pos}(\mathcal{H}^{\otimes n})$, one gets via Eq. (3.13), the more general

$$\|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} = 2 \sup_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] - \text{Tr}[\rho - \sigma] . \quad (3.15)$$

Remark 3.20. It was shown in [MWW09] (and further discussed in [RKW11]), that norms defined via the theory of proper cones (such as the one in Eq. (3.13)) naturally satisfy the triangle inequality, positive definiteness and are absolute homogeneous, i.e.

- *Triangle Inequality:* for all $\rho, \sigma, \tau \in \mathcal{S}(\mathcal{H}^{\otimes n})$

$$\|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} \leq \|\rho - \tau\|_{\overline{\mathbf{M}}_n^{\text{eff}}} + \|\tau - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} . \quad (3.16)$$

- *Absolute Homogeneity:* for all $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$ and $\lambda \in \mathbb{R}$

$$\|\lambda(\rho - \sigma)\|_{\overline{\mathbf{M}}_n^{\text{eff}}} = |\lambda| \|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} . \quad (3.17)$$

- *Positive Definiteness:* for all $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$

$$\|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} = 0 \implies \rho = \sigma. \quad (3.18)$$

One straightforward property of the computational trace norm is that the optimization appearing on the RHS of Eq. (3.14) can be restricted to the set of efficient measurements $\mathbf{E}_n^{\text{eff}}$. In other words, the optimal distinguishing measurement lies in $\mathbf{M}_n^{\text{eff}}$.

Lemma 3.21. *Given any two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, the computational trace norm can alternatively be expressed as:*

$$\|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} = \begin{cases} 2 \max_{E \in \mathbf{E}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] , \\ \max_{M=(E_1, E_2) \in \mathbf{M}_n^{\text{eff}}} \sum_{i=1}^2 |\text{Tr}[E_i(\rho - \sigma)]| , \\ \max_{M \in \mathbf{M}_n^{\text{eff}}} \|\mathcal{M}_M(\rho) - \mathcal{M}_M(\sigma)\|_1 \end{cases} \quad (3.19)$$

Proof. This follows from well-known arguments; for completeness we have included the proof in Section A.2. $\square$

In quantum information literature, the trace distance is defined via the trace norm; see e.g. [KW20, Section 6.1]. In the computational setting, one takes the same approach.

Definition 3.22 (Computational Trace Distance). Given any two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$ and a family of informationally complete polynomially generated convex set of binary POVMs $\{\overline{\mathbf{M}}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, the *computational trace distance* between these states is given by

$$\hat{\Delta}(\rho, \sigma) := \frac{1}{2} \|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}}. \quad (3.20)$$

As discussed in Section 2 the minimum error probability for discriminating between two quantum states via efficient measurements can be related to the computational trace distance. In particular, the minimum error probability using only computationally efficient binary measurements from $\mathbf{M}_n^{\text{eff}}$ is given by

$$\hat{\mathcal{P}}_{\text{err}}(\rho, \sigma) = \frac{1}{2} \left(1 - \hat{\Delta}(\rho, \sigma) \right) = \frac{1}{2} - \frac{1}{4} \|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}}. \quad (3.21)$$

Remark 3.23 (Computational trace distance and cryptography). *To further relate this to computational quantum cryptography, let us consider the following. Two families of quantum states $\{\rho_n\}_{n \in \mathbb{N}}, \{\sigma_n\}_{n \in \mathbb{N}} \in \{\mathcal{S}(\mathbb{C}^{2^n})\}_{n \in \mathbb{N}}$ are said to be computationally indistinguishable if for every quantum polynomial-time distinguisher $\mathcal{D}$ (possibly non-uniform, with quantum advice⁶ α_n),*

$$|\Pr[\mathcal{D}^{\alpha_n}(\rho_n) = 1] - \Pr[\mathcal{D}^{\alpha_n}(\sigma_n) = 1]| \leq \text{negl}(n). \quad (3.22)$$

⁶If one is given quantum advice, i.e., additional quantum side-information, then this should be incorporated into the states ρ_n, σ_n .

This expression is known as the computational distance and, for every $n \in \mathbb{N}$, can be related to the computational trace distance via

$$\hat{\Delta}(\rho_n, \sigma_n) = \sup_{\mathcal{D} \in \mathbf{M}_n^{\text{eff}}} |\Pr[\mathcal{D}^{\alpha_n}(\rho_n) = 1] - \Pr[\mathcal{D}^{\alpha_n}(\sigma_n) = 1]|. \quad (3.23)$$

Under standard quantum cryptographic assumptions (e.g., the existence of pseudorandom quantum states and pseudorandom unitaries), there are families of states that are indistinguishable by any QPT adversary. Therefore, explicit constructions of these cryptographic primitives such as pseudorandom and pseudoentangled quantum states [JLS18, ABF⁺23, ABV23, LREJ25] are also computational indistinguishable —under cryptographic assumptions— within our framework.

It was shown in [GE24, Lemma 2.5] that the computational distance is approximately sub-additive. In the following lemma, we express their result in terms of $\|\cdot\|_{\mathbf{M}_n^{\text{eff}}}$

Lemma 3.24 (Sub-additivity of $\|\cdot\|_{\mathbf{M}_n^{\text{eff}}}$ [GE24]). *Given any two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, the computational trace norm is approximately sub-additive under tensor products, i.e.,*

$$\|\rho^{\otimes m} - \sigma^{\otimes m}\|_{\mathbf{M}_{n \cdot m}^{\text{eff}}} \leq m \max_{i \in \{1, \dots, m\}} \|\rho_i - \sigma_i\|_{\mathbf{M}_n^{\text{eff}}}, \quad (3.24)$$

where $\rho_i = \rho^{\otimes i-1} \otimes \rho \otimes \sigma^{\otimes n-i}$, $\sigma_i = \rho^{\otimes i-1} \otimes \sigma \otimes \sigma^{\otimes n-i}$.

Proof. This follows directly from the triangle inequality property of the computational trace norm. For completeness we provide the proof in Section A.3, using the same steps as [GE24, Lemma 2.5]. $\square$

The ρ_i, σ_i cannot be viewed as simply holding a single copy of ρ, σ . For both states one has the same additional registers which hold multiple copies of ρ and σ . These states have a computational cost associated to them, so there is a difference between having access to them for free and needing to first generate them. The triangle inequality can of course also be used to prove

$$\|\rho_1 \otimes \rho_2 - \sigma_1 \otimes \sigma_2\|_{\mathbf{M}_n^{\text{eff}}} \leq \min \left\{ \begin{aligned} &\|\rho_1 \otimes (\rho_2 - \sigma_2)\|_{\mathbf{M}_n^{\text{eff}}} + \|(\rho_1 - \sigma_1) \otimes \sigma_2\|_{\mathbf{M}_n^{\text{eff}}} \\ &\|\sigma_1 \otimes (\rho_2 - \sigma_2)\|_{\mathbf{M}_n^{\text{eff}}} + \|(\rho_1 - \sigma_1) \otimes \rho_2\|_{\mathbf{M}_n^{\text{eff}}} \end{aligned} \right. . \quad (3.25)$$

4 Computational Quantum Divergences

We introduce two new computational quantum divergences in this section and give them operational meaning. In Section 4.1, we first present a fully quantum computational max-divergence defined via our cone constructions. Here, we utilize the fact that the information-theoretic max-divergence can be expressed as an optimization over elements in a cone. In Section 3, we constructed a cone of efficient binary measurements. This will effectively be the computational analog to the cone of positive semidefinite operators used to define the information-theoretic max-divergence, which is retrieved in the asymptotic circuit-depth limit. In Section 4.2, we then derive a family of computational measured Rényi divergences. Measured Rényi divergences are becoming well-studied objects

in QIT literature, see e.g. [FFF25, RSB24, MH23]. In [FFF25] they were, among others, critical to deriving a generalized quantum asymptotic equipartition theorem (QAEP). This generalized QAEP can be used to derive a variety of statements, including a generalized Quantum Stein’s lemma. Our computational measured divergences can naturally be viewed as computational versions of these information-theoretic measured divergences.

Importantly, in Theorem 4.12, we recover the computational max-divergence as a special case ($\alpha \rightarrow \infty$) of the computational measured Rényi divergences, which can be viewed as one of the main results of this section. This gives the conic max-divergence an operational interpretation and naturally mimics the information-theoretic result of [MH23, Eq. III.65], where it is shown that

$$D_{\max}^{\mathbf{M}}(\rho\|\sigma) = D_{\max}(\rho\|\sigma) \quad (4.1)$$

if $\mathbf{M}$ is the set of all binary POVMs.⁷ Lastly, following the approach of [RKW11], we consider in Section 4.4 a *computational (binary) fidelity* and study its relation to the other quantities, including a straightforward equivalence to the computational measured Rényi divergence at $\alpha = 1/2$ and a computational analogue of the Fuchs-van der Graaf inequality. Lastly, we study an explicit separation between computational measured Rényi divergences when $\alpha \in (0, 1/2]$ and their informational counterparts by using the pseudoentanglement construction proposed by [GE24].

4.1 Computational Max-Divergence

In the rest of this paper, let $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ be an informationally complete polynomially generated set of effect operators, $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ its corresponding informationally complete polynomially generated set of binary POVMs, and its associated family of proper cones $\{\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}\}_{n \in \mathbb{N}}$. For each proper cone of efficient effect operators $\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$, one can define a corresponding max-divergence using Definition 2.13. For any such cone, we call the corresponding divergence, the *computational max-divergence*. We recall that this family of cones implicitly depends on a polynomial $n \mapsto p(n)$, which we sometimes state explicitly when it becomes relevant for clarity, however, most of the time we omit it to simplify notation.

Definition 4.1 (Computational Max-Divergence). Given a family of proper cones $\{\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}\}_{n \in \mathbb{N}}$ and any two positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H}^{\otimes n})$ with $\text{Tr}[\rho] > 0$ and $\rho \ll \sigma$, we denote the corresponding *computational max-divergence* by:

$$\mathring{D}_{\max}(\rho\|\sigma) := \log \inf\{\lambda \in \mathbb{R} \mid \rho \leq_{\mathcal{C}_n^{\mathbf{S}^{\text{eff}}}} \lambda \sigma\} = \log \sup_{v \in \mathcal{C}_n^{\mathbf{E}^{\text{eff}}}} \frac{\text{Tr}[v\rho]}{\text{Tr}[v\sigma]}, \quad (4.2)$$

where we recall that $\mathcal{C}_n^{\mathbf{S}^{\text{eff}}}$ is the dual cone to $\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$ and thus also proper.

We will occasionally also denote the computational max-divergence by $\mathring{D}_{\max}^{p(n)}$ to highlight the underlying polynomial $p(n)$ that is used in the definition of the family $\{\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}\}_{n \in \mathbb{N}}$. The equality in Eq. (4.2) holds whenever $\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$ is a proper cone, see [RKW11, Eqs. 4-6] and [GC24, Proposition 10].

⁷It is also closely related to [MO14, Appendix A], where they show a slightly less general result, in that $\mathbf{M}$ is now the set of all POVMs, not just binary measurements.

Remark 4.2. Since we construct the cone of efficient effects $\mathcal{C}_n^{\text{Eff}}$ rather implicitly, depending on some fixed polynomial and approximately universal gate set, existence of a tractable membership or linear-minimization oracle is unclear. Projection or Frank–Wolfe–type methods would require such an oracle to solve the membership problem. Hence we cannot provide a general algorithm for approximating the computational divergences that are based on these cones and introduced in the following section. Designing relaxations or hierarchies that admit verifiable oracles is an interesting open direction.

4.1.1 Super- and Sub-additivity Properties

Recall that the elements of $\mathbf{E}_n^{\text{eff}}$ are given by *all* POVM elements which can be generated with circuit size of (at most) $p(n)$ and possible polynomial classical post-processing with NOT and OR operations. So if we assume this polynomial to be strictly super-additive, i.e. $p(n+m) \geq p(n) + p(m) + 1$, then the family $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ and the family of its induced cones $\{\mathcal{C}_n^{\text{Eff}}\}_{n \in \mathbb{N}}$ are stable under tensor products, in the sense that if $E_i \in \mathbf{E}_{n_i}^{\text{eff}}$, then $E_1 \otimes E_2 \in \mathbf{E}_{n_1+n_2}^{\text{eff}}$ and the same holds for $\mathcal{C}_n^{\text{Eff}}$. With this in mind we are now ready to study some of the super-additivity and sub-additivity properties of the computational max-divergence, where we follow the proof techniques from [RLW24].

Lemma 4.3 (Super-additivity of $\hat{D}_{\max}$). *The computational max-divergence $\hat{D}_{\max}(\rho \parallel \sigma)$ is super-additive, i.e. for any $\rho = \rho_1 \otimes \rho_2$, $\sigma = \sigma_1 \otimes \sigma_2$ such that $\rho_i, \sigma_i \in \text{Pos}(\mathcal{H}^{\otimes n_i})$,*

$$\hat{D}_{\max}^{c p(n_1+n_2)}(\rho \parallel \sigma) \geq \hat{D}_{\max}^{c p(n_1)}(\rho_1 \parallel \sigma_1) + \hat{D}_{\max}^{c p(n_2)}(\rho_2 \parallel \sigma_2). \quad (4.3)$$

Proof. By construction and super-additivity of p we have for $E_i \in \mathbf{E}_{n_i}^{\text{eff}}$ (for $i \in \{1, 2\}$), that $E_1 \otimes E_2 \in \mathbf{E}_{n_1+n_2}^{\text{eff}}$. Due to convexity, it then naturally follows that if $E_i \in \bar{\mathbf{E}}_{n_i}^{\text{eff}}$ (for $i \in \{1, 2\}$), then $E_1 \otimes E_2 \in \bar{\mathbf{E}}_{n_1+n_2}^{\text{eff}}$. We refer to Remark 3.5 for a more detailed discussion on this.

For any $v_i \in \mathcal{C}_{n_i}^{\text{Eff}}$, there exists a λ_i and $E_i \in \bar{\mathbf{E}}_{n_i}^{\text{eff}}$ such that $v_i = \lambda_i E_i$. Since $E_1 \otimes E_2 \in \bar{\mathbf{E}}_{n_1+n_2}^{\text{eff}}$, it must hold that $v_1 \otimes v_2 \in \mathcal{C}_{n_1+n_2}^{\text{Eff}}$. As such

$$\begin{aligned} \hat{D}_{\max}^{c p(n_1+n_2)}(\rho \parallel \sigma) &= \log \sup_{v \in \mathcal{C}_{n_1+n_2}^{\text{Eff}}} \frac{\text{Tr}[v(\rho_1 \otimes \rho_2)]}{\text{Tr}[v(\sigma_1 \otimes \sigma_2)]} \\ &\geq \log \sup_{v_i \in \mathcal{C}_{n_i}^{\text{Eff}}} \frac{\text{Tr}[(v_1 \otimes v_2)(\rho_1 \otimes \rho_2)]}{\text{Tr}[(v_1 \otimes v_2)(\sigma_1 \otimes \sigma_2)]} \\ &= \log \sup_{v_1 \in \mathcal{C}_{n_1}^{\text{Eff}}} \frac{\text{Tr}[v_1 \rho_1]}{\text{Tr}[v_1 \sigma_1]} + \log \sup_{v_2 \in \mathcal{C}_{n_2}^{\text{Eff}}} \frac{\text{Tr}[v_2 \rho_2]}{\text{Tr}[v_2 \sigma_2]} \\ &= \hat{D}_{\max}^{c p(n_1)}(\rho_1 \parallel \sigma_1) + \hat{D}_{\max}^{c p(n_2)}(\rho_2 \parallel \sigma_2). \end{aligned}$$

□

The same proof can be extended to operators of the form $\rho^{\otimes m}, \sigma^{\otimes m} \in \text{Pos}(\mathcal{H}^{\otimes n \cdot m})$. Here, one

simply finds that

$$\hat{D}_{\max}^{c p(n \cdot m)}(\rho^{\otimes m} \| \sigma^{\otimes m}) \geq m \hat{D}_{\max}^{c p(n)}(\rho \| \sigma) . \quad (4.4)$$

In other words, the super-additivity property follows from the observation that, informally, tensor products of efficient measurements are also an efficient measurement. This measurement can efficiently be reduced to a binary measurement, using logical OR gates if $m \in \text{poly}(n)$.

Sub-additivity cannot be proven via the same techniques. Nevertheless, acting on quantum states, it is possible to prove that the computational max-divergence must also be approximately sub-additive.

Lemma 4.4 (Sub-additivity of $\hat{D}_{\max}$). *The computational max-divergence $\hat{D}_{\max}(\rho \| \sigma)$ is approximately sub-additive for quantum states. For any $\rho = \rho_1 \otimes \rho_2$, $\sigma = \sigma_1 \otimes \sigma_2$ such that $\rho_i, \sigma_i \in \mathcal{S}(\mathcal{H}^{\otimes n_i})$ with cost $\kappa(\rho_i), \kappa(\sigma_i)$,⁸, it holds that*

$$\hat{D}_{\max}^{c p(n_1+n_2)}(\rho \| \sigma) \leq \hat{D}_{\max}^{c p(n_1+n_2)+\kappa}(\rho_1 \| \sigma_1) + \hat{D}_{\max}^{c p(n_1+n_2)+\kappa}(\rho_2 \| \sigma_2) , \quad (4.5)$$

where $\kappa := \max\{\kappa(\rho_1), \kappa(\rho_2), \kappa(\sigma_1), \kappa(\sigma_2)\}$.

Proof. The proof technique is again inspired by [RLW24]. For any $\lambda_1, \lambda_2 \in \mathbb{R}$, it holds that

$$(\lambda_1 \cdot \lambda_2) \sigma_1 \otimes \sigma_2 - \rho_1 \otimes \rho_2 = (\lambda_1 \sigma_1 - \rho_1) \otimes \lambda_2 \sigma_2 + \rho_1 \otimes (\lambda_2 \sigma_2 - \rho_2) .$$

Let us consider any $\lambda = \lambda_1 \cdot \lambda_2 \geq 0$ for which it holds that

$$\text{Tr}[(\lambda \sigma - \rho) E] \geq 0 , \quad \forall E \in \mathbf{E}_{n_1+n_2}^{\text{eff}} . \quad (4.6)$$

By construction it must similarly hold that

$$\text{Tr}[(\lambda \sigma - \rho) v] \geq 0 , \quad \forall v \in \mathcal{C}_{n_1+n_2}^{\mathbf{E}^{\text{eff}}} ,$$

and, by Lemma 2.14, one then finds that

$$\hat{D}_{\max}^{c p(n_1+n_2)}(\rho \| \sigma) \leq \log \lambda .$$

Our goal is to show that $\lambda = \lambda_1 \cdot \lambda_2$ satisfies Eq. (4.6), if one sets

$$\log \lambda_i = \hat{D}_{\max}^{c p(n_1+n_2)+\kappa+1}(\rho_i \| \sigma_i) . \quad (4.7)$$

Note that, in particular, Eq. (4.7) implies $\lambda_i \geq 0$ for $i \in \{1, 2\}$. Since it takes at most κ extra gates to generate σ_2 , for any $E \in \mathbf{E}_{n_1+n_2}^{\text{eff}}$ acting on $\mathcal{H}^{\otimes n_1} \otimes \mathcal{H}^{\otimes n_2}$ there exists another effect operator E' on $\mathcal{H}^{\otimes n_1}$ that first additionally prepares σ_2 and then implements E . By construction, it must hold

⁸Here, the cost is the minimal circuit size required to prepare them using gates from the prior fixed gate set $\mathcal{G}$.

that

$$\text{Tr}[(\lambda_1 \sigma_1 - \rho_1) \otimes \sigma_2 E] = \text{Tr}[(\lambda_1 \sigma_1 - \rho_1) E'] .$$

Moreover, since E' uses at most $p(n_1 + n_2) + \kappa$ gates, it follows from the definition of λ_1 that

$$\text{Tr}[(\lambda_1 \sigma_1 - \rho_1) \otimes \sigma_2 E] = \text{Tr}[(\lambda_1 \sigma_1 - \rho_1) E'] \geq 0 .$$

Similarly, it must hold for any $E \in \mathbf{E}_{n_1+n_2}^{\text{eff}}$ that

$$\text{Tr}[\rho_1 \otimes (\lambda_2 \sigma_2 - \rho_2) E] \geq 0 . \quad (4.8)$$

Combining this, we find for $\lambda = \lambda_1 \cdot \lambda_2$ and any $E \in \mathbf{E}_{n_1+n_2}^{\text{eff}}$ that

$$\text{Tr}[(\lambda \sigma - \rho) E] = \lambda_2 \text{Tr}[(\lambda_1 \sigma_1 - \rho_1) \otimes \sigma_2 E] + \text{Tr}[\rho_1 \otimes (\lambda_2 \sigma_2 - \rho_2) E] \geq 0 ,$$

thus satisfying Eq. (4.6). As a result, it must hold that

$$\begin{aligned} D_{\max}^{c p(n_1+n_2)}(\rho \| \sigma) &\leq \log \lambda \\ &= \log \lambda_1 + \log \lambda_2 \\ &= D_{\max}^{c p(n_1+n_2)+\kappa}(\rho_1 \| \sigma_1) + D_{\max}^{c p(n_1+n_2)+\kappa}(\rho_2 \| \sigma_2) . \end{aligned}$$

□

Remark 4.5. *It generally makes sense to consider quantum states ρ and σ that are efficiently preparable, i.e. where κ scales polynomially in n_1, n_2 . This way, the max-divergences that appear in Lemma 4.4 are all related to cones generated by efficient effect operators. Moreover, the proof can straightforwardly be modified to hold for positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H}^{\otimes n_1} \otimes \mathcal{H}^{\otimes n_2})$. However, for any $\rho_i \in \text{Pos}(\mathcal{H}^{\otimes n_i})$, $\kappa(\rho_i)$ would then be the gate complexity required to generate the corresponding normalized quantum state $\frac{\rho_i}{\text{Tr}[\rho_i]}$ and analogously for σ_i .*

For states of the form $\rho^{\otimes m}, \sigma^{\otimes m} \in \mathcal{S}(\mathcal{H}^{\otimes n \cdot m})$, the same proof can be slightly modified, using [RLW24]

$$\lambda^m \sigma^{\otimes m} - \rho^{\otimes m} = \sum_{j=1}^m \lambda^{j-1} \rho^{\otimes m-j} \otimes (\lambda \sigma - \rho) \otimes \sigma^{\otimes j-1} . \quad (4.9)$$

One then retrieves the bound

$$D_{\max}^{c p(n \cdot m)}(\rho^{\otimes m} \| \sigma^{\otimes m}) \leq m D_{\max}^{c p(n \cdot m) + (m-1)\kappa}(\rho \| \sigma) , \quad (4.10)$$

where $\kappa := \max\{\kappa(\rho), \kappa(\sigma)\}$. For fixed ρ, σ , one should expect the RHS of Eq. (4.10) to converge to the information-theoretic max-divergence in the limit $m \rightarrow \infty$. This is due to the fact that while the states are fixed, the gate complexity of the allowed measurement is increasing as a function of

m . This inequality is not unexpected, as it always holds that

$$\overset{c}{D}_{\max}(\rho^{\otimes m} \parallel \sigma^{\otimes m}) \leq D_{\max}(\rho^{\otimes m} \parallel \sigma^{\otimes m}) = m D_{\max}(\rho \parallel \sigma) . \quad (4.11)$$

Lastly, let us relate the computational max-divergence with the computational trace distance.

Lemma 4.6 (Computational Max-divergence and Computational Trace Distance). *Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, we have that*

$$\overset{c}{D}_{\max}(\rho \parallel \sigma) \geq \log \left(1 + \overset{c}{\Delta}(\rho, \sigma) \right) . \quad (4.12)$$

Proof. The proof is straight forward and can be found in Section B.1. $\square$

4.2 Computational Measured Rényi Divergences

This section is devoted to computational measured Rényi divergences. Here, we consider an informationally complete polynomially generated set of binary POVMs $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, whose underlying polynomial is strictly super-additive. For each set $\mathbf{M}_n^{\text{eff}}$, we will define a measured Rényi divergence.

Definition 4.7 (Computational Measured Rényi Divergence). Given any two positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H}^{\otimes n})$ and an element $\mathbf{M}_n^{\text{eff}}$ of an informationally complete polynomially generated set of binary POVMs $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, we denote the corresponding *computational measured Rényi divergence* for any $\alpha \in (0, 1) \cup (1, \infty)$ by:

$$\overset{c}{D}_{\alpha}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) := \sup_{M \in \mathbf{M}_n^{\text{eff}}} D_{\alpha}(\mathcal{M}_M(\rho) \parallel \mathcal{M}_M(\sigma)) , \quad (4.13)$$

where $D_{\alpha}(\rho \parallel \sigma)$ is the sandwiched Rényi divergence (Definition 2.1) and $\mathcal{M}(\cdot)$ is the measurement channel corresponding to the POVM M .

Moreover, we use $\overset{c}{Q}_{\alpha}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma)$ to denote

$$\overset{c}{Q}_{\alpha}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) := \begin{cases} \inf_{M \in \mathbf{M}_n^{\text{eff}}} Q_{\alpha}(\mathcal{M}(\rho) \parallel \mathcal{M}(\sigma)) & \text{if } \alpha \in (0, 1) \\ \sup_{M \in \mathbf{M}_n^{\text{eff}}} Q_{\alpha}(\mathcal{M}(\rho) \parallel \mathcal{M}(\sigma)) & \text{if } \alpha \in (1, \infty) \end{cases} . \quad (4.14)$$

Definition 4.8 (Computational Measured Relative Entropy & Max-divergence). Given any two positive semidefinite operators $\text{Pos}(\mathcal{H}^{\otimes n})$ with $\text{Tr}[\rho] > 0$ and $\rho \ll \sigma$ and an element $\mathbf{M}_n^{\text{eff}}$ of an informationally complete polynomially generated set of binary POVMs $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, the *computational measured relative entropy* and *max-divergence* between ρ, σ are, respectively, given by:

$$\overset{c}{D}_{\alpha}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) := \sup_{M \in \mathbf{M}_n^{\text{eff}}} \frac{\text{Tr}[\mathcal{M}(\rho) (\log \mathcal{M}(\rho) - \log \mathcal{M}(\sigma))]}{\text{Tr}[\mathcal{M}(\rho)]} = \lim_{\alpha \nearrow 1} \overset{c}{D}_{\alpha}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) , \quad (4.15)$$

$$\overset{c}{D}_{\max}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) := \sup_{M \in \mathbf{M}_n^{\text{eff}}} \log \inf \{ \lambda \in \mathbb{R} \mid \mathcal{M}(\rho) \leq \lambda \mathcal{M}(\sigma) \} = \lim_{\alpha \nearrow \infty} \overset{c}{D}_{\alpha}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) . \quad (4.16)$$

By taking the appropriate limits, one can retrieve the computational measured relative entropy and max-divergence from the computational measured Rényi divergences, see e.g. [RSB24, Lemma 2]. We note that a priori one could have also defined the computational measured Rényi divergences using $\overline{\mathbf{M}}_n^{\text{eff}}$ instead of $\mathbf{M}_n^{\text{eff}}$. We show in Lemma 4.9 below, however, that these definitions are equivalent.

Lemma 4.9. *For any $\mathbb{D} \in \{D_\alpha, D, D_{\max}\}$, where $\alpha \in (0, 1) \cup (1, \infty)$, it holds that*

$$\mathbb{D}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) = \mathbb{D}^{\overline{\mathbf{M}}_n^{\text{eff}}}(\rho \parallel \sigma) . \quad (4.17)$$

Proof. Since $\mathbf{M}_n^{\text{eff}} \subset \overline{\mathbf{M}}_n^{\text{eff}}$, it always holds that

$$\mathbb{D}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) \leq \mathbb{D}^{\overline{\mathbf{M}}_n^{\text{eff}}}(\rho \parallel \sigma) . \quad (4.18)$$

To prove the reverse inequality, we first note that the relative entropy D and D_α are jointly convex on classical states in the range $\alpha \in (0, 1)$; the max-divergence $D_{\max}$ and D_α are jointly quasi-convex for $\alpha \in [1, \infty)$ [Tom16]. Denoting the extremal points of $\overline{\mathbf{M}}_n^{\text{eff}}$ by $\text{extr}(\overline{\mathbf{M}}_n^{\text{eff}})$, a consequence of the (quasi-) convexity is that

$$\mathbb{D}^{\overline{\mathbf{M}}_n^{\text{eff}}}(\rho \parallel \sigma) := \sup_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} \mathbb{D}(\mathcal{M}(\rho) \parallel \mathcal{M}(\sigma)) = \sup_{M \in \text{extr}(\overline{\mathbf{M}}_n^{\text{eff}})} \mathbb{D}(\mathcal{M}(\rho) \parallel \mathcal{M}(\sigma)) .$$

Since the extremal points of $\overline{\mathbf{M}}_n^{\text{eff}}$ satisfy $\text{extr}(\overline{\mathbf{M}}_n^{\text{eff}}) \subset \mathbf{M}_n^{\text{eff}}$ by construction of $\overline{\mathbf{M}}_n^{\text{eff}}$, it holds for all $\mathbb{D} \in \{D, D_\alpha, D_{\max}\}$ that

$$\mathbb{D}^{\overline{\mathbf{M}}_n^{\text{eff}}}(\rho \parallel \sigma) = \sup_{M \in \text{extr}(\overline{\mathbf{M}}_n^{\text{eff}})} \mathbb{D}(\mathcal{M}(\rho) \parallel \mathcal{M}(\sigma)) \leq \sup_{M \in \mathbf{M}_n^{\text{eff}}} \mathbb{D}(\mathcal{M}(\rho) \parallel \mathcal{M}(\sigma)) = \mathbb{D}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) .$$

□

4.2.1 Properties of Measured Rényi Divergences

In [RSB24], properties of generic measured Rényi divergences are derived. For completeness, in this section, we rephrase the results of [RSB24, Lemmas 2 & 5] in our setting of efficient measurements.

Lemma 4.10. *For any element $\mathbf{M}_n^{\text{eff}}$ of an informationally complete polynomially generated set of binary POVMs $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ and $\alpha, \beta \in (0, 1) \cup (1, \infty)$, the corresponding computational measured Rényi entropies satisfy*

1. (Non-negativity): *For any two normalized quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$,*

$$D_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) \geq 0 . \quad (4.19)$$

2. (Monotonicity in α): For any $\alpha \leq \beta$ and $\rho, \sigma \in \text{Pos}(\mathcal{H}^{\otimes n})$,

$$\dot{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma) \leq \dot{D}_\beta^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma). \quad (4.20)$$

3. (Joint (Quasi-) Convexity): For any two normalized quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, we have that $\dot{Q}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma)$ is jointly concave in ρ, σ if $\alpha \in (0, 1)$ and jointly convex if $\alpha \in (1, \infty)$. Moreover, $\dot{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma)$ is jointly convex if $\alpha \in (0, 1)$ and jointly quasi-convex if $\alpha \in (1, \infty)$.

4. (Data Processing Inequality): For any $\rho, \sigma \in \text{Pos}(\mathcal{H}^{\otimes n})$, let $\mathcal{E} \in \text{CPTP}(\mathcal{H}^{\otimes n}, \mathcal{H}^{\otimes n})$ be a completely positive trace-preserving map such that for any $E \in \mathbf{E}_n^{\text{eff}}$, $\mathcal{E}^*(E) \in \bar{\mathbf{E}}_n^{\text{eff}}$. Then

$$\dot{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma) \geq \dot{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\mathcal{E}(\rho)\|\mathcal{E}(\sigma)). \quad (4.21)$$

The first three properties are directly inherited from the information-theoretic sandwiched Rényi divergence. The last property can be understood as stating that we only consider $\mathcal{E}$ such that for every $M \in \mathbf{M}_n^{\text{eff}}$ there exists another measurement $\bar{M} \in \bar{\mathbf{M}}_n^{\text{eff}}$ which satisfies $\bar{\mathcal{M}}(\rho) = \mathcal{M} \circ \mathcal{E}(\rho)$ for every ρ . In this case, optimizing over $M \circ \mathcal{E}$ is more restrictive than simply optimizing over M .

Proof. The proof for Lemma 4.10 directly follows from [RSB24]. However, for completeness, we include it in Section B.2. $\square$

Next let us prove a Pinsker inequality for the computational measured Rényi divergences.

Lemma 4.11 (Computational Pinsker inequality). *Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, we have that for $\alpha \in (0, \infty)$,*

$$\dot{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma) \geq \frac{\min\{1, \alpha\}}{2 \ln 2} \|\rho - \sigma\|_{\bar{\mathbf{M}}_n^{\text{eff}}}^2. \quad (4.22)$$

Proof. As discussed in [RSB24], the bound for $\alpha \in (0, 1]$ follows directly from the classical result [Gil10]. Additionally, we convert the logarithm to base 2 and take the supremum over all efficient measurements. The bound for $\alpha \in (1, \infty)$ follows from the monotonicity in α property of the computational measured Rényi divergence (see Lemma 4.10). $\square$

4.2.2 Equivalence Between Conic and Measured Max-Divergence

We are now ready to prove one of the main results of this section, namely that the initially geometrically defined computational max-divergence ($\dot{D}_{\max}$ from Definition 4.1) and via the measured Rényi divergences constructed computational measured max-divergence ($\dot{D}_{\max}^{\mathbf{M}_n^{\text{eff}}}$ from Definition 4.8) are equivalent in our setting. The fact that these two divergences are actually equivalent is a priori not clear and this result highlights the strength of applying conic techniques to the computational setting.

This also naturally complements the known information-theoretic result, which states that there exists an optimal measurement which leaves the max-divergence invariant [MH23, MO14].

Theorem 4.12 (Max-Divergence Equivalence). *Let the families $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$, and $\{\mathcal{C}_n^{\text{Eeff}}\}_{n \in \mathbb{N}}$ be as in Section 3 and informationally complete and define $\dot{D}_{\max}$ and $\dot{D}_{\max}^{\mathbf{M}_n^{\text{eff}}}$ w.r.t. these as in Section 4.1 and Section 4.2, respectively. Then for any $n \in \mathbb{N}$ and two positive semidefinite operators $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, it holds that*

$$\dot{D}_{\max}(\rho\|\sigma) = \dot{D}_{\max}^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma) =: \lim_{\alpha \rightarrow \infty} \dot{D}_{\alpha}^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma). \quad (4.23)$$

Proof. Using the approach of [RSB24], we first note that the computational max-divergence can alternatively be expressed as

$$\dot{D}_{\max}(\rho\|\sigma) = \log \sup_{v \in \mathcal{C}_n^{\text{Eeff}}} \frac{\text{Tr}[v\rho]}{\text{Tr}[v\sigma]}. \quad (4.24)$$

By construction, for every v , there exists a $\lambda \geq 0$ and an element $E \in \overline{\mathbf{E}}_n^{\text{eff}}$ such that $v = \lambda E$. Since the RHS of Eq. (4.24) is invariant under the scaling of λ , it must also hold that

$$\dot{D}_{\max}(\rho\|\sigma) = \log \sup_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \frac{\text{Tr}[E\rho]}{\text{Tr}[E\sigma]} = \sup_{M=(E^1, E^2) \in \overline{\mathbf{M}}_n^{\text{eff}}} \log \max_{i \in \{1,2\}} \frac{\text{Tr}[E^i\rho]}{\text{Tr}[E^i\sigma]}.$$

The last equality holds due to the condition that $E \in \overline{\mathbf{E}}_n^{\text{eff}}$ implies $\mathbb{1} - E \in \overline{\mathbf{E}}_n^{\text{eff}}$. We will now derive the same expression for the computational measured max-divergence. Let $M = (E^1, E^2) \in \overline{\mathbf{M}}_n^{\text{eff}}$ be a binary measurement with associated measurement map $\mathcal{M}$, then it is easy to check that the condition $\mathcal{M}(\rho) \leq \lambda \mathcal{M}(\sigma)$ is equivalent to

$$\lambda \geq \max_{i \in \{1,2\}} \frac{\text{Tr}[E^i\rho]}{\text{Tr}[E^i\sigma]}.$$

Hence it follows that

$$\inf\{\lambda \in \mathbb{R} \mid \mathcal{M}(\rho) \leq \lambda \mathcal{M}(\sigma)\} = \max_{i \in \{1,2\}} \frac{\text{Tr}[E^i\rho]}{\text{Tr}[E^i\sigma]}.$$

Combining these observations with Lemma 4.9, we directly find that

$$\begin{aligned} \dot{D}_{\max}^{\mathbf{M}_n^{\text{eff}}}(\rho\|\sigma) &= \dot{D}_{\max}^{\overline{\mathbf{M}}_n^{\text{eff}}}(\rho\|\sigma) \\ &= \sup_{M=(E^1, E^2) \in \overline{\mathbf{M}}_n^{\text{eff}}} \log \inf\{\lambda \in \mathbb{R} \mid \mathcal{M}(\rho) \leq \lambda \mathcal{M}(\sigma)\} \\ &= \sup_{M=(E^1, E^2) \in \overline{\mathbf{M}}_n^{\text{eff}}} \log \max_{i \in \{1,2\}} \frac{\text{Tr}[E^i\rho]}{\text{Tr}[E^i\sigma]} \\ &= \dot{D}_{\max}(\rho\|\sigma), \end{aligned}$$

which concludes the proof. $\square$

One interesting consequence of Theorem 4.12 can be stated as follows. If two sets of measure-

ments generate the same cone, then their corresponding measured max-divergences are also equal to each other. As we discussed in Section 3 the cone $\mathcal{C}_n^{\mathbf{E}^{\text{eff}}}$ may contain POVM elements which are on their own not efficiently preparable, however, due to the above argument, they do not aid in distinguishability when using the max-divergence as a distance measure.

Remark 4.13. *That these two divergences —one defined via the geometric construction of cones of efficient effect operators, and the other via the optimization over measured $\alpha = \infty$ -Rényi divergences— are equivalent is a priori not clear in general. Let us consider a slightly more general setting where one starts with a family of admissible (not necessarily binary) POVMs $\mathbf{M}$ and generates from this the cone $\mathcal{C}^E$ as the smallest cone that contains all effect operators (POVM elements) appearing in all $M \in \mathbf{M}$. This is, among others, the setting of [RSB24]. Then, if one defines these two max-divergences w.r.t. these objects, one can show that the measured max-divergence is always upper bounded by the conical max-divergence; see [RSB24, Proposition 13]. In other words, the “ $\leq$ ” inequality of (4.23) is always true. Intuitively, this is because every POVM element is also element of the cone $\mathcal{C}^E$. The other inequality and thus equality, however, may not always be true. This direction requires an extra condition. Up to rescaling, every element of the cone $\mathcal{C}^E$ needs to either be an effect operator that appears in some binary POVM in $\mathbf{M}$ or needs to be expressible as a convex mixture of such binary measurements. In our case this is not an issue, since we consider only binary POVMs. However, if one, e.g., considers $\mathbf{M}$ to be the set of LO measurements, which are necessarily generally non-binary, then the above proof of equality generally breaks down [RSB24]. This is because generating the required two-output measurements would require classical communication, which is not allowed.*

4.3 Regularized Computational Measured Rényi Divergences

Let us define the regularized versions of the computational max-divergence and the computational measured Rényi divergences. We now pass from finite-block, per-instance quantities to *asymptotic rates*. In computational settings, an efficient tester is constrained not only in circuit size but also in the number of samples; accordingly, we adopt a *poly-sample* regime in which the number of copies satisfies $m(k) \in \text{poly}(k)$. Since we are studying asymptotic behavior, we henceforth consider families of states $\{\rho_k\}_{k \in \mathbb{N}}$ and $\{\sigma_k\}_{k \in \mathbb{N}}$. Again, we fix families of efficient measurements $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$. While the single-instance measures are evaluated at each fixed k , the regularized quantities are meaningful primarily at the family level.

Definition 4.14 (Regularized Computational Max-divergence). Given two family of states $\{\rho_k\}_{k \in \mathbb{N}}$, $\{\sigma_k\}_{k \in \mathbb{N}} \in \{\mathcal{S}(\mathcal{H}^{\otimes k})\}_{k \in \mathbb{N}}$, their *regularized computational max-divergence* when $m(k) \in \text{poly}(k)$ is given by,

$$\overset{\circ}{D}_{\max}^{\infty}(\{\rho_k\}_k \| \{\sigma_k\}_k) := \limsup_{k \rightarrow \infty} \frac{1}{m(k)} \overset{\circ}{D}_{\max}(\rho_k^{\otimes m(k)} \| \sigma_k^{\otimes m(k)}) . \quad (4.25)$$

For the simple case in which $\rho_k = \rho^{\otimes k}$ ($\sigma_k = \sigma^{\otimes k}$) for all $k \in \mathbb{N}$, this regularization (denoted by $\overset{\circ}{D}_{\max}^{\infty}(\rho \| \sigma)$) admits a convenient equivalent form.

Lemma 4.15. *Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H})$ such that, their regularized computational max-divergence can be expressed as,*

$$\dot{D}_{\max}^{\infty}(\rho \parallel \sigma) = \lim_{m \rightarrow \infty} \frac{1}{m} \dot{D}_{\max}(\rho_k^{\otimes m} \parallel \sigma_k^{\otimes m}) = \sup_{m > 0} \frac{1}{m} \dot{D}_{\max}(\rho_k^{\otimes m} \parallel \sigma_k^{\otimes m}). \quad (4.26)$$

Proof. The proof follows from the super-additivity property of the computational max-divergence (see Lemma 4.3) together with Fekete's lemma. $\square$

Definition 4.16 (Regularized Computational Measured Rényi Divergences). Given two families of states $\{\rho_k\}_{k \in \mathbb{N}}, \{\sigma_k\}_{k \in \mathbb{N}} \in \{\mathcal{S}(\mathcal{H}^{\otimes k})\}_{k \in \mathbb{N}}$, for any $\alpha \in (0, 1) \cup (1, \infty)$ their *regularized computational measured Rényi divergence* when $m(k) \in \text{poly}(k)$ is given by,

$$\dot{D}_{\alpha}^{\text{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \parallel \{\sigma_k\}_k) := \limsup_{k \rightarrow \infty} \frac{1}{m(k)} \dot{D}_{\alpha}^{\text{M}^{\text{eff}}_{k \cdot m(k)}}(\rho_k^{\otimes m(k)} \parallel \sigma_k^{\otimes m(k)}). \quad (4.27)$$

Definition 4.17 (Regularized Computational Measured Relative Entropy). Given two families of quantum states $\{\rho_k\}_{k \in \mathbb{N}}, \{\sigma_k\}_{k \in \mathbb{N}} \in \{\mathcal{S}(\mathcal{H}^{\otimes k})\}_{k \in \mathbb{N}}$, their *regularized computational measured relative entropy* is given by,

$$\dot{D}^{\text{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \parallel \{\sigma_k\}_k) := \limsup_{k \rightarrow \infty} \frac{1}{m(k)} \dot{D}^{\text{M}^{\text{eff}}_{k \cdot m(k)}}(\rho_k^{\otimes m(k)} \parallel \sigma_k^{\otimes m(k)}). \quad (4.28)$$

Remark 4.18. *In fact, for binary measurements super-additivity fails for general $\alpha \neq \infty$ [MH23]. It remains an interesting open question whether the regularized computational measured relative entropy can be equivalently expressed as a supremum, similar to the computational max-divergence.*

We conclude by relating the various regularized divergences to each other.

Lemma 4.19. *For any two families of quantum states $\{\rho_k\}_{k \in \mathbb{N}}, \{\sigma_k\}_{k \in \mathbb{N}} \in \{\mathcal{S}(\mathcal{H}^{\otimes k})\}_{k \in \mathbb{N}}$, $\alpha \in (0, 1)$, and $\beta \in (1, \infty)$, it holds that*

$$\dot{D}_{\alpha}^{\text{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \parallel \{\sigma_k\}_k) \leq \dot{D}^{\text{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \parallel \{\sigma_k\}_k) \leq \dot{D}_{\beta}^{\text{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \parallel \{\sigma_k\}_k) \leq \dot{D}_{\max}^{\infty}(\{\rho_k\}_k \parallel \{\sigma_k\}_k). \quad (4.29)$$

Proof. This follows directly from the monotonicity property provided in Lemma 4.10. $\square$

4.4 Computational Fidelity

In this section we define the *computational (binary) fidelity* using the approach from [RKW11]. This is the computational analog to the *fidelity* [Tom16, Uhl76, Fuc96] between two post-measurement single-bit outputs and measures the similarity between two quantum states when restricted to binary efficient measurements. Additionally, we show that the resulting fidelity is effectively the computational measured Rényi divergence for $\alpha = \frac{1}{2}$. Lastly, we relate it to the *computational trace distance* and the *computational max-divergence*, following the techniques from [RKW11].

Definition 4.20 (Computational (Binary) Fidelity). Given any two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$ the *computational (binary) fidelity* is given by

$$\hat{F}(\rho, \sigma) := \inf_{M=(E_1, E_2) \in \bar{\mathbf{M}}_n^{\text{eff}}} \left(\sum_{i=1}^2 \sqrt{\text{Tr}[E_i \rho] \text{Tr}[E_i \sigma]} \right)^2. \quad (4.30)$$

Lemma 4.21 (Computational Fidelity and Computational Measured Rényi Divergence). *Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, it follows that*

$$\hat{D}_{1/2}^{\mathbf{M}_n^{\text{eff}}}(\rho \| \sigma) = -\log \hat{F}(\rho, \sigma). \quad (4.31)$$

Proof. The proof can be found in Section B.3 □

Since the computational fidelity is related to the computational measured Rényi divergence for $\alpha = \frac{1}{2}$, due to Lemma 4.9 it automatically follows that

$$\inf_{M=(E_1, E_2) \in \bar{\mathbf{M}}_n^{\text{eff}}} \left(\sum_{i=1}^2 \sqrt{\text{Tr}[E_i \rho] \text{Tr}[E_i \sigma]} \right)^2 = \inf_{M=(E_1, E_2) \in \mathbf{M}_n^{\text{eff}}} \left(\sum_{i=1}^2 \sqrt{\text{Tr}[E_i \rho] \text{Tr}[E_i \sigma]} \right)^2, \quad (4.32)$$

meaning that one could have equivalently defined the computational fidelity by solely optimizing over measurements $\mathbf{M}_n^{\text{eff}}$. The computational fidelity and computational trace distance additionally straightforwardly satisfy a Fuchs-van de Graaf type inequality.

Lemma 4.22 (Computational Fuchs-van de Graaf). *Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, it holds that*

$$1 - \sqrt{\hat{F}(\rho, \sigma)} \leq \hat{\Delta}(\rho, \sigma) \leq \sqrt{1 - \hat{F}(\rho, \sigma)} \quad (4.33)$$

Proof. These inequalities follow directly from [RKW11, Proposition 19] applied to our family of informationally complete polynomially generated set of binary POVMs $\mathbf{M}_n^{\text{eff}}$. For completeness, we include a proof in Section B.4. □

We conclude this section by relating the fidelity to the computational max-divergence. Applying the computational Fuchs-van de Graaf inequality to this bound then yields a result similar to Lemma 4.6.

Lemma 4.23. *Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, we have that*

$$\hat{F}(\rho, \sigma) \geq 2^{-\hat{D}_{\max}(\rho \| \sigma)}. \quad (4.34)$$

Proof. By monotonicity of the measured Rényi α divergences, see Lemma 4.10, and Theorem 4.12 it follows that

$$\hat{D}_{1/2}^{\mathbf{M}_n^{\text{eff}}}(\rho \| \sigma) \leq \hat{D}_{\max}^{\mathbf{M}_n^{\text{eff}}}(\rho \| \sigma) = \hat{D}_{\max}(\rho \| \sigma).$$

Applying Lemma 4.21, one then finds that

$$\tilde{F}(\rho, \sigma) \geq 2^{-\tilde{D}_{\max}(\rho\|\sigma)} .$$

□

The previous bounds allow us to derive another relation between the computational max-divergence and the computational trace distance.

Corollary 4.24. *Given two quantum states $\rho, \sigma \in \mathcal{S}(\mathcal{H}^{\otimes n})$, we have that*

$$\tilde{D}_{\max}(\rho\|\sigma) \geq -\log \left(1 - \left(\tilde{\Delta}(\rho, \sigma) \right)^2 \right) . \quad (4.35)$$

Proof. This follows from Lemma 4.23 together with the computational Fuchs-van de Graaf inequality provided in Lemma 4.22. □

We provide a similar bound in Lemma 4.6. For $\tilde{\Delta}(\rho, \sigma) \approx 0$, Lemma 4.6 is tighter. Conversely, for $\tilde{\Delta}(\rho, \sigma) \approx 1$, we find that Corollary 4.24 provides a substantially tighter bound.

4.5 An explicit cryptographic separation

We now exhibit an explicit pair of states that witnesses a sharp separation between the *computational* and *informational* divergences. The same calculations can be extended to other cryptographic constructions which exhibit a gap between the computational trace distance and the informational counterpart. Nevertheless, due to its simplicity, we focus on the pseudoentanglement construction proposed by [GE24]. Let

$$\psi_n^{AB} := \frac{1}{4} \left(|\Phi^+\rangle\langle\Phi^+|^{AB} + |\Phi^-\rangle\langle\Phi^-|^{AB} \right) \otimes (\rho_{0,n}^A + \rho_{1,n}^A) , \quad (4.36)$$

$$\phi_n^{AB} := \frac{1}{2} \left(|\Phi^+\rangle\langle\Phi^+|^{AB} \otimes \rho_{0,n}^A + |\Phi^-\rangle\langle\Phi^-|^{AB} \otimes \rho_{1,n}^A \right) , \quad (4.37)$$

where $|\Phi^+\rangle^{AB} = \frac{1}{\sqrt{2}}(|00\rangle^{AB} + |11\rangle^{AB})$, $|\Phi^-\rangle^{AB} = \frac{1}{\sqrt{2}}(|00\rangle^{AB} - |11\rangle^{AB})$ and $\{\rho_{0,n}^A, \rho_{1,n}^A\}_{n \in \mathbb{N}}$ are EFI pairs.⁹

Assuming EFI pairs exist, [GE24] proves *poly-copy* computational indistinguishability of the two families, which in our notation implies

$$\tilde{\Delta}(\psi_n^{AB}, \phi_n^{AB}) \leq \text{negl}(n) .$$

Therefore, by the computational Fuchs–van de Graaf inequality (Lemma 4.22) we obtain

$$1 - \text{negl}(n) \leq \tilde{F}(\psi_n^{AB}, \phi_n^{AB}) \leq 1 . \quad (4.38)$$

⁹An EFI pair [BCQ23] consists of two efficiently generated families of quantum states which are far in trace distance ($\Delta(\rho_{0,n}, \rho_{1,n}) \approx 1$), which are indistinguishable by computationally bounded adversaries given $m \in \text{poly}(n)$ copies, i.e., $\left| \Pr[\mathcal{D}(\sigma_n, \rho_{n,0}^{\otimes m}) = 1] - \Pr[\mathcal{D}(\sigma_n, \rho_{n,1}^{\otimes m}) = 1] \right| \leq \nu(n)$.

This allows us to calculate the following upper bound for the computational measured Rényi divergence for $\alpha \in (0, 1/2)$,

$$\mathring{D}_\alpha^{\mathbf{M}^{\text{eff}}_n}(\psi_n^{AB}, \phi_n^{AB}) \leq -\log(1 - \text{negl}(n)) , \quad (4.39)$$

which follows from Lemma 4.21 together with the monotonicity property of the measured Rényi divergences (Lemma 4.10). Nevertheless, in the information-theoretic setting one has, by the Pinsker inequality, e.g., [Gil10], that

$$D_\alpha(\psi_n^{AB}, \phi_n^{AB}) \gtrsim \frac{\min\{1, \alpha\}}{8 \ln 2} ,$$

since the information-theoretic trace distance satisfies $\Delta(\psi_n^{AB}, \phi_n^{AB}) \approx 1/2$ and the fidelity is bounded away from 1:

$$\frac{1}{4} \leq F(\psi_n^{AB}, \phi_n^{AB}) \leq \frac{3}{4} . \quad (4.40)$$

Therefore, under standard hardness assumptions, the computational measures collapse ($\mathring{\Delta}(\psi_n^{AB}, \phi_n^{AB}) \leq \text{negl}(n)$, $1 - \text{negl}(n) \leq \mathring{F}(\psi_n^{AB}, \phi_n^{AB}) \leq 1$, and $\mathring{D}_\alpha(\psi_n^{AB}, \phi_n^{AB})^{\mathbf{M}^{\text{eff}}_n} \leq \text{negl}(n)$ for $\alpha \leq \frac{1}{2}$), whereas their informational counterparts are $\Theta(1)$.¹⁰

5 Applications

In this section we develop applications for the computational divergences introduced above. In Section 5.1 we revisit the quantum Stein’s lemma under computational constraints (Theorem 5.2) and show that the optimal one-sided error exponent is upper bounded by the regularized computational measured relative entropy, thereby giving it an operational meaning (see Definition 4.8). In Section 5.2 we define computational quantum resources based on our computational divergences and establish an asymptotic continuity bound for the so-called computational measured relative entropy of a resource (Theorem 5.7). Finally, further focusing on entanglement (Section 5.3), we introduce the *computational measured relative entropy of entanglement* and relate it to the previously proposed computational entanglement measures from [ABV23] in Lemma 5.15.

5.1 Computational Hypothesis Testing

Let us consider the problem of binary hypothesis testing, where one is tasked with discriminating between two input states. The main result of this section is a rigorous study of the optimal type II error decay rate in asymmetric hypothesis testing, commonly known as the Stein’s exponent, when restricted to efficient binary measurements [HP91, ON00].

In binary quantum hypothesis testing, the goal is to discriminate between two quantum states; one of the states, ρ , is called the *null hypothesis* H_0 and the other state, σ , is known as the *alternate*

¹⁰Indeed, the gap can be polynomially amplified by taking poly-many copies of pseudoentangled states, as proven in [GE24, Lemma 5.1]

hypothesis H_1 . While in the information-theoretic setting one typically studies two fixed states ρ and σ , in our complexity constrained framework the studied objects are families of states $\{\rho_k\}_{k \in \mathbb{N}}$ and $\{\sigma_k\}_{k \in \mathbb{N}}$ of which we are given $m(k) \in \text{poly}(k)$ polynomially many copies.

Thus, we study the distinguishing rate in the asymptotic limit, i.e., when $k \rightarrow \infty$ given $m(k)$ copies of $\rho_k, \sigma_k \in \mathcal{S}(\mathcal{H}^{\otimes k})$ under the restriction that the observer is constrained to implement efficient binary measurements. We say that the observer determines the system to be in state ρ_k , instead of σ_k if the performed measurement M outputs 0. Conversely, if the output is 1, the observer assumes that they initially held $m(k)$ copies of σ_k .

For any $k, m(k) \in \mathbb{N}$, let $\mathbf{M}_{k \cdot m(k)}^{\text{eff}}$ denote the set of efficient binary measurements acting on $\mathcal{H}^{\otimes k \cdot m(k)}$. For any feasible binary measurement $M = (E_{k \cdot m(k)}, \mathbb{1} - E_{k \cdot m(k)}) \in \mathbf{M}_{k \cdot m(k)}^{\text{eff}}$, there are two types of errors that arise:

- **Type-I error:** the probability of incorrectly rejecting the null hypothesis (i.e., mistakenly inferring σ_k when the state is actually ρ_k). It is hence defined as

$$\alpha_{m(k)}(M) := \text{Tr} \left[\rho_k^{\otimes m(k)} (\mathbb{1} - E_{k \cdot m(k)}) \right]. \quad (5.1)$$

- **Type-II error:** the probability of incorrectly accepting the null hypothesis (i.e., mistakenly inferring ρ_k when the state is actually σ_k). It is given by

$$\beta_{m(k)}(M) := \text{Tr} \left[\sigma_k^{\otimes m(k)} E_{k \cdot m(k)} \right]. \quad (5.2)$$

We are primarily interested in the *asymmetric* setting, where the aim is to minimize the Type-II error while the Type-I error is constrained to not exceed a prescribed threshold $\varepsilon \in (0, 1)$ [HP91, ON00]. Formally, one defines

$$\beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}}) := \min_{M \in \mathbf{M}_{k \cdot m(k)}^{\text{eff}}} \{ \beta_{m(k)}(M) \mid \alpha_{m(k)}(M) \leq \varepsilon \}, \quad (5.3)$$

to be the optimal type-II error given a type-I error bound by ε . As mentioned above, our goal is to characterize the scaling of $\beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}})$ in the asymptotic regime. In this setting, the optimal Type-II error probability is expected to decay exponentially with the number of copies $m(k) = \mathcal{O}(\text{poly}(n))$, i.e., $\beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}}) \sim 2^{-\xi^{\text{eff}} m(k) + o(m(k))}$, where the optimal (asymptotic) error exponent can be expressed as,

$$\xi^{\text{eff}} = \lim_{\varepsilon \rightarrow 0} \limsup_{k \rightarrow \infty} -\frac{1}{m(k)} \log \beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}}). \quad (5.4)$$

If one adopts the approach from [YHKH⁺22, MKH⁺25], then this exponent can be expressed via the complexity relative entropy, which we define below for completeness.

Definition 5.1 (Complexity Relative Entropy [MKH⁺25]). Let $\mathbf{E}_n^{\text{eff}}$ be the set of efficient effect operators on $\mathcal{H}^{\otimes n}$ that can be generated using at most $p(n)$ elementary gates. Then for any two positive semidefinite operators $\rho, \sigma \in \text{Pos}(\mathcal{H}^{\otimes n})$ and any $\eta \geq 0$, the *complexity relative entropy* is

given by:

$$D_{\text{H}}^{p(n),\eta}(\rho\|\sigma) := -\log \inf_{\substack{E \in \mathbf{E}_n^{\text{eff}} \\ \text{Tr}[E\rho] \geq \eta}} \frac{\text{Tr}[E\sigma]}{\text{Tr}[E\rho]}. \quad (5.5)$$

It then directly follows from [MKH⁺25, Proposition 1] that the optimal type II error is expressed as

$$\beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}}) = (1 - \varepsilon) 2^{-D_{\text{H}}^{p(k \cdot m(k)), 1-\varepsilon}(\rho_k^{\otimes m(k)} \|\sigma_k^{\otimes m(k)})}.$$

This yields an optimal error exponent of

$$\xi^{\text{eff}} = \lim_{\varepsilon \rightarrow 0} \limsup_{k \rightarrow \infty} -\frac{\log(1 - \varepsilon)}{m(k)} + \frac{D_{\text{H}}^{p(k \cdot m(k)), 1-\varepsilon}(\rho_k^{\otimes m(k)} \|\sigma_k^{\otimes m(k)})}{m(k)} \quad (5.6)$$

$$= \lim_{\varepsilon \rightarrow 0} \limsup_{k \rightarrow \infty} \frac{D_{\text{H}}^{p(k \cdot m(k)), 1-\varepsilon}(\rho_k^{\otimes m(k)} \|\sigma_k^{\otimes m(k)})}{m(k)}. \quad (5.7)$$

Here, our main contribution is Theorem 5.2, which shows that the optimal error exponent is bounded by the regularized computational measured relative entropy. In doing so, we also establish a connection between the computational measured Rényi divergences of this work and the complexity relative entropy from [MKH⁺25].

Theorem 5.2 (Computational Stein's Lemma). *Let $\{\rho_k\}_{k \in \mathbb{N}}, \{\sigma_k\}_{k \in \mathbb{N}} \in \{\mathcal{S}(\mathcal{H}^{\otimes k})\}_{k \in \mathbb{N}}$ be two families of quantum states and let $\{\mathbf{M}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ be a family of informationally complete polynomially generated set of binary POVMs. For any $0 < \varepsilon < 1$, the optimal type II error exponent $\xi^{\text{eff}}(\{\rho_k\}_k \|\{\sigma_k\}_k)$ for testing $H_0 : \sigma_k^{\otimes m(k)}$ against $H_1 : \rho_k^{\otimes m(k)}$, with $m(k) = \mathcal{O}(\text{poly}(k))$, using efficient measurements satisfies:*

$$\xi^{\text{eff}}(\{\rho_k\}_k \|\{\sigma_k\}_k) := \lim_{\varepsilon \rightarrow 0} \limsup_{k \rightarrow \infty} -\frac{1}{m(k)} \log \beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}}) \leq \dot{D}^{\mathbf{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \|\{\sigma_k\}_k), \quad (5.8)$$

where $\beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}})$ is the minimal type II error given the type I error $\leq \varepsilon$, and $\dot{D}^{\mathbf{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \|\{\sigma_k\}_k)$ is the regularized computational measured relative entropy.

Proof. The proof follows from the general result of [BaHLP14]. We adapt it to the polynomially constrained scenario and include it in Section C.1 for completeness. $\square$

In the simple case, where ρ, σ are fixed and one distinguishes $\rho^{\otimes m}$ from $\sigma^{\otimes m}$, this reduces to

$$\xi^{\text{eff}}(\rho\|\sigma) := \lim_{\varepsilon \rightarrow 0} \limsup_{m \rightarrow \infty} -\frac{1}{m} \log \beta_m^\varepsilon(\mathbf{M}_m^{\text{eff}}) \leq \dot{D}^{\mathbf{M}^{\text{eff}}, \infty}(\rho\|\sigma). \quad (5.9)$$

This bound is tight for the original quantum Stein's lemma [ON00], which one recovers by removing the computational constraints on $\mathbf{M}_k^{\text{eff}}$. Moreover, it immediately follows from Lemma 4.19 that the regularized computational max-divergence is an upper bound on $\xi^{\text{eff}}(\{\rho_k\}_k \|\{\sigma_k\}_k)$.

5.2 Computational Resource Theory

Properties of quantum systems such as entanglement or magic can be studied systematically by *quantum resource theories* [CG19]. A resource theory is a pair $\mathcal{R} = (\mathcal{F}, \mathcal{O})$ where, for any Hilbert spaces $\mathcal{H}, \mathcal{H}_1, \mathcal{H}_2$,

- $\mathcal{F}(\mathcal{H}) \subseteq \mathcal{S}(\mathcal{H})$ is the set of *free states* on $\mathcal{H}$, i.e., those that lack the resource and
- $\mathcal{O}(\mathcal{H}_1, \mathcal{H}_2) \subseteq \text{CPTP}(\mathcal{H}_1, \mathcal{H}_2)$ is the set of *free operations*.

A free operation, $\Lambda \in \mathcal{O}(\mathcal{H}_1, \mathcal{H}_2)$, must minimally satisfy $\Lambda(\sigma) \in \mathcal{F}(\mathcal{H}_2)$ for every $\sigma \in \mathcal{F}(\mathcal{H}_1)$. When studying, e.g. entanglement as a resource, one chooses $\mathcal{F} = \text{SEP}$ (separable states) and $\mathcal{O} = \text{LOCC}$ (local operations + classical communication).

When restricted to polynomially implementable operations, families of states with high resource content can become computationally indistinguishable from low-resource families. This phenomenon, known as pseudoresourced quantum states [HBK24, BMB⁺24, GY25] has a direct consequence: when constrained to polynomially implementable operations, information-theoretic resource measures will generally not be operationally meaningful. For entanglement there exist, e.g., exponential separations between information-theoretic and computational measures [ABF⁺23, ABV23, LREJ25]. Nevertheless, to the best of our knowledge, no general measure for polynomially-constrained resources has been proposed in the literature.

There exist several measures for quantifying resources in quantum information theory, ranging from geometric to witness-based approaches. Typically, these measures assess the resource content of a state by evaluating its “distance” from the set of free states. In this section, we focus on entropic measures, defining the computational counterpart of the *measured relative entropy of resource* and the *max-relative entropy of resource*. Throughout this section, $\mathcal{O}_n(\mathcal{H}_1, \mathcal{H}_2)$ will denote the free operations realized by poly-size circuits, i.e., the “efficient” free operations from the Hilbert space $\mathcal{H}_1$ to $\mathcal{H}_2$. In the same way, $\mathcal{F}_n \equiv \mathcal{F}(\mathcal{H}^{\otimes n})$ represents the set of free states, i.e. the ones without the resource.

Definition 5.3 (Set of Efficient Free Quantum Operations). Given $\{\mathbf{E}_n^{\text{eff},(i)}\}_{n \in \mathbb{N}}$, where $\mathbf{E}_n^{\text{eff},(i)} \subset \mathcal{B}(\mathcal{H}_i^{\otimes n})$ are families of informationally complete polynomially generated sets of effect operators on, respectively systems $i = 1, 2$, with possibly different polynomials. On the sets of free states $\mathcal{F}(\mathcal{H}_1^{\otimes n})$ and $\mathcal{F}(\mathcal{H}_2^{\otimes n})$, a CPTP map $\Lambda_n \in \mathcal{O}(\mathcal{H}_1^{\otimes n}, \mathcal{H}_2^{\otimes n})$ is said to be an *efficient free quantum operation* if the following two conditions hold.

1. **State condition:** $\Lambda_n(\sigma) \in \mathcal{F}(\mathcal{H}_2^{\otimes n})$ for all $\sigma \in \mathcal{F}(\mathcal{H}_1^{\otimes n})$.
2. **Test stability:** $\Lambda_n^*(\mathbf{E}_n^{\text{eff}}(\mathcal{H}_2^{\otimes n})) \subseteq \overline{\mathbf{E}}_n^{\text{eff}}(\mathcal{H}_1^{\otimes n})$.

Therefore, the set of free operations can be seen as quantum channels that map free states into free states, not generating the studied resource. The main difference with respect to the information-theoretic case lies in the added complexity constraint: these transformations cannot generate more complexity either. Let us now define computational resource distance measures through our proposed computational divergences.

Definition 5.4 (Computational Measured Relative Entropy of Resource). Given a quantum state $\rho \in \mathcal{S}(\mathcal{H}^{\otimes n})$, its *computational measured relative entropy of resource* is given by,

$$\mathring{D}_{\mathcal{F}_n}(\rho) := \min_{\sigma \in \mathcal{F}_n} \mathring{D}^{\mathbf{M}^{\text{eff}}}_n(\rho \parallel \sigma). \quad (5.10)$$

Definition 5.5 (Computational Max-Relative Entropy of Resource). Given a quantum state $\rho \in \mathcal{S}(\mathcal{H}^{\otimes n})$, its *computational max-relative entropy of resource* is given by,

$$\mathring{D}_{\max, \mathcal{F}_n}(\rho) := \min_{\sigma \in \mathcal{F}_n} \mathring{D}_{\max}(\rho \parallel \sigma). \quad (5.11)$$

In the information-theoretic setting, the (unmeasured) relative entropy of resource and the smoothed max-relative entropy have standard operational roles: the former captures asymptotic hypothesis-testing/interconversion rates, while the latter characterizes one-shot formation/distillation (e.g., entanglement cost and distillable entanglement) under non-entangling or catalytic transformations [Dat09b, BD11, LBT19, RFWG19, RW20]. In the computational setting, a full operational characterization remains open. Nevertheless, by parallelism with the unconstrained case, we adopt their measured and restricted counterparts. Moreover, they satisfy the crucial properties of resource monotones under our allowed maps, as we now prove.

Lemma 5.6. *Assuming that the set of free states $\mathcal{F}_n = \mathcal{F}(\mathcal{H}^{\otimes n})$ is closed, the computational resource measures $\mathring{\mathbb{D}} \in \{\mathring{D}, \mathring{D}_{\max}\}$ that we have defined satisfy the following properties,*

- **Faithfulness:** *given a quantum state $\rho \in \mathcal{S}(\mathcal{H}^{\otimes n})$, its resource measure $\mathring{D}_{\mathcal{F}_n}(\rho)$ is zero iff $\rho \in \mathcal{F}(\mathcal{H}^{\otimes n})$.*
- **Monotonicity:** *For any free operation $\Lambda_n \in \mathcal{O}_n(\mathcal{H}_1^{\otimes n}, \mathcal{H}_2^{\otimes n})$,*

$$\mathring{\mathbb{D}}_{\mathcal{F}(\mathcal{H}_2^{\otimes n})}(\Lambda_n(\rho)) \leq \mathring{\mathbb{D}}_{\mathcal{F}(\mathcal{H}_1^{\otimes n})}(\rho). \quad (5.12)$$

Proof. On the one hand, if $\rho \in \mathcal{F}(\mathcal{H}^{\otimes n})$, then it naturally holds that

$$\mathring{\mathbb{D}}_{\mathcal{F}_n}(\rho) = 0. \quad (5.13)$$

The other direction which is necessary to prove faithfulness then directly follows for $\mathring{D}_{\max}$ from Lemma 4.6 and for the measured relative entropy measures from Lemma 4.11 together with the fact that the computational trace distance $\mathring{\Delta}$ is a norm and the set $\mathcal{F}_n(\mathcal{H}^{\otimes n})$ is closed. For the monotonicity property, it follows from the state condition of Definition 5.3 that,

$$\mathring{\mathbb{D}}_{\mathcal{F}(\mathcal{H}_2^{\otimes n})}(\Lambda_n(\rho)) = \min_{\tau \in \mathcal{F}(\mathcal{H}_2^{\otimes n})} \mathring{D}^{\mathbf{M}^{\text{eff}}}_n(\Lambda_n(\rho) \parallel \tau) \leq \min_{\sigma \in \mathcal{F}(\mathcal{H}_1^{\otimes n})} \mathring{D}^{\mathbf{M}^{\text{eff}}}_n(\Lambda_n(\rho) \parallel \Lambda_n(\sigma)) \leq \mathring{D}^{\mathbf{M}^{\text{eff}}}_n(\Lambda_n(\rho) \parallel \Lambda_n(\sigma)),$$

for $\mathring{D}^{\mathbf{M}^{\text{eff}}}_n \in \{\mathring{D}^{\mathbf{M}^{\text{eff}}}_n, \mathring{D}_{\max}\}$ and any $\sigma \in \mathcal{F}(\mathcal{H}_1^{\otimes n})$, since $\Lambda_n(\mathcal{F}(\mathcal{H}_1^{\otimes n})) \subseteq \mathcal{F}(\mathcal{H}_2^{\otimes n})$. Then, by the test stability property of Definition 5.3 together with Property 4 of Lemma 4.10 (see also [RSB24,

Lemma 5]) it follows that, for all $\sigma \in \mathcal{F}(\mathcal{H}_1^{\otimes n})$,

$$\mathbb{D}^{\mathbf{M}_n^{\text{eff}}}(\Lambda_n(\rho) \|\Lambda_n(\sigma)) \leq \mathbb{D}^{\mathbf{M}_n^{\text{eff}}}(\rho \|\sigma).$$

The proof then concludes by taking the minimum. $\square$

For the case of the computational measured relative entropy, it follows from [SW23, Theorem 11] that it satisfies asymptotic continuity with respect to the trace norm. Concretely, for any convex set $\mathcal{F}_n$ and assuming $\frac{1}{2}\|\rho - \rho'\|_1 \leq \varepsilon$ it then holds that

$$\left| \mathring{D}_{\mathcal{F}_n}(\rho) - \mathring{D}_{\mathcal{F}_n}(\rho') \right| \leq g(\varepsilon) + \varepsilon \sup_{M \in \mathbf{M}_n^{\text{eff}}} \kappa_M \quad (5.14)$$

where $\kappa_M = \sup_{\mu, \nu} |D_{\mathcal{F}_n}^M(\mu) - D_{\mathcal{F}_n}^M(\nu)|$ with $D_{\mathcal{F}_n}^M(\rho) := \inf_{\sigma \in \mathcal{F}_n} D(\mathcal{M}_M(\rho) \|\mathcal{M}_M(\sigma))$ is the maximal absolute difference of the measured relative entropy of resource between any two states and $g(\varepsilon) := (1 + \varepsilon)h\left(\frac{\varepsilon}{1+\varepsilon}\right)$ and $h(\cdot)$ is the binary entropy.

Since we demonstrate an exponential separation between the information-theoretic trace distance and its computational counterpart, continuity bounds phrased in the computational metric can be exponentially sharper. This makes the above bound in practice less useful and motivates a tighter relation between our computational divergences and the corresponding restricted trace distance—so that the right-hand side of the inequality depends only on a computational notion of distinguishability. Theorem 5.7 provides exactly this: an asymptotic continuity bound for the computational measured relative entropy of resource in terms of the computational trace distance, furnishing a direct analytic bridge with clear operational meaning. To the best of our knowledge, this is the first continuity bound that relates a measurement-restricted divergence to its matching restricted trace distance, and it is likely of independent interest.

Theorem 5.7 (Asymptotic Continuity Bound for the Computational Measured Relative Entropy of Resource). *Let $\mathcal{F}_n \subset \mathcal{S}(\mathcal{H}^{\otimes n})$ be closed, convex, and bounded containing a full rank state σ^* . For $\rho, \rho' \in \mathcal{S}(\mathcal{H}^{\otimes n})$ and $\mathring{\Delta}(\rho, \rho') = \frac{1}{2}\|\rho - \rho'\|_{\mathbf{M}_n^{\text{eff}}} \leq \varepsilon$ it holds that,*

$$\left| \mathring{D}_{\mathcal{F}_n}(\rho) - \mathring{D}_{\mathcal{F}_n}(\rho') \right| \leq (1 + \varepsilon)h\left(\frac{\varepsilon}{1+\varepsilon}\right) + \varepsilon \left(\kappa + \log\left(\frac{2}{\varepsilon}\right) \right), \quad (5.15)$$

where $h(\cdot)$ is the binary entropy and $\kappa := -\log(\lambda_{\min}(\sigma^*)) > 0$ is the negative logarithm of the smallest eigenvalue of the full rank state σ^* .

Proof. In order to end up with the desired bound for $\mathring{D}_{\mathcal{F}_n}$, we will first swap the infimum and supremum implicitly appearing in $\mathring{D}_{\mathcal{F}_n}$. We do this by using [BaHLP14, Lemma 13], see also [SW23, Lemma 10], which, however, a priori does not directly apply to our situation, since the set of measurement maps $\mathcal{M}$ corresponding to binary POVMs $\overline{\mathbf{M}}_n^{\text{eff}}$ is not closed under flagged finite convex combinations. We say a set $\mathcal{M}$ of CPTP maps is closed under flagged finite convex combinations [SW23, BaHLP14] if for any finite probability distribution $\{p_i\}_{i=1}^m$ and any $\mathcal{M}_i \in \mathcal{M}$ it follows

that $\bigoplus_{i=1}^m p_i \mathcal{M}_i \in \mathcal{M}$. So as a first step we define

$$\mathcal{M}_n^{\text{eff}} := \left\{ \bigoplus_{i=1}^m p_i \mathcal{M}_i = \sum_{i=1}^m p_i \mathcal{M}_i \otimes |i\rangle\langle i| \mid m \in \mathbb{N}, p_i \geq 0, \sum_{i=1}^m p_i = 1, \mathcal{M}_i \equiv \mathcal{M}_{M_i}, M_i \in \overline{\mathbf{M}}_n^{\text{eff}} \right\},$$

where here $\mathcal{M}_i \equiv \mathcal{M}_{M_i}$ is the measurement channel implementing the binary POVM $M_i \in \overline{\mathbf{M}}_n^{\text{eff}}$. This set of flagged measurement channels is now closed under flagged finite convex combinations by construction, and so it follows by [SW23, Lemma 10] that

$$\inf_{\sigma \in \mathcal{F}_n} \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} D(\mathcal{M}(\rho) \| \mathcal{M}(\sigma)) = \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \inf_{\sigma \in \mathcal{F}_n} D(\mathcal{M}(\rho) \| \mathcal{M}(\sigma)).$$

Importantly by expanding our set of measurement channels we do not change our objective values. It holds that

$$\sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} D(\mathcal{M}(\rho) \| \mathcal{M}(\sigma)) = \sup_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} D(\mathcal{M}_M(\rho) \| \mathcal{M}_M(\sigma)). \quad (5.16)$$

To prove this one easily checks that for a channel $\mathcal{M} = \bigoplus_{i=1}^m p_i \mathcal{M}_i$ it holds that $D(\mathcal{M}(\rho) \| \mathcal{M}(\sigma)) = \sum_{i=1}^m p_i D(\mathcal{M}_i(\rho) \| \mathcal{M}_i(\sigma))$ which is an average and hence the claimed Eq. (5.16) follows. Completely analogously one shows that

$$\sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \|\mathcal{M}(\rho) - \mathcal{M}(\rho')\|_1 = \sup_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} \|\mathcal{M}_M(\rho) - \mathcal{M}_M(\rho')\|_1 = 2\hat{\Delta}(\rho, \rho'). \quad (5.17)$$

Now putting these observations together we get

$$\begin{aligned} |\hat{D}_{\mathcal{F}_n}(\rho) - \hat{D}_{\mathcal{F}_n}(\rho')| &= \left| \min_{\sigma \in \mathcal{F}_n} \sup_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} D(\mathcal{M}_M(\rho) \| \mathcal{M}_M(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sup_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} D(\mathcal{M}_M(\rho') \| \mathcal{M}_M(\sigma)) \right| \\ &= \left| \min_{\sigma \in \mathcal{F}_n} \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} D(\mathcal{M}(\rho) \| \mathcal{M}(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} D(\mathcal{M}(\rho') \| \mathcal{M}(\sigma)) \right| \\ &= \left| \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \min_{\sigma \in \mathcal{F}_n} D(\mathcal{M}(\rho) \| \mathcal{M}(\sigma)) - \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \min_{\sigma \in \mathcal{F}_n} D(\mathcal{M}(\rho') \| \mathcal{M}(\sigma)) \right| \\ &\leq \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \left| \min_{\sigma \in \mathcal{F}_n} D(\mathcal{M}(\rho) \| \mathcal{M}(\sigma)) - \min_{\sigma \in \mathcal{F}_n} D(\mathcal{M}(\rho') \| \mathcal{M}(\sigma)) \right| \\ &= \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \left| \min_{\sigma \in \mathcal{F}_n} \sum_{i=1}^m p_i D(\mathcal{M}_i(\rho) \| \mathcal{M}_i(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sum_{i=1}^m p_i D(\mathcal{M}_i(\rho') \| \mathcal{M}_i(\sigma)) \right|, \end{aligned} \quad (5.18)$$

where in the last line the supremum is over all $\mathcal{M} = \bigoplus_{i=1}^m p_i \mathcal{M}_i$, where $\mathcal{M}_i$ is a measurement channel corresponding to the binary POVM $M_i \in \overline{\mathbf{M}}_n^{\text{eff}}$. Before we now continue to bound the last term of Eq. (5.18) —inspired by the proof of [Win16, Lemma 7]— we introduce some notation. Fix some $\mathcal{M} = \bigoplus_{i=1}^m p_i \mathcal{M}_i \in \mathcal{M}_n^{\text{eff}}$ and define $\delta := \frac{1}{2} \|\mathcal{M}(\rho) - \mathcal{M}(\rho')\|_1$, $\delta_i := \frac{1}{2} \|\mathcal{M}_i(\rho) - \mathcal{M}_i(\rho')\|_1$, then

it follows that

$$\delta = \sum_i p_i \delta_i \leq \tilde{\Delta}(\rho, \rho')$$

and that $\eta_i := \frac{1}{\delta_i} (\mathcal{M}_i(\rho) - \mathcal{M}_i(\rho'))_+$ and $\eta'_i := \frac{1}{\delta_i} (\mathcal{M}_i(\rho') - \mathcal{M}_i(\rho))_+$ are both valid quantum states, where $(A)_+$ is the projection onto the positive part of A . We can now bound

$$\begin{aligned} \mathcal{M}_i(\rho) &= \mathcal{M}_i(\rho') + (\mathcal{M}_i(\rho) - \mathcal{M}_i(\rho')) \\ &\leq \mathcal{M}_i(\rho') + \delta_i \eta_i \\ &= (1 + \delta_i) \left(\frac{1}{1 + \delta_i} \mathcal{M}_i(\rho') + \frac{\delta_i}{1 + \delta_i} \eta_i \right) \\ &=: (1 + \delta_i) \omega_i, \end{aligned}$$

to get that

$$\omega_i = \frac{1}{1 + \delta_i} \mathcal{M}_i(\rho') + \frac{\delta_i}{1 + \delta_i} \eta_i = \frac{1}{1 + \delta_i} \mathcal{M}_i(\rho) + \frac{\delta_i}{1 + \delta_i} \eta'_i.$$

Since the relative entropy is jointly convex, we have that $\min_{\sigma \in \mathcal{F}_n} \sum_i p_i (1 + \delta_i) D(\cdot \| \mathcal{M}_i(\sigma))$ is a convex functional and hence

$$\min_{\sigma \in \mathcal{F}_n} \sum_i p_i (1 + \delta_i) D(\omega_i \| \mathcal{M}_i(\sigma)) \leq \min_{\sigma \in \mathcal{F}_n} \sum_i p_i D(\mathcal{M}_i(\rho') \| \mathcal{M}_i(\sigma)) + \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D(\eta_i \| \mathcal{M}_i(\sigma)),$$

which rearranged gives

$$\min_{\sigma \in \mathcal{F}_n} \sum_i p_i D(\mathcal{M}_i(\rho') \| \mathcal{M}_i(\sigma)) \geq \min_{\sigma \in \mathcal{F}_n} \sum_i p_i (1 + \delta_i) D(\omega_i \| \mathcal{M}_i(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D(\eta_i \| \mathcal{M}_i(\sigma)). \quad (5.19)$$

On the other hand, for any $\sigma \in \mathcal{F}_n$ we have that,

$$\begin{aligned} D(\omega_i \| \mathcal{M}_i(\sigma)) &= -S(\omega_i) - \text{Tr}[\omega_i \log(\mathcal{M}_i(\sigma))] \\ &\geq -h \left(\frac{\delta_i}{1 + \delta_i} \right) - \frac{1}{1 + \delta_i} S(\mathcal{M}_i(\rho)) - \frac{\delta_i}{1 + \delta_i} S(\eta'_i) \\ &\quad - \frac{1}{1 + \delta_i} \text{Tr}[\mathcal{M}_i(\rho) \log(\mathcal{M}_i(\sigma))] - \frac{\delta_i}{1 + \delta_i} \text{Tr}[\eta'_i \log(\mathcal{M}_i(\sigma))] \\ &= -h \left(\frac{\delta_i}{1 + \delta_i} \right) + \frac{1}{1 + \delta_i} D(\mathcal{M}_i(\rho) \| \mathcal{M}_i(\sigma)) + \frac{\delta_i}{1 + \delta_i} D(\eta'_i \| \mathcal{M}_i(\sigma)), \end{aligned}$$

where the first inequality is from [Win16, Eq. (1)] and follows from the strong sub-additivity of the von Neumann entropy. Multiplying with $p_i(1 + \delta_i)$, then rearranging the terms, and subsequently

taking the minimum yields

$$\begin{aligned}
\min_{\sigma \in \mathcal{F}_n} \sum_i p_i D(\mathcal{M}_i(\rho) \| \mathcal{M}_i(\sigma)) &\leq \min_{\sigma \in \mathcal{F}_n} \left(\sum_i p_i (1 + \delta_i) D(\omega_i \| \mathcal{M}_i(\sigma)) + \sum_i p_i (1 + \delta_i) h \left(\frac{\delta_i}{1 + \delta_i} \right) \right. \\
&\quad \left. - \sum_i p_i \delta_i D(\eta'_i \| \mathcal{M}_i(\sigma)) \right) \\
&\leq \min_{\sigma \in \mathcal{F}_n} \sum_i p_i (1 + \delta_i) D(\omega_i \| \mathcal{M}_i(\sigma)) \\
&\quad + \sum_i p_i (1 + \delta_i) h \left(\frac{\delta_i}{1 + \delta_i} \right) - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D(\eta'_i \| \mathcal{M}_i(\sigma)) . \quad (5.20)
\end{aligned}$$

Putting both inequalities together we get that,

$$\begin{aligned}
\min_{\sigma \in \mathcal{F}_n} \sum_i p_i D(\mathcal{M}_i(\rho) \| \mathcal{M}_i(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i D(\mathcal{M}_i(\rho') \| \mathcal{M}_i(\sigma)) &\leq \sum_i p_i (1 + \delta_i) h \left(\frac{\delta_i}{1 + \delta_i} \right) \\
&\quad + \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D(\eta_i \| \mathcal{M}_i(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D(\eta'_i \| \mathcal{M}_i(\sigma)) . \quad (5.21)
\end{aligned}$$

Observing that swapping $\rho \leftrightarrow \rho'$ implies $\eta \leftrightarrow \eta'$ and thus effectively a minus term in the above inequality where ρ, ρ', η, η' yields the same inequality with absolute values. Then, we get

$$\begin{aligned}
&\left| \min_{\sigma \in \mathcal{F}_n} \sum_i p_i D(\mathcal{M}_i(\rho) \| \mathcal{M}_i(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i D(\mathcal{M}_i(\rho') \| \mathcal{M}_i(\sigma)) \right| \\
&\leq \sum_i p_i \left((1 + \delta_i) h \left(\frac{\delta_i}{1 + \delta_i} \right) \right) + \left| \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D(\eta_i \| \mathcal{M}_i(\sigma)) - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D(\eta'_i \| \mathcal{M}_i(\sigma)) \right| \\
&= \sum_i p_i \left((1 + \delta_i) h \left(\frac{\delta_i}{1 + \delta_i} \right) \right) + \left| \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\rho) - \mathcal{M}_i(\rho'))_+}{\delta_i} \| \mathcal{M}_i(\sigma) \right) \right. \\
&\quad \left. - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\rho') - \mathcal{M}_i(\rho))_+}{\delta_i} \| \mathcal{M}_i(\sigma) \right) \right| \\
&\leq \sum_i p_i \left((1 + \delta_i) h \left(\frac{\delta_i}{1 + \delta_i} \right) \right) + \kappa_{\mathcal{M}} , \quad (5.22)
\end{aligned}$$

where in the second equality we substituted by the definitions of η_i, η'_i and, lastly, defined

$$\begin{aligned}
\kappa_{\mathcal{M}} := \sup_{\tau, \tau' \in \mathcal{S}(\mathcal{H}^{\otimes n})} &\left[\min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\tau) - \mathcal{M}_i(\tau'))_+}{\delta_i} \| \mathcal{M}_i(\sigma) \right) \right. \\
&\quad \left. - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\tau') - \mathcal{M}_i(\tau))_+}{\delta_i} \| \mathcal{M}_i(\sigma) \right) \right] ,
\end{aligned}$$

which doesn't require absolute values since exchanging $\tau \leftrightarrow \tau'$ gives a global minus sign.

We bound this last term in the following way,

$$\begin{aligned}
\kappa_{\mathcal{M}} &= \sup_{\tau, \tau' \in \mathcal{S}(\mathcal{H}^{\otimes n})} \left[\min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\tau) - \mathcal{M}_i(\tau'))_+}{\delta_i} \parallel \mathcal{M}_i(\sigma) \right) \right. \\
&\quad \left. - \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\tau') - \mathcal{M}_i(\tau))_+}{\delta_i} \parallel \mathcal{M}_i(\sigma) \right) \right] \\
&\leq \sup_{\tau, \tau'} \min_{\sigma \in \mathcal{F}_n} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\tau) - \mathcal{M}_i(\tau'))_+}{\delta_i} \parallel \mathcal{M}_i(\sigma) \right) \\
&\leq \sup_{\tau, \tau'} \sum_i p_i \delta_i D \left(\frac{(\mathcal{M}_i(\tau) - \mathcal{M}_i(\tau'))_+}{\delta_i} \parallel \mathcal{M}_i(\sigma^*) \right) \\
&\leq - \sum_i p_i \delta_i \log \lambda_{\min}(\mathcal{M}_i(\sigma^*)) \\
&\leq \kappa \cdot \delta + \sum_i p_i \delta_i \log \left(\frac{2}{\delta_i} \right), \tag{5.23}
\end{aligned}$$

where in the second inequality we upper bounded by plugging in the full rank state σ^* . The third inequality follows from the fact that $\tilde{\tau}_i = \frac{(\mathcal{M}_i(\tau) - \mathcal{M}_i(\tau'))_+}{\delta_i}$ is a valid quantum state and hence the inequality $D(\tilde{\tau}_i \parallel \mathcal{M}_i(\sigma^*)) \leq -\log \lambda_{\min}(\mathcal{M}_i(\sigma^*))$ holds. The fourth inequality above stems from the following lower bound

$$\begin{aligned}
\lambda_{\min}(\mathcal{M}_i(\sigma^*)) &= \min\{\text{Tr}[E_i \sigma^*], \text{Tr}[(\mathbb{1} - E_i) \sigma^*]\} \\
&\geq \lambda_{\min}(\sigma^*) \cdot \min\{\text{Tr}[E_i], \text{Tr}[\mathbb{1} - E_i]\} \\
&\geq \lambda_{\min}(\sigma^*) \cdot \frac{\delta_i}{2}, \tag{5.24}
\end{aligned}$$

where $M_i = (E_i, \mathbb{1} - E_i)$ and where the last inequality itself follows from the following observation. We have

$$\begin{aligned}
\delta_i &= |\text{Tr}[E_i(\rho - \rho')]| \leq \|E_i\|_{\infty} \|\rho - \rho'\|_1 \leq 2 \text{Tr}[E_i], \\
\delta_i &= |\text{Tr}[(\mathbb{1} - E_i)(\rho - \rho')]| \leq \|\mathbb{1} - E_i\|_{\infty} \|\rho - \rho'\|_1 \leq 2 \text{Tr}[\mathbb{1} - E_i],
\end{aligned}$$

which imply that $\min\{\text{Tr}[E_i], \text{Tr}[\mathbb{1} - E_i]\} \geq \frac{\delta_i}{2}$. Now setting $\kappa := -\log \lambda_{\min}(\sigma^*)$, recalling $\delta = \sum_i p_i \delta_i$ and applying the logarithm yields the desired inequality.

Now putting everything together we have that,

$$\begin{aligned}
|\dot{D}_{\mathcal{F}_n}(\rho) - \dot{D}_{\mathcal{F}_n}(\rho')| &\leq \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \sum_i p_i \underbrace{\left[(1 + \delta_i) h\left(\frac{\delta_i}{1 + \delta_i}\right) + \delta_i \left(\kappa + \log\left(\frac{2}{\delta_i}\right) \right) \right]}_{=: f(\delta_i)} \\
&\equiv \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} \sum_i p_i f(\delta_i) \\
&\leq \sup_{\mathcal{M} \in \mathcal{M}_n^{\text{eff}}} f\left(\sum_i p_i \delta_i\right) = f(\delta) \leq f(\varepsilon) \\
&= (1 + \varepsilon) h\left(\frac{\varepsilon}{1 + \varepsilon}\right) + \varepsilon \left(\kappa + \log\left(\frac{2}{\varepsilon}\right) \right), \tag{5.25}
\end{aligned}$$

where we have used concavity and monotonicity, since $f(\delta_i) := (1 + \delta_i) h\left(\frac{\delta_i}{1 + \delta_i}\right) + \delta_i \left(\kappa + \log\left(\frac{2}{\delta_i}\right) \right) : [0, 1] \rightarrow [0, 3 + \kappa]$ is a positive, continuous, concave, and monotonically increasing function. $\square$

Moreover, as discussed in [Win16], κ is guaranteed to be finite since $\mathcal{F}_n$ contains at least one full-rank state. For example, in the case of the entanglement resource, $\mathcal{F}_n = \text{SEP}_n \ni \frac{1}{2^n}$ and so $\kappa = n$. Therefore, for the *computational measured relative entropy of resource* another property is fulfilled: *computational faithfulness*.

Corollary 5.8. *Let $\mathcal{F}_n \subset \mathcal{S}(\mathcal{H}^{\otimes n})$ be closed, convex, and bounded containing a full-rank state. Given two families of states $\{\rho_n\}_{n \in \mathbb{N}}$ and $\{\rho'_n\}_{n \in \mathbb{N}}$ which are computationally indistinguishable, then,*

$$|\dot{D}_{\mathcal{F}_n}(\rho_n) - \dot{D}_{\mathcal{F}_n}(\rho'_n)| \leq \text{negl}(n) \tag{5.26}$$

Proof. It directly follows from Theorem 5.7 assuming that $\dot{\Delta}(\rho_k, \rho'_n) \leq \text{negl}(n)$. $\square$

The operational implications of this equation are as follows: if a family of states $\{\rho_n\}_{n \in \mathbb{N}}$ with high (information-theoretic) resource content is computationally indistinguishable from a family of free states $\{\sigma_n\}_{n \in \mathbb{N}}$ with $\sigma_n \in \mathcal{F}_n$, then the computational measured relative entropy of resource of $\{\rho_n\}_{n \in \mathbb{N}}$ is negligible, i.e., $\dot{D}_{\mathcal{F}_n}(\rho_n) = \text{negl}(n)$. This phenomenon has been studied before in the context of pseudoentanglement [ABF⁺23, ABV23, LREJ25] and other pseudoresources [HBK24, BMB⁺24, GY25] from a more heuristic perspective: if a computational distinguisher is able to distill more resource from one of the families, then it can distinguish them. Here, we provide an analytical expression that quantifies this for every resource.

5.3 Computational Entanglement Measures

Let us now focus on the resource of entanglement. Analogously to the information-theoretic scenario, we define the computational measured relative entropy of entanglement as

$$\dot{E}_R(\rho) := \dot{D}_{\text{SEP}_n}(\rho) = \min_{\sigma \in \text{SEP}_n} \dot{D}^{\mathbf{M}_n^{\text{eff}}}(\rho \| \sigma), \tag{5.27}$$

where we take $\mathcal{F}_n = \text{SEP}_n$ to be the set of separable states, i.e.,

$$\text{SEP}_n := \text{conv}\{\rho_A^n \otimes \rho_B^n : \rho_A^n \in \mathcal{S}(\mathcal{H}_A^{\otimes n}), \rho_B^n \in \mathcal{S}(\mathcal{H}_B^{\otimes n})\} \quad (5.28)$$

Let us again show an explicit separation between the computational measures and its information-theoretic counterparts using the explicit cryptographic construction of Section 4.5,

$$\begin{aligned} \psi_n^{AB} &:= \frac{1}{4} \left(|\Phi^+\rangle\langle\Phi^+|^{AB} + |\Phi^-\rangle\langle\Phi^-|^{AB} \right) \otimes (\rho_{0,n}^A + \rho_{1,n}^A), \\ \phi_n^{AB} &:= \frac{1}{2} \left(|\Phi^+\rangle\langle\Phi^+|^{AB} \otimes \rho_{0,n}^A + |\Phi^-\rangle\langle\Phi^-|^{AB} \otimes \rho_{1,n}^A \right), \end{aligned}$$

where $|\Phi^+\rangle^{AB} = \frac{1}{\sqrt{2}}(|00\rangle^{AB} + |11\rangle^{AB})$, $|\Phi^-\rangle^{AB} = \frac{1}{\sqrt{2}}(|00\rangle^{AB} - |11\rangle^{AB})$ and $\{\rho_{0,n}^A, \rho_{1,n}^A\}_{n \in \mathbb{N}}$ are EFI pairs. One can easily see that $E_R(\phi_n^{AB}) \approx 1$ by construction. On the other hand, as stated in Section 4.5, $\dot{\Delta}(\psi_n^{AB}, \phi_n^{AB}) \leq \text{negl}(n)$. Then, by Theorem 5.7, it follows that $\dot{E}_R(\phi_n^{AB}) \leq \text{negl}(n)$. Moreover, this explicit gap can again be (polynomially) amplified as proven in [GE24, Lemma 5.1].

To relate the *computational measured relative entropy of entanglement* to the *(one-shot) computational entanglement cost* and the *(one-shot) computational distillable entanglement* defined by [ABV23], we first fix the class of efficient free operations we work with. In entanglement theory, local operations and classical communication (LOCC) form the canonical class of free maps: they cannot increase entanglement, and they directly model a practical two-party communication setting.

Definition 5.9 (LOCC Map [ABV23]). A quantum channel is said to be an LOCC map

$$\Gamma : \mathcal{H}_A \otimes \mathcal{H}_B \mapsto \mathcal{H}_{\bar{A}} \otimes \mathcal{H}_{\bar{B}}$$

if it can be implemented by a two-party interactive protocol where each party can implement arbitrary local quantum computations and the two parties can exchange arbitrary classical communication.

We now consider their complexity-constrained counterparts.

Definition 5.10 (Circuit Description of an LOCC Map [ABV23]). Given an LOCC map Γ , its circuit description is given by two families of circuits $\{\mathcal{C}_{A,i}\}_{i \in \{1, \dots, r\}}$ and $\{\mathcal{C}_{B,i}\}_{i \in \{1, \dots, r\}}$, each of them acting on $n_A + t_A + c$ and $n_B + t_B + c$ qubits respectively, such that the following procedure implements the map Γ on an arbitrary input $\varphi_{AB} \in (\mathbb{C}^2)^{\otimes n_A} \otimes (\mathbb{C}^2)^{\otimes n_B}$:

1. Registers A and B of n_A and n_B qubits are initialized in the state φ_{AB} . Ancilla registers A' and B' of t_A and t_B qubits are initialized in the $|0\rangle$ state. Communication register C is also initialized in the $|0\rangle$ state.
2. For $i = 1, \dots, r$, the circuit $\mathcal{C}_{A,i}$ is applied to registers A , A' and C . Then, register C is measured in the computational basis. Next, the circuit $\mathcal{C}_{B,i}$ is applied to registers B , B' , and C . Lastly, register C is measured in the computational basis.
3. The final output of the LOCC map in the subspace $\mathcal{H}_{A'}$ corresponds to the state in the registers A and A' . In the same way, the state in the registers B and B' is the final output on $\mathcal{H}_{B'}$.

A family of LOCC maps $\{\Gamma_n\}_{n \in \mathbb{N}}$ is said to be efficient if there exists a polynomial c such that for all n , Γ_n has a circuit description whose total number of gates, including the ancilla creation and qubit measurements, is at most $c(n)$.

Let us take the class of efficient LOCC as the set of free operations as in Definition 5.3. It is easy to see that, by construction, it satisfies the state condition: LOCC operations map separable states to separable states. Moreover, by the efficiency condition, if an input state is efficiently preparable, then so is the output, since composing a polynomial-size state-preparation circuit with a polynomial-size LOCC circuit remains polynomial.

Remark 5.11. For the test stability property, we consider efficient LOCC channels $\Gamma_n : \mathcal{S}(\mathcal{H}_1^{\otimes n}) \rightarrow \mathcal{S}(\mathcal{H}_{2,n})$, where $\dim \mathcal{H}_{2,n} \in 2^{\text{poly}(n)}$ with gate complexity $c(n)$, and an output-side efficient effect operator $E \in \mathbf{E}_n^{\text{eff}}(\mathcal{H}_{2,n})$ with complexity cost $p(n)$.¹¹ Hence, the composed effect operator $\Gamma^*(E)$ belongs to the set of efficient effects $\mathbf{E}_n^{\text{eff}}(\mathcal{H}_1^{\otimes n})$ if the associated complexity cost $q(n)$ of the set $\{\mathbf{E}_n^{\text{eff}}(\mathcal{H}_1^{\otimes n})\}_{n \in \mathbb{N}}$ satisfies,

$$q(n) \geq p(n) + c(n),$$

for all $n \in \mathbb{N}$. Since the set $\{\mathbf{E}_n^{\text{eff}}(\mathcal{H}_1^{\otimes n})\}_{n \in \mathbb{N}}$ can be generated in polynomial time, without loss of generality we assume from now on that both conditions of Definition 5.3 are satisfied by the set of efficient LOCC operations. As such, the computational measured relative entropy of entanglement satisfies the monotonicity property under efficient LOCC operations.

With efficient LOCC fixed as our class of free operations, we are now ready to introduce the computational entanglement measures defined by [ABV23]. Operationally, they encode how many Bell states $\Phi := |\Phi_1\rangle \langle \Phi_1|$ one can distill from or, respectively, are required to produce a given state using only efficient LOCC operations, where the Bell state is defined as $|\Phi_1\rangle := \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$. Moreover, it satisfies that $\Phi^{\otimes n} = |\Phi_n\rangle \langle \Phi_n|$, where $|\Phi_n\rangle := \frac{1}{\sqrt{2^n}} \sum_{i=0}^{2^n-1} |i\rangle |i\rangle$.

Definition 5.12 (Computational One-Shot Entanglement Cost [ABV23]). Let $\varepsilon : \mathbb{N}_+ \rightarrow [0, 1]$ and $n \in \mathbb{N}_+$. Fix polynomial functions $n_A, n_B : \mathbb{N}_+ \rightarrow \mathbb{N}_+$. Let $\{\rho_{AB}^n\}_n$ be a family of quantum states such that, for any $n \geq 1$, $\rho_{AB}^n \in \mathcal{H}_A \otimes \mathcal{H}_B$ is a bipartite state on $n_A(n) + n_B(n)$. The function $k : \mathbb{N} \rightarrow \mathbb{N}$ is an upper bound on the computational entanglement cost of the family $\{\rho_{AB}^n\}_n$, i.e. $\hat{E}_C^\varepsilon(\{\rho_{AB}^n\}_n) \leq k(n)$, if there exists an efficient LOCC map family $\{\Gamma_n\}_n$ such that, for each $n \geq 1$, Γ_n takes an input $k(n)$ maximally entangled d -dimensional states, and

$$1 - F(\rho_{AB}^n, \Gamma_n(\Phi^{\otimes k(n)})) \leq \varepsilon(n).$$

Definition 5.13 (Computational One-Shot Distillable Entanglement [ABV23]). Let $\varepsilon : \mathbb{N}_+ \rightarrow [0, 1]$ and $n \in \mathbb{N}_+$. Fix polynomial functions $n_A, n_B : \mathbb{N}_+ \rightarrow \mathbb{N}_+$. Let $\{\rho_{AB}^n\}_n$ be a family of quantum states such that, for any $n \geq 1$, $\rho_{AB}^n \in \mathcal{H}_A \otimes \mathcal{H}_B$ is a bipartite state on $n_A(n) + n_B(n)$. The function $m : \mathbb{N} \rightarrow \mathbb{N}$ is a lower bound on the computational distillable entanglement of the family $\{\rho_{AB}^n\}_n$,

¹¹ While this kind of mapping is not directly captured by Definition 5.3, it can easily be extended to this form.

i.e. $\hat{E}_D^\varepsilon(\{\rho_{AB}^n\}_n) \geq m(n)$, if there exists an efficient LOCC map family $\{\Gamma_n\}_n$ such that, for each $n \geq 1$, Γ_n outputs a $2m(n)$ -qubit state, and

$$1 - F(\Gamma_n(\rho_{AB}^n), \Phi^{\otimes m(n)}) \leq \varepsilon(n).$$

Let us first evaluate $\hat{E}_R$ on maximally entangled states before comparing it with the previously defined computational entanglement measures.

Lemma 5.14. *Assume that the Bell projector $\Phi_n = |\Phi_n\rangle\langle\Phi_n| = \Phi_1^{\otimes n} \in \mathbf{E}_{2n}^{\text{eff}}$ is efficiently generated.¹² Then it follows that*

$$\hat{E}_R(\Phi^{\otimes n}) = n,$$

where $\Phi^{\otimes n} := |\Phi_n\rangle\langle\Phi_n| \in \mathcal{B}((\mathbb{C}_A^2)^{\otimes n} \otimes (\mathbb{C}_B^2)^{\otimes n})$.

Note that the condition $\Phi^{\otimes n} \in \mathbf{E}_{2n}^{\text{eff}}$ is implied by the much simpler one of $\Phi \in \mathbf{E}_2^{\text{eff}}$ whenever the polynomial in the construction of the family $\{\mathbf{E}_n^{\text{eff}}\}_{n \in \mathbb{N}}$ is (super)-additive.

Proof. We first show that $\hat{E}_R(\Phi^{\otimes n}) \geq n$. Since Φ can be efficiently generated, the measurement $M_{\Phi_n} = (\Phi_n, \mathbb{I} - \Phi_n) \in \mathbf{M}_{2n}^{\text{eff}}$. Then, since $\langle\Phi_n|\sigma|\Phi_n\rangle \leq \frac{1}{2^n}$ for any $\sigma \in \text{SEP}_n$, we have $D(\mathcal{M}_{M_{\Phi_n}}(\Phi_n) \parallel \mathcal{M}_{M_{\Phi_n}}(\sigma)) \geq n$ for any $\sigma \in \text{SEP}_n$. Let us prove this in detail for completeness. Due to convexity of the map $\sigma \mapsto \langle\Phi_n|\sigma|\Phi_n\rangle$ it suffices to consider product states $\sigma = \rho_A \otimes \rho_B$. Now by a standard Choi argument we have

$$\langle\Phi_n|\rho_A \otimes \rho_B|\Phi_n\rangle = 2^{-n} \text{Tr} \left[\left(\sum_{i,j=0}^{2^n-1} |i\rangle\langle j|_A \otimes |i\rangle\langle j|_B \right) (\rho_A \otimes \rho_B) \right] \quad (5.29)$$

$$= 2^{-n} \text{Tr} [\rho_A \rho_B^T] \leq 2^{-n} \|\rho_A\|_2 \|\rho_B^T\|_2 \leq 2^{-n}, \quad (5.30)$$

where in the last line we used Cauchy-Schwartz inequality and normalization of the states.

$$\begin{aligned} \hat{E}_R(\Phi_n) &= \min_{\sigma \in \text{SEP}_n} \sup_{M \in \bar{\mathbf{M}}_n^{\text{eff}}} \hat{D}(\mathcal{M}_M(\Phi_n) \parallel \mathcal{M}_M(\sigma)) \\ &\geq \min_{\sigma \in \text{SEP}_n} D(\mathcal{M}_{M_{\Phi_n}}(\Phi_n) \parallel \mathcal{M}_{M_{\Phi_n}}(\sigma)) \\ &= \min_{\sigma \in \text{SEP}_n} (-\log \langle\Phi_n|\sigma|\Phi_n\rangle) \geq n. \end{aligned}$$

We now show $\hat{E}_R(\Phi_n) \leq n$. By definition,

$$\begin{aligned} \hat{E}_R(\Phi_n) &= \min_{\sigma \in \text{SEP}_n} \sup_{M \in \bar{\mathbf{M}}_n^{\text{eff}}} \hat{D}(\mathcal{M}_M(\Phi_n) \parallel \mathcal{M}_M(\sigma)) \\ &\leq \sup_{M \in \bar{\mathbf{M}}_n^{\text{eff}}} \hat{D}(\mathcal{M}_M(\Phi_n) \parallel \mathcal{M}_M(\sigma^*)), \end{aligned}$$

¹²For example, any set of efficient effects $\mathbf{E}_n^{\text{eff}}$ which is generated by the gateset $\mathcal{G} \supset \{H, CNOT\}$ and the super-additive polynomial $p(n) = n^2$.

where $\sigma_n^* = 2^{-n} \sum_{x \in \{0,1\}^n} |x\rangle\langle x|_A \otimes |x\rangle\langle x|_B$ which is separable. Lastly, by data processing,

$$\sup_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} \dot{D}(\mathcal{M}_M(\Phi_n) \| \mathcal{M}_M(\sigma^*)) \leq D(\Phi_n \| \sigma^*) = -\langle \Phi_n | \log \sigma^* | \Phi_n \rangle = n.$$

□

Therefore, in this simple case of effectively not assuming computational restrictions, our measure attains the expected maximum. Let us now also relate $\dot{E}_R$ to the computational entanglement cost and computational distillable entanglement proposed by [ABV23], assuming that the Bell projector $\Phi_n \in \mathbf{E}_{2n}^{\text{eff}}$ is efficiently preparable.

Lemma 5.15. *Assume as before that the effect operator $\Phi^{\otimes n} \in \mathbf{E}_{2n}^{\text{eff}}$ is efficiently generated. Given a family of states $\{\rho_{AB}^n\}_n \subset \mathcal{B}((\mathbb{C}_A^2)^{\otimes n} \otimes (\mathbb{C}_B^2)^{\otimes n})$, it follows that*

$$\begin{aligned} \dot{E}_D(\rho_{AB}^n) &\leq \dot{E}_R(\rho_{AB}^n) + g(\sqrt{\varepsilon(n)}, n), \\ \dot{E}_C(\rho_{AB}^n) &\geq \dot{E}_R(\rho_{AB}^n) - g(\sqrt{\varepsilon(n)}, n), \end{aligned}$$

where $\dot{E}_D(\rho_{AB}^n)$ and $\dot{E}_C(\rho_{AB}^n)$ are, respectively, the computational distillable entanglement (Definition 5.13) and the computational entanglement cost (Definition 5.12), and

$$g(\sqrt{\varepsilon(n)}, n) := (1 + \sqrt{\varepsilon(n)}) h\left(\frac{\sqrt{\varepsilon(n)}}{1 + \sqrt{\varepsilon(n)}}\right) + \sqrt{\varepsilon(n)} \left(n + \log \frac{2}{\sqrt{\varepsilon(n)}}\right).$$

Proof. We first show the bound for the computational distillable entanglement. By Definition 5.13, $\dot{E}_D(\rho_{AB}^n) \geq m(n)$ if there exists a family of efficient LOCC maps $\{\Gamma_n\}_n$ such that, for each $n \in \mathbb{N}$,

$$1 - F(\eta_{AB}, \Phi^{\otimes m(n)}) \leq \varepsilon(n), \quad \eta_{AB} := \Gamma_n(\rho_{AB}^n).$$

Using the (information-theoretic) Fuchs–van de Graaf and the data-processing inequality, this also implies that $\dot{\Delta}(\eta_{AB}, \Phi^{\otimes m(n)}) \leq \sqrt{\varepsilon(n)}$. Then, by Theorem 5.7, it follows that

$$|\dot{E}_R(\Phi^{\otimes m(n)}) - \dot{E}_R(\eta_{AB})| \leq g(\sqrt{\varepsilon(n)}, n).$$

Since, by Lemma 5.15 $\dot{E}_R(\Phi^{\otimes m(n)}) = m(n)$, and since $\dot{E}_R(\eta_{AB}) \leq \dot{E}_R(\rho_{AB}^n)$ by the monotonicity property under efficient maps, we obtain $m(n) \leq \dot{E}_R(\rho_{AB}^n) + g(\sqrt{\varepsilon(n)}, n)$. Taking the supremum over all achievable $m(n)$ yields the stated bound on $\dot{E}_D$.

The computational entanglement cost bound follows analogously. We have that $\dot{E}_C(\rho_{AB}^n) \leq k(n)$, if there exists a family of efficient LOCC maps $\{\Gamma_n\}_n$ such that, for each $n \in \mathbb{N}$,

$$1 - F(\rho_{AB}^n, \eta_{AB}) \leq \varepsilon(n), \quad \eta_{AB} := \Gamma_n(\Phi^{\otimes k(n)}).$$

Similarly, by Fuchs–van de Graaf and DPI, $\dot{\Delta}(\rho_{AB}^n, \eta_{AB}) \leq \sqrt{\varepsilon(n)}$. Then, by Theorem 5.7 the

following bound holds,

$$|\mathring{E}_R(\eta_{AB}) - \mathring{E}_R(\rho_{AB}^n)| \leq g(\sqrt{\varepsilon(n)}, n).$$

By monotonicity under efficient maps, $\mathring{E}_R(\eta_{AB}) \leq \mathring{E}_R(\Phi^{\otimes k(n)})$. Moreover, by Lemma 5.15 it holds that $\mathring{E}_R(\Phi^{\otimes k(n)}) = k(n)$. Therefore, it follows that $k(n) \geq \mathring{E}_R(\rho_{AB}^n) - g(\sqrt{\varepsilon(n)}, n)$. Then, taking the infimum over all feasible $k(n)$ yields to the desired inequality. $\square$

Consequently, $\mathring{E}_R$ is sandwiched between the computational distillable entanglement and the computational entanglement cost, up to the continuity term $g(\sqrt{\varepsilon(n)}, n)$. This parallels the information-theoretic hierarchy $E_D \leq E_R \leq E_C$ and confirms that $\mathring{E}_R$ behaves as an entanglement measure in the computational setting.

Remark 5.16. *For the computational max-entropy of entanglement defined in Definition 5.5, a direct comparison with the one-shot measures of [ABV23] is not straightforward. In the unconstrained regime, the max-relative entropy of entanglement (equivalently, the log-robustness) attains a one-shot operational meaning after smoothing with respect to non-entangling operations, a class that strictly contains LOCC [Dat09a, BD11]. Analogously, smoothing the computational max-entropy we define and taking the efficient free operations to be (efficient) non-entangling maps may clarify its relation to the measures in [ABV23].*

6 Discussion and Open Questions

We examine central information-theoretic quantities and naturally incorporate computational constraints, building a cohesive framework. Our guiding principle is to retain the clear operational meaning of the original quantities while enforcing that the measurements are efficient.

6.1 Discussion

On the one hand, we take a geometric approach to incorporate computational constraints into the max-divergence. We construct families of proper cones of polynomially generated effect operators, which we define to be generated by efficiently approximate effect operators using non-uniform polynomial circuits. The computational max-divergence then naturally arises [RKW11, GC24], induced by the partial order given by those cones. On the other hand, we define the set of binary POVMs composed by the elements of our polynomially generated effect operators. This set allows us to define a computational notion of measured Rényi divergences, based on constructions from [RSB24, MH23]. We show that these two, a priori, quite different approaches to computational divergences are consistent in the sense that in the limit $\alpha \rightarrow \infty$, the computational measured Rényi divergence coincides with the computational max-divergence (see Theorem 4.12). This equivalence is not only an analogue of the information-theoretic case, but also shows the consistency of our defined divergences and highlights the usefulness of conic theory to computational quantum information. Inspired by [RKW11], we further consider computational notions of the fidelity and trace distance. These quantities are

related in meaningful — yet straightforward — ways to our computational divergences, such as via a computational Pinsker inequality (Lemma 4.11). Moreover, they are related to each other via a computational Fuchs–van de Graaf inequality (Lemma 4.22). These relations reflect the robustness and flexibility of our framework, and allow us to provide an explicit example for which these quantities differ from their information-theoretic counterparts in Section 4.5.

Lastly, we consider two relevant applications. Firstly, in the context of asymmetric binary hypothesis testing, we show that the regularized version of our computational measured relative entropy has a sharp operational meaning as an upper bound on the Stein-exponent, Theorem 5.2. In other words, it upper-bounds the error exponent of asymmetric binary hypothesis testing under our computationally restricted measurements. This result is a direct analog to the information-theoretic setting.

Secondly, in the context of resource theories, these computational divergences allow us to define different resource measures. The main result of that section is an asymptotic continuity bound for the computational measured relative entropy, Theorem 5.7. This bound is the computational analogue of [Win16, SW23] and we believe it to be of independent interest as it is, as far as we are aware, the first asymptotic continuity bound relating a measurement-restricted divergence with its corresponding restricted trace distance. This bound allows us to state the following analytical characterization: computationally indistinguishable families of states will also have computationally indistinguishable resource contents. This phenomenon had been previously stated in a slightly more heuristic manner, under cryptographic reductions. Moreover, focusing on entanglement, Theorem 5.7 lets us compare the computational measured relative entropy of entanglement $\dot{E}_R$ induced by our divergences with the computational distillable entanglement and entanglement cost of [ABV23]: under efficient LOCC (up to a continuity term), one has $\dot{E}_D(\rho_{AB}^n) \leq \dot{E}_R(\rho_{AB}^n) \leq \dot{E}_C(\rho_{AB}^n)$, thereby reproducing the information-theoretic hierarchy.

Apart from these applications we consider, we expect this formalism to be relevant across various areas of computational quantum information theory. In part, this is because our quantities directly incorporate a central practical constraint — scalability — on which manipulations and measurements remain implementable as the systems grow. Complexity and practical polynomial constraints are already relevant in many-body physics, where tools dealing with the exponentially growing Hilbert-space dimension as a function of the particle number have proven very valuable [Has07, PVWC07, CPSV21]. Only transformations with at most polynomial cost are asymptotically viable, as made precise by Hamiltonian-complexity results [AE11, GHLS15]. On the measurement side, compressed-acquisition schemes such as classical shadows estimate observables with polynomial resources, reinforcing the value of complexity-aware information measures [HKP20, KGKB25]. Related ideas surface in quantum thermodynamics, where resource costs are analyzed under explicit complexity restrictions [MKH⁺25], and in high-energy theory, where “complexity = action/volume” links boundary complexity to bulk geometry in AdS/CFT [BRS⁺16, BS18]. Lastly, our approach interfaces naturally with cryptography, where indistinguishability is explicitly computational; see e.g. pseudorandom states [JLS18] and pseudorandom unitaries [MPSY24].

6.2 Open questions

A variety of interesting and promising avenues for future research follow from this work. It is a mathematically natural question to extend our formalism beyond the binary setting to multi-outcome POVMs, keeping implementability and classical post-processing explicit. This would broaden the scope of our work and connect it to operational tasks such as multi-hypothesis testing and multi-party decoupling. This direction is particularly appealing since it opens the possibility of defining a computational min-entropy within our framework and allows one to study its connection to previously studied computational entropies, such as the HILL entropies from [CCL⁺17] or the computational min-/max-entropies defined in [AA25, AHRA25].

On the technical side, a key open problem is to establish nontrivial lower bounds on the computational Stein exponent. From an operational viewpoint, it would be valuable to clarify the role of our computational divergences in one-shot resource tasks under efficient free operations. Pursuing this direction—including smoothed variants of the computational max divergence and (efficient) non-entangling maps—may illuminate further connections between the measures introduced here and prior work in computational entanglement theory [ABV23, LREJ25].

Acknowledgments

A Cone of Efficient Binary Measurements

A.1 Proof of Corollary 3.12

Recall that we want to effectively place a bound on the diamond norm between measurement maps corresponding to binary POVMs, given the operator norm difference between their effect operators.

Proof of Corollary 3.12. By Proposition 3.10 there exists a binary measurement M' such that $M = (E_1, E_2)$ and $M' = (F_1, F_2) = (\frac{1}{k} \sum_{i=1}^k E_{j_i}, \mathbb{1} - \frac{1}{k} \sum_{i=1}^k E_{j_i})$ satisfy

$$\|E_1 - F_1\|_\infty = \|E_2 - F_2\|_\infty \leq \varepsilon. \quad (\text{A.1})$$

Recall that the measurement maps they induce are given by

$$\mathcal{M}(\rho) = \sum_{i=0}^1 \text{Tr}[E_{i+1}\rho] |i\rangle\langle i|, \quad \mathcal{M}'(\rho) = \sum_{i=0}^1 \text{Tr}[F_{i+1}\rho] |i\rangle\langle i|,$$

for any state $\rho \in \mathcal{S}(\mathcal{H}^n)$ (and some choice of n). Alternatively, for any state $\rho \in \mathcal{S}(\mathcal{H}^n \otimes \mathcal{H}')$ on the extended Hilbert space $\mathcal{H}'$, $\mathcal{M} \otimes \text{Id}$ and $\mathcal{M}' \otimes \text{Id}$ are mappings of the form

$$\mathcal{M} \otimes \text{Id}(\rho) = \sum_{i=0}^1 |i\rangle\langle i| \otimes \text{tr}_{\mathcal{H}^{\otimes n}}[E_{i+1}\rho] : \mathcal{S}(\mathcal{H}^{\otimes n} \otimes \mathcal{H}') \rightarrow \mathcal{S}(\mathbb{C}^2 \otimes \mathcal{H}'), \quad (\text{A.2})$$

where $\mathcal{M}' \otimes \text{Id}$ is analogous and tr stands for the partial trace. Hence, for these measurements, it must hold that

$$\begin{aligned} \|\mathcal{M} - \mathcal{M}'\|_\diamond &= \sup_{\rho \in \mathcal{S}(\mathcal{H}^{\otimes n} \otimes \mathcal{H}')} \|((\mathcal{M} - \mathcal{M}') \otimes \text{Id})(\rho)\|_1 \\ &= \sup_{\rho} \left\| \sum_{i=0}^1 |i\rangle\langle i| \otimes \text{tr}_{\mathcal{H}^{\otimes n}}[(E_{i+1} - F_{i+1})\rho] \right\|_1 \\ &= \sup_{\rho} \sum_{i=0}^1 \|\text{tr}_{\mathcal{H}^{\otimes n}}[(E_{i+1} - F_{i+1})\rho]\|_1 \\ &\leq \sup_{\rho} \sum_{i=0}^1 \|(E_{i+1} - F_{i+1})\rho\|_1 \\ &\leq \sup_{\rho} \sum_{i=0}^1 \|E_{i+1} - F_{i+1}\|_\infty \|\rho\|_1 \\ &\leq 2\varepsilon. \end{aligned}$$

The first inequality follows from the fact that the partial trace is trace-norm contractive, and the second is an application of Hölder's inequality. The last inequality follows then from Eq. (A.1). $\square$

A.2 Proof of Lemma 3.21

Recall that we want to prove the following three equivalences

$$\|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} = \begin{cases} 2 \max_{E \in \mathbf{E}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] , & (i) \\ \max_{M=(E_1, E_2) \in \mathbf{M}_n^{\text{eff}}} \sum_{i=1}^2 |\text{Tr}[E_i(\rho - \sigma)]| , & (ii) \\ \max_{M \in \mathbf{M}_n^{\text{eff}}} \|\mathcal{M}_M(\rho) - \mathcal{M}_M(\sigma)\|_1 . & (iii) \end{cases} \quad (\text{A.3})$$

Let us prove them separately.

Proof of first equality (i). By definition of

$$\|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} = 2 \max_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] \geq 2 \max_{E \in \mathbf{E}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] ,$$

we get the first inequality. The other inequality follows since the functional $E \mapsto \text{Tr}[E(\rho - \sigma)]$ is linear and thus convex and so

$$2 \max_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] = 2 \max_{E \in \text{extr}(\overline{\mathbf{E}}_n^{\text{eff}})} \text{Tr}[E(\rho - \sigma)] \leq 2 \max_{E \in \mathbf{E}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] . \quad (\text{A.4})$$

Combining both inequalities proves the desired result. $\square$

Proof of second equality (ii). By the above proven first equivalence, it holds that

$$\begin{aligned} 2 \max_{E \in \mathbf{E}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] &= \max_{E \in \mathbf{E}_n^{\text{eff}}} |\text{Tr}[E(\rho - \sigma)]| + |\text{Tr}[-E(\rho - \sigma)]| \\ &= \max_{E \in \mathbf{E}_n^{\text{eff}}} |\text{Tr}[E(\rho - \sigma)]| + |\text{Tr}[(\mathbb{1} - E)(\rho - \sigma)]| \\ &= \max_{M=(E_1, E_2) \in \mathbf{M}_n^{\text{eff}}} |\text{Tr}[E_1(\rho - \sigma)]| + |\text{Tr}[E_2(\rho - \sigma)]| \\ &= \max_{M=(E_1, E_2) \in \mathbf{M}_n^{\text{eff}}} \sum_{i=1}^2 |\text{Tr}[E_i(\rho - \sigma)]| . \end{aligned}$$

$\square$

Proof of third equality (iii). For any binary measurement $M = (E_1, E_2) \in \mathbf{M}_n^{\text{eff}}$, it further holds that

$$\begin{aligned} \sum_{i=1}^2 |\text{Tr}[E_i(\rho - \sigma)]| &= \left\| \sum_{i=0}^1 \text{Tr}[E_{i+1}(\rho - \sigma)] |i\rangle\langle i| \right\|_1 \\ &= \left\| \sum_{i=0}^1 \text{Tr}[E_{i+1}\rho] |i\rangle\langle i| - \sum_{i=0}^1 \text{Tr}[E_{i+1}\sigma] |i\rangle\langle i| \right\|_1 \\ &= \|\mathcal{M}_M(\rho) - \mathcal{M}_M(\sigma)\|_1 , \end{aligned}$$

Optimizing over $M = (E_1, E_2) \in \mathbf{M}_n^{\text{eff}}$ then yields (iii). $\square$

A.3 Proof of Lemma 3.24

Recall that we want to prove that $\|\cdot\|_{\overline{\mathbf{M}}_{n \cdot m}^{\text{eff}}}$ is sub-additive, i.e.

$$\|\rho^{\otimes m} - \sigma^{\otimes m}\|_{\overline{\mathbf{M}}_{n \cdot m}^{\text{eff}}} \leq m \max_{i \in \{1, \dots, m\}} \|\rho_i - \sigma_i\|_{\overline{\mathbf{M}}_n^{\text{eff}}} ,$$

where $\rho_i = \rho^{\otimes i-1} \otimes \rho \otimes \sigma^{\otimes n-i}$, $\sigma_i = \rho^{\otimes i-1} \otimes \sigma \otimes \sigma^{\otimes n-i}$.

Proof of Lemma 3.24. Note that $\rho_{i-1} = \sigma_i$ and $\rho_m = \rho^{\otimes m}$, $\sigma_1 = \sigma^{\otimes m}$. As such

$$\rho^{\otimes m} - \sigma^{\otimes m} = \rho_m - \sigma_1 = \sum_{j=1}^m \rho_j - \sum_{j=1}^{m-1} \rho_j - \sigma_1 = \sum_{j=1}^m (\rho_j - \sigma_j) .$$

Using this and the triangle inequality repeatedly now yields the claim

$$\|\rho^{\otimes m} - \sigma^{\otimes m}\|_{\overline{\mathbf{M}}_{n \cdot m}^{\text{eff}}} \leq \sum_{j=1}^m \|\rho_j - \sigma_j\|_{\overline{\mathbf{M}}_n^{\text{eff}}} \leq \sum_{j=1}^m \max_{i \in \{1, \dots, m\}} \|\rho_i - \sigma_i\|_{\overline{\mathbf{M}}_n^{\text{eff}}} \leq m \max_{i \in \{1, \dots, m\}} \|\rho_i - \sigma_i\|_{\overline{\mathbf{M}}_n^{\text{eff}}} .$$

□

B Computational Quantum Divergences

B.1 Proof of Lemma 4.6

Recall, we want to prove that

$$\mathring{D}_{\max}(\rho \parallel \sigma) \geq \log \left(1 + \mathring{\Delta}(\rho, \sigma) \right) .$$

Proof of Lemma 4.6. If $\mathring{D}_{\max}(\rho \parallel \sigma) = \infty$, then this trivially holds. Assume that $\mathring{D}_{\max}(\rho \parallel \sigma) < \infty$. Hence there exists some λ such that $\rho \leq_{\mathcal{C}_n^{\text{seff}}} \lambda \sigma$. Then, for any such λ , we have

$$\begin{aligned} \frac{1}{2} \|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}} &= \sup_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \text{Tr}[E(\rho - \sigma)] \\ &\leq \sup_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \text{Tr}[E(\lambda \sigma - \sigma)] \\ &= (\lambda - 1) \sup_{E \in \overline{\mathbf{E}}_n^{\text{eff}}} \text{Tr}[E\sigma] \\ &\leq \lambda - 1 , \end{aligned}$$

where for the inequality we are using that the partial order $\leq_{\mathcal{C}_n^{\text{seff}}}$ is the one induced by the dual cone to $\mathcal{C}_n^{\text{seff}}$ to which $\overline{\mathbf{E}}_n^{\text{eff}}$ contains a base. Rearranging gives, $\lambda \geq 1 + \frac{1}{2} \|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}}$ and taking the

infimum over all such suitable λ yields the statement of the lemma,

$$\begin{aligned}\dot{D}_{\max}(\rho\|\sigma) &:= \log \inf\{\lambda \in \mathbb{R} | \rho \leq_{\mathcal{C}_n^{\text{eff}}} \lambda \sigma\} \\ &\geq \log \left(1 + \frac{1}{2} \|\rho - \sigma\|_{\overline{\mathbf{M}}_n^{\text{eff}}}\right) \\ &= \log \left(1 + \dot{\Delta}(\rho, \sigma)\right) .\end{aligned}$$

□

B.2 Proof of Lemma 4.10

Proof of Lemma 4.10. The properties of the computational measured Rényi divergences follows directly from [RSB24, Lemmas 2 & 5] and [Tom16, Chapter 4]. We will use $\mathbb{D}_\alpha(\mu\|\nu)$ for denoting a classical Rényi divergence over probabilities distributions μ, ν . Recall that, when $\mu_\rho^M(i) = \text{Tr}[\rho E_i]$ and $\nu_\sigma^M(i) = \text{Tr}[\sigma E_i]$, $\dot{D}_\alpha^{\mathbf{M}^{\text{eff}}}(\rho\|\sigma) = \sup_{M \in \mathbf{M}_n^{\text{eff}}} \mathbb{D}_\alpha(\mu_\rho^M\|\nu_\sigma^M)$.

(1) Follows from the positivity of the classical Rényi divergence.

(2) For every pair of probabilities distributions μ, ν , we have that for all α, β such that $0 < \alpha \leq \beta$,

$$\mathbb{D}_\alpha(\mu\|\nu) \leq \mathbb{D}_\beta(\mu\|\nu) .$$

Therefore, by taking the supremum, it directly follows that $\dot{D}_\alpha^{\mathbf{M}^{\text{eff}}}(\rho\|\sigma) \leq \dot{D}_\beta^{\mathbf{M}^{\text{eff}}}(\rho\|\sigma)$.

(3) By linearity of the trace, $\mu_{\lambda\rho_1 + (1-\lambda)\rho_2}^M = \lambda\mu_{\rho_1}^M + (1-\lambda)\mu_{\rho_2}^M$. Let us first consider the case $\alpha \in (0, 1)$. Therefore,

$$\begin{aligned}\dot{Q}_\alpha^{\mathbf{M}^{\text{eff}}}(\lambda\rho_1 + (1-\lambda)\rho_2\|\lambda\sigma_1 + (1-\lambda)\sigma_2) &= \inf_{M \in \mathbf{M}_n^{\text{eff}}} \mathbb{Q}_\alpha(\lambda\mu_{\rho_1}^M + (1-\lambda)\mu_{\rho_2}^M\|\lambda\nu_{\sigma_1}^M + (1-\lambda)\nu_{\sigma_2}^M) \\ &\geq \inf_{M \in \mathbf{M}_n^{\text{eff}}} \lambda\mathbb{Q}_\alpha(\mu_{\rho_1}^M\|\mu_{\rho_2}^M) + (1-\lambda)\mathbb{Q}_\alpha(\nu_{\sigma_1}^M\|\nu_{\sigma_2}^M) \\ &\geq \lambda\dot{Q}_\alpha^{\mathbf{M}^{\text{eff}}}(\rho_1\|\rho_2) + (1-\lambda)\dot{Q}_\alpha^{\mathbf{M}^{\text{eff}}}(\sigma_1\|\sigma_2) ,\end{aligned}$$

where $\dot{Q}_\alpha^{\mathbf{M}^{\text{eff}}}(\cdot\|\cdot)$ and $\mathbb{Q}_\alpha(\cdot\|\cdot)$ are the computational and classical counterparts of Eq. (2.2). The first inequality follows from joint concavity of the classical measure and the last one from the superadditivity of the infimum, proving the joint concavity of the function. Let us also set $f(t) := \frac{1}{\alpha-1} \log(t)$ (see Definition 2.1). In the case of $\alpha \in (0, 1)$, $f(t)$ is a non-increasing convex function. Therefore, it follows that $\dot{D}_\alpha^{\mathbf{M}^{\text{eff}}}$ is jointly convex in (ρ, σ) for $\alpha \in (0, 1)$. $\dot{D}_1^{\mathbf{M}^{\text{eff}}}$ is jointly convex as the supremum of a family of jointly convex functionals (see [RSB24, Prop. 3, Lemma 2]). For $\alpha \in (1, \infty)$, $f(t)$ is non-decreasing and quasi-convex. Moreover, by using the fact of $\mathbb{Q}_\alpha$ being joint convex and the supremum being superadditive, $\dot{Q}_\alpha^{\mathbf{M}^{\text{eff}}}$ is joint convex. Therefore, $\dot{D}_\alpha^{\mathbf{M}^{\text{eff}}}$ is jointly quasi-convex. Lastly, the joint quasi convexity of $\dot{D}_\infty^{\mathbf{M}^{\text{eff}}}$ follows by taking the supremum of a family of jointly quasi-convex functions ([RSB24, Prop. 3, Lemma 2]).

(4) By the duality of the quantum channels, $\mu_{\mathcal{E}(\rho)}^M = \mu_\rho^{\mathcal{E}^*(M)}$. Since for every admissible $\mathcal{E}$, it

follows that $\mathcal{E}^*(M) \in \overline{\mathbf{M}}_n^{\text{eff}}$, then,

$$\dot{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\mathcal{E}(\rho) \parallel \mathcal{E}(\sigma)) = \sup_{M \in \mathbf{M}_n^{\text{eff}}} \mathbb{D}_\alpha(\mu_{\mathcal{E}(\rho)}^M \parallel \nu_{\mathcal{E}(\sigma)}^M) = \sup_{M \in \mathbf{M}_n^{\text{eff}}} \mathbb{D}_\alpha(\mu_\rho^{\mathcal{E}^\dagger(M)} \parallel \nu_\sigma^{\mathcal{E}^\dagger(M)}) \leq \dot{D}_\alpha^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) .$$

□

B.3 Proof of Lemma 4.21

Recall that we want to show that

$$\dot{D}_{1/2}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) = -\log \dot{F}(\rho, \sigma) .$$

Proof of Lemma 4.21. By definition of the computational measured Rényi divergence we have that for $\alpha = 1/2$,

$$\dot{D}_{1/2}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) = -2 \log \dot{Q}_{1/2}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) . \quad (\text{B.1})$$

Then, by Eq. (4.14),

$$\begin{aligned} \dot{Q}_{1/2}^{\mathbf{M}_n^{\text{eff}}}(\rho \parallel \sigma) &= \inf_{M \in \mathbf{M}_n^{\text{eff}}} Q_{1/2}(\mathcal{M}_M(\rho) \parallel \mathcal{M}_M(\sigma)) \\ &= \inf_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} Q_{1/2}(\mathcal{M}_M(\rho) \parallel \mathcal{M}_M(\sigma)) \\ &= \inf_{M \in \overline{\mathbf{M}}_n^{\text{eff}}} \|\mathcal{M}_M(\sigma)^{1/2} \mathcal{M}_M(\rho) \mathcal{M}_M(\sigma)^{1/2}\|_{1/2}^{1/2} \\ &= \inf_{(E_1, E_2) \in \overline{\mathbf{M}}_n^{\text{eff}}} \sum_{i=1}^2 \sqrt{\text{Tr}[E_i \rho] \text{Tr}[E_i \sigma]} \\ &= \sqrt{\dot{F}(\rho, \sigma)} , \end{aligned}$$

where the second equality follows from Lemma 4.9. Together with Eq. (B.1), this yields the claim. □

B.4 Proof of Lemma 4.22

Recall that we want to prove here a computational Fuch-van-Graaf inequality

$$1 - \sqrt{\dot{F}(\rho, \sigma)} \leq \dot{\Delta}(\rho, \sigma) \leq \sqrt{1 - \dot{F}(\rho, \sigma)} .$$

Proof of Lemma 4.22. We note that it suffices to prove that

$$1 - \sqrt{\min_{M \in \mathbf{M}_n^{\text{eff}}} F(\mathcal{M}_M(\rho), \mathcal{M}_M(\sigma))} \leq \max_{M \in \mathbf{M}_n^{\text{eff}}} \Delta(\mathcal{M}_M(\rho), \mathcal{M}_M(\sigma)) \leq \sqrt{1 - \min_{M \in \mathbf{M}_n^{\text{eff}}} F(\mathcal{M}_M(\rho), \mathcal{M}_M(\sigma))} , \quad (\text{B.2})$$

since it directly implies our bounds. Starting with the usual information-theoretic Fuch-van Graaf

inequality [FvdG99] applied to the states $\mathcal{M}_M(\rho), \mathcal{M}_M(\sigma)$ for any $M \in \mathbf{M}_n^{\text{eff}}$, we have

$$1 - \sqrt{F(\mathcal{M}_M(\rho), \mathcal{M}_M(\sigma))} \leq \Delta(\mathcal{M}_M(\rho), \mathcal{M}_M(\sigma)) \leq \sqrt{1 - F(\mathcal{M}_M(\rho), \mathcal{M}_M(\sigma))}.$$

Now optimizing over all $M \in \mathbf{M}_n^{\text{eff}}$ yields Eq. (B.2). $\square$

C Applications

C.1 Proof of Theorem 5.2

Proof. The upper bound on the Stein's exponent can be proven in the following way. Let us consider for an $\varepsilon > 0$ and $m(k) \in \text{poly}(k) > 0$, a binary measurement $M := (E_{k \cdot m(k)}, \mathbb{1} - E_{k \cdot m(k)}) \in \mathbf{M}_{k \cdot m(k)}^{\text{eff}}$ that satisfies $\text{Tr}[E_{k \cdot m(k)} \rho_k^{\otimes m(k)}] \geq 1 - \varepsilon$. Recall that the infimum over all such measurements is the one that defines $\beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}})$ in Eq. (5.3). Then we have

$$\begin{aligned} \sup_{M' \in \mathbf{M}_{k \cdot m(k)}^{\text{eff}}} D(\mathcal{M}_{M'}(\rho_k^{\otimes m(k)}) \| \mathcal{M}_{M'}(\sigma_k^{\otimes m(k)})) &\geq D(\mathcal{M}_M(\rho_k^{\otimes m(k)}) \| \mathcal{M}_M(\sigma_k^{\otimes m(k)})) \\ &= \text{Tr}[E_{k \cdot m(k)} \rho_k^{\otimes m(k)}] \log \text{Tr}[E_{k \cdot m(k)} \rho_k^{\otimes m(k)}] - \text{Tr}[E_{k \cdot m(k)} \rho_k^{\otimes m(k)}] \log \text{Tr}[E_{k \cdot m(k)} \sigma_k^{\otimes m(k)}] \\ &\quad + \text{Tr}[(\mathbb{1} - E_{k \cdot m(k)}) \rho_k^{\otimes m(k)}] \log \text{Tr}[(\mathbb{1} - E_{k \cdot m(k)}) \rho_k^{\otimes m(k)}] \\ &\quad - \text{Tr}[(\mathbb{1} - E_{k \cdot m(k)}) \rho_k^{\otimes m(k)}] \log \text{Tr}[(\mathbb{1} - E_{k \cdot m(k)}) \sigma_k^{\otimes m(k)}] \\ &\geq -h_2\left(\text{Tr}[E_{k \cdot m(k)} \rho_k^{\otimes m(k)}]\right) - \text{Tr}[E_{k \cdot m(k)} \rho_k^{\otimes m(k)}] \log \text{Tr}[E_{k \cdot m(k)} \sigma_k^{\otimes m(k)}] \\ &\geq -1 - (1 - \varepsilon) \log \text{Tr}[E_{k \cdot m(k)} \sigma_k^{\otimes m(k)}], \end{aligned}$$

where $h_2(p) = -p \log(p) - (1 - p) \log(1 - p)$ is the binary entropy. For the second-to-last line, we use the fact that

$$\text{Tr}[(\mathbb{1} - E_{k \cdot m(k)}) \rho_k^{\otimes m(k)}] \log \text{Tr}[(\mathbb{1} - E_{k \cdot m(k)}) \sigma_k^{\otimes m(k)}] \leq 0. \quad (\text{C.1})$$

The last line then follows from the fact that the binary entropy is upper bounded by 1 and the constraint that $\text{Tr}[E_{k \cdot m(k)} \rho_k^{\otimes m(k)}] \geq 1 - \varepsilon$. Rearranging this inequality and subsequently taking the supremum over all such efficient measurements M yields

$$-\log \beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}}) \leq \frac{1}{1 - \varepsilon} \left(1 + \sup_{M' \in \mathbf{M}_{k \cdot m(k)}^{\text{eff}}} D(\mathcal{M}_{M'}(\rho_k^{\otimes m(k)}) \| \mathcal{M}_{M'}(\sigma_k^{\otimes m(k)})) \right).$$

Now dividing by $m(k)$, and taking the lim sup in k , gives

$$\begin{aligned}
\limsup_{k \rightarrow \infty} -\frac{1}{m(k)} \log \beta_{m(k)}^\varepsilon(\mathbf{M}_{k \cdot m(k)}^{\text{eff}}) &\leq \frac{1}{1-\varepsilon} \limsup_{k \rightarrow \infty} \frac{1}{m(k)} \left(1 + \tilde{D}^{\mathbf{M}_{k \cdot m(k)}^{\text{eff}}}(\rho_k^{\otimes m(k)} \|\sigma_k^{\otimes m(k)}) \right) \\
&= \frac{1}{1-\varepsilon} \limsup_{k \rightarrow \infty} \frac{1}{m(k)} \left(\tilde{D}^{\mathbf{M}_{k \cdot m(k)}^{\text{eff}}}(\rho_k^{\otimes m(k)} \|\sigma_k^{\otimes m(k)}) \right) \\
&= \frac{1}{1-\varepsilon} \tilde{D}^{\mathbf{M}^{\text{eff}}, \infty}(\{\rho_k\}_k \|\{\sigma_k\}_k) .
\end{aligned}$$

Finally taking the limit $\varepsilon \rightarrow 0$, yields the claimed result. $\square$

Abstract

Scaling up quantum devices is a central challenge for realizing practical quantum computation. Modular quantum architectures promise scalability, yet experiments to date have relied on either $\lesssim 10^3$ -qubit monolithic chips or fragile interconnects with high loss. Here, we introduce a classical linkage scheme that merges multiple independent quantum processing units (QPUs) into a single logical device, enabling thread-level parallelism (TLP). Theoretically, we show that quantum routines with product-state inputs and low-rank entangling layers can be re-expressed in an efficient parallelizable form. Experimentally, we validate this architecture on clusters comprising up to sixteen benchtop nuclear magnetic resonance (NMR) quantum nodes. A four-qubit Greenberger-Horne-Zeilinger (GHZ) state is partitioned into parallel two-qubit subcircuits, achieving a fidelity of 93.8% with respect to the ideal state. A non-Hermitian evolution, implemented via a truncated Cauchy integral on Hermitian Hamiltonians, reproduces exact observables with high accuracy. Our results demonstrate that classical links suffice to scale up the logical size of quantum computations and realize general,

non-unitary channels on today’s hardware, opening an experimentally accessible route toward software-defined, clustered quantum accelerators.

1 Introduction

For half a century, advances in classical computing have depended critically on increasing parallelism. When single-core performance reached physical and architectural limits, research shifted toward extracting parallelism at multiple levels. Modern architectures use three typical forms of parallelism [see Fig.1(a)]: instruction-level parallelism (ILP) for optimizing execution pipelines, data-level parallelism (DLP) for processing multiple data elements simultaneously, and thread-level parallelism (TLP) for concurrent execution of multiple threads, each handling different data or tasks. Central processing units (CPUs) exploit ILP through pipelining and out-of-order execution, whereas graphics processing units (GPUs), originally designed for rendering, enable DLP and TLP by integrating thousands of lightweight cores onto a single chip[1–3]. This evolution establishes software-hardware co-design, whereby compute-intensive workloads are automatically partitioned and distributed.

Quantum computing now approaches a similar inflection point. Although the accessible state space of an n -qubit device scales as 2^n , the qubit count of a fabricated chip is fixed; expanding it requires entirely new fabrication procedures. Increasing qubits sharply elevates risk from materials non-uniformity, wiring and cryogenic I/O scaling, packaging challenges, and yield degradation, rendering large monolithic QPUs economically and technologically daunting. An alternative is to interconnect existing QPUs, forming clusters that collectively address larger Hilbert spaces and support broader algorithms without redesigning the quantum hardware. Yet, unlike classical workloads, quantum computation must preserve coherence and entanglement across partitions; naive partitioning disrupts quantum correlations and is therefore nontrivial. Recent proposals in distributed quantum computing and quantum networking use long-range entanglement to interconnect distant QPUs [4–6]. Despite rapid experimental progress [7–10], maintaining reliable quantum links remains challenging.

A complementary direction is to coordinate multiple QPUs using only classical communication, for example, with circuit cutting techniques [11–14]. Notably, a 142-qubit superconducting demonstration linked two 127-qubit chips via classical interconnects [15], and software stacks such as CUDA-Q enable programming across multiple QPUs [16]. However, existing approaches do not fully exploit parallelism between distinct QPUs at the hardware-execution level, and experimental demonstrations of a modular architecture designed explicitly to realize TLP remain scarce.

Here, we propose a framework that brings TLP to QPUs through classical links. Conceptually, we develop a modular and parallelizable implementation of completely positive trace-preserving (CPTP) channels, together with a decomposition that distributes the evaluation of a channel across multiple QPUs with bounded classical coordination overhead. In this setting, a single quantum task is compiled into multiple

independent “threads” (small circuits and measurement settings) that can be executed concurrently on different nodes, and whose outcomes are then classically aggregated to recover the target expectation value [Fig. 1(b)]. Architecturally, we realize a scalable cluster that links QPUs using only classical communication and instantiate it with nuclear magnetic resonance (NMR) quantum nodes. Experimentally, we demonstrate two hallmarks of TLP: (i) preparation of a four-qubit Greenberger–Horne–Zeilinger (GHZ) state using three-qubit NMR nodes, emulating a logical system larger than any individual device; and (ii) non-Hermitian Hamiltonian simulation, reproducing observables associated with non-unitary dynamics on unitary hardware. Together, these results show that TLP can substantially extend the algorithmic reach of current quantum hardware and offers an experimentally accessible route toward scalable, practical quantum computation.

Fig. 1: (a) Instruction-, data-, and thread-level parallelism in a classical processor. (b) Factorized evaluation on modular quantum hardware: Trajectory in a generalized Bloch sphere is decomposed into blocks that factorize across subsystems. Local trajectories (on the generalized Bloch sphere of subsystem) are measured independently, and then classically aggregated to recover the global result.

2 Results

2.1 Architecture

A central primitive in quantum computing is to estimate the expectation value of an observable after applying a quantum channel to an input state:

$$\text{Tr}[O \Phi(\rho)], \quad (1)$$

where Φ is a quantum channel, ρ is the input state, and O is the observable of interest. We implement this primitive on a *clustered-QPU* architecture (Fig. 2(a)), in which multiple modular QPUs execute independent quantum subtasks under a classical controller. In our setting, a *thread* is one local circuit together with one measurement setting (optionally using one ancilla qubit), producing one scalar estimator; threads are dispatched to different nodes and executed concurrently, and their outcomes are aggregated classically to recover Eq. (1).

We focus on the practically common case in which both the input state and the measured observable factorize across $\mathcal{A}$ subsystems, $\rho = \bigotimes_{a=1}^{\mathcal{A}} \rho^a$ and $O = \bigotimes_{a=1}^{\mathcal{A}} O^a$. To expose parallel structure in the channel, we consider the representation

$$\Phi(\cdot) = \sum_{p=1}^q A_p(\cdot) A_p^\dagger, \quad A_p = \sum_{i=1}^L c_{p,i} U_{p,i}, \quad (2)$$

which subsumes standard Kraus decompositions and linear-combination-of-unitaries (LCU) forms. The map is completely positive by construction; it is trace-preserving when $\sum_p A_p^\dagger A_p = I$ (see Appendix B for details and the coefficient constraints used in our constructions).

The key additional assumption enabling TLP is that each $U_{p,i}$ admits a low-rank expansion into local operators across the $\mathcal{A}$ subsystems,

$$U_{p,i} = \sum_{\alpha=1}^{\ell} \bigotimes_{a=1}^{\mathcal{A}} U_{p,i\alpha}^a. \quad (3)$$

(For $\mathcal{A} = 2$, ℓ corresponds to the operator-Schmidt rank of $U_{p,i}$ across the chosen bipartition.) Under Eqs. (2)–(3), the global expectation in Eq. (1) factorizes into products of local overlaps. Specifically, Eq. (1) can be rewritten as

$$\sum_{p=1}^q \sum_{i,j=1}^L c_{p,i} c_{p,j}^* \sum_{\alpha,\alpha'=1}^{\ell} \prod_{a=1}^{\mathcal{A}} \text{Tr} \left(U_{p,i\alpha}^a \rho^a U_{p,j\alpha'}^{a\dagger} O^a \right), \quad (4)$$

reducing the computation to local traces on small subsystems [Fig. 1(b)]. For fixed indices $(p, i, j, \alpha, \alpha')$, the quantity in Eq. (4) requires measuring $\mathcal{A}$ local overlaps (one per subsystem). Across all indices, the estimator comprises $qL^2\ell^2$ index configurations; for each configuration, the $\mathcal{A}$ overlaps can be measured independently (and,

given sufficient hardware, concurrently) across the $\mathcal{A}$ QPU nodes. The final value of Eq. (1) is obtained by classically aggregating the resulting scalars with weights $c_{p,i}c_{p,j}^*$ (Appendix B). This provides the theoretical basis for our clustered-QPU architecture: heterogeneous local operations and measurements are executed in parallel, while the classical controller performs scheduling and reduction with overhead that scales linearly in the number of dispatched threads.

Each local overlap in Eq. (4) can be estimated without full state tomography using a single-ancilla interference protocol, requiring only one additional qubit per subsystem and a constant number of measurement settings; see Appendix C (Lemmas C.1 and C.2) for details. When the observable does not strictly factorize, it can be expanded as a sum of product operators, at the cost of additional threads (see Discussion/Appendix B).

As for requirements, beyond tensor-separable ρ and O , Eq. (4) relies on the existence of a low-rank expansion as in Eq. (3). A brute-force operator-Schmidt decomposition is possible in principle, but the cost scales as $O(d^{2n})$ for n qubits (local dimension d) and quickly becomes impractical. Fortunately, structured circuits are common, and low-rank factorizations can be obtained efficiently for layered circuits by choosing a bipartition that minimizes inter-partition entangling structure. We highlight the bisection case ($\mathcal{A} = 2$), which captures the common setting of distributing a workload across two QPUs.

Consider a layered circuit $U_{p,i} = \prod_{t=1}^{m_d} W^{(t)}$ in which each layer can be written as local unitaries composed with an entangling operator across the cut,

$$W^{(t)} = \left(V_1^{(t)} \otimes V_2^{(t)} \right) G^{(t)}, \quad G^{(t)} = \sum_{\alpha_t=1}^{\ell_t} g_{\alpha_t}^{(t,1)} \otimes g_{\alpha_t}^{(t,2)}, \quad (5)$$

where some $g_{\alpha_t}^{(t,a)}$ may be the identity (so layers that do not couple the two sides can be ignored for the cut analysis). For a given bipartition, only the layers whose $G^{(t)}$ have $\ell_t > 1$ contribute to the cross-partition rank. If a cut intersects m' such entangling layers, then $U_{p,i}$ admits an expansion of the form in Eq. (3) with $\ell \leq \prod_{t=1}^{m'} \ell_t$, so that Eq. (4) factorizes into at most

$$q \times L^2 \times \left(\prod_{t=1}^{m'} \ell_t \right)^2 \times 2 \quad (6)$$

single-subsystem traces (two subsystems for $\mathcal{A} = 2$), each executable on an individual QPU node. This motivates selecting a bipartition that minimizes m' (and thereby ℓ). We obtain such bipartitions by recasting the problem as a circuit-graph bisection min-cut [17, 18], solvable with complexity $O(n^2)$ in the number n of graph vertices (Appendix C).

Fig. 2: Hardware overview. (a) Clustered-QPU architecture enabling TLP: a classical controller compiles Eq. (1) into independent threads (local circuits and measurement settings), dispatches them to QPU nodes, and aggregates measured local overlaps to recover the target expectation value. (b) Physical sample assembly employed in this work.

2.2 GHZ state preparation.

We first demonstrate the preparation of a four-qubit GHZ state, a canonical benchmark for multi-qubit coherence and nonclassical correlations [19, 20]. Our goal is to prepare and verify the GHZ state on a clustered-QPU platform in which no individual node can host the full four-qubit circuit.

As shown in Fig. 3(a), we distribute the circuit across nodes by cutting the entangling gate between qubits 2 and 3 and replacing it with a linear combination of local operations. Concretely, the CNOT can be expanded as

$$U_{\text{CNOT}} = \frac{1}{2} \left(\mathbb{1} \otimes \mathbb{1} + \sigma_z \otimes \mathbb{1} + \mathbb{1} \otimes \sigma_x - \sigma_z \otimes \sigma_x \right), \quad (7)$$

where $\sigma_{x,z}$ are Pauli operators and $\mathbb{1}$ is the identity. This identity expresses the action of the original four-qubit circuit as a weighted sum of product contributions that can be implemented using only two-qubit subcircuits. Using the single-ancilla overlap estimator introduced in Sec. 2.1, we measure the required local overlaps and classically aggregate them to reconstruct the global output state. The corresponding circuit templates and the full set of measurement settings are provided in Appendix E. For reference, we also implement a quantum circuit cutting workflow [21] on the same

2.3 Non-Hermitian system simulation.

Efficient Hamiltonian simulation on quantum devices promises insights into quantum dynamics with broad applications [23, 24]. Whereas the GHZ preparation in Sec. 2.2 demonstrates a relatively lightweight clustered workload (on the order of 10^2 subtasks), we next consider more demanding non-unitary dynamics that require on the order of 10^3 subtasks executed across the 16×2 -qubit cluster. We focus on non-Hermitian Hamiltonians and imaginary-time evolution, and implement them using TLP via the linear-combination Hamiltonian simulation (LCHS) method [25].

LCHS formulation and parallel execution.

Consider a time-dependent non-Hermitian generator

$$A(t) = H(t) - iL(t), \quad (8)$$

with Hermitian components $H(t)$ and $L(t)$. LCHS is based on the identity illustrated in Fig. 4(a),

$$\mathcal{T} \exp \left(-i \int_0^t A(s) ds \right) = \int_{\mathbb{R}} \frac{dk}{\pi(1+k^2)} \mathcal{T} \exp \left(-i \int_0^t [H(s) + kL(s)] ds \right), \quad (9)$$

where $\mathcal{T}$ denotes time ordering and the Cauchy–Lorentz kernel $1/(\pi(1+k^2))$ arises from the Fourier representation of $e^{-|x|}$ [25]. Discretizing the k -integral on $[-K, K]$ with step Δk (quadrature nodes $\{k_j\}$ and trapezoidal weights $\{w_j\}$) yields the LCU form

$$u(t) \approx \sum_j c_j U_j(t), \quad U_j(t) = \mathcal{T} \exp \left(-i \int_0^t [H(s) + k_j L(s)] ds \right), \quad c_j = \frac{w_j}{\pi(1+k_j^2)}. \quad (10)$$

Thus, the evolution generated by $A(t)$ is represented as a linear combination of unitary evolutions under Hermitian Hamiltonians $H(t) + k_j L(t)$, and expectation values can be estimated using the overlap-based TLP framework of Sec. 2.1. In particular, for an initial pure state $|u_0\rangle$,

$$\langle O \rangle_t = \frac{\langle u(t) | O | u(t) \rangle}{\langle u(t) | u(t) \rangle} \approx \frac{\sum_{j,j'} c_j^* c_{j'} \langle u_0 | U_j^\dagger(t) O U_{j'}(t) | u_0 \rangle}{\sum_{j,j'} c_j^* c_{j'} \langle u_0 | U_j^\dagger(t) U_{j'}(t) | u_0 \rangle}, \quad (11)$$

where the numerator and denominator are both sums of overlaps of the form $\langle u_0 | U_j^\dagger(\cdot)(\cdot) U_{j'} | u_0 \rangle$. In our architecture, each overlap term is assigned to an independent thread implemented with the single-ancilla estimator circuit, dispatched across the QPU nodes, and aggregated classically.

Experiment 1: single-qubit non-Hermitian dynamics.

We first reproduce time-independent non-Hermitian Hamiltonian dynamics in a single-qubit testbed with

$$H = \sigma_x, \quad L = \mathbb{1} + \sigma_z, \quad (12)$$

a standard model in parity-time-symmetric non-Hermitian physics [26, 27], where $\sigma_{x,z}$ are Pauli matrices and $\mathbb{1}$ is the identity. Initializing the system in $|0\rangle$, we record expectation values of Pauli observables as functions of the evolution time.

Using LCHS, the non-Hermitian dynamics reduces to a collection of overlap-evaluation subtasks whose total count scales quadratically with the number of quadrature nodes (and, in our implementation, is approximately $400T^2$ for evolution time T ; see Appendix F for the discretization parameters and counting). Each subtask corresponds to one experiment executed with the single-ancilla estimator on one node of the 16×2 -qubit NMR-QPU cluster. In total, we perform over 1700 experimental runs (about 106 per node) to resolve the time evolution at $T = 0.1k$ ($k = 1, \dots, 10$), thereby demonstrating TLP at the 10^3 -thread scale.

For benchmarking, we carry out numerical simulations using (i) the same LCHS discretization and (ii) direct integration of the Schrödinger equation. The two numerical approaches agree with fidelity 99.5%, corroborating the accuracy of the LCHS approximation under our chosen discretization. Fig. 4(b) shows the time evolution of $\langle\sigma_y\rangle$ and $\langle\sigma_z\rangle$ obtained from experiment, LCHS simulation, and direct Schrödinger integration. The absolute deviation between experiment and theory is 0.129 ± 0.070 . Additional evidence is provided by Fig. 4(d), which reports the fidelity of each experimentally reconstructed state snapshot relative to the numerical prediction: the median fidelity is 93.1%, with a 90% reference threshold indicated. See Appendix F for full experimental settings and error analysis.

Experiment 2: imaginary-time evolution and ground-energy estimation.

We next demonstrate ground-energy estimation via imaginary-time evolution for

$$H(\gamma) = 2\mathbb{1} + \gamma\sigma_x, \quad \gamma \in [0, 2], \quad (13)$$

whose analytic ground energy is $E_0(\gamma) = 2 - |\gamma|$. Starting from $|0\rangle$, we apply the non-unitary propagator $e^{-H(\gamma)T}$ followed by renormalization, which projects toward the ground state as T increases. The ground energy is then estimated by the expectation value $\langle H(\gamma) \rangle$, providing a clean testbed with a closed-form benchmark.

Similar in spirit to LCHS (and more precisely using a truncated Cauchy integral representation [28]), we approximate the imaginary-time propagator as a finite linear combination of unitary evolutions, producing a collection of independent overlap-evaluation subtasks (approximately 121 per value of γ ; Appendix F). We demonstrate TLP by executing over 1200 subtasks using the single-ancilla estimator circuit on the 16×2 -qubit NMR cluster. In the experiment we set $\gamma = 0.2k$ ($k = 0, \dots, 10$) and measure $\langle H(\gamma) \rangle$ together with $\langle\sigma_x\rangle$ and $\langle\sigma_z\rangle$ at $T = 0.5$.

For benchmarking, we compare against three references: (i) a simulation of the same estimator/discretization used experimentally, (ii) direct imaginary-time evolution at $T = 0.5$, and (iii) exact diagonalization of $H(\gamma)$ (and, as a tighter baseline, direct

Fig. 4: (a) Schematic of LCHS: a non-Hermitian evolution is represented as a weighted integral over unitary evolutions under Hermitian Hamiltonians. (b) Time evolution of $\langle \sigma_y \rangle$ and $\langle \sigma_z \rangle$ (and an additional Hermitian observable) under a non-Hermitian Hamiltonian: experiment (solid with filled markers), simulation of the experimental estimator (open markers), and direct Schrödinger integration (dashed). (c) Imaginary-time evolution benchmark for $H(\gamma)$: measured $\langle H(\gamma) \rangle$ and $\langle \sigma_{x,z} \rangle$ compared with simulations and first-principles calculations; dash-dotted lines denote exact diagonalization and longer-time imaginary-time evolution. (d,e) Fidelity of experimentally prepared states relative to numerical predictions; median fidelity and a 90% reference threshold are highlighted.

imaginary-time evolution at longer time $T = 1.5$). Fig. 4(c) shows the measured and simulated expectation values of $\langle \sigma_x \rangle$, $\langle \sigma_z \rangle$, and $\langle H(\gamma) \rangle$ as functions of γ . The absolute deviation is 0.136 ± 0.088 , confirming that our parallel QPU cluster can accurately realize imaginary-time evolution and ground-energy estimation with moderate total evolution time. Additional support is given by Fig. 4(e), which summarizes the fidelity between the experimentally prepared states and the theoretical ground states for each γ : with $T = 0.5$, all data points exceed 99% fidelity. Increasing T (e.g., to $T = 1.5$) further improves the ground-state approximation but requires additional experimental runs, illustrating the tradeoff between accuracy and experimental cost (Appendix F).

3 Discussion

Building large, general-purpose QPUs remains technologically and economically challenging. In contrast, clustering existing devices can deliver immediate, system-level performance gains without waiting for next-generation hardware. Even once large, fault-tolerant chips become available, re-fabrication and redeployment costs are likely to remain substantial; modular clustering can therefore serve as a practical “performance boost” pathway by scaling *through parallelism* rather than by pushing individual chips beyond their operating envelope. In this sense, clustering is analogous

to performance scaling in classical computing via multi-socket systems and distributed execution, while avoiding additional physical strain on any single QPU.

Our approach is designed to harness the strengths of current processors while respecting their constraints. We identify broad conditions under which quantum routines can be rewritten into a form amenable to TLP: product-state inputs and observables, together with channels (or circuit blocks) admitting low-rank decompositions across a chosen partition. Under these assumptions, global expectation values reduce to weighted sums of products of local overlaps, enabling heterogeneous quantum operations and measurements to be executed independently on small QPUs and aggregated classically. This yields scalability that is unattainable on a single device of the same per-node size, because the effective logical workload is expanded by distributing independent threads across the cluster.

We validate this clustered-QPU architecture experimentally on NMR clusters with eight and sixteen nodes. As a lightweight benchmark, we distribute a four-qubit GHZ preparation across two-qubit nodes by cutting a CNOT and reconstruct the target state with up to 93.8% fidelity. To stress-test the architecture at larger scale, we implement LCHS-based non-unitary simulation that requires thousands of parallel overlap evaluations, and successfully emulate both non-Hermitian and imaginary-time dynamics. To our knowledge, these experiments constitute the first experimental demonstration of LCHS.

In summary, TLP provides an immediately deployable route to enlarging the effective logical register and enabling channel-level operations that are difficult or impossible on standalone chips of comparable size. Because our framework relies only on classical interconnects and classical orchestration, it is compatible with present-day fabrication and networking capabilities and can be scaled by adding more nodes. Beyond the benchmarks shown here, the same parallelization paradigm is directly relevant to other near-term workloads dominated by expectation estimation—including variational quantum algorithms and related hybrid workflows [29, 30]—offering a pragmatic bridge from today’s few-qubit processors to future large-scale, fault-tolerant quantum accelerators.

4 Methods

4.1 Hardware

Fig. 2(a) shows a cluster with loose coupling, where multiple QPUs are integrated. At the core of the system is a classical controller that assigns computational tasks, synchronizes all QPU nodes, generates pulse operations, and coordinates instruction dispatch and measurement collection. Operating in a multi-instruction, multi-data mode, the controller ensures both flexibility and high throughput for realizing TLP on quantum devices. Each QPU node can, in principle, be instantiated on any platform, such as nuclear-spin qubits, photonic qubits, superconducting circuits, or others, provided it supports universal control and high-fidelity state preparation and measurement. This modular design enables seamless integration of heterogeneous quantum processors within a unified computational platform, with all inter-processor signaling carried classically.

During operation, the central scheduler decomposes tasks according to the theoretical framework, dispatches the resulting subtasks to each node, and orchestrates control-pulse timing and data acquisition to maintain precise synchronization. The cluster is fully modular and plug-and-play: nodes can be added, removed, or replaced on the fly, with the controller automatically updating task assignments and preserving system-wide logical consistency. Because all inter-node communication is classical, the architecture is inherently robust and highly scalable.

As a demonstration, we construct clusters comprising 8 or 16 benchtop NMR QPUs [31, 32], where each node hosts 3 or 2 nuclear-spin qubits [Fig. 2(b)]. The physical realization employs different nuclear species, ^1H , ^{19}F , and ^{31}P , each with distinct Larmor frequencies, chemical shifts, and coherence properties. Key parameters, including T_1 and T_2 , are summarized in Fig. 2(b) and Appendix D, highlighting multi-second coherence that supports reliable thread-level parallel computation. This platform validates our architecture along two axes. First, clusters of small QPUs collectively emulate circuits that exceed the size of any single node. Second, general quantum channels are realized efficiently by parallelizing simple unitary evolutions. We next present two representative experimental tasks.

Acknowledgements. We thank texra.ai for helpful suggestions on writing and language. K.L. and SY.H. acknowledge the Scientific Foundation for Youth Scholars of Shenzhen University, Guangdong Provincial Quantum Science Strategic Initiative (GDZX2403001, GDZX2303001).

Author contribution. All authors have had final responsibility for the decision to submit for publication. K.L., G.F., Z. W and SY. H proposed the idea and designed the experiment. K.L., Z.L and SY. H carried out the experiment and processed the data. All authors discussed the result and contributed to the manuscript.

Appendix A Supplementary information for multi-QPU strategies

When several quantum-processing units (QPUs) are asked to execute a single workload, two fundamentally different resources can be used to tie them together:

1. *Quantum correlated links* — Entanglement is distributed between modules and exploited through gate teleportation, remote measurement, or lattice surgery. Theoretical blueprints date back to modular ion-trap architectures with photonic routers [5] and underpin the long-term vision of distributed quantum computing [7–9] or a quantum internet [6, 10].
2. *Classically correlated links* — Each QPU is measured locally; the global observable is then reconstructed from the measurement records with “divide-and-conquer” methods. This family includes wire- and gate-based quantum circuit cutting [12], circuit knitting [11] and dynamic circuits techniques [13, 15].

Both routes trade resources differently. Quantum links preserve coherence across modules and avoid exponential sampling overhead, but they impose stringent latency and loss budgets on the interconnect. Classical links need no fragile quantum channel and can already incorporate non-unitary dynamics, yet their classical post-processing overhead grows with every wire or gate that is cut. Specifically, Table S1 briefly summarizes these representative multi-QPU strategies and their key features.

Quantum-correlated prototypes.

- Spin-photon CMOS integration [7] - Li *et al.* heterogeneously bond diamond colour-centre qubits onto 45 nm CMOS photonics, enabling wafer-scale quantum light sources and detectors.
- Trapped-ion optical link [8] - Two ion chains 2 m apart execute a distributed Grover search via deterministic photonic gate teleportation, reaching 86 % gate fidelity.
- Plug-and-play microwave cable [9] - A detachable coaxial bus swaps microwave photons between two superconducting chips in <100 ns with > 99% efficiency.
- 7 km non-local photonic gate [10] - Quantum memories plus telecom photons realise entangling gates over a 7 km fibre loop.

Classically correlated prototypes.

- Dynamic-circuit cutting - Shallow measure-and-feed-forward protocols teleport CNOTs across 100+ qubits [13], while two 127-qubit processors linked only by real-time classical feed-forward prepare 142-qubit graph states [15].
- Circuit knitting with LOCC [11] - Information-theoretic analysis shows classical messaging reduces sampling overhead for knitted circuits.
- Optimal quantum circuit cuts [12] - Tight bounds on sample cost and an application to clustered Hamiltonian simulation.

This work - thread-level parallelism for quantum channels.

We introduce a method that factorizes an arbitrary completely-positive trace-preserving map into independent Kraus blocks, dispatches those blocks to a cluster of QPUs over standard Ethernet, and recombines the measurement records in $\mathcal{O}(1)$ classical time. Unlike prior “divide-and-conquer” methods that target only unitary circuits [13, 15], our scheme natively supports non-unitary dynamics such as non-hermitian Hamiltonian evolution and imaginary-time propagation.

Hardware demonstration— A 16×2 -qubit (or 8×3 -qubit) NMR cluster prepares a 4-qubit GHZ state with a tomographic fidelity of 93.8%; emulates non-Hermitian Hamiltonian and imaginary-time dynamics. These results establish that purely classical networking can extend both the size and the algorithmic richness of NISQ workloads beyond what any single device can achieve today, delivering the first channel-level TLP benchmark on real hardware.

Appendix B Supplementary information for realizing thread level parallelism

We start from the generic quantum-computing objective

$$\text{Tr}[O\Phi(\rho)],$$

where Φ is a quantum channel, ρ an input state and O the observable of interest.

Φ can be a general structure that admits a linear-combination-of-unitaries form

$$\Phi(\cdot) = \sum_{p=1}^q \left(\sum_{i=1}^m c_{p,i} U_{p,i} \right) (\cdot) \left(\sum_{j=1}^m c_{p,j} U_{p,j} \right)^\dagger, \quad (\text{B1})$$

with complex amplitudes $c_{p,i}$ and unitaries $\{U_{p,i}\}_{i=1}^m$. Substituting Eq. (B1) into the trace and expanding gives

$$\text{Tr}[O\Phi(\rho)] = \sum_{p=1}^q \sum_{i,j=1}^m c_{p,i} c_{p,j}^* \text{Tr}[OU_{p,i}\rho U_{p,j}^\dagger]. \quad (\text{B2})$$

Here, we employ a without losing generosity assumption that both the state and the observable are product states over $\mathcal{A}$ identical subsystems,

$$\rho = \bigotimes_{a=1}^{\mathcal{A}} \rho^a, \quad O = \bigotimes_{a=1}^{\mathcal{A}} O^a.$$

And a non-trivial requirement that every unitary $U_{p,i}$ have an explicit expression of the summation of tensor-product decomposition,

$$U_{p,i} = \sum_{\alpha=1}^{\ell} \bigotimes_{a=1}^{\mathcal{A}} U_{p,i\alpha}^a, \quad (\text{B3})$$

with the same ℓ for all indices. Insert Eq. (B3) (and its Hermitian conjugate) into Eq. (B2); linearity yields

$$\text{Tr}[O \Phi(\rho)] = \sum_{p=1}^q \sum_{i,j=1}^m c_{p,i} c_{p,j}^* \sum_{\alpha,\alpha'=1}^{\ell} \text{Tr}\left[O \left(\bigotimes_a U_{p,i\alpha}^a\right) \rho \left(\bigotimes_a U_{p,j\alpha'}^a\right)^\dagger\right]. \quad (\text{B4})$$

Because both the state, observable and each tensor factor act on disjoint Hilbert spaces, the global trace factorizes into a product of local traces:

$$\text{Tr}\left[O \left(\bigotimes_a U_{p,i\alpha}^a\right) \rho \left(\bigotimes_a U_{p,j\alpha'}^a\right)^\dagger\right] = \prod_{a=1}^{\mathcal{A}} \text{Tr}[U_{p,i\alpha}^a \rho^a U_{p,j\alpha'}^{a\dagger} O^a]. \quad (\text{B5})$$

Substituting this identity into Eq. (B4) yields the fully factorised expression

$$\sum_{p=1}^q \sum_{i,j=1}^m c_{p,i} c_{p,j}^* \sum_{\alpha,\alpha'=1}^{\ell} \prod_{a=1}^{\mathcal{A}} \text{Tr}[U_{p,i\alpha}^a \rho^a U_{p,j\alpha'}^{a\dagger} O^a], \quad (\text{B6})$$

which is exactly Eq. (4) in the main text. Each factor inside the product is measurable on a single subsystem with programmable unitary transformations and measurements, while the outer sums can be accumulated classically. This indicates thread-level parallelism, TLP, can be realized across quantum processors.

In summary, every quantum-information task of the form $\text{Tr}[O \Phi(\rho)]$ can be split into $q \times m^2 \times \ell^2 \times \mathcal{A}$ independent sub-tasks, provided that the state ρ and observable O factorize over $\mathcal{A}$ subsystems, and each operator $U_{p,k}$ admits the tensor-product expansion of Eq. (B3). The integers q, m, ℓ and $\mathcal{A}$ are precisely those introduced in Eqs. (B1) and (B3). Furthermore, if the channel reduces to an incoherent sum of unitaries, $\Phi(\rho) = \sum_{k=1}^q U_k \rho U_k^\dagger$, and every U_k further decomposes as $U_k = \sum_{\alpha=1}^{\ell} \bigotimes_{a=1}^{\mathcal{A}} U_{k\alpha}^a$, then the workload factorizes into only $q \times \ell^2 \times \mathcal{A}$ sub-tasks, because the double index (i, j) collapses to a single index k ($m = 1$).

Appendix C Supplementary information for pre-conditions in architecture

The first is an efficient factorization that rewrites the global unitary into sums of local operators. A brute-force operator-Schmidt decomposition would accomplish factorization step, its cost grows as $\Theta(d^{2n})$ for n qubits and is therefore intractable.

Instead, we exploit the layered structure of quantum circuits to apply precomputed local factorizations. In general, given a depth- m_d circuit

$$U = \prod_{i=1}^{m_d} \left(G_e^{(i)} \otimes_{a=1}^{\mathcal{A}} U_a^{(i)} \right),$$

whose i -th layer contains a single entangling block $G_e^{(i)}$ acting across the $\mathcal{A}$ subsystems, and a factorized expansion of each entangling block,

$$G_e^{(i)} = \sum_{\alpha_i=1}^{\ell_i} \bigotimes_{a=1}^{\mathcal{A}} g_{i\alpha_i}^a, \quad g_{i\alpha_i}^a \in \text{U}(\dim \mathcal{H}_a),$$

we can rewrite the entire circuit as

$$U = \prod_{i=1}^{m_d} \sum_{\alpha_i=1}^{\ell_i} \bigotimes_{a=1}^{\mathcal{A}} g_{i\alpha_i}^a U_a^{(i)},$$

i.e. as a nested linear combination of $\prod_{i=1}^{m_d} \ell_i$ purely local tensor-product operators.

Bisecting the circuit is a good start of the problem. It is trivial that one have a way to bisect a unitary into sub circuits. For current popular circuit, entangling block can be chosen as CNOT or CZ, which have a fixed factorized expansion. Therefore, m_d appears, $\prod_{i=1}^{m_d} \ell_i = \ell$, which influences the number of sub tasks take this form. To optimize it, we introduce an algorithm of layer-wise decomposition (Lemma C.1) to reduce it.

Lemma C.1 (Layer-wise decomposition) Let

$$U = \prod_{i=1}^{m_d} \left(G_e^{(i)} \bigotimes_{a=1}^n U_a^{(i)} \right)$$

be an n -qubit circuit of depth m_d , where at each layer i , $G_e^{(i)}$ is a set of two-qubit gates that may couple any pair of qubits, and $U_a^{(i)}$ acts locally on qubit a .

- (i) Viewing the circuit as a weighted graph $G = (V, E)$ with $|V| = n$ and edge weights w_{uv} equal to the number of two-qubit gates acting on $\{u, v\}$, one can find in $\tilde{O}(|E|) \subseteq \tilde{O}(n^2)$ time (Henzinger-Li-Rao-Wang [18]) a minimum cut. The cut removes $m' \leq m_d$ crossing gates $\{g^{(i)}\}_{i=1}^{m'} \subseteq \{G_e^{(i)}\}$ and partitions the qubits into two subsystems, hereafter indexed by $a \in \{1, 2\}$.
- (ii) Suppose each crossing gate admits a known factorization $g^{(i)} = \sum_{\alpha_i=1}^{\ell_i} V_{i\alpha_i}^{(1)} \otimes V_{i\alpha_i}^{(2)}$, where all $V_{i\alpha_i}^{(a)}$ are unitary ($\ell_i \leq 4$ for CNOT/CZ). Denoting $\tilde{U}_a^{(i)}$ as the local operation within subsystem a , the entire circuit decomposes as

$$U = \prod_{i=1}^{m'} \sum_{\alpha_i=1}^{\ell_i} \bigotimes_{a=1}^2 V_{i\alpha_i}^{(a)} \tilde{U}_a^{(i)},$$

which contains at most $\prod_{i=1}^{m'} \ell_i$ tensor terms, independent of the dimensions of the two subsystems.

Fig. S1: Single-ancilla estimator: an ancillary qubit is used to estimate overlaps.

Remarkably, if each side of the cut must contain roughly $n/2$ qubits, the partition problem becomes NP-hard; an $O(\sqrt{\log n})$ -approximation is available via the SDP + metric-embedding technique of Arora-Rao-Vazirani [17]. Because ℓ_i is a small constant (at most 4 for most common two-qubit gates), the total number of tensor terms grows with the cut size m' , i.e., $\prod_{i=1}^{m'} \ell_i = \ell$, not with the full Hilbert-space dimension 2^n .

Result C.1 (Thread-level parallelism (TLP) criterion) Consider a workload whose objective value is

$$\text{Tr}[O \Phi(\rho)], \quad \Phi(\cdot) = \sum_{p=1}^q \left(\sum_{i=1}^m c_{p,i} U_{p,i} \right) (\cdot) \left(\sum_{j=1}^m c_{p,j} U_{p,j} \right)^\dagger,$$

and assume

1. the data are tensor-separable, $\rho = \bigotimes_{a=1}^A \rho^a$ and $O = \bigotimes_{a=1}^A O^a$;
2. each $U_{p,i}$ is realized by a depth- m_d circuit $U_{p,i} = \prod_{t=1}^{m_d} (G_e^{(t)} \otimes U_a^{(t)})$ in which *every* entangling layer factorizes as $G_e^{(t)} = \sum_{\alpha_t=1}^{\ell_t} \bigotimes_{a=1}^A g_{t\alpha_t}^a$.

Then there exists a cut size $m' \leq m_d$ such that the global expectation value factorizes into at most

$$q \times m^2 \times (\prod_{t=1}^{m'} \ell_t)^2 \times \mathcal{A}$$

independent single-subsystem traces. Each trace can be executed on an individual QPU node, and the final result is obtained by classical post-processing.

Implications. Whenever the input state and observable are already tensor-separable, and all non-local gates admit a known low-rank tensor expansion (e.g. CNOT, CZ), the entire computation can be mapped onto a QPU cluster with one thread per tensor term—no quantum interconnect is required, and the required single-ancilla estimator is depicted as follows.

Lemma C.2 (Single-ancilla estimator) Let $\rho^a = |\psi_0^a\rangle\langle\psi_0^a|$ be a pure state on sub-system a , let $U_{i\alpha}^a$ and $U_{j\alpha'}^a$ be arbitrary unitaries on $\mathcal{H}_a$, and let O^a be any unitary observable. The complex overlap $\text{Tr}(U_{i\alpha}^a \rho^a U_{j\alpha'}^{a\dagger} O^a)$ is obtained with a single ancillary qubit by

$$\langle\sigma_x\rangle_{\text{anc}} + i \langle\sigma_y\rangle_{\text{anc}},$$

where the expectation values are measured in the interferometric circuit, which is shown in Fig. S1. Setting $j = i, \alpha' = \alpha$ recovers channel observables of the form $U_{i\alpha} \rho U_{i\alpha}^\dagger$.

Proof sketch— Prepare the ancilla in $|0\rangle$ and subsystem a in $|\psi_0^a\rangle$. Apply the controlled unitary $|0\rangle\langle 0| \otimes U_{i\alpha}^a + |1\rangle\langle 1| \otimes U_{j\alpha'}^a$ to obtain

$$|\Psi_{i,j,\alpha,\alpha'}^{(a)}\rangle = \frac{1}{\sqrt{2}}(|0\rangle \otimes U_{i\alpha}^a |\psi_0^a\rangle + |1\rangle \otimes U_{j\alpha'}^a |\psi_0^a\rangle).$$

Next, insert O^a only on the $|1\rangle$ branch:

$$|\Psi_{i,j,\alpha,\alpha'}^{O,(a)}\rangle = \frac{1}{\sqrt{2}}(|0\rangle \otimes U_{i\alpha}^a |\psi_0^a\rangle + |1\rangle \otimes O^a U_{j\alpha'}^a |\psi_0^a\rangle).$$

Tracing out subsystem a leaves the ancilla density matrix

$$\rho_{\text{anc}} = \frac{1}{2} \begin{pmatrix} 1 & \langle \psi_0^a | U_{i\alpha}^{a\dagger} O^a U_{j\alpha'}^a | \psi_0^a \rangle \\ \langle \psi_0^a | U_{j\alpha'}^{a\dagger} O^a U_{i\alpha}^a | \psi_0^a \rangle & 1 \end{pmatrix}.$$

The off-diagonal element is precisely the desired overlap. Projective measurements of the ancilla in the σ_x and σ_y bases read out its real and imaginary parts. For channels of the form $U_{i,\alpha} \rho U_{i,\alpha}^\dagger$ one simply sets $j, \alpha' = i, \alpha$, recovering the same protocol. $\square$

Together, Lemma C.1 and C.2 meet both prerequisites of Eq. (4): an efficient factorization whose cost depends only on the interaction cut, and a practical estimator that requires just one extra qubit per subsystem.

Appendix D Supplementary information for configuration of current Hardware

In this work, we implement clusters comprising either 8 or 16 benchtop NMR quantum processors, with each QPU node hosting two or three nuclear spin qubits.

First, we introduce a cluster of 8×3 -qubit QPUs based on the Triangulum platform, as detailed in [32]. As shown in Fig. 2(b), each device consists of three qubits, realized by the ^{19}F nuclei in $\text{C}_2\text{F}_3\text{I}$ molecules.

The relevant relaxation times, T_1 (longitudinal) and T_2 (transverse), are measured for all three nuclei and determine the system's coherence properties. The free evolution of each three-qubit NMR system is governed by the internal Hamiltonian:

$$\mathcal{H}_{\text{int}} = \pi\nu_1\sigma_z^1 + \pi\nu_2\sigma_z^2 + \pi\nu_3\sigma_z^3 + \frac{\pi}{2}J_{12}\sigma_z^1\sigma_z^2 + \frac{\pi}{2}J_{23}\sigma_z^2\sigma_z^3 + \frac{\pi}{2}J_{13}\sigma_z^1\sigma_z^3, \quad (\text{D7})$$

where ν_i ($i = 1, 2, 3$) denote the Larmor frequencies, and J_{ij} are the J -coupling constants between the spins.

Universal quantum control is achieved by applying transverse radio-frequency (RF) pulses, described by

$$\mathcal{H}_{\text{rf}} = -\frac{1}{2}\omega_1 \sum_{i=1}^3 [\cos(\omega_{\text{rf}}t + \phi)\sigma_x^i + \sin(\omega_{\text{rf}}t + \phi)\sigma_y^i]. \quad (\text{D8})$$

By tuning the RF field parameters-amplitude ω_1 , phase ϕ , frequency ω_{rf} , and pulse duration-together with the system's internal evolution, arbitrary three-qubit quantum gates can be realized.

In our experiments, we employ 8 Triangulum units, with their main specifications summarized in Table S2. Device-to-device variations in magnetic field strength, chemical shifts, and other parameters are hard to directly compensated via software calibration and by operating in the rotating frame. Therefore, variant circuit or shaped pulses are employed for robust control or generating standard quantum gates.

Table S2: Specifications of the SPINQ Triangulum Units

Model	Serial No.	Magnetic Field (T)	Homogeneity FWHM (ppm)	^{19}F Freq. (MHz)
Triangulum	T2023089	0.886	0.8	35.470
	T2023043	0.905	0.8	36.249
	T20250617	0.895	0.7	35.858
	T20250618	0.895	0.7	35.858
	T20231213	0.944	0.85	37.809
	T20250208	0.888	0.6	35.581
	T20250504	0.896	0.7	35.875
	T20250420	0.866	0.6	34.684

Second, we introduce 16×2 qubit QPUs, which uses Gemini, referenced in [31]. As shown in Fig. 2(b), the device comprises two qubits, represented by the nuclei ^1H and ^{31}P in Dimethylphosphite $((\text{CH}_3\text{O})_2\text{PH})$ molecules. T_1 and T_2 represent the longitudinal and transverse relaxation times, respectively. The free evolution of this 2-qubit system is primarily governed by the internal Hamiltonian,

$$\mathcal{H}_{\text{int}} = \pi\nu_1\sigma_z^1 + \pi\nu_2\sigma_z^2 + \frac{\pi}{2}J_0\sigma_z^1\sigma_z^2, \quad (\text{D9})$$

where ν_1 and ν_2 can be adjusted to 0 Hz in a rotating frame, and $J_0 = 697.4$ Hz denotes the resonance frequency of the J -coupling strength between the spins. Further details are available in [31]. To control the system's evolution, transverse radio-frequency (r.f.) pulses serve as the control field, expressed as,

$$\mathcal{H}_{\text{rf}} = -\frac{1}{2} \sum_{i=1}^2 \omega_1^i (\cos(\omega_{\text{rf}}t + \phi^i) \sigma_x^i + \sin(\omega_{\text{rf}}t + \phi^i) \sigma_y^i). \quad (\text{D10})$$

By adjusting the parameters in the r.f. field [Eq. (D10)], such as intensity ω_1 , phase ϕ , frequency ω_{rf} , and duration, the theoretical achievement of two-qubit universal quantum gates is possible through the combination of the system's internal dynamics.

In our experiments, we employ 16 Gemini units, with their main specifications summarized in Table S3. While there are device-to-device variations in magnetic field strength, chemical shifts, and other parameters, these differences are compensated in software by appropriate calibration and by working in the rotating frame. Standard NMR techniques such as hard and shaped pulses are employed for robust control.

Table S3: Specifications of the SPINQ Gemini Lab Units

Model	Serial No.	Magnetic Field (T)	Homogeneity FWHM (ppm)	¹ H Freq. (MHz)	³¹ P Freq. (MHz)

Appendix E Supplementary information for GHZ state preparation

E.1 Our method

Fig. S2 provides circuit to generate a 4-qubit GHZ state using a 4 qubit unitary transformation. According to Lemma C.1, the 4-qubit GHZ circuit is decomposed into

Fig. S2: Typical quantum circuit for 4 qubit GHZ state, where control-Z gate between the 2nd and 3rd qubits is cut to generate sub-circuits.

parallel two-qubit subcircuits, each suitable for small-scale hardware. As the CNOT gate between qubits 2 and 3 can be “cut” and replaced by a sum of local operations:

$$U_{cnot} = \frac{1}{2} (\mathbb{1} \otimes \mathbb{1} + \sigma_z \otimes \mathbb{1} + \mathbb{1} \otimes \sigma_x - \sigma_z \otimes \sigma_x),$$

with Pauli operators $\sigma_{x,y,z}$ and identity $\mathbb{1}$, we can generate a replaced circuits, shown in Fig. S3.

Fig. S3: Experimental circuit for 4-qubit GHZ state. circuits in (a-d) are generated by cutting the control-Z gate between the 2nd and 3rd qubits and replace it by a sum of local operations. Those circuit are summed in a superposition way.

Mathematically, the output state is a sum of product of sub-states

$$\sum_{\{j,k\}} (-1)^{j-1 \cdot k-1} |\phi_j\rangle \otimes |\psi_k\rangle,$$

where $j, k = 1, 2$. $|\phi_1\rangle = U_{cnot}(H \otimes I)|00\rangle$, $|\phi_2\rangle = I \otimes \sigma_z|\phi_1\rangle$, $|\psi_1\rangle = U_{cnot}|00\rangle$, and $|\psi_2\rangle = U_{cnot}(\sigma_x \otimes I)|00\rangle$. This indicates the entire preparation process can be parallelized. Via combining single-ancilla estimator, we can form the experimental circuit depicted in Fig. S4, and measure the ancilla qubit with σ_x and σ_y . Through varying M in the circuit for all two-qubit Pauli bases, we can get sufficient information for reconstructing a GHZ state.

In this experiment, two types of circuits are employed, with M varied to cover all Pauli bases required for full tomography. If every expectation value for a given Pauli basis is counted as an independent measurement, a total of 4×16 measurements are required. This is notably reduced compared to conventional four-qubit experiments, as both real and imaginary parts are separately recorded using the ancilla-assisted circuit.

Each node of the Triangulum-pro desktop spectrometer hosts three ^{19}F nuclear spins in a $\text{C}_2\text{F}_3\text{I}$ molecule, with typical coherence times of $T_2 \approx 500 \text{ ms}$ and a calibrated maximum Rabi rate of $|\omega_1|/2\pi = 8.3 \text{ kHz}$. Eight such nodes are synchronized by a common clock and exchange shot data via Gigabit Ethernet. We focus here on one representative experiment to illustrate the procedure:

Fig. S4: Experimental circuit for 4-qubit GHZ state. (a) and (b) simulate the overlaps induced via $|\phi_j\rangle$ and $|\psi_k\rangle$, respectively. By varying M , we can get complete information on 4-qubit GHZ state.

Fig. S5: Spectrum of all spins when system is at pseudo-pure state for $(\text{CH}_3\text{O})_2\text{PHO}$ (left) and $\text{C}_2\text{F}_3\text{I}$ (right). The horizontal axis is the chemical shift while vertical axis is absolute value of signal.

Initialization — A spatial operation sequence is applied to transform the thermal equilibrium state into a pseudo-pure ground state $|000\rangle$. The resulting state fidelity reaches 98.5% (see spectrum in Fig. S5).

Gate Implementation: The unitary operator represented by the sub-circuits (shown in Fig. S4 dashed boxes) is realized by a single shaped pulse of 28 *ms* duration, discretized into $M = 800$ time slices ($\Delta t = 35 \mu\text{s}$).

Pulse Optimization — An initial guess is generated using random spline envelopes $\{B_x(t), B_y(t)\}$ constrained by $|B| \leq 0.4|\omega_1|$, and accepted only if the simulated unitary fidelity exceeds 20%. The GRAPE algorithm is then employed to maximize the worst-case channel fidelity $\mathcal{F}_{\min}$ across nine error configurations, spanning three static B_0 offsets (−20, 0, and +20 Hz) and three RF amplitude miscalibrations (0.95, 1.00, 1.05). Optimization typically converges within 15–20 L-BFGS iterations. The final control amplitudes and phases are discretized to 0.01% resolution and exported as a waveform file with total pulse duration of 28 ms. GRAPE simulations yield an average gate fidelity of $\overline{\mathcal{F}}_{\text{gate}} = 99.3\%$ over all error conditions.

GHZ State Preparation — Finally, the GRAPE-compiled pulse is executed concurrently on all nodes in the cluster. Preparing GHZ State across two neighboring nodes yields a state fidelity of 93.8%.

E.2 Quantum Circuit Cutting

Similarly, we implement quantum circuit cutting to decompose a 4-qubit GHZ preparation circuit into a sum of eleven 2-qubit subcircuits, following the procedure of [21]. Unlike our architecture, which allows coherent superpositions and therefore requires ancillary systems for coherent control, quantum circuit cutting operates entirely classically. That is, the summation in circuit cutting is incoherent-no entanglement or interference is preserved-thereby avoiding the need for ancilla but increasing the classical processing overhead.

Quantum circuit cutting is a powerful strategy to simulate large quantum circuits on smaller hardware by dividing a global circuit into independently executable fragments. This technique is particularly valuable for near-term quantum devices constrained by limited qubit counts, coherence times, and gate fidelities. It enables logical circuit execution beyond physical limitations, relying on classical coordination and tomography-based post-processing.

In the spatial (or state-space) variant of circuit cutting, we approximate a two-subsystem unitary channel as

$$U_{ab}\rho U_{ab}^\dagger \approx \sum_i c_i U_{ai}\rho_a U_{ai}^\dagger \otimes U_{bi}\rho_b U_{bi}^\dagger, \quad (\text{E11})$$

assuming an initially factorized input state $\rho = \rho_a \otimes \rho_b$. This expansion allows the joint evolution under U_{ab} to be mimicked by local operations U_{ai} and U_{bi} on separate devices, followed by classical post-processing. Figure S6 illustrates this decomposition, where the bipartite gate is expressed as a convex combination of local unitaries applied independently to subsystems a and b .

Fig. S6: Schematic of quantum circuit cutting from an entire system to a bi-partition one.

In our demonstration, we apply this scheme to the 4-qubit GHZ circuit shown in Fig. S2. The key component-namely, the controlled-Z gate connecting the two partitions-is decomposed into a sum over tensor products of single-qubit operators. This decomposition reduces the circuit into 2-qubit subcircuits, which can then be distributed across multiple 2-qubit quantum processors.

To reconstruct the final GHZ state, each subcircuit is executed separately and its output measured in all required Pauli bases. In total, 10 distinct subcircuits are used, and each requires measurements in 16 different Pauli settings for full state tomography. Therefore, a total of $10 \times 16 = 160$ measurement configurations are needed for complete reconstruction.

$$\frac{1}{2} \begin{bmatrix} e^{i\pi Z/4} & \\ & e^{i\pi Z/4} \end{bmatrix} + \frac{1}{2} \begin{bmatrix} e^{-i\pi Z/4} & \\ & e^{-i\pi Z/4} \end{bmatrix} - \frac{1}{2} \sum_{\alpha \in \{\pm 1\}^2} \alpha_1 \alpha_2 \left\{ \begin{bmatrix} (I + \alpha_1 Z)/2 & \\ & e^{i(\alpha_1+1)\pi Z/4} \end{bmatrix} - \begin{bmatrix} e^{i(\alpha_2+1)\pi Z/4} & \\ & (I + \alpha_2 Z)/2 \end{bmatrix} \right\}$$

Fig. S7: Decompositions of controlled-Z gate into a sequence of single-qubit operations.

Each node of the Gemini-Lab desktop spectrometer hosts a ^1H nuclear spin and a ^{31}P nuclear spins in a Dimethyl Phosphite molecule $(\text{CH}_3\text{O})_2\text{PH}$, with typical coherence times of $T_2 \approx 500 \text{ ms}$ and a calibrated maximum Rabi rate of $|\omega_1|/2\pi = 6.25 \text{ kHz}$. Eight such nodes are synchronized by a common clock and exchange shot data via Gigabit Ethernet. We focus here on one representative experiment to illustrate the procedure:

Initialization — An operation sequence named relaxation method is applied to transform the thermal equilibrium state into a pseudo-pure ground state $|00\rangle$. The resulting state fidelity reaches 99.5% (See Fig. S5).

Gate Implementation: A parameterized two-qubit circuit is used to realize the sub-circuits shown in Figure S4 (dashed boxes). The parameterized quantum circuit contains single-qubit arbitrary angle rotation gate, rotation parameters and two-qubit gate (controlled-not gate, CNOT gate), which is shown in Fig. S8. We use this one as this is a fully compiled gate set. Each parameter is optimized through the gradient descent algorithm. The duration of each single-qubit rotation gates is about 0.3 ms , and the duration of CNOT gate is about 2 ms . Their theoretical fidelity are both greater than 99%.

GHZ State Preparation — Finally, the circuits are executed concurrently on all nodes in the cluster. Preparing GHZ State across two neighboring nodes yields a state fidelity of 92.3%.

Appendix F Supplementary information for non-hermitian Hamiltonian Simulation

Simulating non-Hermitian Hamiltonian dynamics-central to open quantum systems, $\mathcal{PT}$ -symmetric optics, and gain-loss processes-remains a significant challenge in quantum science. Unlike conventional unitary evolution, non-Hermitian generators produce norm-non-preserving dynamics and complex spectra, rendering classical simulation

especially demanding. Existing quantum algorithms for non-Hermitian channels often require complex ancillary structures. Here, we establish a thread-level parallel protocol, in which modular subtasks can be distributed across multiple quantum processors. This approach systematically enables scalable, parallel simulation of non-Hermitian dynamics, addressing a key bottleneck in both theory and experiment.

Many scientific and engineering tasks require simulating non-unitary evolution. Recent advances, such as linear combination of unitaries (LCU) and dilation methods, use ancillary qubits to enable non-Hermitian Hamiltonian simulation. As a representative protocol, the LCU framework approximates the time-evolution operator as a sum of unitaries:

$$e^{-iHt} \approx \sum_{k=0}^K \gamma_k U_k,$$

with coefficients γ_k and unitary circuits U_k constructed by, e.g., Taylor or Chebyshev expansion. For example, using the Taylor series expansion up to order K , we have

$$e^{-iHt} = \sum_{n=0}^N \frac{(-iHt)^n}{n!} + \mathcal{O}\left(\frac{(Ht)^{N+1}}{(N+1)!}\right).$$

By substituting $H = \sum_{m=1}^M \beta_m V_m$, where β_m are coefficients and V_m are unitary operators,

$$e^{-iHt} \approx \sum_{n=0}^N \frac{(-it)^n}{n!} \left(\sum_{m=1}^M \beta_m V_m \right)^n.$$

This results in a form of $\sum_{k=0}^K \gamma_k U_k$, with

$$U_k = V_{m_1} V_{m_2} \dots V_{m_n},$$

$$\gamma_k = \frac{(-it)^n}{n!} \beta_{m_1} \beta_{m_2} \dots \beta_{m_n},$$

where $m_1, m_2 \dots m_n \in [1, M]$, and $K = (M^{N+1} - 1)/(M - 1)$.

For time-dependent or non-Hermitian Hamiltonians, a linear combination of Hamiltonian simulation (LCHS) protocol (see Algorithm 1) is employed [25, 28], which naturally decomposes the evolution into independent unitary tasks suitable for parallel execution across QPU nodes. The method also needs ancilla systems, in our setting, we use cluster QPU, which leads a plug-and-play paradigm.

Algorithm 1 Hamiltonian Simulation for Non-Hermitian Dynamics

Input: $A(t) = H(t) + iL(t)$, initial state u_0 , simulation time T , precision epsilon.

Output: Final state $u(T)$

- 1: Decompose $A(t)$ into Hermitian part $H(t)$ and anti-Hermitian part $L(t)$.
 - 2: Define function $V(t, k) = T \exp(-i \int_0^t (H(s) + kL(s)) ds)$.
 - 3: Truncate the integral at $K = \frac{c}{\epsilon}$, where c is a constant.
 - 4: Discretize the integral using a trapezoidal rule:
 - 5: $K = \frac{c}{\epsilon}$ and $M = \lfloor \frac{2KT}{\epsilon} \rfloor$
 - 6: **for** $j = 0$ to M **do**
 - 7: $k_j = -K + \frac{2jK}{M}$
 - 8: $w_j = (2 - (\text{if } j == 0 \text{ or } j == M)) \frac{K}{M}$
 - 9: $c_j = \frac{w_j}{\pi(1+k_j^2)}$
 - 10: $U_j(t) = T \exp(-i \int_0^t (H(s) + k_j L(s)) ds)$
 - 11: $v_j = c_j U_j(T) u_0$
 - 12: **end for**
 - 13: Sum up the contributions:
 - 14: $u(T) = \sum_{j=0}^M v_j$
 - 15: **return** $u(T)$
-

F.1 Non-Hermitian Hamiltonian

We consider the open-system evolution of a single qubit governed by a time-independent non-Hermitian operator [26, 27]:

$$\mathcal{A}(t) = H(t) - iL(t), \quad H(t) = \sigma_x, \quad L(t) = \mathbb{1} + \sigma_z, \quad (\text{F12})$$

where $\sigma_{x,y,z}$ denote the Pauli matrices and $\mathbb{1}$ is the identity operator. The system is initialized in the ground state $|\psi_0\rangle = (1, 0)$, and we measure the expectation values of σ_y and σ_z .

This non-Hermitian evolution is experimentally realized on a cluster of 16×2 -qubit nodes, with a total of over 1700 experimental runs (approximately 106 per node). The simulation protocol is based on the linear combination of Hamiltonian simulation (LCHS), which approximates the non-unitary evolution using a truncated Cauchy-integral formula, as detailed in Algorithm 1. In addition, numerical simulations are performed using both this methodology and the exact integration of Schrödinger's equation via a first-order Trotter step.

Table S4 summarizes the numerical parameters. Here, M is the number of nodes and thus sets the count of decomposed unitary terms. Employing the single-ancilla estimator, illustrated in Fig. S9, each value of T requires $1 + \lfloor 2KT/\epsilon \rfloor$ individual experiments per observable. We sweep

$$T \in \{0.1, 0.2, \dots, 1.0\},$$

Symbol	Meaning	Value
T	Total evolution time	0.1-1.0 (step 0.1)
Δt	Trotter step size	0.01
ε	LCHS quadrature step size	0.2
c	Constant in cutoff	0.5
K	Integration cutoff	$\lfloor c/\varepsilon \rfloor = 2$
M	Number of nodes	$\lfloor 2KT/\varepsilon \rfloor$

Table S4: Numerical parameters used in the simulation of non-Hermitian Hamiltonian evolution.

and for each T record the expectation of a random Hermitian operator R as well as of σ_x and σ_z . Altogether, measuring any one observable entails

$$\sum_{j=1}^{10} (1 + \lfloor 2KT_j/\varepsilon \rfloor)^2$$

distinct experiments. Although the ideal count is 1770, stepwise truncation in the computation of M leads to a slight discrepancy, 1747. The reason is one calculating the $T = 0.6$ case. The truncation on machine made the $M = 11$, which makes little influence.

The parameters above are selected via considering the efficiency of experiments and accuracy. Throughout this protocol, the fidelity between the Trotter approximation and the LCHS implementation (with $\Delta t = 0.01$) mostly exceeds 99.2%, confirming the accuracy of our linear-combination approach.

Table S5: Summary of T , nodes M , and resulting fidelity for each sampling point.

k	1	2	3	4	5	6	7	8	9	10
T	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
M	2	4	6	8	10	11	14	16	18	20
Fidelity	0.9999	0.9987	0.9945	0.9870	0.9808	0.9828	0.9929	0.9999	0.9964	0.9871

In Table S6, we report the deviations between the experimentally measured expectation values of σ_y and σ_z and their numerically simulated counterparts, as well as those for a randomly generated Hermitian observable R , over the course of a non-Hermitian Hamiltonian evolution. The mean absolute deviation of 0.116, quoted in the main text, is obtained by averaging all of the absolute values listed in this table.

F.2 Imaginary time evolution

We further investigate the ground-state energy problem for a single-qubit Hamiltonian parameterized by a real coupling $\gamma \in [0, 2]$,

$$H(\gamma) = 2\mathbb{1} + \gamma\sigma_x, \quad (\text{F13})$$

Table S6: Deviations between experimental measurements and numerical simulations for $\langle\sigma_y\rangle$, $\langle\sigma_z\rangle$, and a random Hermitian observable R during non-Hermitian Hamiltonian evolution.

	1	2	3	4	5	6	7	8	9	10
σ_y	-0.1208	-0.1901	-0.1898	-0.0930	-0.0456	-0.0188	0.1648	0.2057	0.2123	0.1044
σ_z	-0.0497	0.0891	0.1104	0.1780	0.2054	0.2645	0.2498	0.1037	0.0895	-0.0411
R	0.0167	-0.0563	-0.1193	-0.0824	-0.1006	-0.1625	-0.1040	-0.0245	-0.0385	0.0471

Fig. S9: Ancilla-assisted quantum circuit for measuring overlaps $\langle U_j^\dagger M U_i \rangle$ required in the LCHS protocol. By varying M , we obtain the desired real and imaginary parts of the relevant observables.

where $\mathbb{I}$ is the identity and σ_x is the Pauli- x operator. The analytic ground-state energy is $E_0(\gamma) = 2 - |\gamma|$, which serves as an independent benchmark. The ground state can also be found via imaginary-time evolution: the qubit is initialized in $|\psi_0\rangle = (1, 0)^T$, propagated in a non-unitary fashion, and the ground-state energy is estimated as $E(\tau) = \langle \psi(\tau) | H(\gamma) | \psi(\tau) \rangle$.

Experimentally, this imaginary-time evolution is implemented as a linear combination of unitary evolutions via the truncated Cauchy-integral formula. On the cluster of 16×2 -qubit nodes, imaginary-time evolution of $H(\gamma)$ for a total time $T = 0.5$ is performed with more than 1331 experimental runs for obtaining single observable (about 83 per node). In addition to the ground-state energy, the expectation values of σ_x and σ_z are also measured for the resulting ground states.

To validate our experimental results, we benchmark three numerical simulations. First is the exact imaginary-time Trotter integration, in which the state is evolved by repeated application of $\exp[-H(\gamma)\Delta t]$ with a fixed step size $\Delta t = 0.01$ and $t = 0.5$. The second is the LCHS-imaginary protocol, where the non-unitary propagator $\exp[-H(\gamma)\tau]$ is approximated via a truncated Cauchy integral with quadrature step $\varepsilon = 0.3$, shown in Algorithm 1. The third is the exact diagonalization on $H(\gamma)$, which yields the ground-state energy, to get a more approximated wavefunction, we use numerical imaginary-time evolution with $T = 1.5$.

The simulation parameters are summarized in Table S7. In particular, M denotes the number of nodes, which in turn determines the total number of decomposed unitary terms, U_i, U_j . To extract the required expectation values, we design a single-ancilla estimator, illustrated in Fig. S9. Thus, this decomposition requires 11×11 ($M + 1 \times M + 1$) individual experiments. We sweep the parameter γ across eleven uniformly spaced values,

$$\gamma_k = 0.2k, \quad k = 0, 1, \dots, 10,$$

Symbol	Meaning	Value
γ	parameter in Hamiltonian	0.0-2.0 (step 0.2)
T	total evolution time	0.5
Δt	Trotter step	0.01
ε	LCHS quadrature step	0.3
c	a constant	1
K	integration cutoff	$\lceil c/\varepsilon \rceil = 3$
M	number of nodes	$\lfloor 2KT/\varepsilon \rfloor = 10$

Table S7: Numerical parameters used in all simulation of imaginary-time evolution.

and for each γ_k we record the expectation values of the Hamiltonian $H(\gamma)$ as well as of σ_x and σ_z on the corresponding ground state. Consequently, measuring any single observable entails

$$11 \times 11 \times 11 = 1331$$

distinct experiments.

At the conclusion of the imaginary-time evolution ($T = 0.5$), the fidelity between the Trotter approximation and the LCHS protocol exceeds 99.5% for most sampling points, thereby confirming the accuracy of the linear-combination approach. Detailed fidelity values are listed in Table S8.

Table S8: Fidelity between the Trotter method and the LCHS protocol after imaginary-time evolution ($T = 0.5$) for $\gamma_k = 0.2k$ (indices $k = 1, \dots, 10$).

	1	2	3	4	5	6	7	8	9	10
fidelity	0.9990	0.9969	0.9950	0.9944	0.9952	0.9967	0.9983	0.9995	0.99998	0.99977

In Table S9, we report the deviations between the experimentally measured expectation values of $\langle \sigma_x \rangle$ and $\langle \sigma_z \rangle$ and their numerically simulated counterparts, as well as those for the Hamiltonian observable $H(\gamma)$, at the conclusion of an imaginary-time evolution ($T = 0.5$). The overall mean absolute deviation of 0.136, quoted in the main text, is obtained by averaging all of the absolute values listed in this table.

Table S9: Deviations between experimental measurements and numerical simulations for $\langle \sigma_x \rangle$, $\langle \sigma_z \rangle$, and the Hamiltonian $H(\gamma)$ after imaginary-time evolution ($T = 0.5$). γ is set as $0.2k$, where k label this horizontal axis.

	1	2	3	4	5	6	7	8	9	10	11
σ_1	-0.3055	-0.2313	-0.2008	-0.3122	-0.2248	-0.2227	-0.0779	-0.0072	-0.0351	0.0761	0.0498
σ_2	-0.2459	-0.1625	-0.0745	-0.2681	-0.1279	-0.1384	-0.0746	-0.0652	-0.0296	-0.0692	-0.1333
σ_3	-0.0108	0.0705	-0.0115	0.0529	0.1826	0.1067	0.1317	0.1807	0.1328	0.1955	0.3062

Finally, we present the experimental implementation on hardware. This is carried out in a two-qubit cluster of the Gemini-Lab desktop spectrometer, as described in the Appendix D.

The overall procedure follows a structure similar to the quantum circuit cutting experiments detailed in Appendix E, and here we focus on a single representative thread.

As in previous sections, a relaxation-based initialization sequence is applied to convert the thermal equilibrium state into a pseudo-pure state that approximates $|00\rangle$. The resulting state fidelity reaches 99.5%.

Next, a parameterized two-qubit quantum circuit is used to implement the sub-circuits illustrated in Fig. S9. The circuit consists of arbitrary angle single-qubit rotation gates and a two-qubit controlled-NOT (CNOT) gate. All parameters are optimized using a gradient descent algorithm. Each single-qubit rotation has a duration of approximately 0.3 ms, while the CNOT gate duration is about 2 ms. Theoretical fidelities for both types of gates exceed 99%. Finally, the compiled circuit is executed and the measurement is performed to extract the desired observables.

Sudden Death of Entanglement, Rebirth of Magic

Chenfeng Cao^{1 2}

¹ Dahlem Center for Complex Quantum Systems, Freie Universität Berlin, 14195 Berlin, Germany

² HK Institute of Quantum Science & Technology, The University of Hong Kong, Hong Kong, China

Abstract. Local Markovian noise cannot bring entanglement back, but it can bring magic back. Unlike separability, stabilizer membership is not preserved by local channels, allowing dissipation to push states out of the stabilizer polytope as well as in. Under local amplitude damping, the n -qubit GHZ family $\alpha|0^n\rangle + \beta|1^n\rangle$ ($0 < \alpha < \beta$) loses its magic at a lower damping strength γ_- and regains it at a higher one γ_+ , while entanglement is irreversibly lost at γ_e . This magic–entanglement complementarity, $\gamma_e + \gamma_+ = 1$ for every n , reflects a system–environment duality of amplitude damping and persists for a broader class of dissipative channels. For small α , the reborn magic resides in a fully separable state with all proper marginals stabilizer, yet parity-syndrome extraction concentrates it onto a single qubit for magic-state distillation. Local dissipation further divides pure stabilizer states into magic-generators and magic-insulators: at two qubits, the Bell state $|\Phi^+\rangle$ generates magic immediately, while its Bell-state partner $|\Psi^+\rangle$ remains stabilizer. Together, magic and entanglement reveal a symmetry invisible to either alone.

Keywords: nonstabilizerness, amplitude damping, stabilizer polytope

Full proofs are available at arXiv:2605.22603.

1 Main Idea and Results

Entanglement sudden death is irreversible under local Markovian noise: once a state is separable, subsequent local channels keep it separable [1, 2, 3, 4]. Magic, the non-Clifford resource promoting stabilizer circuits to universal quantum computation [5, 6, 7, 8], behaves differently: local CPTP channels preserve separability but need not preserve the stabilizer polytope $\mathcal{S}$, so dissipation can push states both into and out of $\mathcal{S}$.

This work gives an exactly solvable open-system instance of this asymmetry. For the GHZ-type line $|\psi_n\rangle = \alpha|0^n\rangle + \beta|1^n\rangle$, with $\alpha, \beta > 0$, $\alpha^2 + \beta^2 = 1$, and $r := \alpha/\beta < 1$, local amplitude damping produces a re-entrant magic trajectory: magic is present, then absent on a finite interval, and then reborn. The striking point is that the rebirth is not a non-Markovian revival or a trajectory-resolved measurement effect. It occurs under a deterministic local Markovian channel whose entanglement dynamics is strictly irreversible.

We prove three results: exact all- n stabilizer membership and closed-form robustness on the amplitude-damped GHZ trajectory; the mirror identity $\gamma_e^{(n)} + \gamma_+^{(n)} = 1$ between entanglement death and magic rebirth; and a lossless stabilizer extraction that converts the reborn nonlocal mixed-state magic into a single-qubit magic state.

2 Magic Rebirth and the Entanglement Mirror

The single-qubit amplitude-damping channel has $E_0 = |0\rangle\langle 0| + \sqrt{1-\gamma}|1\rangle\langle 1|$ and $E_1 = \sqrt{\gamma}|0\rangle\langle 1|$, with $\gamma = 1 - e^{-\kappa t}$. Acting on all qubits gives the real GHZ- X state

$$\rho_n(\gamma) = \sum_{k=0}^n P_k D_k + c(|0^n\rangle\langle 1^n| + |1^n\rangle\langle 0^n|), \quad (1)$$

where D_k is the uniform mixture over Hamming weight k strings, $P_0 = \alpha^2 + \beta^2\gamma^n$, $P_n = \beta^2(1-\gamma)^n$, and $c = \alpha\beta(1-\gamma)^{n/2}$. The central geometric fact is that the full stabilizer-polytope membership problem on this slice reduces to two endpoint inequalities:

$$\rho_n(\gamma) \in \mathcal{S} \iff P_0 \geq c \text{ and } P_n \geq c. \quad (2)$$

The proof uses the affine-support structure of pure stabilizer states [9]: stabilizer mixtures cannot have endpoint coherence larger than either endpoint population; conversely, whenever this bound holds, an explicit stabilizer decomposition realizes $\rho_n(\gamma)$. The same argument gives

$$\mathcal{R}(\rho_n(\gamma)) = 1 + 2 \max\{0, c - P_0, c - P_n\}. \quad (3)$$

Thus the stabilizer window is not inferred from a witness or a low-dimensional numerical calculation. It is exactly the interval on which the GHZ coherence is no larger than both endpoint populations.

Figure 1: Trajectory classes and resource phase diagram. (a) Re-entrant, death-only, and endpoint-only damping trajectories, all ending at the stabilizer vertex $|0^n\rangle$. (b) Two-qubit Yu–Eberly slice: magic dies at γ_- , is reborn at γ_+ , and entanglement dies at γ_e .

Figure 2: Magic–entanglement complementarity and Bell-state splitting. (a,c) Magic can die and return while entanglement dies irreversibly. (b) On the reborn branch for $n = 2$, $\mathcal{R}_A(\gamma) - 1 = [(1 - \gamma)/\gamma]\mathcal{C}(1 - \gamma)$. (d) $|\Phi^+\rangle$ generates magic immediately, whereas $|\Psi^+\rangle$ remains stabilizer.

For $0 < r < 1$, magic dies at $\gamma_-^{(n)}$, the unique solution of $P_0 = c$, and is reborn at $\gamma_+^{(n)} = 1 - r^{2/n}$, the solution of $P_n = c$.

Entanglement gives the reflected threshold. Across any bipartition, partial transposition couples only one 2×2 block, whose determinant vanishes at $\gamma_e^{(n)} = r^{2/n}$. At this same point the state is fully separable [10, 11]. Hence, for every $n \geq 2$,

$$\gamma_e^{(n)} + \gamma_+^{(n)} = 1. \quad (4)$$

This is an all- n identity between full separability and magic rebirth, not merely a two-qubit concurrence statement. For $n = 2$, the reborn branch further obeys the pointwise mirror $\mathcal{R}_A(\gamma) - 1 = [(1 - \gamma)/\gamma]\mathcal{C}(1 - \gamma)$.

The reflection has a channel-level origin. In the canonical Stinespring dilation of amplitude damping, the complementary channel is $\mathcal{E}_\gamma^c = \mathcal{E}_{1-\gamma}$ [12]. Thus the environment at damping γ carries the system trajectory at $1 - \gamma$, exchanging the entanglement-death minor with the magic-rebirth stabilizer facet. This system–environment duality is the structural reason why the constant in Eq. (4) is exactly one and why it is independent of n .

The two-qubit slice is directly testable. Once the amplitude-damped state is validated as an X -state by symmetry or partial tomography, stabilizer membership reduces to the three-Pauli inequality

$$\rho_A(\gamma) \in \mathcal{S} \iff 2|\langle ZI \rangle| + 2|\langle XX \rangle| \leq 1 + \langle ZZ \rangle. \quad (5)$$

In the re-entrant regime, the explicit thresholds are $\gamma_+^{(2)} = 1 - r$, $\gamma_e^{(2)} = r$, and $\gamma_-^{(2)} = [\sqrt{\alpha(4\beta - 3\alpha)} - \alpha]/(2\beta)$. For example, at $\alpha = 0.4$ the stabilizer window lies between the first and second magic thresholds, while entanglement dies inside it; the experimentally visible signature is the independent equality $\gamma_e + \gamma_+ = 1$.

The reflection is not restricted to perfectly homogeneous pure amplitude damping. For qubit-dependent damping strengths γ_i , the two relevant hypersurfaces become $\prod_i \gamma_i = r^2$ and $\prod_i (1 - \gamma_i) = r^2$, exchanged by $\gamma_i \mapsto 1 - \gamma_i$. For real ground-state-preserving phase-covariant channels, the same identity persists precisely when the normalized coherence profile is reflection symmetric on the threshold domain. Thus pure amplitude damping is the clean Stinespring-dual representative of a broader boundary symmetry.

3 Nonlocal Separable Magic and Lossless Extraction

When $\alpha < 1/\sqrt{1 + 2^n}$, one has $\gamma_+^{(n)} > \gamma_e^{(n)}$, so the whole reborn branch lies in the fully separable region. Moreover, every proper marginal is stabilizer, because tracing out any qubit removes the only GHZ coherence. The reborn resource is therefore joint, separable, mixed-state magic: present in the global state, absent from all local reductions, and not carried by entanglement.

This magic is nevertheless operationally useful. Measure the parity stabilizers $Z_i Z_{i+1}$ and postselect the trivial syndrome, with success probability $P_0 + P_n \geq \alpha^2$. Clifford decoding gives

$$\tilde{\rho}(\gamma) = \frac{1}{P_0 + P_n} \begin{pmatrix} P_0 & c \\ c & P_n \end{pmatrix}. \quad (6)$$

Figure 3: Lossless extraction and distillation windows. Parity postselection projects onto the cat subspace and Clifford decoding maps the global GHZ coherence to a single qubit in the Bloch XZ plane. The rotated square is the stabilizer octahedron. Increasing n makes the reborn branch enter the standard $|H\rangle$ - and $|T\rangle$ -type sufficient distillation regions.

Its Bloch coordinates are $x = 2c/(P_0 + P_n)$ and $z = (P_0 - P_n)/(P_0 + P_n)$. The original n -qubit criterion becomes exactly the one-qubit octahedron criterion:

$$\rho_n(\gamma) \notin \mathcal{S} \iff \tilde{\rho}(\gamma) \notin \mathcal{O} \iff |x| + |z| > 1. \quad (7)$$

The extraction is also lossless in expectation:

$$(P_0 + P_n)[\mathcal{R}(\tilde{\rho}) - 1] = \mathcal{R}(\rho_n(\gamma)) - 1. \quad (8)$$

Equation (8) saturates the ensemble monotonicity bound for stabilizer measurement and postselection. On this manifold, parity decoding gives an explicit lossless instance of multiqubit-to-single-qubit magic reduction in the sense of the Triangle Criterion [13].

After Pauli sign correction and Clifford twirling, the decoded state lies on a standard $|H\rangle$ or $|T\rangle$ axis. For fixed $0 < \alpha < 1/\sqrt{2}$, increasing n pushes the reborn branch into the usual Bravyi–Kitaev distillable regions [5, 14]. On the natural large- n scale $n\gamma = O(1)$, the decoded reborn branch becomes asymptotically pure, and the sign-corrected coordinate $x + |z|$ reaches the maximal value $\sqrt{2}$, strictly above both standard sufficient distillation thresholds. Dissipation followed by stabilizer extraction can therefore supply heralded magic-state inputs.

4 Beyond GHZ: Trajectory Classes and Stabilizer-Input Dichotomy

Rebirth is not generic. The smallest anti- W state $|D_3^2\rangle = (|011\rangle + |101\rangle + |110\rangle)/\sqrt{3}$ has finite magic death at $\gamma_* = (\sqrt{3} - 1)/2$ and no rebirth; the next anti- W member has exact threshold

$\gamma_*^{(4)} = 1/2$. Nonstabilizer generalized- W inputs give affine endpoint-only trajectories, and Haar-random inputs are endpoint-only with probability at least $1 - 2^{-n}$. A non-GHZ vacuum–anti- W affine-plane slice gives another exact re-entrant example, showing that death and rebirth are not an artifact of the GHZ endpoint pair.

Pure stabilizer inputs also split sharply. Under homogeneous amplitude damping, $|\Phi^+\rangle$ is a magic-generator with $\mathcal{R}_{\Phi^+}(\gamma) = 1 + \gamma(1 - \gamma)$, whereas the locally Clifford-equivalent $|\Psi^+\rangle$ is a magic-insulator with $\mathcal{R}_{\Psi^+}(\gamma) = 1$. The local-Clifford equivalence is broken because amplitude damping is not Clifford covariant. In general, a pure stabilizer state is an insulator exactly when its computational-basis support has constant Hamming weight; mixed Hamming-weight support generates magic immediately and returns to $\mathcal{S}$ only at $\gamma = 1$. This gives a simple resource-theoretic test for why CSS-type stabilizer supports and amplitude-damping noise can behave very differently from a Pauli-noise intuition.

This distinguishes the present mechanism from magic transitions in monitored circuits [15, 16] and from quantitative studies of nonstabilizerness under noisy circuit dynamics [17]. Here the effect is deterministic, Markovian, non-unital, and exactly solvable. Conceptually, local relaxation can erase entanglement while creating distillable computational magic. Technically, the work solves an all- n mixed-state stabilizer-polytope membership problem on this manifold, with exact thresholds and closed-form robustness, despite the general hardness of deciding magic membership [18, 19]. The robustness formula also makes the classical simulation overhead along the dissipative trajectory explicitly non-monotone: it vanishes in the stabilizer window and revives on the reborn branch.

Experimentally, the two-qubit Yu–Eberly slice is the most direct test: after validating the X -slice, the three Pauli expectations $\langle ZI \rangle$, $\langle ZZ \rangle$, and $\langle XX \rangle$ locate the stabilizer window, while concurrence locates γ_e . The signature is the independently measurable reflection $\gamma_e + \gamma_+ = 1$, accessible with engineered dissipation [20]. At $\alpha = 0.4$, the relevant damping window is $\gamma \in [0.324, 0.564]$, corresponding to $\kappa t \in [0.391, 0.829]$, within typical relaxation-time budgets. The broader implication is that amplitude damping followed by parity-syndrome extraction offers a passive, heralded alternative to active magic-state preparation in Clifford-based fault-tolerant architectures.

ABSTRACT

Inferring the dynamical generator of a many-body quantum system from measurement data is essential for the verification, calibration, and control of quantum processors. When the system is open, this task becomes considerably harder than in the purely unitary case, because coherent and dissipative mechanisms can produce similar measurement statistics and long-time data can be insensitive to coherent couplings. Here we tackle this so-called Lindbladian learning problem of open-system characterisation with maximum-likelihood on Pauli measurements at multiple experimentally friendly *transient* times, exploiting the richer information content of transient dynamics. To navigate the resulting non-convex likelihood loss-landscape, we augment the physical model neural differential-equation term, which is progressively removed during training to distil an interpretable Lindbladian solution. Our method reliably learns open-system dynamics across neutral-atom (with 2D connectivity) and superconducting Hamiltonians, as well as the Heisenberg XYZ, and PXP models on a spin-1/2 chain. For the dissipative part, we show robustness over phase noise, thermal noise, and their combination. Our algorithm can robustly infer these dissipative systems over noise-to-signal ratios spanning four orders of magnitude, and system sizes up to $N = 6$ qubits with fewer than 5×10^5 shots.

1 Introduction

Programmable quantum processors realize many-body dynamics whose microscopic parameters—Hamiltonian couplings and dissipative rates—are often only partially known *a priori*. Extracting these device parameters from experimental data is a critical bottleneck in scaling up near-term quantum technologies [1, 2]. Indeed, inferring microscopic properties of a quantum state or process from measurement data is known to be intrinsically difficult [3, 4], because measurement outcomes are nondeterministic, and typicality implies that finite data often carry limited information about fine-grained microscopic structure [5–7].

In *Hamiltonian learning* (HL), one collects finite-statistics measurements on states evolved for known times from known preparations and seeks to infer the unknown Hamiltonian parameters that generate these dynamics. While forward simulation (predicting dynamics given a known Hamiltonian) is straightforward in principle, the inverse map from dynamical measurement data to microscopic parameters is highly nonlinear, and practical inference is constrained by finite data and the exponential growth of Hilbert space. Indeed, brute-force quantum process tomography scales exponentially in parameters and measurements [1, 8], motivating approaches that exploit structure such as geometric

^{*}timothy.heightman@icfo.eu

locality to reduce sample complexity and parameter count. Existing HL methods include equilibrium-based strategies [9, 10], trajectory-based fitting of time-series data [11–14], and variational schemes based on parametrized circuits [15, 16].

However, realistic quantum hardware is inherently open. Coupling to the environment leads to decoherence and dissipation that are often comparable to coherent timescales in current devices [17, 18]. Under standard Markovian assumptions, the dynamics are generated by a time-homogeneous Lindbladian (GKSL generator) rather than a Hamiltonian alone [17, 19, 20]. Learning the full Lindbladian constituting coherent couplings and dissipative operators alike, defines the *Lindbladian learning* problem.

Lindbladian learning is substantially more challenging than HL. In addition to Hamiltonian parameters, one must determine dissipative rates (and, in general, channel structure), and identifiability can fail in regimes where distinct generators produce the same, indistinguishable steady-state behaviour. In particular, steady-state data can be largely insensitive to the coherent part of the dynamics, since many Hamiltonians may share the same fixed point [20–22]; identifiability is therefore a central concern [23]. More broadly, the same measurement statistics can often be explained by different coherent–dissipative decompositions, breaking the uniqueness of the inverse map. Existing methods include steady-state approaches [21], tomography on small processors [24], learning in weakly dissipative regimes [25], variational Liouvillian learning [26], simulation-assisted strategies [27], and ansatz-free approaches [28]. However, these methods typically require access to steady states, weak dissipation, or apply only to the smallest system sizes of one or two qubits.

Recent progress to address some of these limitations includes the large-scale time-series protocol of [29], which reaches 156-qubit demonstrations by assuming a strictly local Pauli Lindblad model and reducing generator identification to a constrained linear regression on local observables, extending steady-state linearisation of [21] to transient data. As with many hardware-scale identification schemes, this scalability comes with trade-offs. The approach is naturally tied to discrete-depth sampling and relies on extracting dynamical information from fitted time-series, which can reduce sensitivity to fast coherent components outside the resolvable bandwidth and complicate flexible (e.g., non-uniform) sampling. These trade-offs leave open the complementary problem of robust, shot-efficient Lindbladian learning from transient measurement data in regimes where coherent and dissipative contributions induce genuinely non-convex, locally flat or rugged optimization landscapes.

Deep learning offers a promising avenue to overcome these limitations, with applications in quantum science now spanning variational state representation, dynamics prediction, and quantum control [30, 31]. In particular, *Neural Differential Equations* (NDEs) provide a principled way to learn continuous-time dynamics by parametrizing the vector field of an ODE with a neural network [32, 33]. In quantum settings, our previous work Heightman et al. [34] showed that augmenting a physics-based Hamiltonian model with an NDE correction can substantially improve optimization and robustness in HL, dynamically reshaping the loss landscape to help variational parameters escape local minima. On open quantum systems [35] first proposed NDEs for Lindbladian Learning, although their method requires quantum optimal control, and does not report the shot-intensity or robustness of their method. Neural approaches to quantum dynamics have also been pursued for other aspects of quantum information processing, including latent neural ODEs for learning quantum evolution from partial observations [36], dual-capability models that jointly estimate parameters and predict dynamics [37], random-driving protocols combined with deep networks [38], and machine-learning agents for system characterization [39].

In this work we employ NDEs for *Lindbladian learning*: given a known Hamiltonian structure and jump-operator form, we infer all couplings and dissipative rates from finite-shot measurement data. We assume known initial preparations and measurement times, collecting local Pauli snapshots at multiple transient times. We show how maximum-likelihood estimation on this data avoids full process tomography while remaining identifiable under locality assumptions [20, 23, 40]. Crucially, transient data is the primary means of resolving the coherent–dissipative ambiguity, since it retains sensitivity to the Hamiltonian component that is lost once the system relaxes toward a fixed point. The NDE then navigates the resulting non-convex optimization landscape. During the augmented training stage the neural correction is constrained to preserve trace and Hermiticity but is not required to maintain complete positivity, so the combined generator can be unphysical during training. However, through a curriculum learning procedure on a combined ansatz and NDE, we are able to yield an output GKSL form generating a strictly CPTP map. Using transient data is also experimentally attractive, as it avoids waiting for convergence to a fixed point, which can be orders of magnitude slower than coherent timescales in low-noise regimes. Unlike [29], we resolve the inherent nonconvex optimization pathology that arises when coherent and dissipative mechanisms compete and the loss landscape becomes rugged or locally flat. Further, our method requires no optimal control like [35], and we show robustness over an experimentally friendly maximum of 5×10^5 shots up to $N = 6$ qubits.

To highlight the broad applicability of our protocol, we test it on four physically motivated Hamiltonians. These are the Hamiltonians for neutral-atom (with 2D connectivity) and superconducting QPUs, as well as the Heisenberg XYZ,

and PXP models on a spin-1/2 chain. For the dissipative part, we employ three noise models, phase noise, thermal noise, and their combination. We then show how our algorithm can robustly infer these dissipative systems over noise-to-signal ratios spanning four orders of magnitude, and system sizes up to $N = 6$ qubits. By systematically comparing physics-only and NDE-augmented models, we identify when neural augmentation improves robustness. We find the NDE-augmentation improving robustness most notably in regimes where non-commuting coherent and dissipative dynamics induce rugged loss landscapes and degenerate fixed-point structure. Conversely, when jump operators commute with the Hamiltonian and the steady state is unique, we find a physics-only model typically suffices and NDEs can overfit. This leads to a practical guideline: attempt physics-only variational learning first when the Hamiltonian and Lindbladian ansatz commute, and deploy NDE augmentation only when robustness is insufficient (which is often when these two components are non-commuting). Furthermore, we show that unlike unitary systems [34], low state infidelity of open dynamics alone can be misleading. Distinct generators can share the same steady-state manifold, and robustness of parameter recovery is the more informative benchmark.

The remainder of this paper is organized as follows. In Sec. 1.1, we formally define the Lindbladian Learning problem in the white-box scenario as an extension of the white-box Hamiltonian learning problem to open systems. In Sec. 2 we describe how to incorporate NDEs into open-system dynamics, detailing our curriculum learning procedure, measurements, and the maximum-likelihood-based loss function. Next, we describe the details of the numerical experiments, datasets, model architectures and benchmarks in Sec. 3. Sec. 4 then presents the results of these numerical experiments, and offers a detailed analysis around the subtleties of Lindbladian Learning through a study of loss-landscape dynamics. Finally, Sec. 5 offers an outlook and future research directions to scale our algorithm to systems with $N \gg 1$.

1.1 Problem Statement

We consider Markovian open-system dynamics on 1D spin-1/2 chains. We assume the system plus environment evolves unitarily and the environment is not observed. Tracing out the environment, the reduced state $\rho(t)$ evolves under a time-homogeneous CPTP semigroup generated by the Lindblad master equation [19],

$$\dot{\rho}(t) = \mathcal{L}_T[\rho(t)] := -i[H_T, \rho(t)] + \sum_{\alpha} \gamma_{\alpha} (L_{\alpha} \rho(t) L_{\alpha}^{\dagger} - \frac{1}{2} \{L_{\alpha}^{\dagger} L_{\alpha}, \rho(t)\}), \quad (1)$$

with the unitary component generated by Hamiltonian H_T , and Lindblad operators L_{α} with non-negative real-valued rates γ_{α} generating the open component. We refer to this as the Lindblad master equation, with the right-hand-side commonly referred to as the GKSL form. The learning task is to infer a generator, $\mathcal{L}_T$ in the so-called white-box scenario [34]. This means we set a chosen model ansatz that explains observed data and remains physically valid (CPTP), prioritizing interpretability of both coherent and dissipative terms. The Hamiltonian and dissipative channels are expressed in a fixed, physically motivated operator basis, and the fitted dynamics are attributed to these analytic terms alone.

For spin-1/2 chains of length N , we represent the coherent part in the Pauli basis,

$$H_T = \sum_{j=0}^{4^N-1} c_j P_j, \quad P_j \in \mathcal{P}_N, c_j \in \mathbb{R}, \quad (2)$$

which is a complete decomposition for any Hamiltonian on N qubits. Here $\mathcal{P}_N$ refers to the Pauli group on N qubits, and dissipative channels are modelled by local jump operators with rates $\gamma_{\alpha} \in \mathbb{R}_+$. The objective is therefore to learn (c_j, γ_{α}) so that the induced trajectories match observed statistics within the training window and generalize beyond transient times. As such, our learning algorithm applicable to the white-box scenario as described in [34] with the structure fixed by Lindbladian generator $\mathcal{L}_T$ as shown in Fig. 1.

Figure 1: The white-box Lindbladian Learning (LL) setup. The structure of the true Hamiltonian $H_T = \sum_j c_j P_j$ and open-system terms $\sum_{\alpha} \gamma_{\alpha} (L_{\alpha} \rho(t) L_{\alpha}^{\dagger} - \frac{1}{2} \{L_{\alpha}^{\dagger} L_{\alpha}, \rho(t)\})$ structure the ansatz, and the coefficients $c_j, \gamma_{\alpha} \in \mathbb{R}$ are unknown.

We assume only control on the amount of time evolution, and no quantum optimal control. This makes data from time-evolved states experimentally friendly, provided the chosen evolution times are sufficiently short [13, 34].

2 Neural Differential Equations in Open Quantum Systems

A Neural Ordinary Differential Equation (NDE) specifies the vector field of an ODE with a trainable function. Given a state vector $x(t) \in \mathbb{R}^d$ and a neural architecture $f_\theta : \mathbb{R}^d \rightarrow \mathbb{R}^d$ with parameters θ , the NDE dynamics

$$\frac{dx}{dt}(t) = f_\theta(x(t)), \quad x(0) = x_0, \quad (3)$$

are integrated to time T , and the parameters θ are tuned by backpropagating a task loss through the ODE solver. Universal approximation results justify the expressivity of f_θ , and practical training uses stochastic optimizers such as Adam [32, 33, 41]. Despite the GKSL form using partial derivatives, we employ NODEs because when the generator is time-independent, the partial differential equation for $\rho(t)$ becomes an ordinary differential equation. As such an ordinary neural augmentation is sufficient, and we use NDE and NODE interchangeably in the scope of this work.

In our open-system setting the dynamical variable is a density operator $\rho(t)$ evolving under $\mathcal{L}_T$. In line with recent results in Hamiltonian Learning with NDEs [34], we adopt a gray-box decomposition. Specifically, dynamics are computed by adding two superoperators:

$$\mathcal{L}_\Theta = \mathcal{L}_{\text{phys}}(\theta) + \mathcal{L}_{\text{NN}}(\varphi), \quad (4)$$

corresponding to a physics-based ansatz and a neural correction. The physics ansatz is the standard Lindblad generator,

$$\mathcal{L}_{\text{phys}}(\theta)[\rho] = -i[H(\theta_H), \rho] + \sum_\alpha \gamma_\alpha(\theta_\alpha) \left(L_\alpha \rho L_\alpha^\dagger - \frac{1}{2} \{L_\alpha^\dagger L_\alpha, \rho\} \right), \quad (5)$$

where θ_H are the Hamiltonian Pauli coefficients, and θ_α are real-valued free parameters mapped to nonnegative rates by a softplus transformation,

$$\gamma_\alpha(\theta_\alpha) = \text{softplus}(\theta_\alpha) = \log(1 + e^{\theta_\alpha}). \quad (6)$$

The neural correction $\mathcal{L}_{\text{NN}}(\varphi)$ is implemented as a small, neural-network, acting on ρ . An arbitrary neural network does not inherently guarantee that the evolved state remains a valid density matrix. We enforce the physicality of the state during the numerical simulation via explicit projections. To ensure the density matrix maintains unit trace, and is hermitian, we divide the output state by its trace and then average over its conjugate transpose once at the output of the numerical solver (see Fig. 2 and Sec. 3.3 for further detail).

However, explicitly enforcing positive semidefiniteness requires continuous eigenvalue decompositions, which are computationally prohibitive and severely bottleneck the automatic differentiation within the ODE solver. Consequently, we apply no explicit mathematical projection for positive semidefiniteness. Instead, we rely on the empirical observation that, for the physical initial states utilized in our work, the trained network naturally bounds the trajectories, and the density matrices remain positive semidefinite at every point in the simulations. The master equation then reads

$$\dot{\rho}(t) = (\mathcal{L}_{\text{phys}}(\theta) + \mathcal{L}_{\text{NN}}(\varphi))[\rho(t)], \quad \rho(0) = \rho_0, \quad (7)$$

and is integrated with an automatic-differentiation-compatible ODE solver. In practice we use a high-order explicit Runge–Kutta integrator with adaptive step control (Diffax/JAX) [33, 42]. The total trainable set of parameters is then $\{\theta, \varphi\}$.

By the universal approximation theorem, this correction term can fully emulate the physics-based ansatz, as well as dynamics not captured by this ansatz. As such, $\mathcal{L}_{\text{NN}}$ can dominate the dynamics in training rendering a naive NDE-based learning algorithm uninterpretable at the level of Hamiltonian and Lindbladian coefficients. Hence, it is necessary to heavily control the magnitude of $\mathcal{L}_{\text{NN}}$, with an idealised algorithm converging to dynamics whose trajectories are governed only by $\mathcal{L}_{\text{phys}}$ making the output fully interpretable. We can approach this idealised scenario with strong L_2 regularization and by a training curriculum described below.

2.1 Curriculum Learning

The following curriculum gradually reduces reliance on the neural augmentation while refining the interpretable parameters. The rationale behind this is to begin with a more permissive model to navigate rugged landscapes, then constrain capacity to distil an interpretable solution. It works in three steps:

Warm-up Jointly train the analytic parameters θ and the neural parameters φ . This phase leverages the smoothing effect of the neural term to escape poor basins and accelerate convergence.

Analytic refinement Switch off the neural term (both forward and backward), reset the optimizer state, and train only θ . The reset is essential to restore sensitivity to small dissipative rates parameterized via the softplus map, ensuring accurate recovery of the interpretable Hamiltonian and Lindbladian coefficients.

Optional residual fine-tuning With θ frozen, one may briefly train φ to capture small systematic discrepancies not represented in the analytic ansatz. The final weighting of this term can be used as an heuristic indicator of the quality of the ansatz - see Sec. 5.

the warm-up removes sensitivity to initialization and barren plateau effects, while the refinement phase consolidates the physically meaningful parameters. We emphasize that we do not impose additional physics-informed penalties beyond the softplus transformation for dissipative rates. Furthermore, in our synthetic studies where the ground truth admits a Lindbladian form we omit this step.

2.2 Measurements and Loss Function

As mentioned in the introduction, our learning algorithm is based on maximum-likelihood estimation of learned trajectories, comparing them to measurement data of trajectories evolving under the ground truth dynamics. Here we will discuss in detail how our datasets are constructed as well as the loss function.

To train the NDE, we require a loss function that compares an estimated time-evolved state to observed data in an experimentally friendly manner. Access to ground truth trajectories is therefore assumed only through samples of random local Pauli measurements during transient times, avoiding full process tomography while remaining identifiable under locality assumptions [23, 40]. Indeed, transient times speed up the data-gathering process since we don't need to wait for the system to relax into its steady state before measuring. This also means the model gets a good mixed signal from the unitary and dissipative component (because ss data is largely insensitive to the Hamiltonian; many Hamiltonians for the same initial state will collapse to the same (often unique) steady state [20, 22]).

To that end, let $\rho_\Theta(t)$ denote the model-predicted state at time t obtained by integrating Eq. (7) with parameters $\Theta = (\theta, \varphi)$ from a specified initial state $\rho(0)$. For each chosen Pauli measurement basis, we collect binary bitstrings $b \in \{0, 1\}^n$, forming a dataset D of measurement outcomes. Following [13], with J timestamps, M repeats per measurement, and K random Pauli bases, one has $|D| = MKJ$ samples for a single initial state. Varying the number of initial states multiplies the dataset size correspondingly.

Since our pipeline is numerical, we have full access to $\rho_\Theta(t)$ and can evaluate Born-rule probabilities for observing bitstrings b in the chosen Pauli basis,

$$p_\Theta(b; t) = \text{Tr}(\Pi_b \rho_\Theta(t)), \quad (8)$$

where Π_b is the projector associated with b in that Pauli basis. This forms the basis for our loss function, defined as the average negative log-likelihood over the observed outcomes,

$$L(\Theta; D) = - \sum_{(\rho_0, t, \mathcal{P}_N, b) \in D} \log p_\Theta(b; \rho_0, t, \mathcal{P}_N), \quad (9)$$

where D is a dataset of outcomes acquired from evolving the corresponding a set of initial states ρ_0 up to time t with Pauli measurement $\mathcal{P}$ with binary outcome b (see Sec. 3.2 for further detail on datasets). This loss is differentiable with respect to Θ through the ODE solver, enabling end-to-end gradient-based updates of the analytic parameters θ and the neural parameters φ [33].

3 Numerical Experiments and Results

In our numerical experiments, we will compare a NDE model to a base (vanilla) model. The vanilla model contains only variational parameters, θ , which are coefficients of operators in the GKSL form in Eq. 1, whereas the NDE model contains both GKSL variational parameters θ and neural parameters φ . The differences between these two architectures are shown in Fig. 2.

This section specifies the dynamical models and the data protocol used throughout. We consider a broad class of systems, with three types of noise whose strength vary over four orders of magnitude. We begin by laying out the Lindbladian terms considered, then proceeding to the four Hamiltonian models. We then detail how datasets are generated, our choice of neural architecture and training hyperparameters, and finally lay out the benchmarks we will use to assess performance.

3.1 Dynamical Models and Test Cases

The two types of noise considered are phase damping, where $\mathcal{L} = \sigma_z$, and thermal noise. That is, we couple each site to a thermal-like environment using local ladder jump operators defined as

$$L_i^- = \frac{1}{2}(X_i - iY_i), \quad L_i^+ = \frac{1}{2}(X_i + iY_i), \quad (10)$$

with nonnegative rates $\gamma_i^-, \gamma_i^+ \geq 0$, implementing amplitude damping and thermal excitation. For Lindbladian coefficients, we sample true values $\gamma \sim \mathcal{U}(0.2, 1)$. We will also test *combined* thermal and phase noise, where both dissipative terms are enabled.

On the Hamiltonian side, we opt for two models of experimental relevance in the quantum hardware community. These are the Rydberg Hamiltonian from neutral atom QPUs [43],

$$H_R = \frac{1}{2} \Omega \sum_j X_j - \delta \sum_j Z_j + \sum_{i \neq j} \frac{C_6}{r_{ij}^6} Z_i Z_j. \quad (11)$$

and qubit Hamiltonian for superconducting circuits

$$H_{SC} = \sum_i \frac{1}{2} h_i (\mathbb{I}_i - Z_i) + \sum_{\langle i, j \rangle} \frac{1}{2} \zeta_{ij} Z_i Z_j \quad (12)$$

This means that the Hamiltonian component has variational parameters $\theta = \{\Omega, \delta, C_6\}$ for the Rydberg model, and $\theta = \{h_i, \}_{i=1}^N \cup \{\zeta_{ij}\}_{\langle i, j \rangle}$ for the superconducting model.

Indeed combined with the two Lindbladian terms above, the full model captures finite-temperature re-excitation processes and dominant T_1 -type relaxation respectively in neutral atom and superconducting QPUs [44, 45]. This is because there are variational parameters on both the Hamiltonian component (θ) and on the dissipative part (γ). We note here that thermal channels also induce unique steady states that regularize long-time dynamics [20, 22], improving identifiability of both coherent and dissipative parameters from short-time transients and stabilizing extrapolation beyond the training window. These properties align with steady-state identifiability results and transient-time learning strategies reported in recent open-system learning literature [25, 46].

For the neutral atom TFIM, the true parameters to-be-learned are sampled uniformly in ranges applicable to neutral atom QPUs [43], $\Omega \sim \mathcal{U}(0, 1)$, $\delta \sim \mathcal{U}(-4, 4)$, with $C_6 = 10^6 \mu\text{m}^6$. Atoms are arranged into a compact triangular (hexagonal) lattice with spacing $a \sim \mathcal{U}[9, 11] \mu\text{m}$. Positions are perturbed by $\pm 5\%$ of a , so distances differ slightly from the ideal lattice and individual interactions have to be learnt. We choose to model nearest-neighbour and next-nearest-neighbour interactions.

For the superconducting Hamiltonian, true parameters are sampled from normal distributions $h/2\pi \sim \mathcal{N}(0, 10)$ kHz and $\zeta/2\pi \sim \mathcal{N}(-30, 10)$ kHz. Values are scaled by a factor of $1/100$ to normalize the energy scale to $\mathcal{O}(1)$, meaning our results are applicable to current superconducting QPUs [47–49].

Finally, to stress-test our algorithm, we also study spin-1/2 chain Hamiltonians. Following previous benchmarks for challenging unitary dynamics in this context [34], we select two models that probe complementary regimes of identifiability and dynamical complexity: (i) the anisotropic Heisenberg chain,

$$H_H = \sum_{i=1}^{N-1} (J_i^x X_i X_{i+1} + J_i^y Y_i Y_{i+1} + J_i^z Z_i Z_{i+1}) + \sum_{i=1}^N h_i X_i, \quad (13)$$

and (ii) the PXP model [50], a paradigmatic weakly non-ergodic Hamiltonian,

$$H_{\text{PXP}} = \sum_{i=2}^{N-1} J_i P_{i-1} X_i P_{i+1}, \quad \text{with } P_i = |0\rangle\langle 0|_i. \quad (14)$$

Both were previously identified as hard instances for closed-system HL due to rugged loss landscapes and weakly non-ergodic dynamics, respectively, serving as stringent tests for robustness and generalization of our open-system learning algorithm [34]. True values for these two models are sampled uniformly, for Hamiltonian coefficients $J_i \sim \mathcal{U}(-1, 1) \forall i$. To further stress-test our algorithm, we split the unitary and noise terms of Eq. 1, and define a multiplier R for the ground truth values sampled uniformly. After sampling true parameters, we rescale them such that the multiplier induces a noise-to-unitary ratio $R \in \{0.01, 0.1, 1, 10\}$, allowing us to test over four orders of magnitude that interpolate between weak and strong dissipation.

3.2 Datasets

Ground-truth datasets are generated by numerically integrating the Lindblad master equation with the specified H and noise term, using an adaptive high-order explicit integrator applied directly to the density matrix representation. Unless stated otherwise, Hamiltonian parameters are drawn i.i.d. from $[-1, 1]$, and dissipative rates are set by sampling γ_i^-, γ_i^+ in $[0.2, 1.0]$ and rescaling by a global noise-to-unitary level $R \in \{10^{-2}, 10^{-1}, 10^0, 10^1\}$ to probe robustness across weak-to-strong dissipation. For each $N \in \{3, 4, 5, 6\}$ we prepare $L = 5$ product eigenstates of single-qubit Pauli operators, drawn uniformly from the sets of X -, Y - and Z -eigenstates (i.e., “up”/“down” along x, y, z), and evolve to $J = 10$ timestamps $t \in \{0.1, 0.2, \dots, 1.0\}$ (in units where $\hbar = 1$). Measurements follow the protocol from [34]: at each (state, t) pair, we choose $K = 200$ random compatible Pauli bases and collect $M = 100$ shots per basis. This means each numerical experiment uses no more than 5×10^5 shots in total. We test every combination of Hamiltonian and noise, for each value of η meaning 40 different numerical experiments for each value of N , and a total of 200 experiments when $3 \leq N \leq 6$. For robustness, we generate 50 independent ground-truth parameter sets θ for each of the 200 experiments.

Training uses the average negative log-likelihood under the Born rule computed from predicted $\rho(t)$ and the observed bitstrings per Sec. 2.2. This transient, random-Pauli scheme is consistent with identifiability from local measurements [21, 29], avoiding oracle access, optimal control [35], and steady-state requirements such as those in [9].

3.3 Neural Architecture

When used, the NDE component is a simple, shallow Multi-Layer-Perceptron (MLP) with bias [30, 51]. As mentioned in Sec. 2, we employ a scaled soft-plus activation, $f(x) = \frac{1}{5} \log(1 + e^{5x})$ for the neural network component. We initialise the variational parameters for the Hamiltonian by sampling $\theta \sim \mathcal{U}(-1, 1)$, where θ are the variational parameters of a given Hamiltonian model from Sec. 3.1. Meanwhile for the dissipative component we initialise $\gamma \sim \mathcal{U}(0.2, 1)$. This means the structure of the Lindbladian is fixed and only the variational coefficients are fitted in line with the white-box scenario [34].

To train, we integrated the Lindblad master equation using a 5th-order explicit Runge-Kutta method [52] using the diffrax package [33, 53] from the JAX ecosystem [54]. We utilize the Adam optimizer for all training phases [41].

Each training epoch consists of 500 optimization steps. The dataset is randomly shuffled at the start of every epoch. At each step, the model processes a batch consisting of 1 initial state (out of 5), 1 single measurement shot (out of 100), all 10 time points, and all 200 Pauli observables. This yields $5 \text{ states} \times 100 \text{ shots} = 500$ steps per epoch. Per Sec. 2.1 we split training into three phases. Finally, we detail the curriculum learning strategy for both the vanilla and NDE component and their respective learning rates η .

- **Vanilla Training Curriculum:**

1. 20 epochs with learning rate $\eta_H = \eta_L = 10^{-3}$.
2. *Fine-tuning (if required)*: Optimizer reset, followed by 5 epochs with $\eta_H = 10^{-4}, \eta_L = 10^{-3}$, and a final reset for 5 epochs with $\eta_H = \eta_L = 10^{-4}$. (Rates are swapped if the Lindbladian magnitude exceeds the Hamiltonian).

- **NDE Training Curriculum:**

1. 20 epochs with $\eta_H = \eta_L = 10^{-3}, \eta_{\text{NDE}} = 2 \times 10^{-3}$, and L2 regularization $\lambda = 0.1$.
2. 10 epochs with the NDE switched **OFF**, continuing with $\eta_H = \eta_L = 10^{-3}$ after an optimizer reset.
3. *Fine-tuning*: Identical to the Base Training regime.

Crucially, the optimizer state is reset whenever learning rates are updated or when the NDE component is toggled to allow gradient updates to adapt freshly to the new loss landscape. The architectures for vanilla and NDE models as computational graphs for automatic differentiation are shown in Fig. 2.

3.4 Performance Metrics

In order to test the effectiveness of the vanilla and NDE models, we realise 50 numerical experiments for each combination of Hamiltonian and dissipative components. In each experiment, we resample the true-parameters and re-initialise the variational parameters to explore how robust each architecture is over these different realisations. Following [34] we make a scalar robustness metric as follows: Let $\tilde{\theta}$ denote the learned estimator after training via

Figure 2: Computational graphs for automatic differentiation of an ordinary differential equation solver ODEint for a vanilla model (a), and a NDE model, (b). Here by ODE-int we refer to using a numerical solver compatible with automatic differentiation. The subscripts θ and φ indicate the variational parameters assigned to the Lindbladian and Neural component respectively in both (a) and (b). As mentioned in Sec. 2, we enforce physical output states by renormalising via the trace and averaging over the conjugate transpose once on the output of the ODEint numerical solver.

the chosen learning algorithm (vanilla or NDE-enhanced). We calculate the relative absolute error for the coherent parameters,

$$\epsilon_H(\tilde{\theta}) = \frac{|\theta_H - \tilde{\theta}_H|_1}{|\theta_H|_1}, \quad (15)$$

and, when Lindbladian parameters are learned, the analogous error for the dissipative parameters,

$$\epsilon_L(\tilde{\theta}) = \frac{|\theta_L - \tilde{\theta}_L|_1}{|\theta_L|_1}. \quad (16)$$

A trial is declared successful for parameters $S \in H, L$ if $\epsilon_S(\tilde{\theta}) < 0.1$. This threshold mirrors prior practice and cleanly separates converged from failed runs across all experiments. Reported success rates are the proportion of successful trials over the 50 draws for fixed (H, N) and fixed experimental condition (e.g., noise level, learning algorithm).

To quantify generalization, we evaluate the density-matrix fidelity

$$F(\rho_T(t), \rho(t; \theta)) = \left(\text{Tr} \sqrt{\sqrt{\rho_T(t)} \rho(t; \theta) \sqrt{\rho_T(t)}} \right)^2 \quad (17)$$

and define the infidelity loss

$$\mathcal{I}(\rho_T(t), \rho(t; \theta)) = 1 - F(\rho_T(t), \rho(t; \theta)). \quad (18)$$

4 Results

Over the orders of magnitude of noise, $R \in \{0.01, 0.1, 1, 10\}$, the robustness is highest for systems with high noise in both the vanilla and NDE architectures. This is because the system thermalises more rapidly to a steady state. Hence, the transient evolution data used for inference gives a larger representative window of the dynamics over the snapshot times. As such, we found the vanilla model to be sufficiently robust, sometimes converging on 100% of our tests (see e.g. Figs 3 and 7) for $R = 1, 10$, especially in phase and thermal noise. However, over smaller amounts of noise $R = 0.01, 0.1$, we see the NDE architecture significantly outperforming the vanilla architecture on phase and thermal

noise, with the performance gain typically increasing as noise was decreased (see e.g. Fig. 3). In line with [34], we can see what NDEs are providing to this learning problem through loss landscapes. Unlike the unitary dynamics' landscapes in [34], we found that the dissipative dynamics' loss-landscapes were initially rugged, even when the NDE was improving performance.

To that end, it is instructive to define the variational space

$$V = \mathbb{R}^{\dim(c_j)} \times \mathbb{R}^{\dim(\gamma_\alpha)} \times \mathbb{R}^{\dim(\varphi)}, \quad (19)$$

consisting of three subspaces that respectively correspond to Hamiltonian (c_j), Lindbladian (γ_α) and neural variational parameters (φ). This means the vanilla model is variational over only $\mathbb{R}^{\dim(c_j)} \times \mathbb{R}^{\dim(\gamma_\alpha)} \subset V$ and the NODE architecture is variational over all of V via the different stages of the curriculum defined in Sec. 3.3. Having defined V , we can construct random orthogonal directions, $v_1, v_2 \in V$, as well as random orthogonal directions to explore how the variational landscape behaves for the Hamiltonian (we refer to these as $x_1, x_2 \in \mathbb{R}^{\dim(c_j)}$), Lindbladian $y_1, y_2 \in \mathbb{R}^{\dim(\gamma_\alpha)}$, and neural parameters $\varphi_1, \varphi_2 \in \mathbb{R}^{\dim(\varphi)}$, and any combination thereof, such as $z_1, z_2 \in \mathbb{R}^{\dim(c_j)} \times \mathbb{R}^{\dim(\gamma_\alpha)}$.

Indeed when we plot random orthogonal directions in this subspaces of V , we see a richer dynamical structure to the way in which neural methods are offering gains. We found the NDE loss-landscapes to smoothen the Hamiltonian and dissipative loss landscapes later into training epochs, rather than over entire training runs. See e.g. Fig. 11.

For the case of both noise types, performance of the vanilla model degrades slightly on the Lindbladian parameters, and significantly on the Hamiltonian parameters. We also found the NDE performance to be generally poorer in this regime. This is because when many types of noise are present in the dynamics, the measurement data stops being sensitive to variations in the hamiltonian parameters when the system acquires more and/or stronger dissipative variational parameters. We see this in the loss-landscapes of the Hamiltonian parameters in this noise scenario, which show a barren landscape around the true value which is at the origin of each plot (see e.g. Fig. 4). Likewise, the NDE correction cannot restore sensitivity of the Hamiltonian parameters in this case because this insensitivity is in the training data itself.

The advantage of strong noise combined with transient data is especially visible in the infidelity benchmarks, where systems showed better infidelities for higher amounts of noise. Even when we renormalise the training window's snapshot times to the noise magnitude, we see systems with stronger noise showing better infidelities (see e.g. Fig. 6). This is also because, unlike unitary evolution, the infidelity stabilises much lower when the learning algorithm converges to the correct steady state. Indeed, for many system considered, the steady state is unique due on the commutant structure of the Hamiltonian and dissipative component of the Lindbladian [20, 22]. When this is the case, the ODE model infidelities of flatten out, and we see the systems reaching their steady states at the same point on the renormalised infidelity points in Fig. 6. In fact, the similar profile of each systems infidelity curves indicates model's error keeps increasing until the system relaxes to its fixed point and many variational parameters become irrelevant. Indeed this further justification for our use transient times for measurements constructing the training dataset from a learning perspective on top of being experimentally-friendly. If we used only measurements based on steady-state data, the model would only need to correctly learn how to reach the steady state, not *which* transient path was taken, as we highlighted in Sec. 2.2. We see some non-zero infidelity because the learned model's steady-state and true steady-state still differ, usually by $< 0.1\%$ for many of the cases that follow.

We will now proceed to a more detailed study of each system's benchmarks.

4.1 Neutral Atom (TFIM) Hamiltonian

Here, Fig. 3 shows the NDE architecture improves success rates considerably for phase and thermal noise. We see this improvement in prediction accuracy on both the Hamiltonian and dissipative variational parameters, with the gap in performance between the vanilla and NDE model widening as the ratio between the Hamiltonian and dissipative part decreases to the minimum of 10^{-2} considered in this work. Indeed at this noise level, the vanilla architecture failed over all 50 test cases. Whereas the NDE architecture saw significantly improved robustness, with its best change in performance being on thermal noise. Curiously, Fig. 3 shows that the robustness of the NDE model is *increasing* with N , as shown by the $N = 6$ (yellow-square) case sitting firmly above its $N < 6$ counterparts for all variational components except the thermal dissipative component (Fig. 3 lower central). This result, while unexpected, could be a finite-size effect, or a property of thermal dissipative dynamics. Due to computational restrictions, we were unable to run these experiments past $N = 6$, as for $N = 6$ the numerical integration scheme is already running over $4^6 = 4096$ -dimensional vectors. See Sec. 5 for further discussion on scaling.

Next, we turn our attention to the combined noise case showing in Fig 3, in which the Hamiltonian component saw little improvement with NDEs and the dissipative component was actually worsened. This indicates that there are some regimes in which an NDE can improve the inference prospects of a Lindbladian Learning (LL) problem, and others

Figure 3: Success rates for a 1D Transverse-Field Ising Hamiltonian model with phase (left), thermal (centre) and combined phase and thermal (right) noise terms over four orders of magnitude of noise-to-unitary ratios, R . The top row shows the robustness metric over the Hamiltonian parameters and the shows the robustness metric for Lindbladian parameters. Shaded regions correspond to when the NDE term increases (red) or decreases (green) the fitting error.

where it becomes worse. Indeed, following the analysis of [34] we can get a more detailed view of when an NDE improves or worsens a LL problem by examining the loss landscapes of the models considered.

In Figs 4-5, we plot the loss landscape for our model upon initialisation for the Hamiltonian and dissipative parameters respectively in the case of phase noise. Each sub-figure represents one of the four orders of magnitude of noise considered in our work. Figs 4-5 show two contrasting properties between the vanilla and NDE architecture. First, notice that in all cases, the vanilla loss-landscape is more barren for both the Hamiltonian and dissipative parts. Fig. 4 plots contours with the same heat-map for both vanilla and NDE models, and indeed we see a much flatter landscape. This makes it more likely for the vanilla model to get stuck during optimization (rather than converge). Even if we renormalise the vanilla loss-landscape, as is done for dissipative part in Fig. 5, we see often the landscape has ridges within this variation of heights that is $\approx 14\times$ smaller than that of the NDE model. This shows us concretely why the NDE model was able to see the performance gains in Fig. 3.

Inspecting Figs 4-5 further, we might wonder whether the NDE landscape is too rugged for effective learning. This challenges the notion that the NDEs are somehow smoothening the landscape and/or making it steeper. However, thus far our analysis has neglected the fact that the loss landscape of the Hamiltonian and dissipative parameters is *dynamic* and changes between epochs. This is because by plotting the Hamiltonian and dissipative parameters, we are seeing a subset of the total variational space in both the vanilla and NDE architectures from Fig. 2. This follows from the fact that the total variational set for the vanilla model is $\theta = \{c_j, \gamma_\alpha\}$, and two random orthogonal directions in the Hamiltonian (c_j) or Lindbladian sets (γ_α) do not have full support in the total variational space $\{c_j, \gamma_\alpha\}$. Likewise, in the NDE architecture, these remain subsets of an even larger variational set $\{\theta, \varphi\}$. During training, *all* parameters in the variational set are able to change, thus the complement of two random orthogonal directions in $\{c_j\}$ or $\{\gamma_j\}$ changes and the loss landscape is not stationary. We will see this in more detail in Sec. 4.3 (see also, Fig. 11).

For the combined noise case, we see performance degrading on both the vanilla and NDE model as explained in Sec. 4.

Finally, let us turn our attention to the infidelity benchmarks, shown in Fig. 6 for phase and thermal noise respectively. Fig. 6 shows the NDE model improving the infidelity in both the transient (shaded) windows, as well as converging to a steady state which is closer to the true steady state. This can be read off directly by comparing left-to-right each shaded line colour and noting the NDE architecture has a lower infidelity in all cases, for all times simulated. Of note here is that the infidelity for $R = 0.01$ noise amplitude ratio remains below 0.1% for the entire evolution window, which runs

Figure 4: Initial loss landscape of two random orthogonal directions in the Hamiltonian variational subspace of V defined in Eq. (19) for the vanilla (left) architecture and the NDE architecture (right), for all four noise-to-unitary ratios $R = 0.01, 0.1, 1, 10$. In all four cases, notice the heatmap of the contour lines indicating a barren landscape on the vanilla architecture, against a much richer loss-landscape for the NDE. This explains the performance gains of the NDE’s robustness from Fig. 3, corresponding to the experiments in the top-left of Fig. 3

up to $10^3 \times$ for all values of N , converging to a steady state with infidelity $\sim 10^{-4}$. This means our algorithm’s learned action for $0.01 \times$ phase noise can propagate up to $N = 6$ qubit dissipative dynamics with fidelity $\mathcal{F} \geq 0.999$ for times up to $1000 \times$ the training window.

Meanwhile Fig. 6 shows a comparable performance in infidelity between the vanilla and NDE model. This is despite the fact that Fig. 3 showing the NDE model giving significant performance gains in terms of how robustly it can learn the values of the true parameters. This is because when the vanilla ODE model failed to converge, it is still in the neighbourhood of the true Hamiltonian/dissipative parameters, and the parameters it gets stuck at correspond to dynamics with the same fixed point as dynamics governed by the true parameters. As such, despite improving learnability with thermal noise, we do not see an obvious change in infidelity for this set of experiments. This highlights an important subtlety with the infidelity metric: the parameters can fail to converge to the correct parameters and this is not visible in infidelity whenever the converged parameters correspond to a system that shares one or more steady states with the true system. Indeed, this is why the system’s infidelity tends to stabilise at a steady state which is close in Fidelity to the true steady-state.

4.2 Superconducting Hamiltonian

In contrast to neutral atoms, the superconducting model shows NDEs offer no performance gain with phase noise, sometimes even worsening the robustness, especially for $N = 6$. Fig. 7’s left column shows the vanilla model performing better than the NDE model on both the Hamiltonian and dissipative parameters when the system is undergoing phase noise. Indeed, when we analyse the commutant of the dissipative component of Eq. 1, we find that for phase noise, the commutant is trivial, and there is a single unique steady state. This likely simplifies the learning task, rendering the standard Lindblad term sufficient and expressive enough to properly explore the variational landscape. Adding a neural correction term here is therefore training the neural variational parameters to *overfit* to artifacts of the training dataset, rather than to the dynamics.

On the other hand, the central column in Fig. 7 shows the NDE improving robustness in all cases of thermal noise except for the Lindbladian parameters at $N = 3$. Unlike phase noise, which commutes with the Superconducting Hamiltonian

Figure 5: Initial loss landscape of two random orthogonal directions in the Lindbladian variational subspace of V defined in Eq. (19), for the vanilla (left) architecture and the NDE architecture (right), over all four noise-to-unitary ratios $R = 0.01, 0.1, 1, 10$. In all four cases, notice the heatmap of the contour lines indicating a barren landscape on the vanilla architecture, against a much richer loss-landscape for the NDE. The legend for each heatmap shows the NDE having a landscape with heights that vary $\sim 14\times$ that of the vanilla model. This explains the performance gains of the NDE’s robustness from Fig. 3, corresponding to the experiments in the bottom-left of Fig. 3

(and hence has a trivial commutant), thermal noise does not. This non-commutativity increases the complexity of the dynamics, and indeed there are several steady states in this setting [20]. In this regime, the NDE ansatz becomes beneficial, with the improvements of the NDE ansatz increasing with N .

Finally, the right hand column of Fig. 7 corresponds to both phase and thermal noise. It the NDE worsening the robustness marginally on the Hamiltonian parameters, and significantly for the Lindbladian ones. Despite this joint-dissipation having a component with a non-trivial commutant, the smoothing effect of the phase noise dominates, rendering the system solvable with the vanilla ODE alone. An further reason for this worsening is the NDE may be absorbing the noise dynamics itself rather than correcting the evolution based on fixed dissipators. To mitigate this, the regularization penalty on the NDE terms could need to be increased to force the model to prioritize the physical Lindblad terms over the NDE correction.

Let us now turn our attention to the infidelity benchmarks. Since the vanilla ODE architecture was robust on all noise scales $R = 0.1, 1, 10$, we see little to no difference between the vanilla and NDE models for both phase and thermal noise. We highlight here that like the neutral atoms experiments, when there is a failure to converge, the system still relaxes to the steady state of the true system despite. This is because when the steady state is unique. This indicates the fixed point of Eq. 1 is heuristically invariant to these small differences between true and learned parameters. Consequently, the variational parameters often get stuck in the neighbourhood of the true parameters, but do not converge because the dynamics are insensitive to the last updates needed to converge.

4.3 XYZ Heisenberg Model

Having now analysed the neutral atom and superconducting systems, it is clear that the type of Hamiltonian and noise affects both learnability, and the ability of NDEs to improve trajectory-based-learning prospects. Indeed this is most clear in the XYZ system. Here, phase noise is helped by NDEs as shown by Fig. 9, where the left column shows the NDE improving robustness for all noise levels, on both the dissipative and unitary components. However, thermal noise is not helped by NDEs, and indeed they even worsened robustness for the dissipative parameters as seen by the central column of Fig. 9. In line with the above two systems, we see a trend here on the complexity of dynamics and whether

Figure 6: Infidelities against renormalised time for the vanilla (top row) and NDE (bottom row) architectures for the neutral atom TFIM with phase (left column), thermal (central) and combined (right) noise. The shaded region corresponds to the training window, i.e. times over which snapshots were taken, and each system size $N = 3, 4, 5, 6$ is plotted with increasing darker lines for $R = 0.1$ (green), $R = 1$ (red) and $R = 10$ (blue). Here, we renormalise by the noise-to-unitary ratio, R . We see NDE infidelities are shifted lower than the vanilla ones for phase (left) noise, with systems undergoing strong noise performing best as explained in the main text. Notice the vanilla and NDE models do not differ as much for the thermal (central) case, despite the increase in robustness shown in Fig. 3. This is due the unique steady-state effect explained in the main text.

the NDE can help. On the XYZ model, trivial commutant of the thermal operator likely simplifies the learning task, rendering the standard Lindblad term sufficient until the signal is too weak to fit the dissipative parameters. Adding an NDE does not change the learning signal (i.e. training datasets) thus we see no gains by adding an NDE correction. On the other hand, the XYZ model with phase noise has a non-trivial commutant. As such, there are many steady states, so having an NDE correction could help re-connect the different fixed points of the evolution.

Consistent with the neutral atom and superconducting systems, we see that combined noise is also worsened by NDEs. This is again an over-parametrisation problem. Strong noise means the system thermalises quickly and there is a good signal for the noise terms that makes NDEs unnecessary, and they are representing dynamics that could have been attributed to the dissipative parameters were the NDE term not present.

Indeed, these effects are corroborated by the loss landscapes for the systems considered in Fig. 9. Here, Fig. 11 shows how the loss landscape evolves for one of the experiments. The landscape begins rugged, eventually smoothing into smooth landscape in which the parameters have converge to the true values at the origin. This means the overall trajectory for the NDE architecture converges to the true parameters, where the vanilla model fails. Plotting just the parameter values in epochs, as shown in Fig. 10, makes this immediately clear.

Next we again turn our attention to Figs. 12, showing the infidelity in time for phase and thermal noise respectively. Per the neutral atom and superconducting case, we see a very similar performance on this benchmark between the vanilla and NDE correction. This is again because when the variational parameters are in the neighbourhood of the true parameters, the system will often converge to the same steady state as the true parameters. As such the ODE and NDE correction appear to be performing the same, despite the robustness experiments showing differences, see Secs. 4.1 and 4.2 for a full discussion.

Figure 7: Success rates for a 1D superconducting Hamiltonian model with thermal, phase, and combined noise terms as a function of noise-to-unitary ratio R over four orders of magnitude. The top row contains the superconducting model’s Hamiltonian errors and the bottom row contains its Lindbladian errors. These are shown from left to right for (a) phase damping, (b) thermal damping and (c) combined damping. Shaded regions correspond to when the NDE term increases (red) or decreases (green) the fitting error.

Figure 8: Infidelities against renormalised time for the vanilla (top row) and NDE (bottom row) architectures for the superconducting system with phase (left column), thermal (central) and combined (right) noise. The shaded region corresponds to the training window, i.e. times over which snapshots were taken, and each system size $N = 3, 4, 5, 6$ is plotted with increasing darker lines for $R = 0.1$ (green), $R = 1$ (red) and $R = 10$ (blue). Here, we renormalise by the noise-to-unitary ratio, R .

Figure 9: Success rates for the Heisenberg XYZ model with thermal, phase, and combined noise terms as a function of noise ratio R over four orders of magnitude. The top row contains the XYZ model errors and the bottom row contains the noise model errors. These are shown from left to right for (a) phase damping, (b) thermal damping and (c) combined damping. Shaded regions correspond to when the NDE term increases (red) or decreases (green) the fitting error.

4.4 PXP Hamiltonian

On the PXP model with thermal noise, Fig. 13 shows the robustness to be strong for both the vanilla and NDE models, with a slight degradation in solution quality for low noise on the dissipative parameters. As such, the vanilla model suffices on this system. The degradation of robustness of the NDE model’s Lindbladian parameters is again visible in the loss landscapes. Fig. 14 shows the initial loss landscapes for the vanilla and NDE model, with a considerably more rugged loss-landscape. This rugged landscape persists in the training epochs, and as such the parameters fail to converge. Finally, we show the infidelity benchmarks for this system in Fig. 15, which show the learned parameters rapidly approaching a steady state. Of note here is that for the PXP system, the model’s infidelity does not peak in the transient times of evolution. This is unlike the other three models tested, and is indicative of the PXP Hamiltonian with thermal noise having a strongly-attractive fixed point. This also sits in strong contrast with the PXP Hamiltonian alone (i.e. in the unitary case), in which it is weakly non-ergodic [55].

5 Conclusion

In this work we developed a trajectory-based method for Lindbladian learning from random local Pauli measurement snapshots collected at multiple *transient* times. By fitting a maximum-likelihood objective to measurement outcomes, our approach avoids full process tomography while returning an interpretable Lindbladian whose Hamiltonian terms and jump-operator structure are fixed by a physically motivated model.

We adapted neural differential equations to open-system identification in a way that preserves interpretability: a neural correction aids optimization during an initial augmented training stage, after which a curriculum switches off the neural term and refines only the physical parameters. The final model therefore contains only Hamiltonian couplings and dissipative rates, with no residual neural component. Hence our algorithm returns a GKSL form that generates a valid CPTP map.

Across four Hamiltonian families (neutral-atom, superconducting, Heisenberg XYZ, and PXP), phase and thermal noise spanning four orders of magnitude, and system sizes up to $N = 6$ qubits, we find a consistent regime structure. When coherent and dissipative contributions induce rugged, highly non-convex loss landscapes, the neural augmentation substantially increases the probability of successful recovery of both Hamiltonian and dissipative parameters. This

Figure 10: The trajectory of two random orthogonal directions in the Hamiltonian variational subspace of V defined in Eq. (19) (left) and the combined Hamiltonian and Lindbladian variational subspace of V (right) for the XYZ Heisenberg model with $R = 0.01$ noise-to-unitary ratio on $N = 3$ bodies. Comparing the vanilla (blue) and NDE architecture (red), we see the NDE architecture converging to the true values (set at the origin) in both cases. Whereas the vanilla architecture fails to converge in both cases, and its trajectory appears to get stuck, indicating the presence of local minima on those epochs of the vanilla model’s training. Integer values on the plots refer to the start (0) and final (20) epochs.

Figure 11: The loss-landscape of two random orthogonal directions in the Hamiltonian variational subspace of V defined in Eq. (19), for the XYZ Heisenberg Model at the start of epochs 0, 3, 6, 9, 12, 15, 18 and 20. The current parameter value shown by a red marker $\times$. We see an initially rugged loss-landscape smoothing out as training proceeds until we arrive at a smooth landscape that is quasi-quadratic around the true value. The trajectory is shown by a grey line with the red $\times$ marking the current parameter values along the 20-epoch path.

Figure 12: Infidelities against renormalised time for the vanilla (top row) and NDE (bottom row) architectures for the Heisenberg XYZ model with phase (left column), thermal (central) and combined (right) noise. The shaded region corresponds to the training window, i.e. times over which snapshots were taken, and each system size $N = 3, 4, 5, 6$ is plotted with increasing darker lines for $R = 0.1$ (green), $R = 1$ (red) and $R = 10$ (blue). Here, we renormalise by the noise-to-unitary ratio, R . There is little change in infidelity between these architectures, despite the robustness for phase noise improving in Fig. 9. This is due again to the unique steady-state arising from this combined Hamiltonian and phase-noise model as explained in the main text - see also Sec. 4.1.

Figure 13: Success rates for Hamiltonian (left) and Lindbladian (right) parameters on the PXP model with thermal noise, as a function of noise ratio R over four orders of magnitude. Solid lines represent vanilla architecture success rates and dashed lines represent NODE architecture success rates, with green (red) regions indicated the NODE architecture improving (diminishing) performance. Here we show $N = 3, 4, 5, 6$.

Figure 14: Initial loss landscape for two random orthogonal directions in the Lindbladian variational subspace of V defined in Eq. (19) for the PXP hamiltonian with thermal noise, with ratio $R = 0.01$. Here we plot the two random orthogonal variational directions on the dissipative component for the vanilla (left) architecture and the NDE architecture (right). We see the NDE’s rugged landscape, contains many walls, is hindering convergence. This explains the drop in performance we see in the success rate figure for the PXP Hamiltonian with thermal noise, as explained in the main text.

Figure 15: Infidelities against renormalised time for the vanilla (left) and NDE (right) architectures for the PXP system undergoing thermal noise. Here, we renormalise by the noise-to-unitary ratio, R . The shaded region corresponds to the training window, i.e. times over which snapshots were taken, and each system size $N = 3, 4, 5, 6$ is plotted with increasing darker lines for $R = 0.1$ (green), $R = 1$ (red) and $R = 10$ (blue). There is little change in infidelity between these architectures, despite the robustness for phase noise improving in Fig. 9. This is due again to the unique steady-state arising from this combined Hamiltonian and phase-noise model as explained in the main text - see also Sec. 4.1

was most prominent in settings where the coherent and dissipative components of the GKSL form are non-commuting. Conversely, when the physics-only landscape is already well-conditioned, physics-only training typically suffices and neural augmentation can degrade performance via overfitting. These observations motivate a practical guideline: attempt physics-only variational fitting first, and deploy neural augmentation only when robustness is insufficient.

Finally, we emphasize that open-system evaluation requires care. Low state infidelity can persist even when parameters are not reliably recovered, particularly when late-time behavior is dominated by steady-state structure. For this reason we advocate parameter-recovery robustness as the primary figure of merit in synthetic studies where ground truth is known, complemented by extrapolation tests beyond the training window. This sits in contrast to [34] in which the power-law scaling of infidelity in unitary dynamics offered a proxy for the uncertainty in out-of-training times.

The main limitation of our present implementation is how the curse of dimensionality affects scaling. Explicit density-matrix simulation grows exponentially with system size, meaning for $N = 6$ our Hilbert space dimension is already $4^6 = 4096$. Indeed, the ultimate aim of Hamiltonian and Lindbladian learning is to characterize quantum devices directly from measurement data, without requiring such classical simulation in the full system’s Hilbert space. A natural next step toward this goal is to use the present approach as a subroutine within locality-based or patch-learning schemes that learn overlapping reduced generators and stitch them into larger-scale models [56, 57]. The curriculum strategy also suggests a route toward settings where the operator structure is partially or fully unknown: the physical model can be progressively enriched, with the residual magnitude of the neural correction serving as a diagnostic of model misspecification. Indeed an interesting future research direction lies in using the relative contribution of the neural correction term as a proxy for expressivity of the interpretable ansatz. When the ansatz is sufficiently expressive to capture the full generator, the NODE component should converge to 0 contribution with our curriculum. When this fails to be the case, it could be indicative of the ansatz lacking expressivity, and further terms should to be progressively added and tuned. This would introduce a different measure of learning-hardness based on the minimal Choi rank of the true dynamics; a higher-rank channel needs more Kraus operators and thus the ansatz’ Choi rank could be steadily increased until it captures the dynamics and matches the Choi rank of the true channel. Finally, our analysis assumes time-homogeneous Markovian dynamics, known initial preparations, and ideal measurements; extending to time-dependent or non-Markovian generators and incorporating SPAM error models are also important directions for future work and experimental deployment. These considerations, while out of scope for this contribution, are a promising future research direction.

As the second paper in a series of works (see also [34]) systematically investigating NDEs in quantum system characterisation, our next works in this series seeks to address these scaling limitations, as well as the potential for this framework to be applied in black-box settings.

Quantum Control Experiments on Quantum Processors

Nikolay V. Vitanov¹ *

¹ *Center for Quantum Technologies, Department of Physics, St. Kliment Ohridski University of Sofia, 5 James Bourchier Blvd., 1164 Sofia, Bulgaria*

Abstract. I will review recent experiments on cloud-accessible IBM Quantum and IQM superconducting processors. The results combine quantum-control design with direct hardware tests: composite gates robust to amplitude, detuning and duration errors; leakage-aware transmon gates; twin dynamical-decoupling sequences with exact pulse-area-error cancellation and arbitrarily high detuning-error suppression; multipass quantum process tomography; Grover search experiments up to six qubits; and Zanon-Willette–Vitanov dynamically decoupled hyper-Ramsey spectroscopy of ultra-narrow clock transitions, together with pulse-shape engineering for spectral-line control. The common theme is that analytic control ideas can be translated into practical, hardware-efficient tools for calibration, benchmarking, sensing and algorithm execution on noisy quantum processors.

Keywords: quantum control, superconducting qubits, composite pulses, dynamical decoupling, quantum process tomography, Grover search, hyper-Ramsey spectroscopy

1 Motivation

The rapid progress of superconducting quantum processors has created a useful new regime for quantum control. The devices are large enough to run nontrivial circuits, yet still imperfect enough that coherent errors, leakage, drift, crosstalk, finite read-out accuracy and calibration uncertainty remain visible in the experimental data. This makes cloud quantum processors not only platforms for algorithms, but also precision test beds for control ideas. The aim of this talk is to review a set of recent experiments in which analytic quantum-control methods were implemented and tested on IBM Quantum and IQM processors, with emphasis on results that are simple enough to be used as practical calibration or benchmarking tools, but sufficiently general to be relevant beyond a single device generation.

The central message is that a quantum processor should not be viewed only as a fixed gate library. At the pulse or calibrated-gate level, one can deliberately shape phases, pulse areas, pulse sequences and repetition patterns so that the unwanted error amplitudes interfere destructively. This idea is familiar from coherent atomic and molecular control, where composite pulses, adiabatic passage and Ramsey methods have long been used to manipulate two- and multistate systems. The recent experiments reviewed here show that the same logic can be profitably transferred to superconducting quantum information processors. The resulting techniques address three complementary tasks: making elemen-

tary operations robust, characterizing gates more accurately, and improving algorithmic or metrological performance under realistic noise.

2 Robust single-qubit control

A first set of results concerns composite quantum gates. The elementary error model for a driven qubit contains pulse-area errors, detuning errors and timing or duration errors. These errors are not merely academic: in a calibrated processor they appear through amplitude miscalibration, frequency drift, imperfect pulse duration, finite anharmonicity, or slow changes in the hardware environment. Composite pulses replace a single rotation by a short sequence of rotations with analytically chosen phases. The target transformation is preserved, while the leading error terms cancel in the full unitary, not only in a transition probability.

Recent designs implement X , $R_x(\pi/2)$ and Hadamard-equivalent gates while simultaneously compensating amplitude, detuning and duration errors. The construction combines a Cayley-Klein derivative-cancellation approach with direct optimization of the average gate infidelity over prescribed error domains. In the shortest symmetric five-pulse solutions, all first-order terms, including the mixed derivative, are cancelled. Longer sequences, up to fifteen pulses, extend the robustness window and suppress higher-order terms. An important practical point is that the phases are compatible with standard microwave control conventions and with virtual- Z frame updates; hence the robust gates can be benchmarked against the native proces-

*vitanov@phys.uni-sofia.bg

sor operations without changing the logical circuit model.

For transmon qubits, the same control problem must also account for the weakly anharmonic ladder. Fast pulses risk populating the noncomputational $|2\rangle$ level, while overly slow pulses increase exposure to decoherence. Leakage-aware composite gates exploit interference between transition pathways in this ladder. They can reduce sensitivity to qubit-frequency and anharmonicity variations, while maintaining short gate durations. The experiments and simulations therefore connect two requirements that are often treated separately: suppression of coherent gate errors inside the computational subspace, and suppression of leakage outside it.

3 Twin dynamical decoupling

The second part of the talk focuses on a new family of twin dynamical-decoupling sequences. Standard dynamical decoupling protects idle qubits from environmental dephasing, but the refocusing pulses themselves are imperfect. In long sequences, pulse errors can accumulate and eventually defeat the purpose of the protection. The twin construction resolves this conflict by arranging pulse phases in pairs so that the accumulated pulse-area error cancels exactly. The cancellation is analytic, does not require numerical search, and holds to all orders for systematic pulse-area errors.

This is stronger than ordinary low-order composite-pulse compensation. A useful way to present the result is that the sequence is engineered so that the error propagator closes on itself: the faulty parts of the rotations trace a closed algebraic path, whereas the desired refocusing action remains. At the same time, by increasing the sequence length and choosing the corresponding phase pattern, the response to detuning errors can be flattened to any prescribed finite order. Thus pulse-area errors are removed exactly, and frequency errors are suppressed systematically rather than merely tolerated.

The sequences were implemented on superconducting transmon processors from two independent cloud platforms: IBM Quantum’s `ibm_torino` and IQM’s Garnet processor. The measured population plateaus follow the theoretical robustness profiles, demonstrating that the construction survives real hardware constraints such as finite gate calibration accuracy, decoherence and readout noise. For AQIS, the broader relevance is that the method provides a compact, transparent alternative to black-box pulse

optimization: the protection rule is analytic, scalable with sequence length, and portable between providers.

4 Gate characterization by multipass process tomography

High-fidelity control must be accompanied by reliable characterization. Standard quantum process tomography reconstructs the full Pauli-transfer matrix of a gate, but its accuracy is limited by state-preparation and measurement errors, readout errors and shot noise. Randomized benchmarking is more scalable, but compresses the information into a small number of decay parameters. Multipass quantum process tomography offers a middle path. Instead of applying a gate once and reconstructing its process matrix directly, the same gate is applied repeatedly and the multipass process is tomographed. From this amplified process one infers the single-gate Pauli-transfer matrix, either iteratively or through a linearized Sylvester-equation approach.

The advantage is conceptual and practical. Coherent errors become easier to detect because repeated application amplifies them, while the final output remains a full process matrix rather than a single fidelity. The method was tested numerically and experimentally on IBM Quantum hardware, including a CNOT gate on `ibmq_manila`. It can also be illustrated on two-qubit gates such as CNOT, SWAP and controlled-Z, and on three-qubit gates such as Toffoli and Fredkin, where the multipass construction is particularly natural for gates whose ideal powers cycle back to the same operation. In this sense, multipass tomography complements both robust-control design and benchmarking: it provides an error-sensitive diagnostic that still speaks the language of full quantum processes.

5 Algorithmic and spectroscopic demonstrations

The fourth part of the talk turns from elementary control to algorithmic performance. Grover search is a useful benchmark because its success probability depends on the coherent accumulation of many gates, and because the optimal number of Grover iterations is sharply defined in the ideal circuit. Recent experiments tested Grover search on three generations of IBM Heron-family processors. For three-, four- and five-qubit searches, the success probabilities on newer Heron QPUs improve over earlier device generations. For five qubits, dynamical decou-

pling was used to improve the algorithmic output, and for six qubits a clear target bit string was observed on a Heron r3 processor when dynamical decoupling was included. These experiments illustrate a recurring theme of the talk: control pulses are not only a low-level hardware concern, but can directly affect the performance of a complete quantum algorithm.

The final examples come from Ramsey spectroscopy and pulse-shape engineering. On IBM Quantum hardware, power narrowing was observed for Lorentzian-like pulses: instead of broadening with increasing pulse area, the spectral line becomes narrower, with an experimentally observed reduction by more than an order of magnitude. Related work shows the opposite controlled behavior - power superbroadening - using pulse shapes that deliberately enhance off-resonant excitation. Dynamically decoupled hyper-Ramsey interrogation, developed with Zanon-Willette and collaborators [9], extends this control logic to ultra-narrow clock transitions. In this protocol, time-optimized Eulerian cycles of rotary Hahn-echo refocusing pulses toggle the probe detuning and phase between opposite signs. The result is a high-contrast hyper-Ramsey response that is free of AC-Stark shifts and robust against probe-amplitude fluctuations, decoherence, frequency drifts and slow environmental perturbations. These results connect quantum processors with quantum sensing by showing that calibrated control can engineer not only gates, but also spectral response functions for precision metrology.

6 Outlook

Taken together, the experiments show a coherent research program: use analytic control theory to design short, transparent pulse or gate sequences; implement them on available quantum processors; and judge them by hardware-facing metrics such as fidelity, leakage, robustness windows, process matrices, algorithmic success probability and spectroscopic resolution. The work is relevant to several AQIS themes: decoherence mitigation, quantum circuits and architecture, quantum algorithms on real devices, and quantum metrology. It also demonstrates the scientific value of cloud access. IBM Quantum and IQM processors make it possible to compare control ideas across devices, generations and calibration models, thereby turning quantum-control theory into experimentally testable and reusable technology.

Abstract. To overcome the noise limitations of gate-based digital circuits, we develop analog and hybrid quantum kernels that leverage analog quantum computation. Applied to benchmarking datasets and the resource-intensive task of estimating non-Markovianity from sparse data, our models consistently outperform classical RBF kernels, demonstrating empirical quantum advantage. Moreover, we reveal a counterintuitive phenomenon that operational noise actively enhances the performance of the developed quantum kernel when interatomic distances are appropriately tuned.

Keywords: Quantum kernel, Analog quantum computing, Rydberg atom

1 Introduction

The quantum kernel method, which employs quantum feature maps to construct a kernel matrix, is a promising quantum machine learning algorithm with substantial potential for demonstrating quantum advantage. Despite its highly promising path toward practical quantum machine learning [1, 2], their implementation on traditional gate-based digital circuits is severely constrained by noise and strict circuit depth limitations in the noisy intermediate-scale quantum (NISQ) era [3]. To overcome these hardware bottlenecks, the diagram of analog quantum computation offers a noise-robust alternative, leveraging continuous Hamiltonian evolution to effectively replace deep, error-prone circuit blocks [4, 5].

Motivated by this unique characteristic, we construct two quantum kernels in the context of analog quantum computing. The first, termed the analog quantum kernel, encodes data into the local energy difference of a Rydberg atom system to implement a feature map. The second, termed the hybrid quantum kernel, adopts the digital-analog ansatz [6], which combines the flexibility of gate-based data encoding with the robustness to noise of analog evolution [6].

To benchmark their performance, we apply these kernels to a benchmark dataset and a non-Markovianity estimation task, and compare their performance with a widely adopted digital quantum kernel (hardware-efficient ansatz) and a classical radial basis function (RBF) kernel. The numerical results demonstrate competitive performance against both the RBF and digital quantum kernel. Moreover, we investigate the impact of operational noise on the analog and hybrid quantum kernels. While noise is typically considered detrimental to quantum device performance, our results reveal that the performance of these quantum models can be improved in the presence of operational noise. By comparing the performance of the developed kernel across different inter-

atomic distances, we attribute this noise-enhanced performance to improved expressivity of the quantum kernel and to the model's increased complexity due to the noise.

We note that the complete version of this work is available in Ref. [7].

2 Quantum feature map on analog quantum computer

Within the supervised machine learning framework, the hypothesis model f is trained to fit the function that maps data $\vec{x}_j$ to the label y_j . To enlarge the expressivity of the data, a quantum feature map Φ utilize an parametrized unitary $U(\vec{x}_j)$ to encode classical data into high-dimensional quantum states. Then the hypothesis model f can be constructed by machine learning algorithm through the data similarity between $\Phi(\vec{x}_j)$ and $\Phi(\vec{x}_k)$. Here we consider the machine learning algorithm called support vector regression, in which the f is optimized by the following optimization problem

$$\begin{aligned} & \text{minimize} \quad \frac{1}{2}|\vec{\omega}|^2 + C \sum_{j=1}^N \zeta_j + \zeta_j^* \\ & \text{subject to} \quad \begin{cases} y_j - (\vec{\omega} \cdot \Phi(\vec{x}_j) + b) \leq \epsilon + \zeta_j \\ (\vec{\omega} \cdot \Phi(\vec{x}_j) + b) - y_j \leq \epsilon + \zeta_j^*, \quad \forall j \\ \zeta_j, \zeta_j^*, C \geq 0 \end{cases} \end{aligned} \quad (1)$$

Typically, the quantum feature map is constructed by a quantum circuit, which consists of a local rotation encoding gates and a sequence of CNOT gates as an entanglement layer. Alternatively, we developed two quantum feature maps using analog quantum computation with the Rydberg atom system as our computational agent. The first is called the analog quantum kernel, which encodes the classical data into the energy gap between the ground state $|g\rangle\langle g|$ and the excited state $|e\rangle\langle e|$. The

*yuehnan@mail.ncku.edu.tw

†hongbinchen@gs.ncku.edu.tw

corresponding Hamiltonian is given by:

$$\begin{aligned} \hat{H}(\vec{x}_j) = & \frac{\Delta}{2} \sum_{\mu=1}^d x_j^{(\mu)} \hat{\sigma}_z^{(\mu)} + \frac{\Omega}{2} \sum_{\mu=1}^d \hat{\sigma}_x^{(\mu)} \\ & + \sum_{\mu < \nu} V_{\mu\nu} (|e\rangle\langle e|)_\mu (|e\rangle\langle e|)_\nu, \end{aligned} \quad (2)$$

where $\hat{\sigma}_x^{(\mu)}$ and $\hat{\sigma}_z^{(\mu)}$ are the Pauli operators acting on the μ th atom, and $x_j^{(\mu)}$ is the μ th feature of the data. Crucially, the third term denotes the interaction strength follows $V_{\mu\nu} \propto |\vec{r}^{(\mu)} - \vec{r}^{(\nu)}|^{-6}$. Therefore, the effects of this interaction are highly sensitive to the atomic arrangement, and we denote R_b as the interatomic distance such that the Rydberg blockade occurs [6]. Using this data-dependent Hamiltonian, the encoded quantum state is obtained by evolving the initial state through the encoding unitary $\exp(-i\hat{H}(\vec{x}_j)t)$, that is

$$\Phi_a(\vec{x}_j) = e^{-i\hat{H}(\vec{x}_j)t} |\psi_0\rangle. \quad (3)$$

In contrast to the above approach, the hybrid quantum kernel utilizes the local rotation gate to encode the classical data into a quantum state, and employs the continuous analog evolution $\exp(-i\hat{H}(\vec{0})t)$ to replace the CNOT gates for entanglement generation. The resulting encoded quantum states are

$$\Phi_h(\vec{x}_j) = \left[\bigotimes_{\mu=1}^d R_X\left(\frac{\pi}{2} x_j^{(\mu)}\right) \right] e^{-i\hat{H}(\vec{0})t} \left[\bigotimes_{\mu=1}^d R_X\left(\frac{\pi}{2} x_j^{(\mu)}\right) \right] |\psi_0\rangle. \quad (4)$$

To realistically assess these models in the NISQ era, we simulate operational noise on the Rydberg atomic positions $\vec{r}^{(\mu)} \stackrel{\text{iid}}{\sim} \vec{r}^{(\mu)} + \mathcal{N}(0, 0.1 \mu\text{m})$, local detuning $\tilde{\Delta} \sim \Delta + \mathcal{N}(0, 0.1 \text{ MHz})$, and Rabi frequency $\tilde{\Omega} \sim \Omega \cdot \mathcal{N}(1, 0.01)$ in Eq.(2). These noise settings are extracted from a real device and are identical to those reported in Ref. [6]. Under the operational noise, the encoded quantum state is a mixed-state density matrix $\tilde{\rho}(\vec{x}_j)$ constructed from an ensemble of encoded state, and the data similarity is estimated by $\text{Tr}[\tilde{\rho}(\vec{x}_j)\tilde{\rho}(\vec{x}_k)]$.

3 Experimental result and noise-enhanced performance

By setting the size of the noise ensemble to 1,000 and the interatomic distance to $a = 1.05 R_b$, we benchmark the developed quantum kernel against the gate-based quantum kernel constructed by hardware-efficient ansatz [8] and the classical RBF kernel. Crucially, the hybrid quantum kernel, under both ideal and noisy settings, achieved a lower Mean Squared Error (MSE) than the RBF baseline, demonstrating a clear empirical quantum advantage. Furthermore, we observe that introducing operational noise counterintuitively improves the performance of the developed quantum kernel.

To investigate this characteristic, we employ the developed quantum kernel to estimate non-Markovianity, using discrete-time data as input features. The results are

consistent with the findings in the benchmarking dataset; the noise-enhanced performance persists. Extending the analysis across various interatomic distances further reveals that noise consistently improves the performance of the analog quantum kernel when $a > R_b$, and the hybrid quantum kernel when $a < R_b$, as shown in Fig. 1. Within these parameter regimes, the noise-enhanced analog and hybrid kernels achieve low MSEs that are competitive or exceed those of both the RBF and noisy digital models, demonstrating a robust, empirical quantum advantage for real-world physical applications.

We attribute this noise-enhanced performance to a fundamental shift in the kernel's expressivity and the resulting increase in model complexity. While an ideal quantum kernel evaluates similarity via a restricted set of rank-one projectors acting on pure states,

$$k(\vec{x}_k, \vec{x}_j) = \text{Tr} \left[\hat{P}(\vec{x}_k) |\psi(\vec{x}_j)\rangle \langle \psi(\vec{x}_j)| \hat{P}^\dagger(\vec{x}_k) \right]. \quad (5)$$

The noisy kernel expands the feature space to a sub-algebra of Hermitian matrices. It estimates similarity via higher-rank positive operator-valued measurement (POVM) components:

$$\tilde{k}(\vec{x}_k, \vec{x}_j) = \text{Tr} \left[\hat{F}(\vec{x}_k) \tilde{\rho}(\vec{x}_j) \right]. \quad (6)$$

This relaxation from strict rank-one projectors to diverse, higher-rank POVMs enriches the kernel's expressivity. Consequently, this expanded expressivity translates directly into higher model complexity—evidenced by an increased squared weight norm $|\vec{w}|^2$ precisely in the interatomic distance regimes where performance improvements are observed, as shown in Fig. 2. This dynamic alignment suggests that operational noise increases the model's capacity, potentially driving performance through a mechanism akin to "benign overfitting" [9–11], where highly complex decision functions interpolate training data while maintaining robust generalizability.

4 Summary

To overcome the noise limitations that hinder conventional digital quantum kernels, we proposed analog and hybrid quantum architectures leveraging continuous Rydberg atom dynamics and digital-analog ansatzes. When applied to benchmark datasets and the task of estimating non-Markovianity from sparse data, these developed kernels not only outperform the classical RBF kernel but also show a counterintuitive phenomenon: the presence of operational noise actively enhances the performance of both the analog and hybrid kernels. We attribute this phenomenon to a fundamental expansion in expressivity, in which noise relaxes the kernel's feature space from restrictive rank-one projectors to more complex, higher-rank positive-operator-valued measurements (POVMs). By demonstrating that the unique noise-enhanced performance of the quantum kernel based on analog quantum computing, our work paves the way for designing practical quantum kernels in the NISQ era.

Figure 1: Enhancement of performance in the presence of noise at various interatomic distances. We demonstrate the performance of the **a** analog and **b** hybrid models in both cases with and without noise, along with the noisy digital and RBF models for comparison. Generally speaking, both analog and hybrid models can be enhanced in the presence of noise when the interatomic distances are set to $a \geq R_b$ and $a \leq R_b$, respectively. Under the appropriate choice of interatomic distance, the analog and hybrid models achieve performance comparable to, or even surpassing, the noisy digital and RBF models; meanwhile, the magnitude of the enhancement of the analog quantum model is more manifest than the hybrid one, demonstrating an empirical quantum advantage even in the presence of noise.

Figure 2: Enhancement of the norm of weight $|\vec{w}|^2$ in the presence of noise at various interatomic distances. We show the model complexity in terms of the norm of weight $|\vec{w}|^2$ of the decision function $f(\vec{x})$ for the **a** analog and **b** hybrid quantum models. We can observe increased $|\vec{w}|^2$ for both models when $a \geq R_b$ and $a \leq R_b$, respectively. Crucially, this tendency is fully consistent with the noise-enhanced performance shown in Fig. 1. Consequently, noise can improve model performance by enhancing model complexity.

Interval-Graph and Pathwidth Bounds on the Spatial Width of Quantum Circuits

Seungjik Kim^{1 *}

Enhyeok Jang^{1 †}

Won Woo Ro^{1 ‡}

¹ Yonsei University, Seoul, Korea

Abstract. This paper establishes the foundational mathematical boundaries governing the spatial resource dimensions of quantum circuits under the spatial exclusion constraints of logical qubits. By modeling the lifecycles of coherent logical qubits as compact real temporal domains, we abstract the spatial and temporal evolution of the circuit as the intersection graph of compact real supports. We rigorously prove that the minimum spatial channel dimension required to embed a quantum circuit is exactly equal to its maximum concurrency density. This lower bound is shown to be tight by establishing that the domain intersection graph is a chordal co-comparability graph, and thus inherently perfect. Furthermore, we establish the topological robustness of this spatial bound, proving it remains invariant under any continuous, strictly increasing temporal warping by treating such deformations as linear order-isomorphisms. Finally, we model causal dependencies among unitary operations as a strict partial order, specifically a precedence poset. By doing so, we prove that the schedule-independent minimum spatial dimension under any causal schedule is bounded from below by the pathwidth of its causal dependency graph. This pathwidth-theoretic metric serves as a powerful schedule-agnostic tool for evaluating the spatial bounds of quantum circuits.

Keywords: Qubit Persistence, Perfect Graphs, Interval Orders, Pathwidth, Space-Time Orthogonality, Quantum Information Theory

1 Introduction & Axioms of Qubit Persistence

Quantum state tracking and channel mapping are fundamental to the analysis of multi-qubit computational lifecycles. In multi-qubit quantum systems, physical spatial constraints strictly govern overall system viability. Logical states demand physical spatial channels for persistence. Consequently, a critical requirement in evaluating algorithmic bounds in quantum computing is to establish the fundamental, system-independent boundaries of these spatial resources from first principles, independent of specific temporal schedules.

We begin by reformulating the physical permanence of quantum states under the foundational axioms of the No-Cloning Theorem. Because an arbitrary logical quantum state cannot be cloned, split, or projectively duplicated into independent computational streams, each independent logical state s_i in a finite set of generated states $\mathcal{S} = \{s_1, \dots, s_N\}$ must uniquely occupy a continuous temporal domain on the one-dimensional real timeline $\mathbb{R}$.

To formalize this physical spatial occupancy, we classify this lifecycle into three phases: (i) *Generation Phase* ($t = t_s(i)$) where the logical state is physically instantiated via state preparation (e.g., $|0\rangle$, $|+\rangle$) or as the output of a multi-qubit operation; (ii) *Persistence Phase* ($t_s(i) < t < t_e(i)$) where the state undergoes coherent memory storage (idling) or sequential single-qubit transformations, maintaining an uninterrupted physical locus under spatial exclusion; and (iii) *Consumption Phase* ($t = t_e(i)$) where the state is logically and physically erased via measurement, state erasure, or system resets.

We define this lifecycle formally as the *temporal sup-*

port of state s_i : $\mathcal{D}_i = [t_s(i), t_e(i)] \subset \mathbb{R}$ with $t_s(i) < t_e(i)$. At the coordinate $t = t_e(i)$, the state is officially erased, releasing the spatial channel for subsequent state occupancy.

Physical Spatial Exclusion: To prevent irreversible interference or premature state collapse, any two active logical states coexisting at a given timeline coordinate t must be mapped to entirely distinct, isolated spatial channels. This physical exclusivity motivates a rigorous set-theoretic formulation of spatial resource boundaries, framing the spatial footprint not as an optimization problem, but as a graph-theoretic boundary value problem.

2 Set-Theoretic Setup & Preliminary Definitions

We formalize the physical boundaries of a generic universal quantum circuit through the following mathematical definitions.

Definition 1 *At any continuous temporal coordinate $t \in \mathbb{R}$, the active set of concurrent logical states is $\mathcal{A}(t) = \{s_i \in \mathcal{S} \mid t \in \mathcal{D}_i\}$. The maximum concurrency density of the circuit, representing the maximum size of the concurrent active set across the entire algorithmic timeline, is denoted by $Q_{\min} = \max_{t \in \mathbb{R}} |\mathcal{A}(t)|$. By physical necessity, at the peak temporal coordinate t^* , all concurrent states contained within $\mathcal{A}(t^*)$ must project onto mutually orthogonal spatial degrees of freedom within the available physical space. Thus, any viable physical spatial channel capacity K must rigorously satisfy $K \geq Q_{\min}$.*

Definition 2 *Let $\mathcal{K} = \{1, \dots, K\}$ represent K distinct spatial channels. A valid spatial embedding of dimension K is a discrete coordinate mapping function $f : \mathcal{S} \rightarrow \mathcal{K}$ satisfying the non-overlapping constraint $\mathcal{D}_i \cap \mathcal{D}_j \neq$*

*seungjik.kim@yonsei.ac.kr

†enhyeok.jang@yonsei.ac.kr

‡wro@yonsei.ac.kr

$\emptyset \implies f(s_i) \neq f(s_j)$ for all $s_i \neq s_j \in \mathcal{S}$. The minimal spatial embedding dimension K^* is the minimum cardinality K for which a globally valid embedding mapping f exists.

Definition 3 For a family of compact state supports $\mathbb{D} = \{\mathcal{D}_1, \dots, \mathcal{D}_N\}$, the domain intersection graph $G = (\mathcal{S}, E)$ is an undirected graph where $(s_i, s_j) \in E \iff \mathcal{D}_i \cap \mathcal{D}_j \neq \emptyset$. By definition, the maximum clique size of G is $\omega(G) = Q_{\min}$, and the minimal spatial embedding dimension K^* corresponds to the chromatic number $\chi(G) = K^*$.

3 Spatial Minimality and Perfect Graph Tightness Limits

We now prove that the fundamental lower bound of physical channels required to embed the quantum circuit is tight, achievable without residual mapping overhead. We first establish the structural graph-theoretic properties of our mathematical model.

Lemma 4 Let $\mathbb{D}$ be a family of compact temporal intervals on $\mathbb{R}$. The resulting domain intersection graph G is chordal, and its graph complement $\bar{G}$ is a comparability graph.

Proof. First, we prove G is chordal. Since temporal lifecycles are modeled as compact real intervals on $\mathbb{R}$, their intersection graph G is an interval graph, which natively forms a subclass of chordal perfect graphs as established by Proposition 1.2 of [1].

Second, we analyze the complement graph $\bar{G} = (\mathcal{S}, \bar{E})$. An edge $(s_i, s_j) \in \bar{E}$ exists if and only if $\mathcal{D}_i \cap \mathcal{D}_j = \emptyset$. Because the domains are compact intervals on $\mathbb{R}$, disjointness strictly implies a natural temporal ordering. We define a transitive orientation for $\bar{G}$:

$$s_i \rightarrow s_j \iff t_e(i) < t_s(j) \quad (1)$$

If $s_i \rightarrow s_j$ and $s_j \rightarrow s_k$, then $t_e(i) < t_s(j) \leq t_e(j) < t_s(k)$, directly implying $t_e(i) < t_s(k)$, which necessitates $s_i \rightarrow s_k$. The existence of this transitive orientation confirms that $\bar{G}$ is a comparability graph under Gilmore and Hoffman (1964) and Theorem 2.3 of [2], completing the proof. $\square$

Theorem 5 For any family of compact temporal supports $\mathbb{D}$, the minimal spatial coordinate dimension K^* required for a valid embedding is exactly equal to the maximum concurrency density $Q_{\min}$:

$$K^* = Q_{\min} \quad (2)$$

Proof. We establish the algebraic identity by proving both necessity and sufficiency.

For necessity, let $t^* \in \mathbb{R}$ be the temporal coordinate where the concurrency density is globally maximized: $|\mathcal{A}(t^*)| = Q_{\min}$. For any distinct pair of states $s_i, s_j \in \mathcal{A}(t^*)$, we observe $t^* \in \mathcal{D}_i \cap \mathcal{D}_j$, meaning their temporal supports intersect. In the intersection graph

$G = (\mathcal{S}, E)$, the subset of vertices corresponding to $\mathcal{A}(t^*)$ induces a clique of size $Q_{\min}$. Under physical spatial exclusion, the restriction of the global embedding mapping f to $\mathcal{A}(t^*)$ must be injective. Since the codomain of f has cardinality K^* , we have:

$$K^* \geq |\mathcal{A}(t^*)| = Q_{\min} \quad (3)$$

which establishes $Q_{\min}$ as a necessary lower bound under the stated spatial exclusion model.

For sufficiency, we prove $\chi(G) \leq \omega(G)$. By Lemma 4, G is chordal and a co-comparability graph. Every chordal graph is perfect (Theorem 4.11 of [1]), which guarantees the algebraic identity:

$$\chi(H') = \omega(H') \quad (4)$$

for every possible induced subgraph $H' \subseteq G$. Applying this to the macro-graph G , we obtain $\chi(G) = \omega(G)$. Substituting $\chi(G) = K^*$ and $\omega(G) = Q_{\min}$ yields the exact equality $K^* = Q_{\min}$. Operationally, this is constructively achievable in polynomial time. By sorting all state generation coordinates $t_s(i)$ in ascending order and assigning the lowest available spatial index from $\{1, \dots, Q_{\min}\}$, we constructively guarantee a valid spatial embedding without ever exceeding $Q_{\min}$ channels. This proves the physical spatial bound is strictly tight. $\square$

4 Topological Invariance under Order-Isomorphisms

Temporal execution paths in physical quantum platforms are rarely uniform. Variations in operation durations, active stabilizer cycles, and spatial transport all distort the literal timeline. We prove that the fundamental spatial limit $Q_{\min}$ is a topological invariant under continuous temporal warping, rendering the spatial boundaries robust against timing fluctuations.

Theorem 6 Let $\mathcal{T} : \mathbb{R} \rightarrow \mathbb{R}$ be a continuous, strictly increasing bijection acting as a global time-warping function. Let $G' = (\mathcal{S}, E')$ be the domain intersection graph of the warped supports $\mathcal{D}'_i = [\mathcal{T}(t_s(i)), \mathcal{T}(t_e(i))]$. Then, $G' \cong G$, and the minimal spatial dimension remains invariant: $K'^* = K^* = Q_{\min}$.

Proof. Let $\mathcal{D}_i = [a_i, b_i]$ and $\mathcal{D}_j = [a_j, b_j]$ represent two compact intervals. Their intersection is non-empty if and only if $\max(a_i, a_j) \leq \min(b_i, b_j)$, defining the standard interval representation of the graph [1, 2]. Because the temporal warping function $\mathcal{T}$ is a continuous, strictly increasing bijection, it acts as an order-isomorphism on $\mathbb{R}$. Monotonicity ensures that $\mathcal{T}$ commutes with finite extremum operators:

$$\begin{aligned} \mathcal{T}(\max(a_i, a_j)) &= \max(\mathcal{T}(a_i), \mathcal{T}(a_j)) \\ \mathcal{T}(\min(b_i, b_j)) &= \min(\mathcal{T}(b_i), \mathcal{T}(b_j)) \end{aligned}$$

Thus, we establish the chain of equivalences for domain intersection:

$$\begin{aligned}
\mathcal{D}_i \cap \mathcal{D}_j \neq \emptyset &\iff \max(a_i, a_j) \leq \min(b_i, b_j) \\
&\iff \mathcal{T}(\max(a_i, a_j)) \leq \mathcal{T}(\min(b_i, b_j)) \\
&\iff \max(\mathcal{T}(a_i), \mathcal{T}(a_j)) \\
&\quad \leq \min(\mathcal{T}(b_i), \mathcal{T}(b_j)) \\
&\iff \mathcal{D}'_i \cap \mathcal{D}'_j \neq \emptyset
\end{aligned}$$

which guarantees that the warping function preserves interval intersections.

Since adjacency is preserved, the edge sets satisfy $(s_i, s_j) \in E' \iff (s_i, s_j) \in E$. The identity vertex mapping defines a graph isomorphism $G \cong G'$, which conserves all structural invariants: $\omega(G') = \omega(G) = Q_{\min}$ and $\chi(G') = \chi(G) = K^*$. Applying Theorem 5, we obtain $K'^* = \chi(G') = K^* = Q_{\min}$. Therefore, continuous timeline deformation leaves the maximal concurrency limit invariant, meaning that spatial boundaries depend exclusively on the relative topological sequencing of events. $\square$

5 Causal Poset Theory and Topological Pathwidth Bounds

While Theorem 5 assumes a fixed temporal schedule, logical quantum states possess deep causal dependencies derived from the circuit's multi-qubit unitary operations. We now establish a schedule-independent fundamental lower bound governed strictly by the causal precedence relation.

Lemma 7 *A universal quantum circuit defined by a Directed Acyclic Graph $G_{DAG} = (V, E_{DAG})$ induces a strict partial order $\mathcal{P}_Q = (\mathcal{S}, \prec_Q)$ on the set of logical states, representing the transitive closure of causal dependencies.*

Proof. Let $v_{\text{sink}}(s_i)$ denote the operation consuming state s_i , and $v_{\text{source}}(s_j)$ denote the operation generating s_j . We define the precedence relation:

$$s_i \prec_Q s_j \iff v_{\text{sink}}(s_i) \rightsquigarrow v_{\text{source}}(s_j) \text{ in } G_{DAG} \quad (5)$$

where $u \rightsquigarrow v$ indicates a directed path. Because G_{DAG} is acyclic, the relation is irreflexive ($s_i \not\prec_Q s_i$), asymmetric:

$$s_i \prec_Q s_j \implies s_j \not\prec_Q s_i \quad (6)$$

and transitive. Thus, $\mathcal{P}_Q$ forms a strict partial order defining the qubit precedence poset. This poset dictates that the physical lifespan of s_i must terminate entirely before that of s_j begins. $\square$

Theorem 8 *For any quantum circuit represented by a Directed Acyclic Graph $G_{DAG} = (V, E_{DAG})$ capturing the causal precedence dependencies among operations, let a spatial channel allocation be defined as a mapping from states to a set of spatial channels. The schedule-independent minimum number of spatial channels $K_{\min}$*

required to execute the circuit under any causally valid schedule is bounded from below by the pathwidth of the underlying undirected gate dependency graph G_{DAG} :

$$K_{\min} \geq \text{pathwidth}(G_{DAG}) \quad (7)$$

where $\text{pathwidth}(G_{DAG})$ is defined as the pathwidth of the undirected graph obtained by ignoring the orientation of edges in G_{DAG} [3].

Proof. A causally valid schedule corresponds to a topological sort $v_1, \dots, v_n$ of G_{DAG} . At step i , the active states (edges crossing the cut from prefix $\{v_1, \dots, v_i\}$ to suffix $\{v_{i+1}, \dots, v_n\}$) are denoted by $E_{\text{active}}(i)$. Let $V_{\text{active}}(i)$ denote prefix vertices with neighbors in the suffix. Because each vertex in $V_{\text{active}}(i)$ is associated with at least one active edge, we have:

$$|E_{\text{active}}(i)| \geq |V_{\text{active}}(i)| \quad (8)$$

and the peak active states satisfy:

$$\max_i |E_{\text{active}}(i)| \geq \max_i |V_{\text{active}}(i)| \quad (9)$$

The quantity $\max_i |V_{\text{active}}(i)|$ is precisely the vertex separation of the ordering $v_1, \dots, v_n$ on the undirected G_{DAG} . The minimum vertex separation over all vertex orderings equals its pathwidth [4]:

$$\min_{\text{orderings}} \max_i |V_{\text{active}}(i)| = \text{pathwidth}(G_{DAG}) \quad (10)$$

Since topological sorts are a restricted class of vertex orderings, the minimum peak active states $K_{\min}$ over all causally valid schedules satisfies:

$$\begin{aligned}
K_{\min} &= \min_{\text{schedules}} \max_i |E_{\text{active}}(i)| \\
&\geq \min_{\text{schedules}} \max_i |V_{\text{active}}(i)| \\
&\geq \text{pathwidth}(G_{DAG})
\end{aligned} \quad (11)$$

This limit bridges graph pathwidth with evaluation complexity, extending expression graph pebbling bounds [5]. $\square$

6 Discussion and Theoretical Implications

We establish a comprehensive topological order-geometry for quantum circuits, demonstrating that the physical spatial footprint of universal quantum computation is governed by strict mathematical invariants rather than specific scheduling timelines. Importantly, the pathwidth of G_{DAG} bounds the fundamental spatial width of a quantum circuit before a temporal schedule is constructed. If a circuit satisfies $\text{pathwidth}(G_{DAG}) > K$, it is mathematically impossible to embed its temporal supports into K channels under any causally valid execution schedule. This limit is a direct physical consequence of state persistence under spatial exclusion, establishing the pathwidth of the causal dependency graph as a fundamental, schedule-agnostic physical property of the underlying logical quantum circuit.

A Comprehensive Survey on AI for Quantum Computing and Quantum Computing for AI; Challenges, Trends, Applications, and Future Directions

Khan Md Abidur Rahman^{1 *}

Alve Nusrat Jahan^{1 †}

¹ *College of Artificial Intelligence Convergence, Sejong University, Seoul 05006, Republic of Korea*

Abstract. Artificial intelligence (AI) and quantum computing (QC) are increasingly combined in two opposite directions that are usually studied apart: AI used to operate quantum hardware, and quantum hardware proposed to accelerate AI. We survey both together under one consistent standard of hardware realism, separating results shown only in simulation from those validated on real devices. A clear asymmetry emerges: AI has already become part of how quantum computers run, reaching error-corrected hardware in machine-learned decoding, whereas the reverse direction’s established advantages remain in constructed settings, with no widely accepted practical advantage on ordinary data against strong classical baselines. We explain why and propose reporting standards to keep such claims honest.

Keywords: quantum machine learning, AI for quantum computing, hardware realism, quantum advantage, neural decoders, benchmarking

1 Motivation and Scope

Artificial intelligence and quantum computing are now being brought together in two opposite directions at the same time. In the first, classical machine learning is used to make quantum computers work better: interpreting the error signals of a quantum processor, calibrating and steering its qubits, and translating quantum programs into the operations a given device can actually run. In the second, quantum computers are proposed as a new kind of engine for machine learning itself—either as accelerators or as fundamentally new model families. We call these directions *AI for Quantum Computing* (AI4QC) and *Quantum Computing for AI* (QC4AI).

Most existing reviews examine only one of these directions, and—more importantly—tend to place results obtained in idealized computer simulations next to results demonstrated on real, noisy hardware as though the two carried the same weight. They do not. This survey treats both directions together and holds each to a single, explicit standard of *hardware realism*. Our guiding question is deliberately deflationary: for each topic, what claims actually survive once we account for noise, the cost of repeated measurements, the limitations of real devices, and a properly tuned conventional competitor? The answer turns out to be very different for the two directions, and that difference is the survey’s central message.

2 A Common Yardstick: The Hardware Realism Tier Framework

A persistent difficulty in this field is that the phrase “it works” means very different things in different papers. A method that works in an idealized, noise-free simulation has shown something far weaker than a method that works on an actual device, where every measurement is noisy and must be repeated many times. To make this difference explicit rather than buried, we introduce a simple five-level *Hardware Realism Tier* (HRT) scale and apply it uniformly to every method we discuss: **T1** idealized noise-free simulation; **T2** simulation that includes realistic noise; **T3** execution on today’s noisy quantum hardware; **T4** early error-corrected hardware with a small number of protected logical qubits; and **T5** large-scale, fully fault-tolerant machines that do not yet exist.

We are careful to present HRT as an interpretive aid, not a law of nature or a single performance score. Its value is that it forces a distinction the literature often blurs: the level at which a result has actually been *demonstrated* versus the level its claimed benefit would *require* in order to matter. When these two coincide, a result is close to practical reality; when they are far apart, apparent maturity is an illusion. A well-known proposal for quantum recommendation systems, for example, was demonstrated only as an idealized algorithm (T1) yet would require a full fault-tolerant machine with fast quantum memory (T5) before its claimed

*ak.abid241@gmail.com

†mkha0172@gmail.com

Figure 1: The Hardware Realism Tier (HRT) ladder. AI for quantum computing has reached a demonstrated result on early error-corrected hardware (T4) in machine-learned decoding; the firmly established benefits of quantum computing for AI sit at the fully fault-tolerant level (T5) or are independent of near-term hardware; most near-term quantum machine learning operates on today’s noisy devices (T3) without an established advantage.

speed-up could ever apply—and it was later shown that an ordinary classical computer can do essentially the same task, dissolving the advantage entirely [6]. By contrast, a typical near-term quantum learning model is both demonstrated and required at the same level (T3), so there is no such gap—though, as we stress, matching levels shows only that a method *runs* on real hardware, not that it *beats* a strong classical alternative.

3 Naming the Kinds of “Quantum Advantage”

Much of the confusion surrounding quantum computing for AI comes from the single phrase “quantum advantage” being used for several quite different claims. We separate five of them, each with its own way of failing: an *asymptotic* advantage (faster in principle as problems grow); a *practical* advantage (genuinely faster or more data-efficient on a real machine than the best classical method); a *sample-efficiency* advantage (needing fewer training examples); a *resource* advantage (using less energy or memory); and an *expressivity* advantage (representing functions a classical model cannot easily reach). These are not interchangeable: being more expressive does not make a model practically faster; an in-principle speed-up can be irrelevant if the data cannot be loaded efficiently; and the long-running “dequantization” debate is precisely about whether certain in-principle advantages survive once a classical method is given a fair comparison. Our recommendation is simple: every advantage claim should

state which of these it means, and be judged by that standard alone.

4 The Central Finding: A Structural Asymmetry

Viewed through this common lens, the two directions look strikingly different, and this contrast is the survey’s principal observation.

AI has already entered quantum hardware.

The clearest case is quantum error correction—the machinery that will make large quantum computers reliable. Here, machine-learned models that interpret a processor’s error signals have progressed from simple networks to advanced architectures now built directly into a working, error-corrected memory on real superconducting hardware, where they outperform the long-standing conventional decoding method [1, 2]. This regime suits machine learning unusually well: interpreting error signals is a pattern-recognition task; real hardware produces complex, correlated errors that the conventional method cannot fully capture but a trained model can; and yet the model must keep up with the processor in real time, a demanding speed requirement on which the conventional method remains very strong. That a learned component now sits inside a system which genuinely crosses the reliability threshold is, to our knowledge, among the strongest evidence that AI is becoming an essential *part of* the path to large-scale quantum computing rather than a peripheral tool. Across the AI4QC subfields we survey, a clear and explicable maturity ordering emerges—decoding (now on early error-corrected hardware) ahead of control and calibration (on today’s noisy devices) ahead of program compilation and circuit routing (mostly still in simulation)—tracking how directly each task exposes a learned model to real hardware.

The reverse direction’s advantages remain narrow.

On the other side, the most firmly established benefits of quantum computing for AI are real but confined. They appear either for artificially constructed problems designed to favour the quantum method [3], or when the data being learned is *itself* quantum—for example, the output of a quantum sensor or simulation—rather than ordinary classical data [4]. For the case that matters most in everyday practice—learning from ordinary data on near-term machines—we find no widely accepted demonstration of a genuine practical advantage once the clas-

sical baseline is upgraded from a weak default to a properly tuned modern method [5]. Importantly, the line of work that repeatedly deflates such claims should be read not as “quantum lost” but as a sharpening of exactly which assumptions a credible advantage would require.

5 Why the Asymmetry Is Not Accidental

We argue this imbalance follows from the kind of problem each direction faces. AI for quantum computing applies a *mature* technology (modern machine learning) to a *well-defined* engineering problem—it need only beat a conventional engineering method on today’s hardware. Quantum computing for AI asks *immature* hardware to beat a *mature and still rapidly improving* classical competitor, a much higher bar that rises further every year. Three themes recur: a strict real-time speed requirement that plays to AI’s strengths on the quantum side; a classical competitor that keeps getting stronger on the AI side; and the observation that the most promising opening for quantum computing in AI is quantum data, not ordinary data. The full survey also sets out the strongest evidence *against* our reading—promising niches in quantum kernels, in regimes where classical simulation becomes hard, and in analog and photonic systems—and explains why we judge it encouraging but not yet decisive.

6 Where the Two Directions Stand Across Application Domains

The same hardware-realistic lens, applied to the application areas most often cited for quantum advantage in AI, yields deliberately sober verdicts. *Quantum chemistry and materials science* is the most defensible case: small-scale demonstrations on real hardware are genuine, a structural advantage is physically plausible, and it is the likeliest first domain of real advantage—but present demonstrations remain classically reproducible, and decisive impact awaits fault-tolerant machines. *Combinatorial optimization* shows high activity but, as yet, no verified advantage over strong classical heuristics, and it faces a classical baseline that keeps improving. *Finance* is largely derivative, inheriting the uncertainties of optimization and quantum learning, with its headline speed-ups resting on fault-tolerant subroutines. *Healthcare and drug discovery* is the most projective: credible mainly as a future fault-tolerant quantum subroutine embedded inside an otherwise classical AI pipeline. A recurring pattern

unifies these verdicts—in every domain, the level at which results have been *demonstrated* falls short of the level their claimed advantage would *require*, and the size of that gap is the most honest single measure of the domain’s maturity.

7 Keeping Claims Honest: A Reporting Standard

Because so many advantage claims fail for avoidable methodological reasons rather than fundamental ones, we propose a short checklist that any empirical AI–quantum study should report: the hardware-realism level demonstrated and the level actually required; the hardware and noise conditions; how data was loaded into the quantum system; the number of measurement repetitions used; the strongest comparable classical method and how carefully it was tuned; an honest accounting of running time; the spread of results across repeated runs; and, for any speed-up claim, the assumptions about how data is accessed. Adopting this consistently would remove most of the recurring problems—weak comparisons, overly easy test problems, undisclosed reliance on simulation, and hidden measurement costs—that currently make the field look more advanced than it is.

8 Importance to Quantum Information Science

The contribution we wish to emphasize for this community is one of clarity and discipline rather than a new algorithm. The hardware-realism scale gives a shared language for separating what has been *shown* from what has merely been *projected*; naming the kinds of advantage makes “quantum advantage” claims testable; the central finding points effort toward where quantum resources most plausibly help—error correction today, and learning on quantum data in the longer term; and the reporting standard offers a concrete remedy for the periodic overclaiming that damages the field’s credibility. We believe an honest, hardware-grounded synthesis of this kind is especially timely now, as the first genuinely error-corrected building blocks of quantum computing begin to appear. An extended technical version of this work, with full taxonomies, comparison tables, and complete references, is available from the authors.

Abstract. Quasi-probability decomposition-based importance sampling underpins many widely used techniques, including error mitigation, circuit knitting, and virtual quantum resource distillation. However, these protocols are limited to expectation value estimation. We present a framework lifting any quasi-probability-based protocol to a weak simulator, enabling sampling from target distributions using only restricted quantum resources. Our method incurs sampling cost proportional to the quasi-probability negativity, whereas the naive approach requires significantly more samples in many important scenarios. We demonstrate this advantage concretely for error mitigation, entanglement distillation, and magic state distillation, achieving weak simulation of quantum resources without physical distillation.

Keywords: Distillation, Robustness, Weak simulation

1 Overview

While recent technological advances offer growing potential of quantum information processing, the actual realization of quantum advantages faces inevitable challenges due to operational restrictions and experimental limitations. It is therefore of paramount importance to obtain higher-quality quantum resources [1], such as entanglement [2, 3], magic [4, 5] and coherence [6] among many more, from available components in order to perform a given task.

Resource distillation [7, 8, 9] is one of the most common methods to obtain a resource state using low-quality states available under the given operational capabilities. However, distillation protocols typically require many state copies and accurate coherent interactions between them, which are practically challenging. To address this problem, the framework of virtual quantum resource distillation has recently been proposed [10, 11]. The idea is to represent a resourceful quantum state not available in the given setting by a quasi-probability distribution of the available low-quality states. This allows one to employ the importance sampling technique to estimate an arbitrary expectation value of the desired resourceful state by only using low-quality states and classical post-processing. The additional sampling overhead scales with the amount of negativity needed in the quasi-probability decomposition, which can be understood as a quantifier of how resourceful the target state is with respect to the set of easily prepared states in the setting [12, 5, 13]. This circumvents the need to directly prepare the high-quality quantum state, making the protocol practically appealing. Furthermore, the framework of virtual quantum resource distillation is highly general and encompasses various techniques—such as error mitigation [14, 15], circuit knitting [16, 17], implementation of unphysical maps [18, 19], and classical simulation of quantum circuits [20, 21, 5, 22, 23]—in the unified framework.

Despite the versatility of this approach, quasi-probability-based methods come with a severe restriction—they only admit expectation value estimation. Although this is sufficient for several applications [24], many important algorithms, such as Shor’s algorithm for factoring [25] and sampling

tasks for certification of quantum advantages [26, 27, 28, 29], require direct access to samples of the measurement outcomes. Indeed, the expectation value estimation is known to be a weaker form of simulation compared to the capability of sampling from the desired distribution—known as *weak simulation* [30]. Despite its confusing terminology, weak simulation is the natural and strong notion of simulation, in the sense that it directly mimics what quantum computers accomplish. Therefore, asking whether virtual quantum resource distillation, a quasi-probability-based method to simulate resourceful objects, can be extended to support sampling tasks is well motivated.

One direct approach would be to estimate the full probability distribution by the quasi-probability-based method and then sample from it, as recently discussed in the context of error mitigation [31]. However, this method always has to estimate a probability distribution, even if one simply wants to obtain a sample from an available resource, which can be done without estimating the probability distribution. This unnatural discontinuity in the simulation cost, particularly in the small negativity regime incurs a substantial overhead. Therefore, an efficient way that naturally extends the quasi-probability-based framework to allow for sampling access is currently missing.

In this work, we fill this gap by introducing a general framework of *weak resource distillation*, which lifts an expectation value estimation based on quasi-probability to weak simulation. Our framework enables sampling without explicitly preparing the high-quality state, thereby removing the requirement for large quantum memory. The sampling cost of our methods scales directly with the negativity of the quasi-probability, not only circumventing the aforementioned discontinuity in the small negativity regime, but also providing a novel operational interpretation of the negativity of the quasi-probability decomposition, also known as the robustness measure of quantum resources [12, 5, 13]. Our method requires significantly fewer samples in several important scenarios, such as error mitigation, entanglement distillation, and magic state distillation, than the naive method. Together with the high generality of our framework, our results open the door to use the power of quasi-probability methods in many relevant scenarios.

2 Preliminaries

We consider the setting where one aims to run a protocol that requires a certain state under physical restriction, often discussed in the framework of resource theories [1]. We let $\mathcal{O}$ denote the set of operations that are accessible in the given setting and $\mathcal{F}$ denote the set of quantum states that can be prepared by the operation in $\mathcal{O}$. Our framework is fully general as long as the sets $\mathcal{O}$ and $\mathcal{F}$ are finite dimensional and convex. We also note that, by definition of $\mathcal{F}$, it is ensured that an operation in $\mathcal{O}$ can never map a state in $\mathcal{F}$ to another state outside of $\mathcal{F}$.

If the desired state ρ required in the protocol is not directly available in the given setting, i.e., $\rho \notin \mathcal{F}$, one can aim to simulate the process by only using states in $\mathcal{F}$. The virtual quantum resource distillation [10, 11] provides a way of accomplishing this when the goal of the tasks is to estimate the expectation value of some observable. The core idea is to express the resource state ρ in terms of the linear combination of the states in $\mathcal{F}$ as $\rho = \sum_i c_i \sigma_i$, $\sigma_i \in \mathcal{F}$, $c_i \in \mathbb{R}$ where some c_i 's can be negative. Noting also the unit trace condition for quantum states, c_i 's need to be normalized as $\sum_i c_i = 1$. Because of the convexity of $\mathcal{F}$, the quasi-probability decomposition can generally be written in the form $\rho = c_+ \sigma_+ - c_- \sigma_-$ with positive constants $c_{\pm} \geq 0$ satisfying $c_+ - c_- = 1$ and states $\sigma_{\pm} \in \mathcal{F}$. Given the quasi-probability decomposition, the expectation value estimation can be done by employing importance sampling, using the number of samples that scales with the absolute sum $\gamma := c_+ + c_-$ of the quasi-probability. As the quasi-probability decomposition is generally not unique, it is meaningful to consider the optimal decomposition that minimizes the negativity. This minimized negativity is also known as the robustness measure of quantum resources [12, 5, 13], which serves as a resource quantifier with respect to the set $\mathcal{F}$ and $\mathcal{O}$ of free states and operations.

This framework encompasses many scenarios by flexibly choosing the set $\mathcal{F}$, e.g., stabilizer or positive Wigner states for classical simulation of quantum circuits [5, 32, 33], separable states for entanglement distillation [2], the states preparable by local subcircuits for circuit knitting [16, 34], and the states produced by the inverse map of the noise channel for an error mitigation method known as probabilistic error cancellation [14, 35, 36].

3 Weak resource distillation

We now aim to lift the expectation value estimation realized in the virtual quantum resource distillation to the weak simulation of the process involving the resource state. Weak simulation aims to obtain a sample from a distribution $\{\tilde{p}_x\}_x$ that is close to the true distribution $\{p_x\}_x$ in the total variation distance as $d_{\text{tv}}(p, \tilde{p}) = \frac{1}{2} \sum_x |p_x - \tilde{p}_x| \leq \epsilon$ with probability at least $1 - \delta$. In the context of resource distillation, we are generally interested in the samples from a resource state ρ . The true probability distribution in this case is $p_x = \langle x | \rho | x \rangle$ where $\{|x\rangle\}_x$ is the computational basis. We aim to get a sample from the distribution close to p_x by using N samples of the states in $\mathcal{F}$. If $\rho \in \mathcal{F}$, the sampling cost N is trivially one, because the state $\rho \in \mathcal{F}$ can directly be prepared by the given device. On the other hand, if $\rho \notin \mathcal{F}$, one generally

needs a larger number N of samples from the available states $\mathcal{F}$ to construct a desired sampler. We call this sampling process *weak distillation* of a resource state ρ and call the required number N the *sampling cost*. The major question then is to characterize the sampling cost N with respect to the target trace distance error ϵ and the failure probability δ .

Let us begin with the most intuitive approach based on the probability estimation, which first estimates the probability distribution $\{\langle x | \rho | x \rangle\}_x$ and then samples from it. This approach was discussed in the context of error mitigation [31], where the mean-square error is considered. We provide a detailed analysis of this approach with trace distance error—a more operationally meaningful error quantifier—applicable to the general setting beyond error mitigation.

Proposition 1. *For a quantum state written as $\rho = c_+ \sigma_+ - c_- \sigma_-$ with $\sigma_{\pm} \in \mathcal{F}$ and $c_{\pm} \geq 0$, the probability-estimation-based method realizes the weak distillation of state ρ with trace distance accuracy ϵ with probability at least $1 - \delta$ by using*

$$N \leq \frac{\gamma^2}{4\epsilon^2} \left(2^{\frac{1}{2} H_{\frac{1}{2}}(q_x)} + \sqrt{8 \log \frac{2}{\delta}} \right)^2 \quad (1)$$

samples of σ_+ and σ_- , where $q_x = \frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-$, $p_x^{\pm} = \langle x | \sigma_{\pm} | x \rangle$ and $\gamma = c_+ + c_-$. $H_{\alpha}(P_x)$ is the α -Rényi entropy defined as

$$H_{\alpha}(P_x) = \frac{1}{1 - \alpha} \log_2 \left(\sum_x P_x^{\alpha} \right). \quad (2)$$

Proposition 1 holds for any quasi-probability decomposition $\rho = c_+ \sigma_+ - c_- \sigma_-$, and it can be minimized to provide the smallest sample cost, in which case γ coincides with the robustness resource measure [13] with respect to the set $\mathcal{F}$. We also note that, we have $H_{\frac{1}{2}}(q_x) \sim n$ in the worst case, and the sampling cost grows exponentially with n .

This direct method has a major drawback. If we consider the scenario where the target state ρ is close to a free state, or even a free state itself, we can simply use ρ to directly obtain a sample from the output distribution. However, the above method still needs to estimate the probability distribution using a substantial number of states regardless of the small negativity, resulting in discontinuous behavior around $c_- = 0$ as can be seen in (1).

To address this discontinuous sampling cost, we propose the main framework of this work to perform weak resource distillation. The core problem underlying the weak resource distillation is entirely classical—we would like to sample from $\{p_x\}_x$ while only having sampling access to other distributions $\{q_x\}_x$. This setting is addressed by the method known as rejection sampling [37] and has also recently been employed in the context of classical simulation [38].

The idea of rejection sampling is to get a sample from the available distribution q_x and accept the sample with probability proportional to the fraction $\frac{p_x}{q_x}$ of *acceptance ratio*. In our setting, this can be done by sampling from the distribution $q_x = \frac{c_+}{c_+ + c_-} \langle x | \sigma_+ | x \rangle + \frac{c_-}{c_+ + c_-} \langle x | \sigma_- | x \rangle$ and accept the sample with respect to $p_x = \langle x | \rho | x \rangle$. The problem is that we do not know the value of the acceptance ratio $\frac{p_x}{q_x}$ beforehand. We therefore estimate the acceptance ratio using some number of states in $\mathcal{F}$.

The sampling cost to construct a sampler based on this approach can be characterized as follows. We provide a detailed procedure of the protocol and the proof of theorem 2 in the main text [39] appended after the extended abstract.

Theorem 2. *For a quantum state written as $\rho = c_+\sigma_+ - c_-\sigma_-$ with $\sigma_{\pm} \in \mathcal{F}$ and $c_{\pm} \geq 0$, the weak distillation of state ρ with trace distance accuracy ϵ with probability at least $1 - \delta$ can be accomplished by using*

$$N \leq 8c_-\gamma \left(\frac{1+\epsilon}{\epsilon} \right)^2 \left(2^{\frac{1}{2}H_{\frac{1}{2}}(p_x)} + \delta_1^{-\frac{1}{2}} \right)^2 + M(\gamma, \delta_2, \epsilon) \quad (3)$$

samples of σ_+ and σ_- , where $p_x^{\pm} = \langle x | \sigma_{\pm} | x \rangle$, $\gamma = c_+ + c_-$ and $(1 - \delta_1)(1 - \delta_2) = 1 - \delta$. Also, M is an integer that satisfies

$$M(\gamma, \delta_2, \epsilon) \geq \frac{\log\left(\frac{1}{\delta_2}\right)}{\log\left(\frac{(1+\epsilon)\gamma}{(1+\epsilon)c_- + \epsilon\gamma}\right)}. \quad (4)$$

The first term in (3) corresponds to the sampling cost to estimate the acceptance ratio $\frac{p_x}{q_x}$, and the second term is the general overhead incurred on the rejection sampling provided the estimated acceptance ratio, whose contribution is typically negligibly small compared to the first term. The first term is now proportional to c_- , which ultimately becomes zero when ρ is a free state. With the second term that approaches 1 when $c_- \rightarrow 0$, the overall cost in (3) reduces to 1 in the limit of $c_- \rightarrow 0$. In this case, we get that the acceptance ratio always becomes 1, corresponding to the procedure that makes a measurement on ρ and accepts any measurement outcome at all times. This clarifies that our protocol is smoothly connected to the case of $c_- = 0$ and efficiently takes into account the overhead due to the negativity of quasi-probability, particularly in the regime of small negativity.

Our methods only require preparing one state at a time. We therefore avoid the need for joint operations across multiple copies of states, which greatly reduces the experiential difficulty. The requirement of preparing many copies of a state and performing joint operations on all of them makes conventional distillation experimentally challenging, while our framework avoids this difficulty. Additionally, there are many no-go theorems constraining distillation protocols. [40, 41, 42]. Our framework does not suffer from such no-go theorems; we can “distill” any state as long as we know its quasi-probability decomposition.

4 Applications

Having the general framework in place, we now consider a specific scenario, error mitigation, especially in the framework of the probabilistic error cancellation [14, 35, 36]. Let $\mathcal{E}(\cdot)$ be the effective error channel of the whole circuit. The inverse map of the noise channel is not implementable generally, as it is commonly not a CPTP map. For any output state ρ of the noisy circuit, when we can come up with the decomposition of the inverse channel of $\mathcal{E}(\cdot)$ as $\mathcal{E}^{-1}(\rho) = c_+\Lambda_+(\rho) - c_-\Lambda_-(\rho)$ ($c_{\pm} \geq 0$, $c_+ - c_- = 1$) where $\Lambda_{\pm}$ is CPTP map so that it is physically implementable, our framework allow to weak simulate $\mathcal{E}^{-1}(\rho)$ by taking $\sigma_{\pm} = \Lambda_{\pm}(\rho)$. In fig. 1, we consider mitigating local depolarizing noise and plot analytical upper bounds in proposition 1

Figure 1: The simulation of the probabilistic error cancellation for local depolarizing noise. We take the average of 20 outcomes. For each qubit, we use the decomposition $\rho = \frac{1}{1-p}\mathcal{E}(\rho) - \frac{p}{1-p}\frac{I}{2}$ where $\mathcal{E}(\cdot)$ is the local depolarizing noise channel. We take $p = 0.005$, and prepared a random 4 qubit system. We use $\delta = 0.1$. Blue line named “Rejection TVD” represents the numerical simulation’s outcome of the actual total variation distance we obtain with our framework. The orange line named “Estimation TVD” represents the outcome with the probability distribution estimation method. Dotted lines represent the bounds shown in the theorems. Since the total variation distance is at most 1, we take 1 as the maximum value for both bounds.

and theorem 2, as well as actual sampling cost numerically obtained by simulating both methods. Numerical simulations in other settings can be found in the main text [39].

One thing we note is that our protocol has a lower total variation distance and a better upper bound than the probability-estimation-based method in the studied settings, particularly in regions with small sample sizes. The reason is that we cannot construct meaningful probability distributions for the probability distribution estimation method with such a small sampling size. On the other hand, our framework already allows us to access the probability distribution $\{\frac{c_+}{c_++c_-}p_x^+ + \frac{c_-}{c_++c_-}p_x^-\}_x$ without any sampling cost. For small c_- , that is already a good approximation of the target distribution, and therefore it provides a better outcome.

5 Discussion

We introduced a framework of weak resource distillation, providing sampling access to a general class of quasi-probability methods, which previously only allowed for expectation value estimation. Our framework inherits the wide applicability of the quasi-probability-based method, such as error mitigation. We show that our method has distinct features, such as directly scaling with the negativity of the quasi-probability. We supported the practical relevance of our framework through numerical simulation, where we demonstrated that our approach significantly outperforms the direct probability-estimation-based approach in many relevant settings, particularly reflecting the efficient construction of our method in terms of the negativity of quasi-probability.

Importance sampling based on quasi-probability decomposition is the backbone of many widely used techniques, such as error mitigation, circuit knitting, and, more generally, virtual quantum resource distillation, as it allows one to simulate operations that are not accessible in a given setting. However, this class of protocols faces a fundamental problem—it only allows to estimate expectation values. Here, we provide a general framework that lifts any quasi-probability-based protocol from expectation value estimation to a weak simulator, realizing sampling from the desired distribution only using a restricted class of quantum resources. Our method runs with the sampling cost proportional to the negativity of the quasi-probability, in stark contrast to the naive estimation-based approach that requires a large number of samples even in the case of small negativity. We show that our method requires significantly fewer samples in a number of relevant scenarios, such as error mitigation, entanglement distillation and magic state distillation. Our framework realizes the weak simulation of quantum resources without actually distilling the state, introducing a new notion of quantum resource distillation.

While recent technological advances offer growing potential of quantum information processing, the actual realization of quantum advantages faces inevitable challenges due to operational restrictions and experimental limitations. It is therefore of paramount importance to obtain higher-quality quantum resources [1], such as entanglement [2, 3], magic [4, 5] and coherence [6] among many more, from available components in order to perform a given task.

Resource distillation [7–9] is one of the most common methods to obtain a resource state using low-quality states available under the given operational capabilities. However, distillation protocols typically require many state copies and accurate coherent interactions between them, which are practically challenging. To address this problem, the framework of virtual quantum resource distillation has recently been proposed [10, 11]. The underlying idea is to represent a resourceful quantum state not available in the given setting by a quasi-probability distribution of the available low-quality states. This allows one to employ the importance sampling technique to estimate an arbitrary expectation value of the desired resourceful state by only using low-quality states and classical post-processing. The additional sampling overhead scales with the amount of negativity needed in the quasi-probability decomposition, which can be understood as a quantifier of how resourceful the target state is with respect to the set of easily prepared states in the setting [5, 12, 13]. This circumvents the need to directly prepare the high-quality quantum state, making the protocol practically appealing. Furthermore, the framework of virtual quantum resource distillation is highly general and encompasses various techniques—such as error mitigation [14, 15], circuit knitting [16, 17], implementation of unphysical maps [18, 19], and classical simulation of quantum circuits [5, 20–23]—in the unified framework.

Despite the versatility of this approach, quasi-probability-based methods come with a severe restriction—they only admit

expectation value estimation. Although this is sufficient for several applications [24], many important algorithms, such as Shor’s algorithm for factoring [25] and sampling tasks for certification of quantum advantages [26–29], require direct access to samples of the measurement outcomes. Indeed, the expectation value estimation is known to be a weaker form of simulation compared to the capability of sampling from the desired distribution—known as *weak simulation* [30]. Despite its confusing terminology, weak simulation is the natural and strong notion of simulation, in the sense that it directly mimics what quantum computers accomplish. Therefore, asking whether virtual quantum resource distillation, a quasi-probability-based method to simulate resourceful objects, can be extended to support sampling tasks is well motivated.

One direct approach would be to estimate the full probability distribution by the quasi-probability-based method and then sample from it, as recently discussed in the context of error mitigation [31]. However, this strategy fails to naturally reflect the excess resource contents of the target state with respect to the given setting. In fact, even when the desired state is close to an available one with small negativity in the quasi-probability decomposition, it incurs a substantial overhead for estimating the entire probability distribution. Considering that there is no extra cost to pay when there is no negativity, in which case one can directly take a sample from the given device, this naive approach shows an unnatural discontinuity in the simulation cost, particularly in the small negativity regime. Therefore, an efficient way that naturally extends the quasi-probability-based framework to allow for sampling access is currently missing.

In this work, we fill this gap by introducing a general framework of *weak resource distillation*, which lifts an expectation value estimation based on quasi-probability to weak simulation. Analogous to virtual quantum resource distillation, our framework enables sampling without explicitly preparing the high-quality state, thereby removing the requirement for large quantum memory. The sampling cost of our methods scales directly with the negativity of the quasi-probability, not only circumventing the aforementioned discontinuity in the small negativity regime, but also providing a novel operational interpretation of the negativity of the quasi-probability decomposition, also known as the robustness measure of quantum

resources [5, 12, 13]. We further support the practical significance of our approach by numerical simulation and find that our method requires significantly fewer samples compared to the naive probability-estimation-based approach in several important scenarios such as error mitigation, entanglement distillation, and magic state distillation. Together with the high generality of our framework, our results open the door to use the power of quasi-probability methods in many relevant scenarios.

Preliminaries. — We consider the setting where one aims to run a protocol that requires a certain state under physical restriction. The framework of resource theories [1] lends itself to such scenarios. In particular, we let $\mathcal{O}$ denote the set of operations that are accessible in the given setting and $\mathcal{F}$ denote the set of quantum states that can be prepared by the operation in $\mathcal{O}$. Our framework is fully general as long as the sets $\mathcal{O}$ and $\mathcal{F}$ are finite dimensional and convex. We also note that, by definition of $\mathcal{F}$, it is ensured that an operation in $\mathcal{O}$ can never map a state in $\mathcal{F}$ to another state outside of $\mathcal{F}$, reflecting the natural operational restriction.

If the desired state ρ required in the protocol is not directly available in the given setting, i.e., $\rho \notin \mathcal{F}$, one can aim to simulate the process by only using states in $\mathcal{F}$. The framework of the virtual quantum resource distillation [10, 11] provides a way of accomplishing this when the goal of the tasks is to estimate the expectation value of some observable. The core idea is to express the resource state ρ in terms of the linear combination of the states in $\mathcal{F}$ as $\rho = \sum_i c_i \sigma_i$, $\sigma_i \in \mathcal{F}$, $c_i \in \mathbb{R}$. The crucial part is that some c_i 's can be negative, allowing it to express any state in the linear span of $\mathcal{F}$, which is typically much larger than the set $\mathcal{F}$ itself. Noting also the unit trace condition for quantum states, c_i 's need to be normalized as $\sum_i c_i = 1$. This ensures that $\{c_i\}_i$ constructs a *quasi-probability* distribution, which sums to one but each value can be negative. Because of the convexity of $\mathcal{F}$, the quasi-probability decomposition can generally be written in the form $\rho = c_+ \sigma_+ - c_- \sigma_-$ with positive constants $c_{\pm} \geq 0$ satisfying $c_+ - c_- = 1$ and states $\sigma_{\pm} \in \mathcal{F}$. Given the quasi-probability decomposition, the expectation value estimation can be done by employing importance sampling, using the number of samples that scales with the absolute sum $\gamma := c_+ + c_- = 1 + 2c_-$ of the quasi-probability, which grows with the size of the negativity c_- in the quasi-probability decomposition. As the quasi-probability decomposition is generally not unique, it is meaningful to consider the optimal decomposition that minimizes the negativity. This minimized negativity is also known as the robustness measure of quantum resources [5, 12, 13], which serves as a resource quantifier with respect to the set $\mathcal{F}$ and $\mathcal{O}$ of free states and operations. We refer readers to Sec. 1 of the Supplemental Material for more detailed descriptions of the virtual quantum resource distillation.

This framework encompasses many scenarios by flexibly choosing the set $\mathcal{F}$, e.g., stabilizer or positive Wigner states for classical simulation of quantum circuits [5, 32, 33], separable states for entanglement distillation [2], the states preparable by local subcircuits for circuit knitting [16, 34], and the states produced by the inverse map of the noise channel for an error mitigation method known as probabilistic error cancellation [14, 35, 36]. Importantly, this framework goes beyond these standard examples when some degrees of resources can be created in

the given setting. For instance, in the context of entanglement distillation, if we have access to a device that can create weakly entangled states, the virtual quantum resource distillation admits more efficient entanglement distillation by taking the set of weakly entangled states for $\mathcal{F}$ rather than the set of separable states, allowing us to incorporate the full capability of the given setting.

Weak resource distillation. — We now aim to lift the expectation value estimation realized in the virtual quantum resource distillation to the weak simulation of the process involving the resource state. Recall that weak simulation aims to obtain a sample from a distribution $\{\tilde{p}_x\}_x$ that is close to the true distribution $\{p_x\}_x$ in the total variation distance as $d_{\text{tv}}(p, \tilde{p}) = \frac{1}{2} \sum_x |p_x - \tilde{p}_x| \leq \epsilon$ with probability at least $1 - \delta$, where ϵ and δ are some small constants characterizing the performance of the simulation. In the context of resource distillation, we are generally interested in the samples from a resource state ρ . The true probability distribution in this case is $p_x = \langle x | \rho | x \rangle$ where $\{|x\rangle\}_x$ is the computational basis. We aim to get a sample from the distribution close to p_x by using N samples of the states in $\mathcal{F}$. If $\rho \in \mathcal{F}$, the sampling cost N is trivially one, because the state $\rho \in \mathcal{F}$ can directly be prepared by the given device. On the other hand, if $\rho \notin \mathcal{F}$, one generally needs a larger number N of samples from the available states $\mathcal{F}$ to construct a desired sampler. We call this sampling process *weak distillation* of a resource state ρ and call the required number N the *sampling cost* for weak resource distillation. The major question then is to characterize the sampling cost N with respect to the target trace distance error ϵ and the failure probability δ .

Let us begin with the most intuitive approach based on the probability estimation, which first estimates the probability distribution $\{\langle x | \rho | x \rangle\}_x$ using the virtual quantum resource distillation and then samples from it. This approach was discussed in the context of error mitigation [31], where the mean-square error is considered. We provide a detailed analysis of this approach with trace distance error—a more operationally meaningful error quantifier—applicable to the general setting beyond error mitigation.

Proposition 1. *For a quantum state written as $\rho = c_+ \sigma_+ - c_- \sigma_-$ with $\sigma_{\pm} \in \mathcal{F}$ and $c_{\pm} \geq 0$, the probability-estimation-based method realizes the weak distillation of state ρ with trace distance accuracy ϵ with probability at least $1 - \delta$ by using*

$$N \leq \frac{\gamma^2}{4\epsilon^2} \left(2^{\frac{1}{2} H_{\frac{1}{2}}(q_x)} + \sqrt{8 \log \frac{2}{\delta}} \right)^2 \quad (1)$$

samples of σ_+ and σ_- , where $q_x = \frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-$, $p_x^{\pm} = \langle x | \sigma_{\pm} | x \rangle$ and $\gamma = c_+ + c_-$. $H_{\alpha}(P_x)$ is the α -Rényi entropy defined as

$$H_{\alpha}(P_x) = \frac{1}{1 - \alpha} \log_2 \left(\sum_x P_x^{\alpha} \right). \quad (2)$$

Proof can be found in Sec. 2 of the Supplemental Material. Proposition 1 holds for any quasi-probability decomposition $\rho = c_+ \sigma_+ - c_- \sigma_-$, and it can be minimized to provide the smallest

sample cost, in which case γ coincides with the robustness resource measure [13] with respect to the set $\mathcal{F}$. We also note that, we have $H_{\frac{1}{2}}(q_x) \sim n$ in the worst case, and the sampling cost grows exponentially with n . On the other hand, if we somehow know that $H_{\frac{1}{2}}(q_x)$ is small, the sampling cost can be suppressed accordingly.

This direct method has a major drawback. If we consider the scenario where the target state ρ is close to a free state or even a free state itself, we could simply use ρ to directly obtain a sample from the output distribution. However, the above method still needs to estimate the probability distribution using a substantial number of states regardless of the small negativity, resulting in discontinuous behavior around $c_- = 0$ as can be seen in (7).

To address this discontinuous sampling cost, we propose the main framework of this work to perform weak resource distillation. To this end, we first realize that the core problem underlying the weak resource distillation is entirely classical—we would like to sample from $\{p_x\}_x$ while only having sampling access to other distributions $\{q_x\}_x$. This is the standard setting addressed by the method known as rejection sampling [37] and has also recently been employed in the context of classical simulation [38].

The idea of rejection sampling is to get a sample from the available distribution q_x and accept the sample with probability proportional to the fraction $\frac{p_x}{q_x}$ of acceptance ratio. In our setting, this can be done by sampling from the distribution $q_x = \frac{c_+}{c_+ + c_-} \langle x | \sigma_+ | x \rangle + \frac{c_-}{c_+ + c_-} \langle x | \sigma_- | x \rangle$ and accept the sample with respect to $p_x = \langle x | \rho | x \rangle$. The problem caused by the difference between our setting and the standard rejection sampling is that we do not know the value of the acceptance ratio $\frac{p_x}{q_x}$ beforehand, which prevents us from deciding whether to accept the sample. We therefore estimate the acceptance ratio using some number of states in $\mathcal{F}$. The crucial observation we employ is that we can control the accuracy of the simulation by appropriately choosing the estimation accuracy of the acceptance ratio, while one does not need to estimate the acceptance ratio accurately when c_- is small. This flexible adjustment of the accuracy can be done because we have access to the value of $c_{\pm}$ while not knowing the values of p_x or q_x .

The sampling cost to construct a sampler based on this approach can be characterized as follows. We provide a detailed procedure of the protocol and the proof of Theorem 2 in Sec. 3 of the Supplemental Material.

Theorem 2. *For a quantum state written as $\rho = c_+ \sigma_+ + c_- \sigma_-$ with $\sigma_{\pm} \in \mathcal{F}$ and $c_{\pm} \geq 0$, the weak distillation of state ρ with trace distance accuracy ϵ with probability at least $1 - \delta$ can be accomplished by using*

$$N \leq 8c_- \gamma \left(\frac{1 + \epsilon}{\epsilon} \right)^2 \left(2^{\frac{1}{2} H_{\frac{1}{2}}(p_x^-)} + \delta_1^{-\frac{1}{2}} \right)^2 + M(\gamma, \delta_2, \epsilon) \quad (3)$$

samples of σ_+ and σ_- , where $p_x^{\pm} = \langle x | \sigma_{\pm} | x \rangle$, $\gamma = c_+ + c_-$ and $(1 - \delta_1)(1 - \delta_2) = 1 - \delta$. Also, M is an integer that satisfies

$$M(\gamma, \delta_2, \epsilon) \geq \frac{\log \left(\frac{1}{\delta_2} \right)}{\log \left(\frac{(1 + \epsilon)\gamma}{(1 + \epsilon)c_- + \epsilon\gamma} \right)}. \quad (4)$$

Similar to the probability distribution estimation method, the bound can be tightened if one chooses the optimal quasi-probability decomposition minimizing the negativity c_- .

The first term in (3) corresponds to the sampling cost to estimate the acceptance ratio $\frac{p_x}{q_x}$, and the second term is the general overhead incurred on the rejection sampling provided the estimated acceptance ratio, whose contribution is typically negligibly small compared to the first term. (See Sec. 3 A in the Supplemental Material for details.) Importantly, the first term is now proportional to c_- , which ultimately becomes zero when ρ is a free state. Together with the second term that approaches 1 when $c_- \rightarrow 0$, the overall cost in (3) reduces to 1 in the limit of $c_- \rightarrow 0$. In this case, we get that the acceptance ratio always becomes 1, corresponding to the procedure that makes a measurement on ρ and accepts any measurement outcome at all times. This clarifies that, unlike the direct probability-estimation-based method characterized in Proposition 1, our protocol is smoothly connected to the case of $c_- = 0$ and efficiently takes into account the overhead due to the negativity of quasi-probability, particularly in the regime of small negativity.

On the other hand, our bound in (3) comes with a polynomial scaling with respect to the failure probability δ unlike the logarithmic scaling seen in (1). In Sec. 5 of the Supplemental Material, we show another bound of our framework that has an exponentially better scaling with δ , which ensures our framework still inherently has $O(\log \frac{1}{\delta})$ dependency, while the bound loses c_- proportionality.

Our framework has a practically interesting feature: if we know either of the entropies of $\{p_x^+\}_x$ or $\{p_x^-\}_x$, we can readily apply the bound in (3). The entropies may be derived if either σ_+ or σ_- is well known, or the entropy is classically efficiently computable. This can be accomplished by decomposing either of $\sigma_{\pm}$ as a known state or a classical simulatable state. On the other hand, the probability-estimation-based method characterized in Proposition 1 requires the knowledge of both entropies of $\{p_x^+\}_x$ and $\{p_x^-\}_x$.

Our methods only require preparing one state at a time, similar to the virtual quantum resource distillation framework. We therefore avoid the need for joint operations across multiple copies of states, which greatly reduces the experiential difficulty. The requirement of preparing many copies of a state and performing joint operations on all of them makes conventional distillation experimentally challenging, while our framework avoids this difficulty. Additionally, there are many no-go theorems constraining distillation protocols. For example, one cannot distill a pure state with zero error from a highly mixed state, no matter how many copies we can prepare [39–41]. Our framework does not suffer from such no-go theorems; we can “distill” any state as long as we know its quasi-probability decomposition.

Applications.— Having the general framework in place, we now consider specific scenarios that are of practical interest and compare our method based on rejection sampling and the intuitive method based on probability estimation.

Error mitigation is of central interest for near-term quantum devices. One application of our frameworks is probabilistic

FIG. 1. Comparison between the total variation distance of two frameworks with respect to sampling cost. For all plots, we take the average of 20 outcomes. Blue line named “Rejection TVD” represents the numerical simulation’s outcome of the actual total variation distance we obtain with our framework. The orange line named “Estimation TVD” represents the outcome with the probability distribution estimation method. Dotted lines represent the tightest bounds shown in the theorems. Since the total variation distance is at most 1, we take 1 as the maximum value for both bounds. We use $\delta = 0.1$. (a) The simulation of error mitigation for local depolarizing noise. For each qubit, we use the decomposition $\rho = \frac{1}{1-p}\mathcal{E}(\rho) - \frac{p}{1-p}\frac{I}{2}$ where $\mathcal{E}(\cdot)$ is the local depolarizing noise channel. We take $p = 0.005$, and prepared a random 4 qubit system. (b) The simulation of entanglement distillation. The goal is to obtain a noiseless n -pair of Bell states. Consider the decomposition $\Phi^{\otimes n} = \frac{1}{1-p}\rho_p^n - \frac{p}{1-p}\frac{I - \Phi^{\otimes n}}{2^{2n}-1}$ where $\rho_p^n = (1-\alpha)\Phi^{\otimes n} + \alpha\frac{I - \Phi^{\otimes n}}{2^{2n}-1}$ is the isotropic state, we simulate the setting for 10 qubit case with $p = 0.01$. (c) The simulation of the 5 qubit T -doped IQP circuit, which has 5 T gates in the circuit. With the dephased T state defined as $\rho_p^T = (1-p)T + p\frac{I}{2}$, and dephased flipped T state $\rho_p^{\bar{T}}$, we know the decomposition $T = \frac{2-p}{2(1-p)}\rho_p^T - \frac{p}{2(1-p)}\rho_p^{\bar{T}}$. We implement the T gate with T -state injection, with the decomposition parameter set to $p = 0.1$.

error cancellation [14, 35, 36]. Let $\mathcal{E}(\cdot)$ be the effective error channel of the whole circuit. If one could apply the inverse channel, then the output would just be the ideal noiseless circuit we wanted to apply. This cannot be done generally, as the inverse noise map is commonly not a CPTP map. For any output state ρ of the noisy circuit, when we can come up with the decomposition of the inverse channel of $\mathcal{E}(\cdot)$ as $\mathcal{E}^{-1}(\rho) = c_+\Lambda_+(\rho) - c_-\Lambda_-(\rho)$ ($c_{\pm} \geq 0$, $c_+ - c_- = 1$) where $\Lambda_{\pm}$ is CPTP map so that it is physically implementable, our framework allow to weak simulate $\mathcal{E}^{-1}(\rho)$ by taking $\sigma_{\pm} = \Lambda_{\pm}(\rho)$. In Fig. 1(a), we consider mitigating local depolarizing noise and plot analytical upper bounds in Proposition 1 and Theorem 2, as well as actual sampling cost numerically obtained by simulating both methods. We also apply our framework to entanglement distillation (Fig. 1(b)). In the case of entanglement distillation, we aim to prepare a Bell state $|\Phi\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$. Although separable states are usually considered as free states in the theory of entanglement [7], we consider the setting where our experiment can produce isotropic states, $\rho_p^n = (1-p)\Phi^{\otimes n} + p\frac{I - \Phi^{\otimes n}}{2^{2n}-1}$ and can perform LOCC. We also consider the scenario of magic state distillation, which is of major importance for fault-tolerant quantum computation [4, 5]. The goal of this task is to prepare an ideal $|T\rangle = \frac{1}{\sqrt{2}}(|0\rangle + e^{\frac{i\pi}{4}}|1\rangle)$, which enables us to implement T gate through a teleportation gadget. As in Refs. [42, 43], we consider the setting where partially dephased T states are available. We then consider sampling from an IQP circuit [26, 44], where we can only prepare a dephased T state instead of an ideal one. The sampling cost to approximately sample from the output distribution can be found in Fig. 1(c).

Interestingly, all scenarios in Fig. 1 share common behavior.

One is that our protocol has a lower total variation distance and a better upper bound than the probability-estimation-based method in the studied settings, particularly in regions with small sample sizes. The reason is that we cannot construct meaningful probability distributions for the probability distribution estimation method with such a small sampling size. On the other hand, our framework already allows us to access the probability distribution $\{\frac{c_+}{c_++c_-}p_x^+ + \frac{c_-}{c_++c_-}p_x^-\}_x$ without any sampling cost. For small c_- , that is already a good approximation of the target distribution, and therefore it provides a better outcome.

The other is that, for our framework, we observe that the total variation distance increases as the sampling number increases from 0, but it eventually decreases. By definition, the acceptance ratio changes drastically when the sample size is small. It starts from 1, but can be 0 by getting only one sample from σ_- . This sudden change sometimes makes the deviation between the ideal and empirical rates larger. As the number of samples increases, this change becomes smoother and ultimately improves the total variation distance. The extent of this bump-shaped behavior depends on the setting. When $c_{\pm}$ are large, the initial probability distribution is far from the target distribution, and obtaining a sample can improve the total variation distance, even when the acceptance ratio changes substantially. Also, when $\{\langle x|\sigma_-|x\rangle\}_x$ has a large entropy, the jump of the acceptance ratio is likely to happen everywhere.

Conclusions.— We introduced a framework of weak resource distillation, providing sampling access to a general class of quasi-probability methods, which previously only allowed for expectation value estimation. Our framework inherits the wide applicability of the quasi-probability-based method, including

entanglement distillation, classical simulation, error mitigation, and circuit knitting. We show that our method based on rejection sampling has distinct features such as directly scaling with the negativity of the quasi-probability, which drastically reduces the sampling cost compared to the direct approach based on probability estimation. We further supported the practical relevance of our framework through numerical simulation, where we demonstrated that our approach significantly outperforms the direct probability-estimation-based approach in many relevant settings, particularly reflecting the efficient construction of our method in terms of the negativity of quasi-probability.

Given the gap between the upper bound and the practical observed performance, a future alleyway is to tighten the analytical bounds. Also, all results presented in this work deal implicitly with finite-dimensional convex sets of available states.

Nonetheless, there are many instances where quasi-probability distributions are used in infinite-dimensional systems [23, 45–47], motivating the extension of our framework to infinite-dimensional systems or systems with non-convex sets of free states [48].

Supplemental Material

I. LIST OF SYMBOLS

$\text{Prob}(X = x)$	Probability of obtaining a random variable X as x
$\text{Prob}(X = x Y)$	Conditional probability given Y
$\mathbb{E}[X]$	Expectation value of the random variable X
$\mathbb{E}[X Y]$	Conditional expectation value of X for given Y
$\mathbb{V}[X]$	Variance of the random variable X
$\mathbb{V}[X Y]$	Conditional variance value of X for given Y
$\text{Cov}(X, Y)$	Covariance between X and Y
$\ \cdot\ _1$	Trace norm
$\lceil x \rceil$	The ceiling function, the minimum integer no less than x
$\gamma := c_+ + c_-$	
$p_x^\pm := \langle x \sigma_\pm x\rangle$	
$p_x := c_+ \langle x \sigma_+ x\rangle - c_- \langle x \sigma_- x\rangle$	
$q_x := \frac{c_+}{c_+ + c_-} \langle x \sigma_+ x\rangle + \frac{c_-}{c_+ + c_-} \langle x \sigma_- x\rangle$	

1. PROBABILITY ESTIMATION WITH VIRTUAL QUANTUM RESOURCE DISTILLATION

In this section, we introduce the general idea of virtual quantum resource distillation [10, 11]. The aim of this framework is to estimate the expectation value of an observable M . Suppose our state of interest is ρ' and that we can access another state ρ which is β close to $\rho'^{\otimes m}$, i.e. $\frac{1}{2}\|\rho - \rho'^{\otimes m}\|_1 \leq \beta$. Then, for an observable M with $-\frac{I}{2} \leq M \leq \frac{I}{2}$, which can be satisfied by normalization, we know that

$$\frac{1}{2}|\text{Tr}[M^{\otimes m}\rho] - \text{Tr}[M^{\otimes m}\rho'^{\otimes m}]| \leq \frac{1}{2}\|\rho - \rho'^{\otimes m}\|_1 \leq \beta. \quad (5)$$

This fact ensures that if we can estimate the expectation value $\text{Tr}[M^{\otimes m}\rho]$ within the error of ϵ , we can estimate the target expectation value $\text{Tr}[M^{\otimes m}\rho']$ within the error of $\beta + \epsilon$.

Now, we recap the procedure of simulating the expectation value $\text{Tr}[M^{\otimes m}\rho]$. We denote the set of free states as $\mathcal{F}$ and the set of free operations as $\mathcal{O}$. Any free state that is acted by a free operation is also a free state, i.e. $\Lambda(\rho) \in \mathcal{F}$ for all $\rho \in \mathcal{F}, \Lambda \in \mathcal{O}$. We assume the state ρ , which is β closed to $\rho'^{\otimes m}$, can be written using quasi-probability decomposition as

$$\rho = c_+\sigma_+ - c_-\sigma_- \quad (\sigma_\pm \in \mathcal{F}, c_\pm \geq 0). \quad (6)$$

We can then estimate the expectation value using this decomposition as follows. The procedure starts with flipping a biased coin that lands heads with probability $\frac{c_+}{c_+ + c_-}$ and tails with probability $\frac{c_-}{c_+ + c_-}$. When the coin lands heads, prepare σ_+ and measure m commuting observable $M \otimes I^{\otimes m-1}, I \otimes M \otimes I^{\otimes m-2}, \dots, I^{\otimes m-1} \otimes M$, multiply all values by $\gamma = c_+ + c_-$, and store all the measurement outcome in the classical register. When the coin lands tails, use σ_- and measure the m observables and multiply all values by $-\gamma$, store all values in the classical register. Repeat this procedure and take the sample average of the outcomes stored in the classical register. Then, the Hoeffding bound [49] suggests that the number of samples required to estimate $\text{Tr}[M\rho']$ within the error of $\beta + \epsilon$ with at least success probability $1 - \delta$ is upper bounded by $O((\gamma^2/m) \log(1/\delta)/\epsilon^2)$.

In particular, if we take the observable M as a projector onto the computational basis $|x\rangle\langle x|$, we can estimate the probability distribution $\{p_x\}_x = \{\langle x|\rho|x\rangle\}_x$. This can be used for the probability distribution estimation method mentioned in the main text.

2. PROOF OF PROPOSITION 1

In this section, we prove Proposition 1 of the main text. We repeat the proposition for the reader's convenience.

Proposition 1. For a quantum state written as $\rho = c_+\sigma_+ - c_-\sigma_-$ with $\sigma_\pm \in \mathcal{F}$ and $c_\pm \geq 0$, the probability-estimation-based method realizes the weak distillation of state ρ with trace distance accuracy ϵ with probability at least $1 - \delta$ by using

$$N \leq \frac{\gamma^2}{4\epsilon^2} \left(2^{\frac{1}{2}H_{\frac{1}{2}}(q_x)} + \sqrt{8 \log \frac{2}{\delta}} \right)^2 \quad (7)$$

samples of σ_+ and σ_- , where $q_x = \frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-$, $p_x^\pm = \langle x | \sigma_\pm | x \rangle$ and $\gamma = c_+ + c_-$. $H_\alpha(P_x)$ is the α -Rényi entropy defined as

$$H_\alpha(P_x) = \frac{1}{1-\alpha} \log_2 \left(\sum_x P_x^\alpha \right). \quad (8)$$

Proof. This can be shown by using ideas presented in Ref. [50]. However, contrary to Ref. [50], we are interested in the setting of quasi-probability distributions, which yields both positive and negative outcomes by sampling. Here, we extend the analysis to this setting.

From Ref. [50, Sec. 1], we know

$$\mathbb{E}[d_{\text{TV}}(p, \tilde{p})] \leq \frac{1}{2} \sum_x \sqrt{\mathbb{E}[(p_x - \tilde{p}_x)^2]} \quad (9)$$

where $\tilde{p}_x$ is empirical distribution that we estimate. We get

$$\begin{aligned} \mathbb{E}[(p_x - \tilde{p}_x)^2] &= \mathbb{V}[\tilde{p}_x] \\ &= \frac{\gamma^2}{N} \left(\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^- - \left(\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^- \right)^2 \right) \\ &\leq \frac{\gamma^2}{N} \left(\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^- \right) = \frac{\gamma^2}{N} q_x. \end{aligned} \quad (10)$$

Therefore, we obtain

$$\mathbb{E}[d_{\text{TV}}(p, \tilde{p})] \leq \frac{\gamma}{2\sqrt{N}} \sum_x \sqrt{q_x}. \quad (11)$$

With $t > 0$, when we take N as

$$N \geq \frac{\gamma^2}{4s^2} \left(\sum_x \sqrt{q_x} \right)^2, \quad (12)$$

it is ensured that $\mathbb{E}[d_{\text{TV}}(p, \tilde{p})] \leq s$.

Also, let N be the total number of samples. Changing one sample from another cannot change the total variation distance more than $\frac{2\gamma}{N}$, which is two times as large as the one in Ref. [50] due to the fact that we can get a negative value as a sampling outcome. This gives

$$\begin{aligned} \delta := \text{Prob}(|d_{\text{TV}}(p, \tilde{p}) - \mathbb{E}[d_{\text{TV}}(p, \tilde{p})]| \geq t) &\leq 2 \exp \left[-\frac{2t^2}{\sum_{n=1}^N \left(\frac{2\gamma}{N} \right)^2} \right] \\ &= 2 \exp \left(-\frac{Nt^2}{2\gamma^2} \right) \end{aligned} \quad (13)$$

where the dummy parameter n in the denominator represents each sample. This means by taking N as

$$N \geq \frac{2\gamma^2}{t^2} \log \frac{2}{\delta}, \quad (14)$$

the inequality $|d_{\text{TV}}(p, \tilde{p}) - \mathbb{E}[d_{\text{TV}}(p, \tilde{p})]| \geq t$ holds at least probability $1 - \delta$. Overall, we know that, as long as we take N as

$$N \geq \max \left\{ \frac{\gamma^2}{4s^2} \left(\sum_x \sqrt{q_x} \right)^2, \frac{2\gamma^2}{t^2} \log \frac{2}{\delta} \right\}, \quad (15)$$

we can estimate the probability distribution with total variation distance smaller than $t + s$ at least probability $1 - \delta$. Consider minimization of the bound with respect to r by setting $s = r\epsilon$, $t = (1 - r)\epsilon$ with the target error ϵ . This minimization is accomplished by choosing r 's such that both arguments inside the $\max\{\cdot\}$ are equal. By doing so, we get the upper bound in Proposition 1. $\square$

3. NEW FRAMEWORK

In this section, we provide a detailed explanation of our new framework based on rejection sampling [37].

A. Rejection sampling

Let us begin by reviewing the rejection sampling. Rejection sampling is a general protocol for obtaining a sample from the probability distribution $\{p_x\}_x$ using a support probability distribution $\{q_x\}_x$. We consider $q_x \neq 0$ for all x such that $p_x \neq 0$. Let us define the set of numbers $R \equiv \{R_x\}_x$ as $R_x = \frac{p_x}{K q_x}$ where $K = \sup_x \frac{p_x}{q_x}$. The first step of the protocol is to draw a sample from the support probability distribution $\{q_x\}_x$, denoted x . We accept the sample with probability R_x . Otherwise, we reject the sample and get another sample from the support until the sample is accepted. Following this way, the accepted sample follows the target probability distribution $\{p_x\}_x$.

The last step can be seen as follows. Let X be a random variable obtained by a rejection sampling framework. Also, define a random variable Y as the one obtained from $\{q_x\}_x$. The probability that we get x as a sample given that we know the sample gets accepted can be calculated as

$$\begin{aligned} \text{Prob}(X = x) &= \text{Prob}(Y = x | Y \text{ accepted}) \\ &= \frac{\text{Prob}(Y = x, Y \text{ accepted})}{\text{Prob}(Y \text{ accepted})}. \end{aligned} \quad (16)$$

Because we accept Y with probability $\left\{ \frac{p_x}{K q_x} \right\}_x$, we can evaluate the numerator as

$$\begin{aligned} \text{Prob}(Y = x, Y \text{ accepted}) &= \text{Prob}(Y = x | Y \text{ accepted}) \text{Prob}(Y \text{ accepted}) \\ &= \frac{p_x}{K q_x} q_x = \frac{p_x}{K}. \end{aligned} \quad (17)$$

Also, we can evaluate the denominator as

$$\begin{aligned} \text{Prob}(Y \text{ accepted}) &= \sum_x \text{Prob}(Y = x, Y \text{ accepted}) \\ &= \sum_x \frac{p_x}{K} = \frac{1}{K}. \end{aligned} \quad (18)$$

Thus, we obtain a sample of x with probability p_x .

Suppose that we sample M times from $\{q_x\}_x$. Then, (18) tells that the probability that none of the samples is accepted is $\left(1 - \frac{1}{K}\right)^M$. Therefore, a sufficient M such that the sample is accepted (i.e., obtaining a sample from $\{p_x\}_x$) at least probability δ is given by $\left(1 - \frac{1}{K}\right)^M \leq \delta$, which gives $M \geq \frac{\log\left(\frac{1}{\delta}\right)}{\log\left(\frac{K}{K-1}\right)}$. The minimum M satisfy this condition is

$$M = \left\lceil \frac{\log\left(\frac{1}{\delta}\right)}{\log\left(\frac{K}{K-1}\right)} \right\rceil. \quad (19)$$

B. Procedure of our framework

We now provide the procedure of our framework to construct a sampler. The first step is to estimate the set $\{R_x\}_x$ of acceptance ratios in order to use rejection sampling.

We first prepare the lists of numbers $\{N_x^+\}_x$ and $\{N_x^-\}_x$ in classical registers. We take $N_x^\pm = 0$ for all x . Then we flip a biased coin that gives heads with probability $\frac{c_+}{c_+ + c_-}$ and tails with probability $\frac{c_-}{c_+ + c_-}$. When we obtain heads, we measure σ_+ , get measurement outcome x with probability $\langle x | \sigma_+ | x \rangle$, and add one to N_x^+ . Similarly, when we obtain tails, we use σ_- and do computational basis measurement, add 1 to N_x^- when we get x as the measurement outcome. After repeating this process N times, compute $\left\{ \frac{N_x^+ - N_x^-}{N_x^+ + N_x^-} \right\}_x$ and replace it with zero when the value is negative. When $N_x^+ + N_x^- = 0$, we define the rate as 1. We use this set of values as $R \equiv \{R_x\}_x$.

C. The framework under an estimated acceptance ratio

After having prepared our rejection rates R , we use them for rejection sampling. In the end, we want to obtain samples from a probability distribution that is ϵ close in total variation distance to the ideal distribution with at least probability $1 - \delta$.

In the following, we find the requirements to obtain the desired simulator using the set $\{R_x\}_x$ of acceptance ratios that satisfy $\frac{p_x}{Kq_x} = R_x + \epsilon_x$. Let $\{\tilde{p}_x\}_x$ be the probability distribution obtained by rejection sampling using these alternative values. $\{\tilde{p}_x\}_x$ can be calculated as

$$\begin{aligned} \text{Prob}(X = x) &= \frac{\text{Prob}(Y = x, Y_{\text{accepted}})}{\text{Prob}(Y_{\text{accepted}})} \\ &= \frac{R_x q_x}{\sum_y R_y q_y} = \frac{\frac{p_x}{K} - \epsilon_x q_x}{\sum_y (\frac{p_y}{K} - \epsilon_y q_y)} \\ &= \frac{p_x - K \epsilon_x q_x}{1 - K \sum_y \epsilon_y q_y}. \end{aligned} \quad (20)$$

Note that to consider this as a valid probability, we require $K \sum_x \epsilon_x q_x < 1$. As we see later, this condition is always satisfied under the requirements we impose. We can calculate the total variation distance between $\{p_x\}_x$ and $\{\tilde{p}_x\}_x$ as

$$\begin{aligned} d_{\text{TV}}(p, \tilde{p}) &= \frac{1}{2} \sum_x |p_x - \tilde{p}_x| \\ &= \frac{1}{2} \sum_x \left| p_x - \frac{p_x - K \epsilon_x q_x}{1 - K \sum_y \epsilon_y q_y} \right| \\ &= \frac{1}{2} \sum_x \left| \frac{K \epsilon_x q_x + K p_x \sum_y \epsilon_y q_y}{1 - K \sum_y \epsilon_y q_y} \right| \leq \frac{1}{2} \left(\sum_x \left| \frac{K \epsilon_x q_x}{1 - K \sum_y \epsilon_y q_y} \right| + \sum_x \left| \frac{K p_x \sum_y \epsilon_y q_y}{1 - K \sum_y \epsilon_y q_y} \right| \right) \\ &\leq \frac{K \sum_x |\epsilon_x| q_x}{1 - K \sum_x |\epsilon_x| q_x}, \end{aligned} \quad (21)$$

where we used the triangle inequality twice. If the last term of Eq. (21) is smaller than ϵ with probability at least $1 - \delta$, then the total variation distance d_{TV} is upper bounded by ϵ with probability at least $1 - \delta$ as well, meaning we can prepare the desired simulator under this condition. Moreover, the condition is equivalently written as

$$K \sum_x |\epsilon_x| q_x \leq \frac{\epsilon}{1 + \epsilon} := \tilde{\epsilon} < 1. \quad (22)$$

This implies that Eq. (20) is a valid probability since $K \sum_x \epsilon_x q_x < 1$ because of Eq.(22).

We also derive a slightly different condition for a later discussion. In the framework we proposed, we first compute the set of values $\left\{ \frac{N_x^+ - N_x^-}{N_x^+ + N_x^-} \right\}_x$ which could contain negative values. Note that when $N_x^+ + N_x^- = 0$, we take this value as 1. We then replace every negative value element with 0 to get the final $\{R_x\}_x$. Let $f(\cdot)$ as the function to obtain $\{R_x\}_x$ i.e. $f\left(\frac{N_x^+ - N_x^-}{N_x^+ + N_x^-}\right) = R_x$. We can equivalently write

$$\frac{p_x}{Kq_x} = \frac{N_x^+ - N_x^-}{N_x^+ + N_x^-} + \epsilon'_x. \quad (23)$$

Because $|\epsilon'_x| \geq |\epsilon_x|$ for all x , we know that

$$d_{\text{tv}}(p, \tilde{p}) \leq \frac{K \sum_x |\epsilon_x| q_x}{1 - K \sum_x |\epsilon_x| q_x} \leq \frac{K \sum_x |\epsilon'_x| q_x}{1 - K \sum_x |\epsilon'_x| q_x}. \quad (24)$$

This means that both

$$K \sum_x |\epsilon_x| q_x \leq \tilde{\epsilon}, \quad K \sum_x |\epsilon'_x| q_x \leq \tilde{\epsilon} \quad (25)$$

are valid conditions to make the desired simulator. We will use either of these conditions depending on the situation.

Lastly, because

$$\begin{aligned} K &= \sup_x \frac{c_+ \langle x | \sigma_+ | x \rangle - c_- \langle x | \sigma_- | x \rangle}{\frac{c_+}{c_+ + c_-} \langle x | \sigma_+ | x \rangle + \frac{c_-}{c_+ + c_-} \langle x | \sigma_- | x \rangle} \\ &\leq c_+ + c_- = \gamma \end{aligned} \quad (26)$$

we use K as γ . We might be able to use a smaller K , and it will give us a tighter bound on sampling cost, but for convenience we choose $K = \gamma$.

The above analysis ensure that if we take sufficiently large N in Sec. 3 B such that ϵ_x satisfies (25), we can construct the desired simulator. In the next section, we find how such N can be characterized.

After estimating the acceptance ratio, we run rejection sampling using some additional number of samples. Suppose that we sample M times and conduct rejection sampling with the determined set of values $\{R_x\}_x$. A sufficient M such that at least one sample is accepted with a probability of at least Δ is given by

$$\begin{aligned} (1 - \text{Prob}(Y_{\text{accepted}}))^M &\leq \left(1 - \frac{1}{\gamma} + \sum_x \epsilon_x q_x\right)^M \\ &\leq \left(1 - \frac{1}{\gamma} + \sum_x |\epsilon_x| q_x\right)^M \\ &\leq \left(1 - \frac{1}{\gamma} + \tilde{\epsilon}\right)^M. \end{aligned} \quad (27)$$

Therefore, a sufficient M such that the sample is accepted (i.e., obtaining a sample from $\{p_x\}_x$) at least probability δ' is given by

$$M \geq \left(\log \left(\frac{\gamma}{(1 + \tilde{\epsilon})\gamma - 1} \right) \right)^{-1} \log \left(\frac{1}{\delta'} \right) = \left(\log \left(\frac{(1 + \epsilon)\gamma}{(1 + \epsilon)c_- + \epsilon\gamma} \right) \right)^{-1} \log \left(\frac{1}{\delta'} \right). \quad (28)$$

The minimum M satisfying this condition is

$$M = \left\lceil \left(\log \left(\frac{(1 + \epsilon)\gamma}{(1 + \epsilon)c_- + \epsilon\gamma} \right) \right)^{-1} \log \left(\frac{1}{\delta'} \right) \right\rceil. \quad (29)$$

Note that when $c_-, \epsilon \rightarrow 0$, we get that M is 1.

4. PROOF OF THEOREM 2

In this section, we obtain a sufficient number of samples used in the estimation stage described above. Together with the additional samples (29) used for running the rejection sampling, it serves as a proof of Theorem 2 in the main text. Here, we provide several forms of a sufficient number of total samples, which shows Theorem 2 as its consequence.

Theorem 3 (Theorem 2 in the main text). *Let S be*

$$S = \left(\sum_x \sqrt{\frac{c_+ c_- p_x^+ p_x^-}{c_+ p_x^+ + c_- p_x^-}} \right)^2. \quad (30)$$

For a quantum state written as $\rho = c_+\sigma_+ - c_-\sigma_-$ with $\sigma_{\pm} \in \mathcal{F}$ and $c_{\pm} \geq 0$, the weak distillation of state ρ with trace distance accuracy ϵ with probability at least $1 - \delta$ can be accomplished by using

$$\begin{aligned} N &\leq \min_{(1-\delta_1)(1-\delta_2) \leq 1-\delta} \left\{ 8\gamma \left(\frac{1+\epsilon}{\epsilon} \right)^2 \left(\sqrt{S} + \sqrt{\frac{c_-}{\delta_1}} \right)^2 + M \right\} \\ &\leq \min_{(1-\delta_1)(1-\delta_2) \leq 1-\delta} \left\{ 8c_-\gamma \left(\frac{1+\epsilon}{\epsilon} \right)^2 \left(2^{\frac{1}{2}H_{\frac{1}{2}}(p_x^-)} + \delta_1^{-\frac{1}{2}} \right)^2 + M \right\} \\ &\leq \min_{(1-\delta_1)(1-\delta_2) \leq 1-\delta} \left\{ 8c_+\gamma \left(\frac{1+\epsilon}{\epsilon} \right)^2 \left(2^{\frac{1}{2}H_{\frac{1}{2}}(p_x^+)} + \sqrt{\frac{c_-}{c_+\delta_1}} \right)^2 + M \right\} \end{aligned} \quad (31)$$

where $\gamma = c_+ + c_-$, $p_x^{\pm} = \langle x | \sigma_{\pm} | x \rangle$ and M is an integer that satisfies

$$M \geq \left(\log \left(\frac{(1+\epsilon)\gamma}{(1+\epsilon)c_- + \epsilon\gamma} \right) \right)^{-1} \log \left(\frac{1}{\delta_2} \right). \quad (32)$$

Also $H_{\alpha}(P_x)$ is the α -Rényi entropy

$$H_{\alpha}(P_x) = \frac{1}{1-\alpha} \log_2 \left(\sum_x P_x^{\alpha} \right). \quad (33)$$

Note that the second bound in (31) is used in the main text. Also, δ_1 is the failure probability to prepare an ϵ close simulator, and δ_2 is the failure probability of accepting at least one sample with the rejection sampling scheme. It tells us

$$1 - \delta = (1 - \delta_1)(1 - \delta_2). \quad (34)$$

Proof. The second term M is due to (29), which is the number of samples generally required for rejection sampling after the estimation of the acceptance ratio $\{R_x\}_x$. In the following, we focus on deriving the first terms, i.e., the sampling cost for estimating the acceptance ratio for rejection sampling sufficiently well.

Here, we treat $K|\epsilon'_x|q_x$ for every x as a random variable in the sense that we get different ϵ'_x each time when we prepare the simulator to get N samples. We denote it as Z_x . The first step is to check if $\{Z_x\}_x$ are negatively associated, as this later allows us to bound the variance of $\sum_x K|\epsilon'_x|q_x$ by the sum of the variance of each term. For an introduction to the negative association, see Ref. [51].

Definition 4 (Negative association). A set of random variable $X_1, X_2, \dots, X_n$ is negatively associated if any two disjoint index set $I, J \in [n]$ and any two functions f, g , both monotones increasing or both monotones decreasing, it holds

$$\mathbb{E}[f(X_i : i \in I)g(X_j : j \in J)] \leq \mathbb{E}[f(X_i : i \in I)]\mathbb{E}[g(X_j : j \in J)] \quad (35)$$

In our setting, we can consider $N_x := N_x^+ + N_x^-$ for all x as random variables. In Ref. [51, Sec. 5.3], the example named “Balls and Bins, and Balls and Bins” implies that $\{N_x\}_x$ are negatively associated. This fact is intuitively understood by the fact that if one N_x has a large value, other random variables N_y tend to have small values. According to the definition, as long as f and g are both monotonically increasing or both monotonically decreasing, we can use those functions for the random variables satisfying the inequality (35).

Here, we want to know if $\{\epsilon'_x\}_x$ satisfy Eq. (35). In order to show this, we first prove the following lemma.

Lemma 5. Let $\{X_1, X_2, \dots, X_n\}$ be random variables obtained by a Bernoulli distribution where we get 1 with probability p , and get -1 with probability $1 - p$. Also, $\theta_p(n)$ is the function that represents the absolute error of the average of random variables, i.e.

$$\begin{aligned} \theta_p(n) &= \mathbb{E} \left[\left| \frac{1}{n} \sum_{i=1}^n X_i - \mathbb{E} \left[\frac{1}{n} \sum_{i=1}^n X_i \right] \right| \right] \\ &= \mathbb{E} \left[\left| \frac{1}{n} \sum_{i=1}^n X_i - 2p + 1 \right| \right] \end{aligned} \quad (36)$$

when $n = 0$, we define $\theta_p(0) = 2(1 - p)$. Then, $\theta_p(n)$ is a monotonously decreasing function with respect to n , i.e.,

$$\theta_p(n) > \theta_p(n+1) \quad (37)$$

Proof. Let $\{X_1, X_2, \dots, X_n, X_{n+1}\}$ be random variables obtained by a Bernoulli distribution where we get 1 with probability p , and get -1 with probability $1 - p$. Let Y be a random variable obtained by choosing j from 1 to $n + 1$ with equal probability and then calculating

$$Y = \sum_{i \neq j}^{n+1} X_i. \quad (38)$$

Even when all $\{X_1, X_2, \dots, X_n, X_{n+1}\}$ are determined, in the sense that we choose j randomly, Y is still a random variable. In this case, we know that

$$\begin{aligned} \mathbb{E}[Y|X_1, X_2, \dots, X_{n+1}] &= \sum_{j=1}^{n+1} \frac{1}{n+1} \frac{1}{n} \sum_{i \neq j}^{n+1} X_i \\ &= \frac{1}{n+1} \frac{1}{n} \sum_{i=1}^{n+1} X_i \\ &= \frac{1}{n+1} \sum_{i=1}^{n+1} X_i \end{aligned} \quad (39)$$

meaning when we fix $\{X_1, X_2, \dots, X_n, X_{n+1}\}$, the expectation value of Y is equal to the average of $\{X_1, X_2, \dots, X_n, X_{n+1}\}$. Because the function $|x|$ is convex with respect to x , for fixed $\{X_1, X_2, \dots, X_n, X_{n+1}\}$, (39) gives us

$$\begin{aligned} \left| \frac{1}{n+1} \sum_{i=1}^{n+1} X_i - 2p + 1 \right| &= |\mathbb{E}[Y|X_1, X_2, \dots, X_{n+1}] - 2p + 1| \\ &= |\mathbb{E}[Y - 2p + 1|X_1, X_2, \dots, X_{n+1}]| \\ &< \mathbb{E}[|Y - 2p + 1||X_1, X_2, \dots, X_{n+1}] \end{aligned} \quad (40)$$

In the last inequality we used Jensen's inequality [52], meaning for a convex function f it holds that $f(\mathbb{E}[X]) \leq \mathbb{E}[f(X)]$. Note that because the function $|x|$ is not linear in $-1 \leq x \leq 1$, which is the range the random variables $Y - 2p + 1$ can take, the equality of Jensen's inequality does not hold. Finally by taking the expectation value of overall $X_1, X_2, \dots, X_{n+1}$ on both sides of (40) we obtain

$$\begin{aligned} \theta_p(n+1) &= \mathbb{E} \left[\left| \frac{1}{n+1} \sum_{i=1}^{n+1} X_i - 2p + 1 \right| \right] < \mathbb{E}[|Y - 2p + 1|] \\ &= \mathbb{E} \left[\left| \sum_{i \neq j}^{n+1} X_i - 2p + 1 \right| \right] \\ &= \mathbb{E} \left[\left| \sum_{i=1}^n X_i - 2p + 1 \right| \right] \\ &= \theta_p(n). \end{aligned} \quad (41)$$

□

Ref. [51, Sec. 5.3] ensures that $\{N_x\}_x$ are also negatively associated. For all x , the Lemma 5 says $\theta_{q_x}(n)$ as well as $K\theta_{q_x}(n)q_x$ are monotonous decreasing functions with respect to n . This means the random variables $\{K\theta_{q_x}(N_x)q_x\}_x$ satisfy Eq. (35). This ensures that the covariance of two random variables is negative, which follows from Corollary 1 of Ref. [51]. This yields the following inequality

$$\begin{aligned} \mathbb{V} \left[\sum_x K|\epsilon'_x|q_x \right] &= \mathbb{V} \left[\sum_x K\theta_{q_x}(N_x)q_x \right] \\ &= \sum_x \mathbb{V}[K\theta_{q_x}(N_x)q_x] + \sum_{x,y,x \neq y} \text{Cov}(K\theta_{q_x}(N_x)q_x, K\theta_{q_y}(N_y)q_y) \\ &\leq \sum_x \mathbb{V}[K\theta_{q_x}(N_x)q_x] = \sum_x \mathbb{V}[K|\epsilon'_x|q_x] \end{aligned} \quad (42)$$

where we use $|\epsilon'_x| = \theta_{q_x}(N_x)$ by definition. Next, we calculate each variance. When $N_x > 0$ is fixed, the process of getting ϵ'_x is the same as calculating the error from the Bernoulli distribution. Recalling $p_x^\pm = \langle x | \sigma_\pm | x \rangle$, we can calculate the variance as

$$\mathbb{V}[\epsilon'_x | N_x] = \frac{4}{N_x} \frac{\frac{c_+}{c_+ + c_-} p_x^+}{\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-} \frac{\frac{c_-}{c_+ + c_-} p_x^-}{\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-} = \frac{4}{N_x} \frac{\frac{c_+}{c_+ + c_-} p_x^+ \frac{c_-}{c_+ + c_-} p_x^-}{(\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-)^2}. \quad (43)$$

When $N_x = 0$, we define $\mathbb{V}[\epsilon'_x | N_x] = 0$.

Also, since $\mathbb{E}[\epsilon'_x | N_x] = 0$,

$$\begin{aligned} \mathbb{V}[|\epsilon'_x| | N_x] &= \mathbb{E}[|\epsilon'_x|^2 | N_x] - \mathbb{E}[|\epsilon'_x| | N_x]^2 \\ &\leq \mathbb{E}[\epsilon'^2_x | N_x] = \mathbb{E}[\epsilon'^2_x | N_x] - \mathbb{E}[\epsilon'_x | N_x]^2 \\ &= \mathbb{V}[\epsilon'_x | N_x]. \end{aligned} \quad (44)$$

Recalling that $q_x = \frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-$, the overall variance is upper bounded as

$$\begin{aligned} \mathbb{V}[|\epsilon'_x|] &\leq \mathbb{V}[\epsilon'_x] \\ &= \mathbb{E}_{N_x} [\mathbb{V}[\epsilon'_x | N_x]] + \mathbb{V}_{N_x} [\mathbb{E}[\epsilon'_x | N_x]] \\ &= \sum_{N_x=0}^N \text{Prob}(N_x) \mathbb{V}[\epsilon'_x | N_x] \\ &= \sum_{N_x=0}^N \binom{N}{N_x} q_x^{N_x} (1 - q_x)^{N - N_x} \mathbb{V}[\epsilon'_x | N_x] \\ &= \frac{4 \frac{c_+}{c_+ + c_-} p_x^+ \frac{c_-}{c_+ + c_-} p_x^-}{(\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-)^2} \sum_{n_x=1}^N \binom{N}{N_x} q_x^{N_x} (1 - q_x)^{N - N_x} \frac{1}{N_x} \end{aligned} \quad (45)$$

where the first equality is due to the general relation $\mathbb{V}[X] = \mathbb{E}_Y [\mathbb{V}[X|Y]] + \mathbb{V}_Y [\mathbb{E}[X|Y]]$ with $\mathbb{E}_Y$ and $\mathbb{V}_Y$ being the expected value and variance with respect to the random variable Y .

To evaluate this, we first note that

$$\begin{aligned} \sum_{n=0}^N \frac{1}{n+1} \binom{N}{n} q^n (1-q)^{N-n} &= \sum_{n=0}^N \frac{1}{n+1} \binom{N}{n} q^n (1-q)^{N-n} \\ &= \sum_{n=0}^N \frac{1}{n+1} \frac{N!}{(N-n)!n!} q^n (1-q)^{N-n} \\ &= \sum_{n=0}^N \frac{1}{N+1} \frac{(N+1)!}{(N-n)!(n+1)!} q^n (1-q)^{N-n} \\ &= \frac{1}{(N+1)q} \sum_{n=0}^N \binom{N+1}{n+1} q^{n+1} (1-q)^{N+1-n-1} \\ &= \frac{1}{(N+1)q} (1 - (1-q)^{N+1}) \\ &\leq \frac{1}{Nq}. \end{aligned} \quad (46)$$

Together with the relation $\frac{1}{N_x} \leq \frac{2}{N_x+1}$ for $N_x \geq 1$, Eq. (45) can be further evaluated as

$$\begin{aligned}
\mathbb{V}[|\epsilon'_x|] &\leq \frac{4 \frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{(\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-)^2} \sum_{N_x=1}^N \binom{N}{N_x} q_x^{N_x} (1-q_x)^{N-N_x} \frac{1}{N_x} \\
&\leq \frac{4 \frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{(\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-)^2} \sum_{N_x=1}^N \frac{2}{N_x+1} \binom{N}{N_x} q_x^{N_x} (1-q_x)^{N-N_x} \\
&\leq \frac{4 \frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{(\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-)^2} \sum_{N_x=0}^N \frac{2}{N_x+1} \binom{N}{N_x} q_x^{N_x} (1-q_x)^{N-N_x} \\
&\leq \frac{4 \frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{(\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-)^2} \frac{2}{N q_x} \\
&= \frac{8}{N} \frac{\frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{(\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-)^3}.
\end{aligned} \tag{47}$$

Putting (42) and (47) together, we obtain

$$\begin{aligned}
\mathbb{V}\left[\sum_x K|\epsilon'_x|q_x\right] &\leq \sum_x K^2 q_x^2 \frac{8}{N} \frac{\frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{(\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-)^3} \\
&= \frac{8(c_++c_-)^2}{N} \sum_x \frac{\frac{c_+}{c_++c_-} p_x^+}{\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-} \frac{c_-}{c_++c_-} p_x^- \\
&\leq \frac{8(c_++c_-)^2}{N} \sum_x \frac{c_-}{c_++c_-} \langle x|\sigma_-|x\rangle \\
&= \frac{8c_-(c_++c_-)}{N}.
\end{aligned} \tag{48}$$

On top of that, we know that

$$\begin{aligned}
\mathbb{E}[K|\epsilon'_x|q_x] &= K q_x \mathbb{E}[|\epsilon'_x|] = K q_x \sqrt{\mathbb{E}[|\epsilon'_x|^2] - \mathbb{V}[|\epsilon'_x|]} \\
&= K q_x \sqrt{\mathbb{V}[\epsilon'_x] - \mathbb{V}[|\epsilon'_x|]} \\
&\leq K q_x \sqrt{\mathbb{V}[\epsilon'_x]} \\
&\leq K q_x \sqrt{\frac{8}{N} \frac{\frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{(\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-)^3}} \\
&\leq \gamma \sqrt{\frac{8}{N} \frac{\frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-}}.
\end{aligned} \tag{49}$$

Using this fact and Chebyshev's inequality [52] we obtain the following bound with $t > 0$

$$\begin{aligned}
\delta_1 &:= \text{Prob}\left(\sum_x K|\epsilon'_x|q_x - \mathbb{E}\left[\sum_x K|\epsilon'_x|q_x\right] > t\right) \leq \text{Prob}\left(\left|\sum_x K|\epsilon'_x|q(x) - \mathbb{E}\left[\sum_x K|\epsilon'_x|q_x\right]\right| > t\right) \\
&\leq \frac{\mathbb{V}[\sum_x K|\epsilon'_x|q_x]}{t^2} \\
&\leq \frac{8c_-\gamma}{Nt^2}.
\end{aligned} \tag{50}$$

When $N \geq \frac{8c_-\gamma}{t^2\delta}$, then the bound implies that $|\sum_x K|\epsilon'_x|q_x - \mathbb{E}[\sum_x K|\epsilon'_x|q_x]|$ is smaller than t at least probability $1 - \delta_1$.

We also bound the expected value. Together with Eq. (49), choosing N as

$$\begin{aligned} N &\geq \frac{8\gamma^2}{s^2} \left(\sum_x \sqrt{\frac{\frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-}} \right)^2 \\ &= \frac{8\gamma}{s^2} \left(\sum_x \sqrt{\frac{c_+ c_- p_x^+ p_x^-}{c_+ p_x^+ + c_- p_x^-}} \right)^2 \end{aligned} \quad (51)$$

for the given $s > 0$ ensures that

$$s \geq \sum_x \gamma \sqrt{\frac{8}{N} \frac{\frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-}} \geq \mathbb{E}[K|\epsilon'_x|q_x]. \quad (52)$$

Overall, taking $t + s = \tilde{\epsilon}$ to be the bound of the total variation distance, and N satisfying both (50) and (52), meaning

$$N \geq \max \left\{ \frac{8c_- \gamma}{t^2 \delta_1}, \frac{8\gamma}{s^2} \left(\sum_x \sqrt{\frac{c_+ c_- p_x^+ p_x^-}{c_+ p_x^+ + c_- p_x^-}} \right)^2 \right\}, \quad (53)$$

we can ensure that

$$\text{Prob} \left(\sum_x K|\epsilon'_x|q_x \geq \tilde{\epsilon} \right) \leq \delta_1. \quad (54)$$

Eq. (53) is a sufficient condition in order to obtain a (ϵ, δ) -simulator for our framework, as was Eq. (22). By taking $s = (1 - r)\tilde{\epsilon}$, $t = r\tilde{\epsilon}$, and minimizing the bound with respect to r , i.e. $\min_r \max \left\{ \frac{8c_- \gamma}{r^2 \tilde{\epsilon}^2 \delta_1}, \frac{8\gamma}{(1-r)^2 \tilde{\epsilon}^2} \left(\sum_x \sqrt{\frac{c_+ c_- p_x^+ p_x^-}{c_+ p_x^+ + c_- p_x^-}} \right)^2 \right\}$. This minimization is accomplished by choosing r such that both arguments inside the $\max\{\cdot\}$ are equal. This gives the first term in the first inequality of (31). The statement is concluded by noting that $(1 - \delta_1)(1 - \delta_2)$ is the probability that we successfully get a valid sample after running the rejection sampling, whose sampling cost M is given by (29).

To get the second and third inequalities in (31), note that

$$\frac{c_+ c_- p_x^+ p_x^-}{c_+ p_x^+ + c_- p_x^-} = \gamma \frac{\frac{c_+}{c_++c_-} p_x^+ \frac{c_-}{c_++c_-} p_x^-}{\frac{c_+}{c_++c_-} p_x^+ + \frac{c_-}{c_++c_-} p_x^-} \leq c_- p_x^- \leq c_+ p_x^+ \quad (55)$$

for every x . This gives

$$S = \left(\sum_x \sqrt{\frac{c_+ c_- p_x^+ p_x^-}{c_+ p_x^+ + c_- p_x^-}} \right)^2 \leq c_- 2^{H_{\frac{1}{2}}(p_x^-)} \leq c_+ 2^{H_{\frac{1}{2}}(p_x^+)}, \quad (56)$$

resulting in the second and third inequalities. $\square$

5. ALTERNATIVE BOUND FOR OUR FRAMEWORK

In addition to Theorem 2 in the main text, we also have an alternative upper bound of the sample complexity.

Theorem 6. *For a quantum state written as $\rho = c_+ \sigma_+ + c_- \sigma_-$ with $\sigma_{\pm} \in \mathcal{F}$ and $c_{\pm} \geq 0$, the weak distillation of state ρ with trace distance accuracy ϵ with probability at least $1 - \delta$ can be accomplished by using*

$$N \leq \min_{(1-\delta_1)(1-\delta_2) \leq 1-\delta} \left\{ 2\gamma^2 \left(\frac{1+\epsilon}{\epsilon} \right)^2 \left(2^{\frac{1}{2} H_{\frac{1}{2}}(q_x)} + \left(\frac{2}{v} \log \frac{1}{\delta_1} \right)^{\frac{1}{2}} \right)^2 + M \right\} \quad (57)$$

with $v = 1 - e^{-\frac{1}{2}}$ and $q_x = \frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-$. Also, M is an integer that satisfies

$$M \geq \left(\log \left(\frac{(1 + \epsilon)\gamma}{(1 + \epsilon)c_- + \epsilon\gamma} \right) \right)^{-1} \log \left(\frac{1}{\delta_2} \right). \quad (58)$$

The main difference between this bound and Theorem 2 in the main text is that this bound has an exponentially better scaling with the failure probability bound, but loses the explicit c_- dependency. The only advantage of this bound compared to the estimation-based method is the number inside the logarithm. This implies that the upper bound in the estimation method is lower than the upper bound presented in this section for most cases. However, this bound suggests that our framework can have a $O(\log \frac{1}{\delta})$ scaling, which ensures our framework is still useful for scenarios where a small δ is required.

Proof. Contrary to the previous section, we focus on ϵ_x , which is the error of the final set of numbers $\{R_x\}_x$ from the ideal set of values $\left\{ \frac{p_x}{Kq_x} \right\}_x$. First of all, for fixed N_x and $t > 0$, it holds that

$$\begin{aligned} \text{Prob}(K|\epsilon_x|q_x \geq t|N_x) &\leq \text{Prob}(K|\epsilon'_x|q_x \geq t|N_x) \\ &\leq 2 \exp \left(\frac{-N_x t^2}{2K^2 q_x^2} \right). \end{aligned} \quad (59)$$

In the last inequality, we used the Hoeffding inequality [49, 52]. By considering the possible outcomes of $K|\epsilon_x|q_x$, we obtain

$$\begin{aligned} K|\epsilon_x|q_x &\leq \max\{2c_- \langle x|\sigma_-|x \rangle, c_+ \langle x|\sigma_+|x \rangle - c_- \langle x|\sigma_-|x \rangle\} \\ &\leq c_+ \langle x|\sigma_+|x \rangle + c_- \langle x|\sigma_-|x \rangle = Kq_x. \end{aligned} \quad (60)$$

Obviously, when $t \geq Kq_x$,

$$\text{Prob}(K|\epsilon_x|q_x > t|N_x) = 0 \quad (t > Kq_x). \quad (61)$$

Considering every possible N_x (even including $N_x = 0$) within the range of $0 \leq t \leq Kq_x$, we get

$$\begin{aligned} \text{Prob}(K|\epsilon_x|q_x > t) &= \sum_{k=0}^N \text{Prob}(N_x = k) \text{Prob}(K|\epsilon_x|q_x > t|N_x) \\ &\leq 2 \sum_{k=0}^N \binom{N}{k} q_x^k (1 - q_x)^{N-k} \exp \left(\frac{-kt^2}{2K^2 q_x^2} \right) \\ &\leq 2 \sum_{k=0}^N \binom{N}{k} \left[q_x \exp \left(\frac{-t^2}{2K^2 q_x^2} \right) \right]^k (1 - q_x)^{N-k} \\ &= 2 \left[1 - q_x + q_x \exp \left(\frac{-t^2}{2K^2 q_x^2} \right) \right]^N \quad (t < Kq_x) \end{aligned} \quad (62)$$

where we use Eq. (59) in the second line. Also, because q_x is the probability of getting x as the measurement outcome, we know that $\text{Prob}(N_x = k) = \binom{N}{k} q_x^k (1 - q_x)^{N-k}$. Because we consider $t \in [0, Kq_x]$, by taking $y = \frac{t^2}{K^2 q_x^2}$ for $y \in [0, 1]$, we get

$$\begin{aligned} 1 - q_x + q_x e^{-\frac{y}{2}} &\leq 1 - q_x (1 - e^{-\frac{1}{2}}) y \leq \exp \left(-q_x (1 - e^{-\frac{1}{2}}) y \right) \\ &= \exp \left(-q_x (1 - e^{-\frac{1}{2}}) \frac{t^2}{K^2 q_x^2} \right) \\ &= \exp \left(-\frac{vt^2}{K^2 q_x} \right) \end{aligned} \quad (63)$$

where we take $v = 1 - e^{-\frac{1}{2}} = 0.393\dots$. Then, we obtain

$$\text{Prob}(K|\epsilon_x|q_x > t) \leq \text{Prob}(K|\epsilon'_x|q_x > t) \leq 2 \exp \left(-\frac{vNt^2}{K^2 q_x} \right). \quad (64)$$

We can use this bound even when $t > Kq_x$ because in that case, the probability is equal to zero see Eq. (61).

Our goal here is to combine the probability of all x . To do that, we use the following lemma.

Lemma 7. *Let X be a random variable that satisfies*

$$\text{Prob}(|X| > \epsilon) < 2 \exp\left(\frac{-\epsilon^2}{2\sigma^2}\right) \quad (65)$$

with $\sigma^2 \in \mathbb{R}$ which does not depend on ϵ . Also, let $a = \sqrt{2\sigma^2 \log 2}$ and consider

$$\mathbb{E}[|X| - a] \leq 0. \quad (66)$$

Then, for $t > 0$, it holds that

$$\mathbb{E}[e^{t(|X|-a)}] < e^{4t^2\sigma^2}. \quad (67)$$

Proof. Taking $a = \sqrt{2\sigma^2 \log 2}$, we get

$$\begin{aligned} \text{Prob}(|X| - a > \epsilon) &< 2 \exp\left(\frac{-(\epsilon + a)^2}{2\sigma^2}\right) \\ &= 2 \exp\left(\frac{-(\epsilon^2 + 2a\epsilon + a^2)}{2\sigma^2}\right) \\ &\leq 2 \exp\left(\frac{-(\epsilon^2 + a^2)}{2\sigma^2}\right) \\ &= 2 \exp\left(\frac{-\epsilon^2}{2\sigma^2}\right) \exp\left(\frac{-2\sigma^2 \log 2}{2\sigma^2}\right) \\ &= \exp\left(\frac{-\epsilon^2}{2\sigma^2}\right). \end{aligned} \quad (68)$$

Let $k \geq 0$ be an integer. When k is an odd number, following the proof of Ref. [53, Lemma 1.4], we obtain

$$\begin{aligned} \mathbb{E}((|X| - a)^k) &= \int_0^\infty \text{Prob}((|X| - a)^k > t) dt - \int_0^\infty \text{Prob}((|X| - a)^k < -t) dt \\ &\leq \int_0^\infty \text{Prob}(|X| - a > t^{\frac{1}{k}}) dt \\ &\leq \int_0^\infty \exp\left(-\frac{t^{\frac{2}{k}}}{2\sigma^2}\right) dt \\ &= \frac{1}{2}(2\sigma^2)^{\frac{k}{2}} k \Gamma\left(\frac{k}{2}\right) \\ &\leq (2\sigma^2)^{\frac{k}{2}} k \Gamma\left(\frac{k}{2}\right) \end{aligned} \quad (69)$$

where $\Gamma(\cdot)$ denotes the Gamma function. Because $\text{Prob}(|X| < t) \leq 1$ for $t \geq 0$ and $\text{Prob}(|X| < t) = 0$ for $t < 0$, when k is even number, we know

$$\begin{aligned} \mathbb{E}((|X| - a)^k) &= \int_0^\infty \text{Prob}((|X| - a)^k > t) dt \\ &= \int_0^\infty \left(\text{Prob}(|X| - a > t^{\frac{1}{k}}) + \text{Prob}(|X| - a < -t^{\frac{1}{k}}) \right) dt \\ &\leq \int_0^\infty \exp\left(-\frac{t^{\frac{2}{k}}}{2\sigma^2}\right) dt + \int_0^{a^k} 1 dt \\ &= \frac{1}{2}(2\sigma^2)^{\frac{k}{2}} k \Gamma\left(\frac{k}{2}\right) + a^k \\ &= \frac{1}{2}(2\sigma^2)^{\frac{k}{2}} k \Gamma\left(\frac{k}{2}\right) + (2\sigma^2)^{\frac{k}{2}} (\log 2)^{\frac{k}{2}} \\ &\leq (2\sigma^2)^{\frac{k}{2}} k \Gamma\left(\frac{k}{2}\right). \end{aligned} \quad (70)$$

In the last inequality, we used the fact that $\frac{1}{2}k\Gamma(\frac{k}{2}) > (\log 2)^{\frac{k}{2}}$. The reason is that $(\log 2)^{\frac{k}{2}}$ is a monotonically decreasing function and for $k \geq 2$, $\frac{1}{2}k\Gamma(\frac{k}{2})$ is monotonically increasing. When $k = 1, 2$, we can get $\frac{1}{2}k\Gamma(\frac{k}{2}) > (\log 2)^{\frac{k}{2}}$ by numerical calculation. Therefore, for all k , $\frac{1}{2}k\Gamma(\frac{k}{2}) > (\log 2)^{\frac{k}{2}}$ holds.

Overall, analogously to Lemma 1.5 in Ref [53], we get

$$\begin{aligned}\mathbb{E}[e^{s(|X|-a)}] &= 1 + \mathbb{E}[|X| - a]s + \sum_{k=2}^{\infty} \frac{s^k \mathbb{E}[|X| - a]^k}{k!} \\ &\leq 1 + \mathbb{E}[|X| - a]s + \sum_{k=2}^{\infty} \left(\frac{(2\sigma^2 s^2)^{\frac{k}{2}} k\Gamma(\frac{k}{2})}{k!} \right) \\ &\leq 1 + \sum_{k=2}^{\infty} \frac{(2\sigma^2 s^2)^{\frac{k}{2}} k\Gamma(\frac{k}{2})}{k!} \\ &\leq \exp(4\sigma^2 s^2)\end{aligned}\tag{71}$$

where in the third line, we used the assumption (66). $\square$

Now we prove the main theorem. We define

$$a(x) = \sqrt{\frac{2K^2 q_x}{N}} \geq \sqrt{\frac{K^2 q_x}{vN} \log 2}.\tag{72}$$

Note that $2 \geq \frac{\log 2}{v} = 1.76\dots$. Then we get

$$\begin{aligned}\text{Prob}(|K|\epsilon_x|q_x - a(x)| > t) &\leq \text{Prob}(K|\epsilon_x|q_x - a(x) > t) = \text{Prob}(K|\epsilon_x|q_x > a(x) + t) \\ &< 2 \exp\left(\frac{-vN(t + a(x))^2}{K^2 q_x}\right) \\ &= 2 \exp\left(\frac{-vN(t^2 + 2ta(x) + a(x)^2)}{K^2 q_x}\right) \\ &\leq 2 \exp\left(\frac{-vN(t^2 + a(x)^2)}{K^2 q_x}\right) \\ &\leq 2 \exp\left(\frac{-vN(t^2 + \frac{K^2 q_x}{vN} \log 2)}{K^2 q(x)}\right) \\ &= 2 \exp\left(\frac{-vN t^2}{K^2 q_x}\right) \exp\left(\frac{-vN \frac{K^2 q_x}{vN} \log 2}{K^2 q_x}\right) \\ &= \exp\left(\frac{-t^2}{2 \frac{K^2 q_x}{2vN}}\right).\end{aligned}\tag{73}$$

Also, since for $a, b > 0$, we know that $\frac{8ab}{a+b} \leq 2(a+b)$. This implies that

$$\begin{aligned}\mathbb{E}[K|\epsilon_x|q_x] &\leq \mathbb{E}[K|\epsilon'_x|q_x] \\ &\leq \gamma \sqrt{\frac{8}{N} \frac{\frac{c_+}{c_+ + c_-} p_x^+ \frac{c_-}{c_+ + c_-} p_x^-}{\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^-}} \\ &\leq \gamma \sqrt{\frac{2}{N} \left(\frac{c_+}{c_+ + c_-} p_x^+ + \frac{c_-}{c_+ + c_-} p_x^- \right)} \\ &= a(x)\end{aligned}\tag{74}$$

and therefore

$$\mathbb{E}[K|\epsilon_x|q_x - a(x)] \leq 0.\tag{75}$$

Because of Eq. (64) and Eq. (75) we can now apply Lemma 7 for our case as

$$\begin{aligned}
\mathbb{E} \left[\exp \left(s \sum_x (K|\epsilon_x|q_x - a) \right) \right] &\leq \mathbb{E} \left[\exp \left(s \sum_x (K|\epsilon'_x|q_x - a) \right) \right] \\
&\leq \prod_x \mathbb{E} [\exp(s(K|\epsilon'_x|q_x - a))] \\
&\leq \prod_x \exp \left\{ \left(4 \frac{K^2 q_x}{2vN} s^2 \right) \right\} \\
&= \exp \left(\frac{2s^2 K^2}{vN} \sum_x q_x \right) \\
&= \exp \left(\frac{2s^2 K^2}{vN} \right)
\end{aligned} \tag{76}$$

where the second inequality comes from the fact $\{K|\epsilon'_x|q_x\}_x$ are negatively associated, which we showed after the proof of Lemma 5. By using the Chernoff bound [54] which suggests $\text{Prob}(X > t) < \mathbb{E}[e^{sX}]e^{-st}$ for any $s > 0$, we get

$$\begin{aligned}
\delta_1 = \text{Prob} \left(\sum_x (K|\epsilon_x|q_x - a(x)) \geq t \right) &\leq \text{Prob} \left(\sum_x (K|\epsilon'_x|q_x - a(x)) \geq t \right) \\
&< \mathbb{E} \left[\exp \left(s \sum_x (K|\epsilon'_x|q_x - a) \right) \right] e^{-st} \\
&\leq \exp \left(\frac{s^2 K^2}{vN} - st \right) \\
&= \exp \left(\frac{-vt^2 N}{4K^2} \right) \quad (s = \frac{vtN}{2K^2}).
\end{aligned} \tag{77}$$

This implies the fact that when N satisfies

$$N \geq \frac{4\gamma^2}{vt^2} \log \frac{1}{\delta_1}, \tag{78}$$

$\sum_x (K|\epsilon_x|q_x - a(x))$ gets smaller than t with probability at least $1 - \delta_1$. In addition to that, for

$$s \geq \sum_x a(x) = \sum_x \gamma \sqrt{\frac{2}{N} q_x} \tag{79}$$

or equivalently

$$N \geq \frac{2\gamma^2}{s^2} \left(\sum_x \sqrt{q_x} \right)^2, \tag{80}$$

it holds that $|\mathbb{E}[\sum_x K|\epsilon_x|q_x] - \sum_x a(x)| \leq s$. With the same discussion as in the previous section, we upper bound the sampling cost by using Eq.(78) and Eq.(80) and taking $\tilde{\epsilon} = t + s$. Similar to the proof of Proposition 1, taking $t = r\tilde{\epsilon}$, $s = (1-r)\tilde{\epsilon}$, we get $\min_r \max \left\{ \frac{4\gamma^2}{vr^2\tilde{\epsilon}^2} \log \frac{1}{\delta_1}, \frac{2\gamma^2}{(1-r)^2\tilde{\epsilon}} \left(\sum_x \sqrt{q_x} \right)^2 \right\}$. This minimization is accomplished by choosing r 's such that both arguments inside the $\max\{\cdot, \cdot\}$ are equal. Finally, by considering the failure probability δ_2 of getting at least one accepted sample from the rejection sampling scheme, we get the statement. $\square$

Classical algorithms for measurement-adaptive Gaussian circuits

² Department of Physics, Chungbuk National University, Cheongju, Chungbuk 28644, Korea

Abstract. Gaussian building blocks are central to photonic quantum information processing, and adaptive measurements with feedforward provide a practical route toward universal quantum computation. This raises a basic question: how much adaptivity is needed before such circuits become classically hard for tasks of practical interest? We address this question for the quantum mean-value problem, which captures expectation-value estimation in simulation and variational algorithms. We show that circuits with only a small number of adaptive measurement-and-feedforward steps can be efficiently simulated classically, even with highly non-Gaussian input states, whereas more general adaptive regimes are computationally hard. Thus, adaptivity provides a natural complexity parameter for photonic quantum advantage.

Keywords: Gaussian circuits, Photonic quantum computation, Classical simulation, Quantum advantage

1 Introduction

Photonic quantum systems provide a promising route to quantum information processing because Gaussian operations—linear optics, squeezing, homodyne detection, and more general Gaussian measurements—are experimentally accessible and often classically tractable [3]. Universality, however, requires going beyond purely Gaussian processes, for example by introducing non-Gaussian input states, photon-number measurements, or adaptive measurement-and-feedforward operations [2, 4].

Most photonic quantum-advantage proposals have been formulated as sampling problems, most notably boson sampling [1]. In contrast, many algorithmic applications of quantum computers are naturally phrased as expectation-value estimation tasks. We therefore study the *quantum mean-value problem*: given an input state ρ , a circuit $\mathcal{C}$, and an observable O , estimate $\text{Tr}[O\mathcal{C}(\rho)]$ to additive precision.

Our main finding is that, for measurement-adaptive Gaussian circuits, the complexity of mean-value estimation is controlled not simply by the presence of non-Gaussianity, but by the number of adaptive measurements. Even with highly non-Gaussian product input states, the mean-value problem remains efficiently classically solvable when the number of adaptive measurement-and-feedforward steps is constant. In contrast, with unrestricted adaptivity, the same physical ingredients can realize universal quantum computation. Thus, adaptivity provides a natural complexity parameter separating classical simulability from photonic quantum advantage.

2 Circuit families and computational task

We consider bosonic circuits composed of Gaussian unitary transformations, intermediate measurements, and feedforward operations. The input state is allowed to be a product state across modes and may be highly non-Gaussian. After the circuit is applied, the goal is not

Figure 1: See the main text.

necessarily to sample from the output distribution, but to estimate an expectation value

$$\text{Tr}[\hat{O}\hat{\rho}_{\text{out}}], \quad (1)$$

where $\hat{\rho}_{\text{out}}$ is the output state and $\hat{O}$ is an observable of interest. We focus on product observables or observables whose relevant norm is polynomially bounded, which captures many physically motivated mean-value estimation tasks.

We study three related families of bosonic circuits (see Fig. 1):

- Gaussian circuit without intermediate measurement and feedforward (family 1);
- Gaussian circuit augmented by photon-number-resolving measurements, where the measurement outcomes determine subsequent Gaussian feedforward operations (family 2);
- Gaussian circuit augmented by Gaussian measurements and Gaussian feedforward (family 3).

With suitable non-Gaussian resources, measurement-adaptive Gaussian circuits of the last two types can realize universal quantum computation [7, 8]; consequently, the corresponding quantum mean-value problem is BQP-complete.

The key parameter in the adaptive circuits is the number of intermediate measurements whose outcomes are used for feedforward. We denote this number by L . The question is how the classical computational cost scales with L , the number of modes, and the desired additive precision. When L is small, the adaptive circuit contains

*changhun0218@gmail.com

Table 1: Summary of sampling and quantum mean-value estimation complexities. Here M is the number of modes and L is the number of adaptive measurement-and-feedforward steps. Asterisks indicate our results [6].

Circuit family	Sampling	Quantum mean-value problem
Family 1	Efficient [3]	*Efficient
Family 2	*Efficient for $L = O(\log M)$	*Efficient for $L = O(1)$; BQP-complete for general L
Family 3	Efficient [3]	*Efficient for $L = O(1)$; BQP-complete for general L

only a limited amount of measurement-induced nonlinearity. When L is large, the circuit family can become powerful enough to implement universal quantum computation, depending on the available input resources.

The resulting complexity landscape is summarized in Table 1. The table highlights the main task-level contrast: sampling and mean-value estimation can have different complexity, and the number of adaptive measurements controls the transition from efficient classical simulation to BQP-completeness for the mean-value problem.

3 Main results

We summarize the main results of Ref. [6] in an informal form. Throughout, M denotes the number of output modes and L denotes the number of modes measured for adaptive control. For the quantum mean-value problem, the input is an $(M + L)$ -mode product state $|\psi\rangle$, and the goal is to estimate the expectation value of an M -mode product observable $\hat{O} = \hat{O}_A \otimes \hat{1}_B$, where $\hat{O}_A$ acts non-trivially only on an l -mode subsystem A . The central question is when

$$\langle \psi_{\text{out}} | \hat{O} | \psi_{\text{out}} \rangle \quad (2)$$

can be approximated to additive error ϵ with success probability at least $1 - \delta$ in time polynomial in M , $1/\epsilon$, and $\log(1/\delta)$.

Theorem 1: (informal) Gaussian circuits without feedforward. Consider an M -mode Gaussian circuit $\hat{G}$ and an arbitrary product input state $|\psi\rangle$. Then the expectation value $\langle \psi | \hat{G}^\dagger \hat{O} \hat{G} | \psi \rangle$ can be approximated classically in time polynomial in M , $1/\epsilon$, and $\log(1/\delta)$, provided the relevant Hilbert–Schmidt norm of $\hat{O}_A$ and the purity of the reduced output state are polynomially bounded. In particular, arbitrary local non-Gaussianity in the product input does not by itself make the mean-value problem hard.

Theorem 2: (informal) Photon-number-measurement adaptivity. Consider a Gaussian circuit augmented by photon-number-resolving measurements on at most L modes and Gaussian feedforward depending on the outcomes. Let $\mathbf{n} = (n_1, \dots, n_L)$ denote the photon-number outcomes, and let $\hat{G}_{\mathbf{n}}$ be the corresponding feedforwarded Gaussian circuit. If $L = O(1)$, then the expectation value of an M -mode product observable $\hat{O} = \hat{O}_A \otimes \hat{1}_B$ can be approximated classically in polynomial time for arbitrary product input states with a fixed maximum photon-number cutoff. The runtime may scale exponentially in L , but is polynomial in M for constant L .

Theorem 3: (informal) Gaussian-measurement adaptivity. Consider a Gaussian circuit augmented by Gaussian measurements on at most L modes and Gaussian feedforward depending on the measurement outcome β . If $L = O(1)$, then the expectation value of an M -mode product observable can again be approximated classically in polynomial time for arbitrary product input states with a fixed maximum photon-number cutoff.

These results show that the relevant complexity parameter is not simply the amount of local non-Gaussianity in the input state, but the number L of measurement-and-feedforward operations. This gives a task-level contrast with sampling, where non-Gaussian ingredients can already induce hardness.

4 Technical ideas

The first ingredient is a phase-space rewriting of the mean value. For any M -mode operator $\hat{O}$, we use the characteristic-function representation

$$\hat{O} = \frac{1}{\pi^M} \int d^{2M} \alpha \chi_{\hat{O}}(\alpha) \hat{D}^\dagger(\alpha), \quad \chi_{\hat{O}}(\alpha) = \text{Tr}[\hat{D}(\alpha) \hat{O}]. \quad (3)$$

For the product observable $\hat{O} = \hat{O}_A \otimes \hat{1}_B$, only the l -mode subsystem A has to be sampled. In the nonadaptive case, the desired mean value can be written as

$$\langle \psi | \hat{G}^\dagger (\hat{O}_A \otimes \hat{1}_B) \hat{G} | \psi \rangle = \int d^{2l} \alpha_A p(\alpha_A) X(\alpha_A), \quad (4)$$

where

$$p(\alpha_A) = \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2}, \quad X(\alpha_A) = \frac{\chi_{\hat{\rho}_A}^*(\alpha_A) \|\hat{O}_A\|_2^2}{\chi_{\hat{O}_A}^*(\alpha_A)}. \quad (5)$$

Here $\hat{\rho}_A$ is the reduced density matrix of the output state on subsystem A . The distribution $p(\alpha_A)$ is normalized by the twirling identity for displacement operators. Moreover, the product structure of $|\psi\rangle$ and $\hat{O}$ makes both sampling from $p(\alpha_A)$ and evaluating $X(\alpha_A)$ efficient.

For photon-number-measurement adaptivity, the measurement outcomes are $\mathbf{n} = (n_1, \dots, n_L)$, and the corresponding unnormalized post-measurement state is written as $|\psi_{\mathbf{n}}\rangle \equiv \hat{G}_{\mathbf{n}} |\psi\rangle$. The outcome probability is

$$p(\mathbf{n}) = \langle \psi_{\mathbf{n}} | (\hat{1} \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle. \quad (6)$$

Averaging over the adaptive branches, the target mean value becomes

$$\langle \hat{O} \rangle = \sum_{\mathbf{n}} \langle \psi | \hat{G}_{\mathbf{n}}^\dagger (\hat{O}_A \otimes \hat{1}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) \hat{G}_{\mathbf{n}} | \psi \rangle. \quad (7)$$

Using the same phase-space sampling over α_A , this is rewritten as

$$\langle \hat{O} \rangle = \int d^{2l} \alpha_A \sum_{\mathbf{n}} p(\mathbf{n}) q(\alpha_A) X(\mathbf{n}, \alpha_A), \quad (8)$$

with $q(\alpha_A) = |\chi_{\hat{O}_A}(\alpha_A)|^2 / (\pi^l \|\hat{O}_A\|_2^2)$. Thus, the algorithm samples $\mathbf{n} \sim p(\mathbf{n})$ and $\alpha_A \sim q(\alpha_A)$, then applies a median-of-means estimator to $X(\mathbf{n}, \alpha_A)$.

The main technical contribution is the following generalized Gurvits-type subroutine. It is needed whenever the adaptive circuit requires marginal probabilities of a small number of measured modes, while all other modes are summed out. The relevant quantity has the form

$$q(n_1, \dots, n_L) = \sum_{n_{L+1}, \dots, n_M} \langle \phi | \hat{G}_0^\dagger | \mathbf{n} \rangle \langle \mathbf{n} | \hat{G}_0 | \psi \rangle, \quad (9)$$

where $|\psi\rangle$ and $|\phi\rangle$ are arbitrary product states with bounded local photon-number cutoff, $\hat{G}_0$ is a general Gaussian circuit, and only the first L photon numbers are specified.

Lemma: (informal) Generalized Gurvits algorithm. For constant L , the marginal quantity $q(n_1, \dots, n_L)$ can be computed exactly in time polynomial in the number of modes M , for arbitrary product input states with bounded local photon-number cutoff and arbitrary Gaussian circuits $\hat{G}_0$.

This lemma can be viewed as a Gaussian and product-input generalization of Gurvits's second algorithm for boson sampling [5]. In the boson-sampling setting, Gurvits's second algorithm computes low-order output marginals exactly in polynomial time: if only a constant number of output occupation numbers are specified and all other modes are summed over, the resulting marginal probability can be evaluated efficiently. Our setting requires a substantially broader version of this idea. The circuit is no longer restricted to passive linear optics, the input and output states are not restricted to Fock states, and the Gaussian circuit may contain squeezing. Moreover, the marginal quantities appear as subroutines inside a measurement-adaptive mean-value estimator, rather than as standalone sampling marginals.

The proof follows the same high-level philosophy as Gurvits's second algorithm—replace a high-dimensional summation over unobserved photon numbers by a low-dimensional coefficient-extraction problem—but extends it to general Gaussian circuits with arbitrary product states.

Concretely, the desired marginal is encoded into the generating function

$$\tilde{G}(\varphi) = \langle \phi | \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0 | \psi \rangle, \quad \hat{P}(\varphi) = e^{i \sum_{j=1}^L \varphi_j \hat{n}_j}, \quad (10)$$

where $\hat{P}(\varphi)$ is a phase shifter acting only on the L measured modes. The marginal $q(n_1, \dots, n_L)$ is obtained as a Fourier coefficient of $\tilde{G}(\varphi)$. Since $L = O(1)$, the coefficient extraction is over only constantly many variables. At the same time, $\tilde{G}(\varphi)$ can be evaluated efficiently

because inserting $\hat{P}(\varphi)$ preserves Gaussianity, while the bounded-cutoff product structure of $|\psi\rangle$ and $|\phi\rangle$ makes the resulting local evaluations efficient.

This generalized Gurvits subroutine is the technical engine behind the adaptive algorithms. It converts the potentially high-dimensional summation over unmeasured photon numbers into a constant-dimensional coefficient-extraction problem. Consequently, the dependence on the number of adaptive measurements can be exponential in L , but the dependence on the total number of modes remains polynomial for constant L .

The Gaussian-measurement case uses the same principle, but with continuous rather than discrete outcomes. The photon-number outcome $\mathbf{n}$ is replaced by a Gaussian-measurement outcome β , with POVM element

$$\hat{\Pi}(\beta) = \frac{1}{\pi^L} \hat{D}(\beta) |\psi_G\rangle \langle \psi_G| \hat{D}^\dagger(\beta). \quad (11)$$

The expectation value becomes

$$\langle \hat{O} \rangle = \int d^{2L} \beta d^{2l} \alpha_A p(\beta) q(\alpha_A) X(\beta, \alpha_A). \quad (12)$$

For constant L , the integration over β is low-dimensional, while the evaluation of $X(\beta, \alpha_A)$ again reduces to Gaussian marginal quantities with product inputs. Thus the same generalized Gurvits-type mechanism controls both photon-number-measurement adaptivity and Gaussian-measurement adaptivity.

The overall message is that we never simulate the full output distribution. Instead, we estimate the desired observable directly by combining phase-space sampling with efficient computation of low-dimensional adaptive marginals. This is why the mean-value problem can remain easy even when sampling from related non-Gaussian bosonic circuits is hard.

5 Discussion

Our results refine the resource theory of photonic quantum advantage by showing that local non-Gaussianity alone does not determine the hardness of practical mean-value tasks. We show that when the number L of adaptive measurement-and-feedforward steps is constant, expectation values remain classically tractable even for highly non-Gaussian product inputs; when L grows, the same architectures can realize universal quantum computation. This suggests that demonstrating practical photonic quantum advantage requires a sufficiently rich adaptive measurement structure.

A key technical ingredient is the generalized Gurvits second algorithm developed here, which computes constant-size photon-number marginals of general Gaussian circuits with arbitrary bounded-cutoff product inputs in polynomial time. This subroutine may be useful beyond the present setting, especially for bosonic simulation problems involving marginal probabilities or expectation values rather than full output sampling. It would be interesting to sharpen the dependence on L , extend the framework to noisy adaptive circuits, and identify intermediate regimes between constant adaptivity and full universality.

Gaussian building blocks are essential for photonic quantum information processing, and universality can be practically achieved by equipping Gaussian circuits with adaptive measurement and feedforward. The number of adaptive steps then provides a natural parameter for computational power. Rather than assessing power only through sampling problems—the usual benchmark—we follow the ongoing shift toward tasks of practical relevance and study the quantum mean-value problem, i.e., estimating observable expectation values that underpin simulation and variational algorithms. More specifically, we analyze bosonic circuits with adaptivity and prove that when the number of adaptive measurements is small, the mean-value problem admits efficient classical algorithms even if a large amount of non-Gaussian resources are present in the input state, whereas less constrained regimes are computationally hard. This yields a task-level contrast with sampling, where non-Gaussian ingredients alone often induce hardness, and provides a clean complexity boundary parameterized by the number of adaptive measurement-and-feedforward steps between classical simulability and quantum advantage. Beyond the main result, we introduce classical techniques—including a generalization of Gurvits’ second algorithm to arbitrary product inputs and Gaussian circuits—for computing the marginal quantities needed by our estimators, which may be of independent interest.

I. INTRODUCTION

Quantum computers are promised to provide computational power for solving various problems, such as integer factorization [1] and time-dynamics simulation of quantum systems [2], which are believed to be intractable for any classical computer. However, due to demanding experimental requirements, including a large number of qubits and small error rates, achieving quantum computational advantage for solving practical problems remains highly challenging. Thus, although the ultimate goal is to build a universal quantum computer, many recent experiments have focused on demonstrating quantum advantage through sampling problems that are relatively easier to implement in experiments [3–12] while many debates are going on regarding the precise boundary between classical simulability and genuine quantum advantage [13–26].

In bosonic systems, particularly in photonic platforms, the most prominent paradigm for quantum advantage is boson sampling due to a relatively more straightforward requirement, a linear-optical circuit [27–29]; consequently, numerous experiments have been conducted to demonstrate quantum advantage using boson sampling [7–12]. Despite its hardness results [27–29], it is also widely recognized that universal quantum computation requires more than linear-optical circuits, such as non-Gaussian operations or measurement-and-feedforward operations [30–34].

In theory, nonlinear gates such as Kerr interactions are sufficient for universality [35]. In practice, however, such gates are extremely difficult to realize

because photons rarely interact, and inevitable loss and noise further degrade the effect [36]. Consequently, feasible bosonic gates in experiments are largely limited to Gaussian unitaries. Since nonlinearity remains indispensable for universality, many experiments instead rely on non-Gaussian measurements combined with post-selection or feedforward [30, 37–42]. For example, heralding can generate single-photon states from two-mode squeezed vacua, while GKP states can be approximately prepared by post-selecting certain outcomes in Gaussian boson sampling circuits [41–43]. Alternatively, non-Gaussian resources can be supplied entirely through the input states, provided that the measurement and feedforward operations are available, for the universal quantum computation [34]. This has motivated recent experimental efforts to go beyond the boson-sampling framework by incorporating non-Gaussian resources, such as measurement-induced nonlinear effects, to unlock more versatile and powerful photonic processors. Representative directions include nonlinear boson sampling [40] and adaptive boson sampling [44, 45].

Importantly, some of these recent works aim not only to demonstrate sampling-based quantum advantage but also to move towards more practical computational advantages, ultimately aligned with building a universal quantum computer. From this perspective, it becomes increasingly critical to understand the complexity of simulating bosonic circuits for tasks beyond sampling. A particularly important computational task is the quantum mean-value problem because of its generality and practicality (e.g., Refs. [46, 47]). More specifically, the quantum mean-value problem encompasses various practical problems, such as variational quantum algorithms and kernel-based machine learning applications [44, 45, 48]. Furthermore,

* changhun0218@gmail.com

the quantum mean-value problem for a universal quantum circuit is known to be BQP-complete [49, 50]; hence, this problem essentially captures the universal quantum computer’s power, provided that the necessary resources are supplied. This shift reflects a broader transition: extending the role of photonic devices from demonstrating quantum advantage in sampling problems to realizing practical advantages in tasks more relevant to real-world applications. In this context, clarifying the boundary between classical and quantum computational power is essential.

In this work, we investigate the complexity of simulating bosonic circuits with measurement and feedforward operations, focusing on how the computational cost of the simulation depends on the number of measurements for feedforward operations (See Table I for the main results). Among various notions of simulation [51, 52], we mainly analyze and compare two: sampling and the quantum mean-value problem. While non-Gaussian resources generally render the sampling problem classically intractable [27–29, 53, 54], we show that the quantum mean-value problem can remain efficiently solvable classically even with highly non-Gaussian inputs, as long as the number of adaptive measurements is limited. Hence, our main results characterize the classical costs of these tasks as functions of the number of measurements and feedforward. Additionally, it suggests that the requirement for the hardness of the quantum mean-value problem is significantly more demanding. We show this by presenting classical algorithms that can efficiently estimate the expectation value of a product observable when (i) the number of measurements used for feedforward is at most constant and (ii) the Hilbert-Schmidt norm of the observable is at most polynomially large.

In this work, we use the term *measurement-adaptive Gaussian circuit* for the following class of photonic architectures. We consider a collection of bosonic modes that undergo layers of Gaussian unitaries, possibly interleaved with L layers of measurements on some of the modes. The measurement outcomes are processed classically and can be used to choose the subsequent Gaussian unitaries (feedforward). We allow general, possibly non-Gaussian, product input states on some modes (e.g., single-photon or GKP states), while the dynamical gates acting during the circuit are Gaussian. The special case $L = 0$ corresponds to a non-adaptive Gaussian circuit, whereas $L \geq 1$ yields a measurement-adaptive Gaussian circuit in our terminology.

More specifically, considering practical relevance, we analyze three circuit families in detail: (i) Gaussian circuits without feedforward, (ii) Gaussian circuits with photon-number-resolving detection for feedforward, and (iii) Gaussian circuits with Gaussian measurements for feedforward. It is worth emphasizing that if a sufficient number of photon-number measurements or Gaussian measurements for feedforward is provided,

the circuits (ii) and (iii) become a universal quantum computer [30, 34]. Hence, the quantum mean-value problem becomes BQP-complete. Therefore, understanding the complexity of the quantum mean-value problem is crucial for delineating regimes where such circuits remain classically simulable (for example, with a bounded amount of adaptivity) and regimes where they are powerful enough to enable universal quantum computation. We also emphasize that our classical algorithms are efficient when the Hilbert-Schmidt norm of the observable is at most polynomially large, which is precisely the regime targeted by many proposals for *practical* quantum advantage. In photonic platforms, such proposals typically consider expectation values of few-mode or k -local observables, for example, local Hamiltonian terms, correlation functions, witnesses, or other figures of merit used as quantum-advantage benchmarks, whose Hilbert-Schmidt norms grow at most polynomially with the system size (e.g., photonic variational quantum algorithms (VQAs) [55–60]). In these scenarios, additive-error estimation of such observables is the natural accuracy notion, so our results identify a regime where practically motivated mean-value tasks remain efficiently classically simulable, even though the same architectures become BQP-complete once unrestricted adaptivity is allowed.

To prove the efficiency of our classical algorithms, we exploit low-rank structures of matrices arising in these circuits, inspired by Gurvits’ second algorithm, which enables us to compute the marginal probabilities of Fock-state boson sampling [27, 61]. It is well-known that low-rankness often significantly reduces the computational complexity in evaluating functions such as the permanent, hafnian, and loop hafnian [62–64]. Using these observations, we design efficient classical algorithms for simulating bosonic circuits with a limited number of measurements for feedforward. In particular, by extending Gurvits’ second algorithm to more general setups, our algorithms exploit the low-rank structure of matrices associated with Gaussian circuits, which enables us to approximate relevant quantities with significantly reduced computational costs. We expect that our extension of Gurvits’ second algorithm is of independent interest for the complexity analysis of bosonic systems.

Our paper is organized as follows. In Sec. II, we first compare our work to previously known results to clarify our contributions. In Sec. III, we provide preliminaries for our main results. In Sec. IV, we provide the details of the problem setups. In Sec. V, we provide the main results about classical algorithms that simulate measurement-adaptive Gaussian circuits. More specifically, in Sec. VA, we consider Gaussian circuits without feedforward and provide the classical algorithms that solve the sampling and quantum mean-value problems associated with the circuits, respectively. In Sec. VB, we introduce measurement-adaptive Gaussian circuits by photon-number-resolving detectors and provide the classical algorithms solving the sampling

and quantum mean-value problems, respectively. In Sec. V C, we consider measurement-adaptive Gaussian circuits by Gaussian measurements and provide the classical algorithms solving the sampling and quantum mean-value problems, respectively. In Sec. VI, we provide the main techniques that are necessary for the classical algorithms. In Sec. VII, we conclude.

II. RELATED PREVIOUS STUDIES

Conceptually, our study aims to find an analogous classical algorithm in bosonic systems to those for simulating quantum circuits composed mainly of Clifford gates with a few T -gates [65, 66]. The analogy is that, in qubit systems, circuits with stabilizer input states, Clifford operations, and computational basis measurements are efficiently simulable on classical computers by the Gottesman-Knill theorem [67], whereas the addition of T -gates provides the necessary “magic” for universal quantum computation. In bosonic systems, Gaussian input states, Gaussian circuits, and Gaussian measurements play the role of stabilizer-Clifford circuits, i.e., easy to classically simulate, while non-Gaussian gates correspond to T -gates, which make the circuit hard to classically simulate [31, 33]. Moreover, just as T -gates can be simulated via gadgets that rely on measurement and feedforward, we also consider measurement-induced non-Gaussian elements in bosonic circuits [30, 37].

This analogy has motivated a line of work on the classical simulation of Gaussian circuits augmented by limited non-Gaussian resources [53, 54, 68–74] while many of which particularly focuses on strong simulation, i.e., computing the output (marginal) probabilities [53, 54, 69, 72]. For example, Chabaud et al. and Mele et al. [53, 74] analyzed the role of non-Gaussian resources in continuous-variable circuits and identified which types of resources are necessary to achieve quantum computational advantage. Chabaud et al. [69], Dias et al. [72], and Hahn et al. [54] developed classical algorithms for simulating Gaussian circuits with a small number of non-Gaussian gates or inputs, primarily targeting sampling problems and their strong simulations. Other works, such as Veitch et al. [68], explored the role of Wigner function negativity as a resource for quantum computational power, while Bourassa et al. [70] investigated fast classical simulation methods for restricted classes of photonic circuits. More recently, Calcluth et al. [73] provided sufficient conditions for efficient simulation of bosonic circuits under resource constraints. Overall, these studies mainly focus on classical simulation in the context of sampling problems, with a focus on strong simulations, rather than the quantum mean-value problem that we emphasize here.

Meanwhile, there is also a rich literature on estimating output probabilities of bosonic circuits with additive error, which is a special case of the quantum mean-value problem. In particular, quasi-probability-based methods

have been studied for estimating output probability distributions [51, 75, 76]. For example, Pashayan et al. [51, 75] showed that such estimation techniques can be carried out classically with complexity depending on the negativity of the quasi-probability representation. While these methods have been applied to several interesting systems, they have not been specifically developed for the class of bosonic circuits we consider in this work. Additionally, whereas their algorithms concentrate on estimating output probabilities, our work addresses a more general problem: the quantum mean-value problem. Furthermore, our method does not explicitly depend on the negativity of the quantum circuits, which is in stark contrast to the previous works, making our method more generally applicable.

Finally, our previous work initiated the study of the complexity of the quantum mean-value problem in non-adaptive linear-optical circuits [77]. While the main motivation there was to investigate the practicality of boson-sampling-type architectures, passive linear optics alone is not believed to render a universal quantum computer. More generally, Gaussian circuits by themselves are also non-universal; universality is recovered only when one supplements Gaussian or linear-optical unitaries with suitable non-Gaussian resources or measurement-based feedforward, as in the KLM scheme and Gaussian cluster-state architectures. Motivated by this, in the present work, we extend this line of research from passive linear optics to a broader class of bosonic circuits, namely measurement-adaptive Gaussian circuits, where Gaussian unitaries are interleaved with a finite number of measurement-and-feedforward layers acting on possibly non-Gaussian resource states. We emphasize that there are increasing attentions to the adaptive circuits due to their potential practical applications [44, 45, 78]. From a technical standpoint, we employ a similar method for the main routine of the classical algorithms. However, extending from linear-optical circuits to Gaussian circuits with measurement and feedforward requires a more challenging subroutine, which is computing marginal probabilities for general Gaussian circuits. To do this, we extend Gurvits’ second algorithm, which works only for Fock states and linear-optical circuits, to arbitrary product states and Gaussian circuits [27, 61]. To this end, we also provide a classical algorithm for computing the overlap of a low-mode quantum state evolved through a linear-optical circuit with an arbitrary product state.

III. PRELIMINARY

In this section, we provide some preliminaries for the main results (more details can be found in Refs. [79–81]). We will mainly focus on M -mode bosonic systems throughout this work. Here, the annihilation and creation operators for i th mode are denoted by $\hat{a}_i$ and $\hat{a}_i^\dagger$, respectively, and they satisfy the canonical commutation

	Sampling (Gaussian input and measurement)	Quantum mean-value problem
Gaussian circuits without feedforward	Efficient [31–33]	*Efficient [Sec. V A, Theorem 1]
Gaussian circuits + photon number counting	*Efficient when $L = O(\log M)$ [Sec. V B, Theorem 2]	*Efficient when $L = O(1)$ [Sec. V B, Theorem 3], BQP-complete for general L [30]
Gaussian circuits + Gaussian measurement	Efficient [31–33]	*Efficient when $L = O(1)$ [Sec. V C, Theorem 4], BQP-complete for general L [34]

TABLE I. Comparison of sampling and quantum mean-value estimation complexities for different families of bosonic quantum circuits: Gaussian circuit without feedforward, Gaussian circuits augmented by photon number counting and Gaussian feedforward, and Gaussian circuits augmented by Gaussian measurement and Gaussian feedforward. Here, M is the number of modes and L is the number of measurement-and-adaptive operations. Asterisks represent the results from this work.

relation, $[\hat{a}_i, \hat{a}_j^\dagger] = \delta_{ij}$ and $[\hat{a}_i, \hat{a}_j] = [\hat{a}_i^\dagger, \hat{a}_j^\dagger] = 0$. In such systems, any M -mode operator $\hat{O}$ can be written as a linear combination of displacement operators:

$$\hat{O} = \frac{1}{\pi^M} \int d^{2M} \alpha \chi_{\hat{O}}(\alpha) \hat{D}^\dagger(\alpha), \quad (1)$$

where $\chi_{\hat{O}}(\alpha) \equiv \text{Tr}[\hat{D}(\alpha)\hat{O}]$ is called the characteristic function of an operator $\hat{O}$, $\hat{D}(\alpha)$ is an M -mode displacement operator of an amplitude $\alpha \in \mathbb{C}^M$ which is a tensor product of single-mode displacement operators, i.e., $\hat{D}(\alpha) = \otimes_{i=1}^M \hat{D}(\alpha_i) = \otimes_{i=1}^M e^{\alpha_i \hat{a}_i^\dagger - \alpha_i^* \hat{a}_i}$ with $\alpha_i \in \mathbb{C}$. The displacement operator with zero amplitude is equal to the identity operator $\hat{D}(\mathbf{0}) = \hat{1}_M$, where $\hat{1}_M$ denotes the identity operator for the M -mode system. An important property of the displacement operator that we frequently use is the following twirling relation:

$$\frac{1}{\pi^M} \int d^{2M} \alpha \hat{D}(\alpha) \hat{O} \hat{D}^\dagger(\alpha) = \text{Tr}[\hat{O}] \hat{1}_M. \quad (2)$$

Note that the convention of integration is $\int d^{2M} \alpha = \int_{\mathbb{C}^M} \prod_{j=1}^M d^2 \alpha_j$ and $\int_{\mathbb{C}} d^2 \alpha_j = \int_{-\infty}^{\infty} d \text{Re } \alpha_j d \text{Im } \alpha_j$, where $\alpha_j = \text{Re } \alpha_j + i \text{Im } \alpha_j$ throughout this work.

Gaussian states, circuits, and measurements.— In this work, we frequently consider Gaussian states, Gaussian unitary circuits, and Gaussian measurements [32, 80, 81]. Thus, we provide definitions for these objects.

First of all, Gaussian states are defined as the ones whose characteristic function (or equivalently, the Wigner function) is Gaussian. The states that are not Gaussian are called non-Gaussian states.

Gaussian unitary circuits are those that map Gaussian states to Gaussian states. Otherwise, the circuits are referred to as non-Gaussian. An essential property of Gaussian unitary circuits is that by the Bloch-Messiah decomposition, any Gaussian unitary circuit can be written as a linear-optical circuit $\hat{U}$, the M -mode tensor product of single-mode squeezing gates $\hat{S}(\mathbf{r}) = \otimes_{i=1}^M \hat{S}(r_i)$, and another linear-optical circuit $\hat{V}$, i.e., $\hat{G} = \hat{D}(\beta) \hat{U} \hat{S}(\mathbf{r}) \hat{V}$, where $\beta \in \mathbb{C}^M$ is the displacement vector and $\mathbf{r} \in \mathbb{R}^M$ is the squeezing parameter vector. Here,

a linear-optical circuit, a restricted family of Gaussian circuits, is defined as an operator that transforms bosonic annihilation operators as

$$\hat{U}^\dagger \hat{a}_i \hat{U} = \sum_{j=1}^M U_{ij} \hat{a}_j, \quad (3)$$

where U is the associated $M \times M$ unitary matrix to the linear-optical circuit $\hat{U}$. Another important property that is frequently exploited is that a Gaussian unitary circuit transforms a displacement operator into another displacement operator [32, 80, 81]

$$e^{2i \text{Im}(\alpha^\dagger \beta)} \hat{D}^\dagger(\alpha') = \hat{G}^\dagger \hat{D}^\dagger(\alpha) \hat{G}, \quad (4)$$

where β is the displacement in $\hat{G}$'s Bloch-Messiah decomposition and $\alpha' \in \mathbb{C}^M$ is a function of α that depends on the Gaussian circuit $\hat{G}$. More specifically, for a Gaussian unitary that transforms the annihilation operators as

$$\hat{G}^\dagger \hat{a} \hat{G} = X \hat{a} + Y \hat{a}^\dagger + \beta, \quad (5)$$

where $\hat{a} = (\hat{a}_1, \dots, \hat{a}_M)$, we have

$$\alpha' = X^\dagger \alpha - Y^T \alpha^*. \quad (6)$$

Gaussian measurements are the ones whose POVMs are given as [32, 81]

$$\hat{\Pi}(\alpha) = \frac{1}{\pi^M} \hat{D}(\alpha) \hat{\rho}_G \hat{D}^\dagger(\alpha), \quad (7)$$

where $\hat{\rho}_G$ is a Gaussian state that defines the Gaussian measurement. Gaussian measurements include homodyne, heterodyne, and general-dyne detections, which are frequently employed in current quantum optical circuits. Without loss of generality, the Gaussian state $\hat{\rho}_G$ that defines the measurement can be assumed to be a pure Gaussian state $|\psi_G\rangle\langle\psi_G|$ because the Gaussian measurements represented by a mixed Gaussian state can be simulated by those with a pure Gaussian state. Thus, we write the Gaussian measurements' POVMs as

$$\hat{\Pi}(\alpha) = \frac{1}{\pi^M} \hat{D}(\alpha) |\psi_G\rangle\langle\psi_G| \hat{D}^\dagger(\alpha). \quad (8)$$

The completeness of POVMs is guaranteed by the twirling property of the displacement operator, Eq. (2).

The median-of-means estimator.— Finally, since all the estimators we use for our classical algorithms to solve the quantum mean-value problem are based on the median-of-means estimator [77, 82], let us provide the relevant parameters. Suppose we want to estimate the mean of a random variable $X(\alpha)$:

$$\mathbb{E}[X] = \int d^{2M} \alpha p(\alpha) X(\alpha), \quad (9)$$

where $p(\alpha)$ is a proper probability distribution, i.e., $\mathbb{E}[X]$ is the average of the random variable $X(\alpha)$ over $\alpha \sim p(\alpha)$. Let $\text{Var}(\alpha)$ be the variance of the random variable $X(\alpha)$. Then, the median-of-means estimator is an estimator μ constructed by taking the median of means of subsamples, and, importantly, it satisfies

$$\Pr[|\mu - \mathbb{E}[X]| \geq \epsilon] \leq 1 - \delta, \quad (10)$$

if we use N samples, where $N \geq 544 \text{Var}(X) \epsilon^{-2} \log(1/\delta)$ [77, 82]. Hence, to bound the sample complexity, it suffices to find an upper bound on the variance (or the second moment) of the random variable X .

Sampling by chain rule.— Finally, our classical algorithms are randomized algorithms based on sampling using the chain rule of conditional probabilities. More specifically, when we have a probability distribution $p(\mathbf{n})$, one way to sample $\mathbf{n}$ from the probability distribution is to use the chain rule of the conditional probability:

$$p(\mathbf{n}) = p(n_1)p(n_2|n_1) \cdots p(n_M|n_1, \dots, n_{M-1}). \quad (11)$$

Hence, if one can compute the marginal probability, by sampling each random variable n_i using the marginal probabilities, one can sample $\mathbf{n}$ from the full probability distribution $p(\mathbf{n})$ [83]. Therefore, the complexity of computing the marginal probabilities determines that of sampling.

IV. PROBLEM SETUP

For computational tasks, we will examine two problems: (i) the sampling problem and (ii) the quantum mean-value problem. We now provide precise definitions of these two problems.

The sampling problem is defined as simulating the output probability distribution of a given quantum circuit, which is the basis of the current quantum advantage experiments, such as random circuit sampling [3–6] and boson sampling [7–12]. Its definition is as follows:

Definition 1 (Sampling problem). *Given as input an efficient description of an $(M + L)$ -mode product input state $|\psi\rangle$, a quantum circuit $\mathcal{E}$ acting on $(M + L)$ modes that performs measurements on L modes with adaptive*

control, and a measurement on the remaining M output modes described by a POVM $\{\Pi_{\mathbf{x}}\}$, generate output samples according to the probability distribution $p(\mathbf{x}) \equiv \text{Tr}[\Pi_{\mathbf{x}} \mathcal{E}(|\psi\rangle\langle\psi|)]$.

In the definition, two parameters, the number of output modes M and the number of modes that are used for measurement for adaptive control L , appear. When $L = 0$, there is no adaptive control in the circuit. Our main focus in this work is to investigate for which scalings of L as a function of M the corresponding sampling problem admits an efficient classical simulation, i.e., can be solved in time polynomial in M , depending on the class of quantum circuits $\mathcal{E}$.

Note that in our definition, we choose the notion of sampling as exact sampling; hence, it is the hardest for classical computers (compared to approximate sampling).

For the quantum mean-value problem, the goal is to estimate the expectation value of a product operator $\hat{O} = \hat{O}_1 \otimes \cdots \otimes \hat{O}_M$ for an output state of a quantum circuit, $|\psi_{\text{out}}\rangle$, with an additive error,

$$\langle \psi_{\text{out}} | \hat{O} | \psi_{\text{out}} \rangle. \quad (12)$$

For a finer complexity analysis, we consider a product structure $\hat{O} = \hat{O}_A \otimes \hat{1}_B$. Thus,

$$\langle \psi_{\text{out}} | \hat{O}_A \otimes \hat{1}_B | \psi_{\text{out}} \rangle, \quad (13)$$

where $\hat{O}_A$ is the nontrivial part of the observable on subsystem A , still assumed to be in a product form, i.e., $\hat{O}_A = \prod_{i \in A} \hat{O}_i$. We let l denote the number of modes in the subsystem A .

Definition 2 (Quantum mean-value problem). *Given as input an efficient description of an $(M + L)$ -mode product input state $|\psi\rangle$, a quantum circuit $\mathcal{E}$ acting on $(M + L)$ modes that performs measurements on L modes with adaptive control, and an M -mode product observable $\hat{O} = \hat{O}_A \otimes \hat{1}_B$, estimate the expectation value of $\hat{O}$ with respect to the output state of the circuit, $\text{Tr}[\hat{O} \mathcal{E}(|\psi\rangle\langle\psi|)]$ to within additive error ϵ with success probability at least $1 - \delta$.*

In this setting, the relevant size parameters are again the number of output modes M and the number L of modes used for adaptive control. Our goal in this work is to identify regimes of L and classes of observables $\hat{O}_A$ for which this quantum mean-value problem admits an efficient classical algorithm, namely one whose running time is polynomial in M , $1/\epsilon$, and $\log(1/\delta)$.

For quantum circuits, we will focus on the following three different families: (i) Gaussian circuits without feedforward, (ii) Gaussian circuits augmented by photon-number measurement and adaptive Gaussian unitary gates depending on the photon-number measurement outcomes, (iii) Gaussian circuits augmented by Gaussian measurement and adaptive Gaussian unitary gates

depending on the Gaussian measurement outcomes. Here, the choice of the input states and measurements depends on the tasks. The main reason that we investigate these three families is the feasibility of their implementations in practice. One may notice that we assume that all gate elements, including adaptive operations, are composed of Gaussian gates, which are experimentally accessible. Hence, for the hardness results, non-Gaussian elements, necessary resources for the hardness, are introduced through the input states and measurements.

Whenever the underlying circuit model is universal for quantum computation, in the sense that it can realize any polynomial-size adaptive circuit, the corresponding quantum mean-value problem is BQP-complete: additive-error estimation of suitable observables already captures the full power of a universal quantum computer. In our measurement-adaptive Gaussian architecture, this universality can be achieved by allowing the number L of adaptive measurements to grow polynomially with the system size [30, 34], whereas our main results show that for any fixed constant L the quantum mean-value problem for a broad class of observables remains efficiently classically simulable.

For the sampling problem, we restrict to Gaussian input states and Gaussian measurements; otherwise, the corresponding sampling problems are already known to be hard to classically simulate due to boson sampling's hardness results [27–29, 84]. Under this restriction, the first and third circuit families are already known to be efficiently simulable, since all elements are Gaussian [85]. In contrast, the second family is still nontrivial because it necessarily involves non-Gaussian elements. On the other hand, for the quantum mean-value problem, a general product input state and measurement, which may be non-Gaussian, is considered.

Finally, for simplicity, we will frequently assume that relevant quantum states (not for Gaussian states) have a finite maximum photon number:

$$|\psi\rangle = \bigotimes_{i=1}^M \left(\sum_{m_i=0}^{n_{\max}} a_{m_i}^{(i)} |m_i\rangle \right), \quad (14)$$

where $|m_i\rangle$ is the Fock state with photon number m_i and $a_{m_i}^{(i)}$ is the coefficient of the i th mode's m_i Fock state. When a given state does not satisfy this, we can approximate it by truncating the state by choosing the maximum photon number $n_{\max}$ appropriately. Although it induces an approximation error, such an approximation error is negligible if we choose $n_{\max}$ sufficiently large. Since the high photon occupation probability decays quickly in typical physical states, $n_{\max}$ does not have to be high in practice. For example, the system with dual-rail qubit encodings, such as the KLM protocol, requires only $n_{\max} = 1$, and few-photon Fock states or weakly squeezed states may not require more than $n_{\max}$ larger than 10 in general. As an example, Ref. [24], simulating large-scale Gaussian boson sampling experiments, uses

$n_{\max} = 7 \sim 10$ to suppress the truncation error.

V. CLASSICAL ALGORITHMS

A. Gaussian circuits without feedforward

In many optical quantum circuits, Gaussian circuits are relatively easy to implement, but not sufficient for universal quantum computation. Hence, additional resources are introduced through non-Gaussian state preparation, non-Gaussian measurements, and measurement and feedforward [30, 37–39, 41, 42]. In this section, however, we investigate Gaussian circuits without any measurement and feedforward operations, but allow arbitrary input states and measurements, and we consider the associated computational tasks.

Sampling.— For sampling, we consider the following configuration:

- Input state: product state;
- Quantum circuit: Gaussian unitary circuit;
- Measurement: Gaussian measurement.

As emphasized in the previous section, since such a configuration can realize boson sampling circuits [27–29], classical simulation of their sampling behavior is known to be hard. On the other hand, if the input state is restricted to Gaussian states and hence the entire circuit is Gaussian, it is well established that such circuits are efficiently classically simulable [31–33].

Quantum mean-value problem.— We now consider the quantum mean-value problem in this setup with the following configuration:

- Input state: product state;
- Quantum circuit: Gaussian unitary circuit;
- Observable: product observable.

Thus, we consider approximation of $\langle \psi | \hat{G}^\dagger \hat{O} \hat{G} | \psi \rangle$, where $\hat{G}$ is a Gaussian unitary circuit, $|\psi\rangle$ is an arbitrary product state, and $\hat{O} = \hat{O}_A \otimes \hat{1}_B$ is a product observable: For linear-optical circuits, it was proven in Ref. [77] that estimating the expectation value within additive error ϵ with success probability $1 - \delta$ requires $O(M^2 \|\hat{O}_A\|_2^2 \text{Tr}[\hat{\rho}_A^2] \log(1/\delta)/\epsilon^2)$ computational cost, where $\hat{\rho}_A \equiv \text{Tr}_B[\hat{G}|\psi\rangle\langle\psi|\hat{G}^\dagger]$ is the reduced density matrix on the system A . Here we extend this result from linear-optical circuits to general Gaussian circuits:

Theorem 1 (Quantum mean-value problem in Gaussian circuits without feedforward). *Consider an M -mode Gaussian circuit $\hat{G}$ and an arbitrary product input state $|\psi\rangle$, and an M -mode product operator $\hat{O} = \hat{O}_A \otimes \hat{1}_B$. The expectation value $\langle \psi | \hat{G}^\dagger \hat{O} \hat{G} | \psi \rangle$ can be approximated*

within additive error ϵ with probability $1 - \delta$ in running time

$$O\left(\frac{M^2 \|\hat{O}_A\|_2^2 \text{Tr}[\hat{\rho}_A^2] \log(1/\delta)}{\epsilon^2}\right), \quad (15)$$

where $\hat{\rho}_A \equiv \text{Tr}_B[\hat{G}|\psi\rangle\langle\psi|\hat{G}^\dagger]$ is the reduced density matrix on the system A .

Proof Sketch. Details are provided in Appendix A 1. Using Eq. (1), the mean value can be rewritten as

$$\langle\psi|\hat{G}^\dagger(\hat{O}_A \otimes \hat{1}_B)\hat{G}|\psi\rangle = \int d^{2l} \alpha_A p(\alpha_A) X(\alpha_A), \quad (16)$$

where l is the number of modes in the subsystem A , and we defined a probability distribution and a random variable,

$$p(\alpha_A) = \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2}, \quad X(\alpha_A) = \frac{\chi_{\hat{\rho}_A}^*(\alpha_A) \|\hat{O}_A\|_2^2}{\chi_{\hat{O}_A}^*(\alpha_A)}, \quad (17)$$

respectively. By the twirling property, Eq. (2), $p(\alpha_A)$ is a normalized probability distribution. Thus, the expectation value equals the mean of the random variable $X(\alpha_A)$, which allows us to employ the median-of-means estimator.

By direct calculation, we show that the variance of X is bounded above by $\|\hat{O}_A\|_2^2 \|\hat{\rho}_A\|_2^2$. Moreover, the product structure of $p(\alpha_A)$ and Eq. (4) guarantee that sampling $\alpha_A \sim p(\alpha_A)$ and evaluating $X(\alpha_A)$ can be done efficiently, respectively. Explicitly, they can be written in a product structure:

$$p(\alpha_A) = \prod_{i \in A} \frac{|\chi_{\hat{O}_i}(\alpha_i)|^2}{\pi \|\hat{O}_i\|_2^2}, \quad (18)$$

$$X(\alpha_A) = \prod_{i=1}^M \chi_{\psi_i}^*(\alpha'_i) \prod_{i \in A} \frac{\|\hat{O}_i\|_2^2}{\chi_{\hat{O}_i}^*(\alpha_i)}, \quad (19)$$

where α' is defined by

$$\hat{D}^\dagger(\alpha') = \hat{G}^\dagger(\hat{D}^\dagger(\alpha_A) \otimes \hat{D}^\dagger(\mathbf{0}_B))\hat{G}, \quad (20)$$

and computed in $O(lM)$. Hence, applying the median-of-means estimator (10) with the above variance bound then yields the claimed complexity. $\square$

Hence, the algorithm runs as follows:

1. Sample $\alpha_A \in \mathbb{C}^l$ from $p(\alpha_A)$ by independently sampling α_i from $|\chi_{\hat{O}_i}(\alpha_i)|^2/(\pi \|\hat{O}_i\|_2^2)$;
2. Compute $X(\alpha_A)$ for the sampled α_A by using Eq. (6).

3. Apply the median-of-mean estimator to estimate the expectation value.

Here, for sampling from $|\chi_{\hat{O}_i}(\alpha_i)|^2/(\pi \|\hat{O}_i\|_2^2)$, one may consider various well-known classical algorithms. For example, for general purposes rejection sampling and Markov Chain Monte Carlo algorithms are natural choices to perform the sampling [86] since we can efficiently compute the probability density.

On the other hand, Theorem 1 shows that whenever $\|\hat{O}_A\|_2^2 = O(\text{poly}(M))$, there exists a classical algorithm that efficiently solves the quantum mean-value problem for Gaussian circuits. This condition is naturally met in many relevant scenarios, such as local observables with support on $l = O(1)$ modes and low-rank (possibly global) observables whose Hilbert-Schmidt norm remains polynomially bounded. The former is particularly relevant for near-term applications that focus on estimating local quantities (e.g., VQAs [55–60]), as discussed in the Introduction.

We note that the dependence of the classical complexity on the number of modes l in the subsystem A enters mainly through the Hilbert-Schmidt norm $\|\hat{O}_A\|_2^2$ and the local purity $\text{Tr}[\hat{\rho}_A^2]$. When $l = \omega(1)$, the Hilbert-Schmidt norm can become extensive or even grow exponentially with l (for instance, for highly non-local observables with large support), which in turn can make the runtime exponentially large. In contrast, for genuinely local few-body observables or low-rank observables with bounded spectrum, $\|\hat{O}_A\|_2^2$ typically remains polynomial in M , so that this potential source of hardness is absent. On the other hand, if the output state is highly entangled, the purity of the reduced state $\text{Tr}[\hat{\rho}_A^2]$ can be significantly suppressed. This suppression always reduces the complexity, but for typical highly entangled states, one still expects at most an inverse-polynomial suppression in M since typical highly entangled states' purity is at least inverse-polynomial in the system size M [87, 88].

We emphasize that the input state may be arbitrary as long as it is a product state. Hence, even if the input state has a large amount of non-Gaussian resources, such as a high stellar rank [89], the corresponding quantum mean-value problem is still easy, which is in stark contrast to the sampling problem.

B. Photon-number-measurement-adaptive Gaussian circuits

The Gaussian circuits considered in the preceding section are not believed to be as powerful as a universal quantum computer, even when supplemented with non-Gaussian inputs or measurements [27]. Consequently, in many photonic architectures, universal quantum computation is pursued through intermediate measurements and feedforward, as the direct implementation of non-Gaussian gates is often

FIG. 1. Schematics of quantum circuits of interest in this work. The input state is a product state, and the quantum circuits are composed of Gaussian circuits, measurements, and feedforward operations. More specifically, we consider photon number measurements (Sec. VB) and Gaussian measurements (Sec. VC) for feedforward operations. The final measurement on the computing register is always Gaussian for sampling and implicit for the quantum mean-value problem, depending on the observable. Note that the final measurement can also be adaptive through the final circuit layer $\hat{G}_{L+1}$.

experimentally demanding. For feasibility, we assume that the feedforward unitaries are Gaussian.

In this section, we consider photon-number-resolving detections for feedforward operations. In other words, conditioned on the detected photon numbers, a measurement-outcome-dependent Gaussian operation is applied. We now analyze the computational complexity of simulating such circuits for both sampling and mean-value estimation, with particular emphasis on the dependence on the number of measurements and adaptive steps.

Measurement and feedforward.— We now formulate circuits augmented with measurement and feedforward (see Fig. 1). The circuit consists of a computing register and a measurement register: the modes in the computing register are retained until the final measurement, while the modes in the measurement register are measured in the middle, and the outcomes are used to determine feedforward operations on either the computing or measurement registers.

We begin with a product input state $|\psi\rangle$ and apply a Gaussian unitary $\hat{G}^{(1)}$,

$$|\psi^{(1)}\rangle = \hat{G}^{(1)}|\psi\rangle. \quad (21)$$

Next, one of the modes is measured using a rank-one POVM $\{|n_1\rangle\langle n_1|\}_{n_1}$, and an adaptive Gaussian unitary is applied to the remaining modes:

$$|\psi^{(1)}\rangle \rightarrow \hat{G}_{n_1}^{(2)}(\hat{\mathbb{I}} \otimes \langle n_1|)|\psi^{(1)}\rangle \equiv |\tilde{\psi}_{n_1}^{(2)}\rangle, \quad (22)$$

where $|\tilde{\psi}_{n_1}^{(2)}\rangle$ is a unnormalized state. More generally, at the k th step, we have

$$|\tilde{\psi}_{n_1, \dots, n_{k-1}}^{(k)}\rangle \rightarrow \hat{G}_{n_1, \dots, n_k}^{(k+1)}(\hat{\mathbb{I}} \otimes \langle n_k|)|\tilde{\psi}_{n_1, \dots, n_{k-1}}^{(k)}\rangle \quad (23)$$

$$\equiv |\tilde{\psi}_{n_1, \dots, n_k}^{(k+1)}\rangle. \quad (24)$$

The intermediate (unnormalized) state can be rewritten

as

$$|\tilde{\psi}_{n_1, \dots, n_k}^{(k+1)}\rangle = \langle n_1, \dots, n_k | \hat{G}_{n_1, \dots, n_k}^{(k+1)} \dots \hat{G}_{n_1}^{(2)} \hat{G}^{(1)} |\psi\rangle \quad (25)$$

$$\equiv \langle n_1, \dots, n_k | \hat{G}_{n_1, \dots, n_k} |\psi\rangle \quad (26)$$

$$\equiv \langle n_1, \dots, n_k | \psi_{n_1, \dots, n_k} \rangle, \quad (27)$$

and the probability of observing outcome $(n_1, \dots, n_k)$ is

$$p(n_1, \dots, n_k) \equiv \langle \tilde{\psi}_{n_1, \dots, n_k}^{(k+1)} | \tilde{\psi}_{n_1, \dots, n_k}^{(k+1)} \rangle. \quad (28)$$

After L steps of measurement and adaptive operations, the final state is written as

$$|\tilde{\psi}_{n_1, \dots, n_L}^{(L+1)}\rangle, \quad (29)$$

and the corresponding probability distribution factorizes as

$$p(n_1, \dots, n_L) = p(n_1)p(n_2|n_1) \dots p(n_L|n_1, \dots, n_{L-1}). \quad (30)$$

By measuring the final quantum state $|\tilde{\psi}_{n_1, \dots, n_L}^{(L+1)}\rangle$, the computation is completed. Now, let us consider the sampling problem and the quantum mean-value problem, respectively.

Sampling.— We now consider a Gaussian input state and a Gaussian measurement at the final stage. Thus, the configuration is as follows:

- Input state: Gaussian input state;
- Quantum circuit: Gaussian unitary circuit with L adaptive photon-number measurements;
- Final measurement: Gaussian measurement.

This restriction is natural because if we allow a non-Gaussian measurement, then even without mid-circuit measurements, the classical simulation of sampling is already hard due to the hardness of boson sampling [27–29]. Similarly, if we allow a non-Gaussian input with

Gaussian measurements, the resulting configuration has also been proven to be classically hard [84]. Therefore, throughout this subsection, we assume Gaussian inputs and Gaussian final measurements.

Let L denote the number of modes used for adaptive photon-number measurements. We prove that when $L = O(\log M)$, the sampling problem can be simulated efficiently. More specifically, since the intermediate measurements that are not used for Gaussian adaptive feedforward can be deferred to the end of the circuit, we prove that the sampling problem can be efficiently simulated if the output measurement is composed of M Gaussian measurements and L photon-number resolving measurements, where the latter can be used for Gaussian feedforward.

Theorem 2 (Sampling in Gaussian circuits with photon-number measurement and Gaussian feedforward). *Consider an $(M + L)$ -mode Gaussian input state, an $(M + L)$ -mode Gaussian circuit, and a measurement scheme on the output modes that consists of (i) photon-number-resolving measurements on at most L modes and (ii) Gaussian measurements on the remaining M modes. The photon-number measurements may be performed adaptively, in the sense that arbitrary Gaussian operations may depend on the previous outcomes (Gaussian feedforward). If $L = O(\log M)$, then the sampling from the resulting output distribution can be efficiently simulated on a classical computer.*

Proof. The output probability distribution of the final Gaussian measurement $\{\hat{\Pi}(\alpha)\}$ under adaptive operations on M modes can be written as

$$p(\alpha) = \sum_{\mathbf{n}} p(\mathbf{n}) p(\alpha|\mathbf{n}) \quad (31)$$

$$= \sum_{\mathbf{n}} p(\mathbf{n}) \frac{\langle \psi_{\mathbf{n}} | (\hat{\Pi}(\alpha) \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle}{\langle \psi_{\mathbf{n}} | (\hat{\mathbb{1}}_M \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle}, \quad (32)$$

where $\mathbf{n} \equiv (n_1, \dots, n_L)$, $|\psi_{\mathbf{n}}\rangle \equiv \hat{G}_{\mathbf{n}}|\psi\rangle$, and

$$p(\mathbf{n}) = \langle \psi_{\mathbf{n}} | (\hat{\mathbb{1}}_M \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle. \quad (33)$$

Here, $\hat{G}_{\mathbf{n}}$ denotes the feedforward Gaussian circuit conditioned on outcome $\mathbf{n}$, and $\hat{\Pi}(\alpha)$ is a Gaussian POVM. Hence, $p(\mathbf{n})$ is normalized to 1 as

$$1 = \sum_{\mathbf{n}} p(\mathbf{n}) = \sum_{\mathbf{n}} \langle \psi_{\mathbf{n}} | (\hat{\mathbb{1}}_M \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle = \sum_{\mathbf{n}} \langle \tilde{\psi}_{\mathbf{n}} | \tilde{\psi}_{\mathbf{n}} \rangle, \quad (34)$$

where $|\tilde{\psi}_{\mathbf{n}}\rangle \equiv \langle \mathbf{n} | \psi_{\mathbf{n}} \rangle$ is the unnormalized post-measurement state obtained when the measurement for feedforward is $\mathbf{n}$.

Our classical sampling algorithm proceeds as follows. First, sample $\mathbf{n}$ from $p(\mathbf{n})$ using a chain-rule-based algorithm:

$$p(\mathbf{n}) = p(n_1)p(n_2|n_1)\cdots p(n_L|n_1, \dots, n_{L-1}), \quad (35)$$

where the computational cost mainly depends on the complexity of computing the marginal probabilities $p(n_1, \dots, n_k)$. Next, for the obtained $\mathbf{n}$, sample α from

$$p(\alpha|\mathbf{n}) = \frac{\langle \psi_{\mathbf{n}} | (\hat{\Pi}(\alpha) \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle}{\langle \psi_{\mathbf{n}} | (\hat{\mathbb{1}}_M \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle}, \quad (36)$$

which completes the procedure.

The computational bottleneck is thus (i) computing the marginal probabilities of $p(\mathbf{n})$ and (ii) evaluating $\langle \psi_{\mathbf{n}} | (\hat{\Pi}(\alpha) \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle$. Since $|\psi_{\mathbf{n}}\rangle$ is Gaussian, these quantities reduce to evaluating loop hafnians [19, 28], whose cost scales exponentially in the number of measured modes L [20]. Because $\hat{\Pi}(\alpha)$ is Gaussian, the numerator also reduces to a loop hafnian of size L .

Therefore, the overall simulation is efficient whenever $L = O(\log M)$, establishing the theorem. $\square$

Hence, in summary, the algorithm runs as follows:

1. Sample $\mathbf{n}$ from $p(\mathbf{n})$ by using the chain-rule-based algorithm, where $p(\mathbf{n})$'s marginal probabilities are given by loop hafnians [19, 28];
2. Sample α from $p(\alpha|\mathbf{n})$ for a given $\mathbf{n}$ by using the chain-rule-based algorithm, which again reduces to computing loop hafnians.

Quantum mean-value problem.— We now turn to the quantum mean-value problem in this circuit configuration. Thus, we now consider the quantum mean-value problem in this setup with the following configuration:

- Input state: product state;
- Quantum circuit: Gaussian unitary circuit with L adaptive photon-number measurements;
- Observable: product observable.

Here, we assume a general product state as the input, and the measurement is implicit since the goal is to estimate the expectation value of an observable $\hat{O}$. We show that if the number of adaptive measurements L is constant, i.e., $L = O(1)$, the observable can be efficiently estimated on a classical computer, provided the Hilbert-Schmidt norm of the operator $\hat{O}$ is at most polynomially large:

Theorem 3 (Quantum mean-value problem in Gaussian circuits with photon-number measurement and Gaussian feedforward). *Consider an arbitrary product input state and a Gaussian circuit, augmented by photon-number measurements and Gaussian feedforward, which outputs an M -mode quantum state, and assume that the input state has a fixed maximum photon number. If the number of photon-number measurements used for feedforward is $L = O(1)$, then the expectation value of an M -mode observable $\hat{O} = \hat{O}_A \otimes \hat{\mathbb{1}}_B$ can be approximated within*

additive error ϵ and success probability $1 - \delta$ in running time

$$O\left(\frac{\text{poly}(M)\|\hat{O}_A\|_2^2\mathbb{E}_{\mathbf{n}}[\text{Tr}(\hat{\rho}_{\mathbf{n}}^2)]\log(1/\delta)}{\epsilon^2}\right), \quad (37)$$

where $\hat{\rho}_{\mathbf{n}}$ is the reduced density matrix on the system A when the photon-number measurement outcome is $\mathbf{n}$ and $\mathbb{E}_{\mathbf{n}}[\text{Tr}(\hat{\rho}_{\mathbf{n}}^2)]$ is the average purity.

Again, we emphasize that because the input can be an arbitrary product state, it may have a large non-Gaussian resource. However, this resource does not change the complexity, unlike sampling; instead, the number of measurements for feedforward drastically changes the complexity.

Finally, we remark that, as in the sampling task, if the input state is Gaussian instead of an arbitrary state, then sampling from $p(\mathbf{n})$ and computing $X(\mathbf{n}, \alpha_A)$ that appear in the proof remain efficient up to $L = O(\log M)$ because computing $p(\mathbf{n})$ and $X(\mathbf{n}, \alpha_A)$ reduces to computing (loop-)hafnians associated to L -mode Gaussian states, which can be computed in $O(\exp(L))$ [20].

Proof sketch. Details are provided in Appendix A 2. Consider a general product input $|\psi\rangle$. The probability of obtaining measurement outcome $\mathbf{n}$ is then written as

$$p(\mathbf{n}) = \langle\psi_{\mathbf{n}}|(\hat{\mathbb{1}} \otimes |\mathbf{n}\rangle\langle\mathbf{n}|)|\psi_{\mathbf{n}}\rangle, \quad (38)$$

where $|\psi_{\mathbf{n}}\rangle \equiv \hat{G}_{\mathbf{n}}|\psi\rangle$ is the (unnormalized) post-measurement state for outcome $\mathbf{n}$.

For a given measurement outcome $\mathbf{n}$, the conditional expectation value of $\hat{O} = \hat{O}_A \otimes \hat{\mathbb{1}}_B$ is given by

$$\frac{\langle\psi|\hat{G}_{\mathbf{n}}^\dagger(\hat{O}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|)\hat{G}_{\mathbf{n}}|\psi\rangle}{\langle\psi|\hat{G}_{\mathbf{n}}^\dagger(\hat{\mathbb{1}}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|)\hat{G}_{\mathbf{n}}|\psi\rangle}, \quad (39)$$

and averaging over all outcomes gives

$$\langle\hat{O}\rangle = \sum_{\mathbf{n}} \langle\psi|\hat{G}_{\mathbf{n}}^\dagger(\hat{O}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|)\hat{G}_{\mathbf{n}}|\psi\rangle, \quad (40)$$

which is thus the expectation value we want to estimate. We now rewrite the expectation value of $\hat{O}$ as

$$\langle\hat{O}\rangle = \int d^2l \alpha_A \sum_{\mathbf{n}} p(\mathbf{n}) q(\alpha_A) X(\mathbf{n}, \alpha_A), \quad (41)$$

where l is the number of modes in the subsystem A , and we defined a probability distribution and a random variable

$$q(\alpha_A) \equiv \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2}, \quad (42)$$

$$X(\mathbf{n}, \alpha_A) \equiv \frac{\|\hat{O}_A\|_2^2 \langle\psi_{\mathbf{n}}|(\hat{D}^\dagger(\alpha_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|)|\psi_{\mathbf{n}}\rangle}{p(\mathbf{n}) \chi_{\hat{O}_A}^*(\alpha_A)}, \quad (43)$$

respectively. Here, the normalization of $q(\alpha_A)$ follows from the twirling property of displacement operators, Eq. (2). Due to the above expression of the expectation value, our algorithm estimates $\langle\hat{O}\rangle$ by sampling $\mathbf{n} \sim p(\mathbf{n})$ and $\alpha_A \sim q(\alpha_A)$, and then applying the median-of-means estimator to $X(\mathbf{n}, \alpha_A)$.

By direct calculation, we upper-bound the variance of X by $\|\hat{O}_A\|_2^2 \mathbb{E}_{\mathbf{n}}[\text{Tr}(\hat{\rho}_{\mathbf{n}}^2)]$, where $\hat{\rho}_{\mathbf{n}}$ is the reduced density matrix on subsystem A for outcome $\mathbf{n}$.

Finally, efficient implementation requires analyzing three subroutines: (i) sampling from $p(\mathbf{n})$, (ii) sampling from $q(\alpha_A)$, and (iii) computing $X(\mathbf{n}, \alpha_A)$.

Sampling from $q(\alpha_A)$ is straightforward due to its product structure, cf. Eq. (18). Sampling from $p(\mathbf{n})$ amounts to computing marginal photon-number probabilities of a state obtained by applying a Gaussian circuit to a general product input. This is nontrivial in general. For Fock input states and linear-optical circuits, Gurvits introduced an algorithm (the so-called Gurvits' second algorithm) that is efficient whenever the number of marginal modes is constant [27, 61]. We extend this algorithm to arbitrary product input states and Gaussian circuits (see Sec. VI and Appendix F for more details):

Lemma 1 (Computing photon-number marginal probabilities in Gaussian circuits). *Consider an M -mode bosonic system, product states $|\psi\rangle, |\phi\rangle$, a Gaussian unitary $\hat{G}_0$, and an L -mode Fock state $|\mathbf{n}\rangle$. Here, we assume that the states $|\phi\rangle$ and $|\psi\rangle$ have a fixed maximum photon number. Then*

$$\langle\phi|\hat{G}_0^\dagger(\hat{\mathbb{1}} \otimes |\mathbf{n}\rangle\langle\mathbf{n}|)\hat{G}_0|\psi\rangle \quad (44)$$

can be exactly computed in polynomial time in M if $L = O(1)$.

Note that $|\psi\rangle$ and $|\phi\rangle$ may differ, which is an additional generalization beyond Gurvits' original setting. Using this lemma, we can efficiently sample from $p(\mathbf{n})$ whenever $L = O(1)$.

Finally, evaluating $X(\mathbf{n}, \alpha_A)$ requires computing a similar overlap term. Since the lemma also applies when $|\psi\rangle$ and $|\phi\rangle$ differ, we can absorb $\hat{D}^\dagger(\alpha_A)$ into the input and compute the random variable $X(\mathbf{n}, \alpha_A)$ efficiently when $L = O(1)$.

This completes the proof of the theorem. More detailed analysis can be found in Sec. VI and Appendix F. $\square$

Thus, in summary, the algorithm runs as follows:

1. Sample $\alpha_A \in \mathbb{C}^l$ from $|\chi_{\hat{O}_A}(\alpha_A)|^2$ by sampling α_i independently from $|\chi_{\hat{O}_i}(\alpha_i)|^2$;
2. Given α_A , we compute $X(\mathbf{n}, \alpha_A)$ by invoking Lemma 1;
3. Apply the median-of-means estimator for the collected samples.

As in Theorem 1, the dependence on the system size A , l , is implicitly determined by the Hilbert-Schmidt norm of the operator $\hat{O}_A$ and the average purity. For example, the $l = O(1)$ case can be efficiently solved using our algorithm if $L = O(1)$, whereas $l = \omega(1)$ can be hard for our algorithm. We remark that this clearly suggests a transition between a setup with limited adaptivity and the universal quantum computer through increasing the adaptive steps because while the universal quantum computer, i.e., $L = \text{poly}(M)$ with $l = O(1)$ is sufficient to solve BQP-complete problems, our theorem shows that the $l = O(1)$ case is easy for classical computer.

C. Gaussian-measurement-adaptive Gaussian circuits

In this section, instead of photon-number-measurement-based feedforward, we consider feedforward based on Gaussian measurements, which is more experimentally accessible. Although the operations remain Gaussian, it is known that if non-Gaussian input states are provided, Gaussian circuits with Gaussian-measurement-based feedforward and Gaussian final measurements are sufficient for universal quantum computation [34].

Sampling.— Since this family includes, as a subset, the Gaussian circuits considered in the previous section, simulating the sampling problem with either general non-Gaussian input states or general non-Gaussian measurements is classically hard. On the other hand, if both the input states and final measurements are Gaussian, then the entire process remains Gaussian, and simulating such circuits is efficiently possible on a classical computer.

Quantum mean-value problem.— Let us consider the quantum mean-value problem in this circuit configuration with a general product input $|\psi\rangle$. Thus, we now consider the quantum mean-value problem in this setup with the following configuration:

- Input state: product state;
- Quantum circuit: Gaussian unitary circuit with L adaptive Gaussian measurements;
- Observable: product observable.

We now show that the computational complexity for solving this problem is at most polynomial in the system size if the number of measurements for feedforward operations is $L = O(1)$:

Theorem 4 (Quantum mean-value problem in Gaussian circuit augmented by Gaussian measurement and Gaussian feedforward). *Consider an arbitrary product input and a Gaussian circuit, augmented by Gaussian measurements and Gaussian feedforward, which outputs an M -mode quantum state, and assume that the input state has a fixed maximum photon number. If the*

number of Gaussian measurements for feedforward is at most constant, i.e., $L = O(1)$, the expectation value of an M -mode product observable $\hat{O} \equiv \hat{O}_A \otimes \hat{1}_B$ can be approximated within additive error ϵ with probability $1 - \delta$ in running time,

$$O\left(\frac{\text{poly}(M)\|\hat{O}_A\|_2^2\mathbb{E}_\beta[\text{Tr}(\hat{\rho}_\beta^2)]\log(1/\delta)}{\epsilon^2}\right), \quad (45)$$

where $\hat{\rho}_\beta$ is the reduced density matrix on the system A when the Gaussian measurement outcome is β and $\mathbb{E}_\beta[\text{Tr}(\hat{\rho}_\beta^2)]$ is the average purity.

Interestingly, even if the measurements for feedforward are Gaussian, the complexity increases as in the photon-number measurement case. While surprising, on a high level, this is consistent with a known result in Ref. [34], which demonstrates that Gaussian operations, including measurements and feedforward, are sufficient when GKP states are provided as input.

Proof Sketch. The details of the proof are provided in Appendix A 3. First of all, the probability of obtaining β for feedforward is

$$p(\beta) = \langle\psi_\beta|(\hat{1}_A \otimes \hat{1}_B \otimes \hat{\Pi}(\beta))|\psi_\beta\rangle, \quad (46)$$

where $|\psi_\beta\rangle \equiv \hat{G}_\beta|\psi\rangle$ is the (unnormalized) post-measurement state upon measurement outcome β and $\{\hat{\Pi}_\beta = \hat{D}(\beta)|\psi_G\rangle\langle\psi_G|\hat{D}^\dagger(\beta)/\pi^L\}$ is Gaussian POVMs. Thus, the expectation value when the outcome is β is

$$\frac{\langle\psi|\hat{G}_\beta^\dagger(\hat{O}_A \otimes \hat{1}_B \otimes \hat{\Pi}(\beta))\hat{G}_\beta|\psi\rangle}{\langle\psi|\hat{G}_\beta^\dagger(\hat{1}_A \otimes \hat{1}_B \otimes \hat{\Pi}(\beta))\hat{G}_\beta|\psi\rangle}. \quad (47)$$

If we take average over β , we obtain the expectation value, which is written as

$$\langle\hat{O}\rangle = \int d^{2L}\beta \langle\psi_\beta|(\hat{O}_A \otimes \hat{1}_B \otimes \hat{\Pi}(\beta))|\psi_\beta\rangle \quad (48)$$

$$= \int d^{2l}\alpha_A d^{2L}\beta p(\beta) q(\alpha_A) X(\beta, \alpha_A), \quad (49)$$

where l is the number of modes in the subsystem A , and we defined a probability distribution

$$q(\alpha_A) \equiv \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2}, \quad (50)$$

and the random variable

$$X(\beta, \alpha_A) = \frac{\|\hat{O}_A\|_2^2 \langle\psi_\beta|(\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{\Pi}(\beta))|\psi_\beta\rangle}{p(\beta) \chi_A^*(\alpha_A)}. \quad (51)$$

By direct calculation, we prove that the variance of the random variable is upper-bounded by

$O(\|\hat{O}_A\|_2^2 \mathbb{E}_\beta[\text{Tr}(\hat{\rho}_\beta^2)])$, where $\hat{\rho}_\beta$ is the reduced density matrix on the Hilbert space A when the measurement outcomes are β and the average is taken over the probability distribution $p(\beta)$.

For the algorithm, we need to be able to (i) sample from $q(\alpha_A)$, (ii) sample from $p(\beta)$, and (iii) compute $X(\beta, \alpha_A)$. As before, (i) is easy because of the product structure of $\hat{O}_A$. Computing the marginal probability of $p(\beta)$ can be done efficiently when the number of modes involved in $\hat{\Pi}(\beta)$ is at most constant, i.e., $L = O(1)$ due to Lemma 1. Similarly, using Lemma 1, $X(\beta, \alpha_A)$ can be efficiently computed when $L = O(1)$. Hence, the theorem. $\square$

Thus, in summary, the algorithm runs as follows:

1. Sample $\alpha_A \in \mathbb{C}^l$ from $|\chi_{\hat{O}_A}(\alpha_A)|^2$ by sampling α_i independently from $|\chi_{\hat{O}_i}(\alpha_i)|^2$;
2. Given α_A , we compute $X(\beta, \alpha_A)$ by invoking Lemma 1;
3. Apply the median-of-means estimator for the collected samples.

As we have seen from the two previous theorems, Lemma 1 plays a crucial role in our classical algorithms. For the rest of this paper, we introduce the classical algorithm for the lemma.

VI. CLASSICAL ALGORITHMS USING LOW-RANK STRUCTURES

In this section, we present the details of Lemma 1, which plays a crucial role in our classical algorithms. First, we reduce the task of computing marginal probabilities in the photon-number basis to evaluating an associated generating function (see below for the precise definition). We then compute this generating function. As a first step, we show that the amplitudes of few-mode quantum states can be computed efficiently. Building on this, we demonstrate that the generating function corresponding to photon-number marginals over a small number of modes can likewise be computed efficiently on a classical computer. The latter can be viewed as an extension of Gurvits' second algorithm [27, 61]. Conceptually, these results leverage the correspondence between few-mode structure and low-rank matrices, making the relevant quantities amenable to efficient classical computation or simulation. We expect that the results—and their proofs—are of independent interest in the study of computational complexity for quantum optical systems.

A. Computing the marginal probabilities of Gaussian circuits on photon-number basis

In this section, we show a way to compute the marginal probability in the photon-number basis for the output state generated by a Gaussian circuit $\hat{G}_0$ applied to a product state $|\psi\rangle$. Let us consider a general expression:

$$q(\mathbf{n}) = \langle \phi | \hat{G}_0^\dagger | \mathbf{n} \rangle \langle \mathbf{n} | \hat{G}_0 | \psi \rangle. \quad (52)$$

and its marginal

$$q(n_1, \dots, n_L) = \sum_{n_{L+1}, \dots, n_M=0}^{\infty} q(\mathbf{n}) \quad (53)$$

$$= \langle \phi | \hat{G}_0^\dagger (|n_1, \dots, n_L\rangle \langle n_1, \dots, n_L| \otimes \hat{1}) \hat{G}_0 | \psi \rangle. \quad (54)$$

One may see that when $|\phi\rangle = |\psi\rangle$, $q(\mathbf{n})$ represents the (marginal) probability in the photon number basis. Thus, we call this function a marginal probability in a broader sense even when $|\psi\rangle \neq |\phi\rangle$. We have seen that this function plays a central role in the classical algorithms introduced in Sec. V. We present a general recipe to compute this function below. Note that we now assume that $|\psi\rangle$ and $|\phi\rangle$ have a maximum photon number cutoff $n_{\max}$ for simplicity, as discussed in Sec. IV.

Before considering general cases, we first note that in the case of a Gaussian state $|\psi\rangle$, this is expressed simply as a loop hafnian with matrix size given by L [20, 63, 90] and thus the complexity is exponential in the number of modes. Thus, when L is at most logarithmic, we can compute this quantity in polynomial time. However, in more general cases, i.e., for non-Gaussian states, it may not be written as a simple loop hafnian. Remarkably, for Fock-state input $|\psi\rangle = |\mathbf{m}\rangle$ and linear-optical circuit, there is a well-known algorithm, so-called Gurvits' second algorithm, which enables us to compute $q(\mathbf{n})$ with complexity $O(N^{2L+1})$, where N is the total photon number of $|\mathbf{m}\rangle$ (see Sec. VIB1) [27, 61]. Hence, when $L = O(1)$, i.e., the number of marginal modes is at most constant, the corresponding quantity can be efficiently computed using classical computers. Our main contribution is to generalize this result for Fock states and linear-optical circuits to general product input states $|\phi\rangle$ and $|\psi\rangle$ and Gaussian circuits.

The main idea is to exploit the following Fourier relation [27, 64] (see Appendix B for the details):

$$\tilde{G}(k) \equiv \langle \phi | \hat{G}_0^\dagger e^{-ik\theta \hat{\mathbf{n}} \cdot \boldsymbol{\omega}} \hat{G}_0 | \psi \rangle, \quad (55)$$

$$G(\Omega) \equiv \sum_{\mathbf{n}=0}^{\infty} q(\mathbf{n}) \delta(\Omega - \boldsymbol{\omega} \cdot \mathbf{n}) = \frac{1}{\Omega_{\max} + 1} \sum_{k=0}^{\Omega_{\max}} \tilde{G}(k) e^{ik\Omega}, \quad (56)$$

where $\hat{\mathbf{n}} \equiv (\hat{n}_1, \dots, \hat{n}_M)$ is the photon number operator vector for M modes, where $\hat{n}_i \equiv \hat{a}_i^\dagger \hat{a}_i$, $k, \Omega \in \{0, \dots, \Omega_{\max}\}$, $\theta \equiv 2\pi/(\Omega_{\max} + 1)$, and $\boldsymbol{\omega} \in \mathbb{R}^M$. Thus, if we want to compute the marginal probability of $q(\mathbf{n})$

on the Fock basis up to the L th mode, we set

$$\omega = (\omega_1, \dots, \omega_L, 0, \dots, 0), \quad (57)$$

where $\omega_i = (n_{\max} + 1)^{i-1}$. Then, each $\Omega \in \{0, \dots, (n_{\max} + 1)^L - 1\}$ corresponds to distinct marginal probabilities of $q(\mathbf{n})$ where $n_i \leq n_{\max}$. More explicitly, if we want to compute $q(n_1, \dots, n_L)$, we set $\Omega = \sum_{i=1}^L \omega_i n_i$ with ω defined above and compute the corresponding $G(\Omega)$, which is equivalent to $q(n_1, \dots, n_L)$. Therefore, if we can compute $\tilde{G}(k)$, in principle, we can compute $G(\Omega)$ and thus its marginal probabilities. Here, because we need to sum k from 0 to $\Omega_{\max}$, the complexity increases as $O((n_{\max} + 1)^L)$. With this in mind, computing $q(\mathbf{n})$ or its marginal probabilities boils down to exactly computing

$$\langle \phi | \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0 | \psi \rangle \equiv \langle \phi | \hat{G} | \psi \rangle, \quad (58)$$

where $\hat{P}(\varphi) \equiv e^{i\varphi \cdot \hat{\mathbf{n}}}$ is a phase shifter with $(\varphi_1, \dots, \varphi_L, 0, \dots, 0)$, which has exactly the same form of $\tilde{G}(k)$. We refer to this function as a generating function. Hence, the main complexity of this algorithm is attributed to computing $\tilde{G}(k)$.

B. Generalized Gurvits' second algorithm

In this section, we prove that

$$\tilde{G}(k) = \langle \phi | \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0 | \psi \rangle \quad (59)$$

is easy to compute when $|\psi\rangle$ and $|\phi\rangle$ are product states and φ has at most constant non-zero phases. Without loss of generality, let $\varphi = (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$ throughout this section.

As mentioned above, it has been known for Fock states and linear-optical circuits, $|\psi\rangle = |\phi\rangle = |\mathbf{n}\rangle$ and $\hat{G}_0 = \hat{U}$ is a linear-optical circuit, that $\tilde{G}(k)$ can be computed in a polynomial time when L is at most a constant:

Lemma 2 (Gurvits' second algorithm [27, 61]). *Consider an M -mode linear-optical circuit $\hat{U}$, a phase shifter operator $\hat{P}(\varphi)$ with $\varphi \equiv (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$, and a Fock state $|\mathbf{n}\rangle$. If $L = O(1)$,*

$$\langle \mathbf{n} | \hat{U}^\dagger \hat{P}(\varphi) \hat{U} | \mathbf{n} \rangle \quad (60)$$

can be exactly computed in polynomial time in the total photon number in $|\mathbf{n}\rangle$ and the number of modes M .

We generalize this to arbitrary product states $|\psi\rangle$ and $|\phi\rangle$, which may be different, and an arbitrary Gaussian circuit $\hat{G}_0$:

Lemma 3 (Generating function). *Consider an M -mode bosonic system. Let $\hat{G}_0$ be a Gaussian unitary circuit and $\hat{P}(\varphi)$ be the phase shifter with phase φ and $|\psi\rangle$ and $|\phi\rangle$ be product states. If the number of non-zero elements in $\varphi \equiv (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$ is $L = O(1)$,*

$$\langle \phi | \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0 | \psi \rangle \quad (61)$$

can be exactly computed in polynomial time in M and $n_{\max}$.

Using the above lemma, we can immediately see that Lemma 1 is true by using the relationship between $G(\Omega)$ and $\tilde{G}(k)$, which is restated here:

Lemma 4 (Lemma 1 restated). *Consider an M -mode bosonic system, product states $|\psi\rangle$, $|\phi\rangle$, a Gaussian unitary $\hat{G}_0$, and an L -mode Fock state $|\mathbf{n}\rangle$. Then*

$$\langle \phi | \hat{G}_0^\dagger (|\mathbf{n}\rangle \langle \mathbf{n}| \otimes \hat{1}) \hat{G}_0 | \psi \rangle \quad (62)$$

can be exactly computed in polynomial time in M and $n_{\max}$ if $L = O(1)$.

Hence, from now on, we will focus on proving Lemma 3.

Before we do that, we emphasize that the generating function is reduced to the permanent of a matrix with rank depending on L [27, 61] when $|\psi\rangle = |\phi\rangle$ are Fock states and the circuit is a linear-optical circuit. We will demonstrate how to compute this quantity as a warm-up example to generalize the approach further below. On the other hand, for Fock states and general Gaussian circuits, the generating function reduces to a loop hafnian [64, 90], which also allows a classical algorithm to exploit a low-rank structure to reduce the computational complexity [64]. Notably, such a structure still allows us to compute the generating function even when $|\psi\rangle$ and $|\phi\rangle$ are general product states by using the classical algorithm from Ref. [64], which will be shown in Appendix F.

1. Warm-up example: Permanent

To provide the main technique, we first consider the simplest example: permanent. The permanent of an $N \times N$ matrix A is defined as

$$\text{Per}(A) \equiv \sum_{\sigma \in \mathcal{S}_N} \prod_{i=1}^N A_{i, \sigma(i)}. \quad (63)$$

There are many ways to compute the permanent of a matrix, such as Ryser's formula [91]. One of the methods that is relevant to our work is the polynomial method [91]. To be more specific, we define a polynomial of indeterminates $x_1, \dots, x_N$ as

$$F(x_1, \dots, x_N) = \prod_{i=1}^N \left(\sum_{j=1}^N A_{ij} x_j \right). \quad (64)$$

One may then notice that the coefficient of $x_1 \cdots x_N$ corresponds to the permanent of the matrix A .

To illustrate how we leverage the low-rank structure of a relevant matrix, let us review Gurvits' second

algorithm [27, 61]. Let $A = W + I$, where W is a rank- L matrix, i.e., W 's matrix elements can be written as

$$W_{ik} \equiv \sum_{s=1}^L u_i^{(s)} v_k^{(s)}. \quad (65)$$

Then, Ref. [61] shows that if we define a polynomial of indeterminates $\{a_u^{(s)}\}_{s=1}^L, \{a_v^{(s)}\}_{s=1}^L$,

$$F(\{a_u^{(s)}\}_{s=1}^L, \{a_v^{(s)}\}_{s=1}^L) = \prod_{i=1}^N \left[1 + \sum_{s,s'=1}^L a_u^{(s)} a_v^{(s')} u_i^{(s)} v_i^{(s')} \right] \quad (66)$$

and sum the coefficients of monomials whose degrees of $\{a_u^{(s)}\}$ and $\{a_v^{(s)}\}$ match each other with multiplying the factorial of the degrees of $\{a_u^{(s)}\}$ (or equivalently $\{a_v^{(s)}\}$), then we obtain the permanent. Note that the number of monomials that appear in the computation is $O(N^{2L})$. The calculation of the coefficients of the monomials involves multiplying out N terms, where at each multiplication the $O(N^{2L})$ coefficients have to be updated. Therefore, the total cost is $O(N^{2L+1})$. Thus, when the rank of the matrix W is at most a constant, the permanent of the matrix $W + I$ can be efficiently computed, unlike that of general matrices.

2. Amplitude of low-mode states

In the section, for the subroutine of our algorithm for computing the generating function, we consider the amplitude in the form of $\langle \phi | \hat{U} | \psi \rangle$, where $\hat{U}$ is a linear-optical circuit and we assume that $|\phi\rangle$ is an L -mode state, which is defined as

$$|\phi\rangle = |\phi'\rangle \otimes |\mathbf{0}_{M-L}\rangle, \quad (67)$$

where $|\phi'\rangle$ is the nontrivial part and an arbitrary product state on L modes and $|\mathbf{0}_{M-L}\rangle$ is the vacuum state on the remaining $M - L$ modes. We show that the amplitude is easy to compute when L is small:

Lemma 5. *Let $\hat{U}$ be an M -mode linear-optical circuit, $|\psi\rangle$ be an M -mode general product state, and $|\phi\rangle$ be an arbitrary L -mode state. More precisely, all but L modes are vacuum. Then,*

$$\langle \phi | \hat{U} | \psi \rangle \quad (68)$$

can be exactly computed in $O(M(Mn_{\max} + 1)^L)$, where $n_{\max}$ is the maximum photon number for each mode. Hence, it can be efficiently computed when $L = O(1)$.

Proof. Let us first examine Fock states. Consider a few-mode Fock state $|\mathbf{n}\rangle = |n_1, \dots, n_L, 0, \dots, 0\rangle$ and arbitrary Fock state $|\mathbf{m}\rangle$. Then, the amplitude can be

simplified as

$$\langle \mathbf{n} | \hat{U} | \mathbf{m} \rangle = \langle \mathbf{n} | \prod_{i=1}^M \frac{1}{\sqrt{m_i!}} \left(\sum_{j=1}^M U_{ij} \hat{a}_j^\dagger \right)^{m_i} | 0 \rangle \quad (69)$$

$$= \langle \mathbf{n} | \prod_{i=1}^M \frac{1}{\sqrt{m_i!}} \left(\sum_{j=1}^L U_{ij} \hat{a}_j^\dagger \right)^{m_i} | 0 \rangle. \quad (70)$$

Now, note that the creation operators in the form of $(\hat{a}_1^\dagger)^{n_1} \dots (\hat{a}_L^\dagger)^{n_L}$ survive and others are zero when contracted with $\langle \mathbf{n} |$. Also, such a term renders $\prod_{i=1}^M \sqrt{n_i}$ after contracting with $\langle \mathbf{n} |$. This can also be interpreted using the polynomial method by replacing the creation operators by indeterminates $x_1, \dots, x_L$ and introducing the prefactor $\prod_{i=1}^M \sqrt{n_i}$ as

$$\prod_{i=1}^M \frac{\sqrt{n_i!}}{\sqrt{m_i!}} \left(\sum_{j=1}^L U_{ij} x_j \right)^{m_i}. \quad (71)$$

We then just need to pick up the monomials of x_j after expansion such that their degree matches with $\mathbf{n}$, i.e., $x_1^{n_1} \dots x_L^{n_L}$ to compute $\langle \mathbf{n} | \hat{U} | \mathbf{m} \rangle$. In this procedure, the number of monomials we need to take care of is at most $O((MN + 1)^L)$, where N is the total photon number. Also, because we need to keep track of the coefficient for M multiplications, the total cost is $O(M(MN + 1)^L)$.

Now, let us consider general product states $|\psi\rangle$ and $|\phi\rangle$, which are explicitly written as

$$|\psi\rangle = \bigotimes_{i=1}^M \left(\sum_{m_i=0}^{n_{\max}} a_{m_i}^{(i)} |m_i\rangle \right), \quad |\phi\rangle = \bigotimes_{i=1}^M \left(\sum_{n_i=0}^{n_{\max}} b_{n_i}^{(i)} |n_i\rangle \right). \quad (72)$$

For a general case, as in the lemma, we can simply use the same method

$$\langle \phi | \hat{U} | \psi \rangle = \sum_{\mathbf{n}} b_{\mathbf{n}}^* \langle \mathbf{n} | \prod_{i=1}^M \sum_{m_i=0}^{n_{\max}} \frac{a_{m_i}^{(i)}}{\sqrt{m_i!}} \left(\sum_{j=1}^M U_{ij} \hat{a}_j^\dagger \right)^{m_i} | 0 \rangle \quad (73)$$

$$= \sum_{\mathbf{n}} b_{\mathbf{n}}^* \langle \mathbf{n} | \prod_{i=1}^M \sum_{m_i=0}^{n_{\max}} \frac{a_{m_i}^{(i)}}{\sqrt{m_i!}} \left(\sum_{j=1}^L U_{ij} \hat{a}_j^\dagger \right)^{m_i} | 0 \rangle \quad (74)$$

$$\rightarrow \prod_{i=1}^M \sum_{n_i, m_i=0}^{n_{\max}} \frac{a_{m_i}^{(i)} b_{n_i}^{(i)*} \sqrt{n_i!}}{\sqrt{m_i!}} \left(\sum_{j=1}^L U_{ij} x_j \right)^{m_i}, \quad (75)$$

where $a_{\mathbf{m}} \equiv \prod_{i=1}^M a_{m_i}^{(i)}$. For the last arrow, we apply the same method for the Fock state above. Thus, again, after expanding the polynomial of indeterminates $x_1, \dots, x_L$ and taking the summation over the coefficients of all the monomials, we obtain the amplitude $\langle \phi | \hat{U} | \psi \rangle$. Since the

FIG. 2. Schematics of Lemma 6. The lemma shows that for a Gaussian unitary circuit $\hat{G}_0$ and a phase shifter $\hat{P}(\varphi)$ where $\varphi \equiv (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$, $\hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0$ is equivalent to $\hat{U} \hat{S}(\mathbf{r}) \hat{V}$, where $\mathbf{r} = (r_1, \dots, r_{2L}, 0, \dots, 0)$.

number of monomials we need to consider is at most $(Mn_{\max} + 1)^L$, the complexity is bounded by $(Mn_{\max} + 1)^L$, where $n_{\max}$ is the maximum photon number for each mode. Again, for the update for each multiplication, the total cost becomes $O(M(Mn_{\max} + 1)^L)$. $\square$

3. Low-rank structure

As shown in the permanent case [61], a low-rank structure of a relevant matrix is crucial to reducing the complexity. Now, we reveal the low-rank structure of the Gaussian circuit that is obtained by $\hat{G} = \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0$ when φ has a few non-zero phases, which is depicted in Fig. 2. To be more precise,

Lemma 6 (Bloch-Messiah decomposition and low-rank structure). *Consider a general Gaussian unitary circuit $\hat{G}_0$ and phase-shifter operator $\hat{P}(\varphi)$ with $\varphi = (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$. Then, $\hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0$ can be decomposed into a linear-optical circuit, at most $2L$ non-zero squeezing operators, and another linear-optical circuit.*

Proof Sketch. See Appendix C for the details. We prove this lemma by direct calculation of the transformation of bosonic annihilation operators through the Gaussian unitary circuit $\hat{G} = \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0$, where $\hat{G}_0$ is an M -mode general Gaussian unitary operation, so that using the Bloch-Messiah decomposition it can be written as $\hat{G}_0 = \hat{U} \hat{S}(\mathbf{s}) \hat{V}$, where $\hat{U}$ and $\hat{V}$ are linear-optical circuits and $\hat{S}(\mathbf{s})$ is squeezing operator with squeezing parameter $\mathbf{s} \in \mathbb{R}^M$. For this circuit, we can show that

$$\hat{G}_0 \hat{a}_i \hat{G}_0^\dagger = \sum_{k=1}^M \left(A_{ik} \hat{a}_k + B_{ik} \hat{a}_k^\dagger \right), \quad (76)$$

where we defined $M \times M$ matrices

$$A_{ik} \equiv \sum_{j=1}^M V_{ji}^* \cosh s_j U_{kj}^*, \quad B_{ik} \equiv - \sum_{j=1}^M V_{ji}^* \sinh s_j U_{kj}^*. \quad (77)$$

Here, one can see that the rank of the matrix B is equal to the number of non-zero squeezing parameters s_j 's, which is crucial for later use.

Using the above transformation, by direct calculation, one may easily show that after the entire process $\hat{G}$, we have

$$\hat{G}_0^\dagger \hat{a}_i \hat{G}_0 = \hat{a}_i + \sum_{k=1}^M \left(W_{ik} \hat{a}_k + Z_{ik} \hat{a}_k^\dagger \right), \quad (78)$$

where, if assume that $\varphi_j = 0$ for $j > L$, W and Z 's matrix elements are written as

$$W_{ik} = \sum_{j=1}^L \left[(e^{i\varphi_j} - 1) A_{ij} A_{kj}^* - (e^{-i\varphi_j} - 1) B_{ij} B_{kj}^* \right], \quad (79)$$

$$Z_{ik} = \sum_{j=1}^L \left[-(e^{i\varphi_j} - 1) A_{ij} B_{kj} + (e^{-i\varphi_j} - 1) B_{ij} A_{kj} \right]. \quad (80)$$

Hence, the ranks of W and Z are at most $2L$. Thus, we can write the matrices as

$$W = \sum_{j=1}^{2L} u^{(j)} v^{(j)\text{T}}, \quad Z = \sum_{j=1}^{2L} w^{(j)} z^{(j)\text{T}}. \quad (81)$$

In addition, the low-rankness of the matrix Z implies that the Gaussian transform by $\hat{G} = \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0$ has a structure in which its squeezing parameters are nonzero only for $2L$ modes, which completes the proof. $\square$

4. Proof sketch of Lemma 3

In this section, we finally present the sketch of the classical algorithm that computes the generating function for Lemma 3. More specifically, the circuit is a general Gaussian unitary $\hat{G}_0$, and thus the relevant quantity to be computed is written as

$$\langle \phi | \hat{G}_0^\dagger \hat{P}(\varphi) \hat{G}_0 | \psi \rangle \equiv \langle \phi | \hat{G} | \psi \rangle = \sum_{\mathbf{n}, \mathbf{m}} a_{\mathbf{m}} b_{\mathbf{n}}^* \langle \mathbf{n} | \hat{G} | \mathbf{m} \rangle, \quad (82)$$

where $|\psi\rangle$ and $|\phi\rangle$ are arbitrary product states, which are written as Eq. (72). Also, the phase vector is assumed to be written as $\varphi = (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$, without loss of generality. By using Lemma 6, the Bloch-Messiah decomposition of the Gaussian unitary $\hat{G}$ is written as $\hat{U}\hat{S}(\mathbf{r})\hat{V}$, where $\hat{U}$ and $\hat{V}$ are linear-optical unitary circuits, and $\mathbf{r}$ is the squeezing parameter vector with at most $2L$ nonzero elements.

Let us focus on a simpler case: $\langle \mathbf{n} | \hat{G} | \mathbf{m} \rangle$. Using the low-rank structure, it can be rewritten as

$$\langle \mathbf{n} | \hat{G} | \mathbf{m} \rangle = \frac{1}{\sqrt{\mathbf{n}!}} \langle \mathbf{r} | \hat{V} \left[\prod_{i \in [M]} (\hat{A}_i + \hat{B}_i^\dagger)^{n_i} \right] | \mathbf{m} \rangle, \quad (83)$$

where we defined

$$\hat{A}_i = \hat{a}_i + \sum_{k=1}^M W_{ik} \hat{a}_k, \quad \hat{B}_i^\dagger = \sum_{k=1}^M Z_{ik} \hat{a}_k^\dagger, \quad (84)$$

$$C_{ij} = [\hat{A}_i, \hat{B}_j^\dagger] = Z_{ji} + \sum_{k=1}^M W_{ik} Z_{jk}. \quad (85)$$

Note that by Lemma 6, the rank of the matrix C is at most $2L$ since W and Z have at most $2L$ ranks and the number of nonzero squeezing parameters is limited to at most $2L$ as shown in Lemma 6.

By using the antinormal ordering [92] (See Appendix E), we expand Eq. (83) and move all the creation operators to the right,

$$\begin{aligned} & \frac{1}{\sqrt{\mathbf{n}! \mathbf{m}!}} \sum_{Y \subset X_{\mathbf{n}}} \sum_{\mathcal{M} \in \text{Match}(F_{X_{\mathbf{n}}}; Y \rightarrow Y^c)} (-1)^{|\mathcal{M}|} \left(\prod_{(i,j) \in \mathcal{M}} C_{ij} \right) \\ & \times \langle \mathbf{r} | \hat{V} \left(\prod_{i \in Y \setminus A(\mathcal{M})} \hat{A}_i \right) \left(\prod_{i \in Y^c \setminus B(\mathcal{M})} \hat{B}_i^\dagger \right) \prod_{i \in X_{\mathbf{m}}} \hat{a}_i^\dagger | 0 \rangle, \end{aligned} \quad (86)$$

where $X_{\mathbf{n}}$ is the multiset composed of the elements of $\mathbf{n}$. For example, if $\mathbf{n} = (0, 2, 1)$, $X_{\mathbf{n}} = \{2, 2, 3\}$. $\text{Match}(F_{X_{\mathbf{n}}}; Y \rightarrow Y^c)$ is the match of the Ferrers graph [93] with vertices Y and Y^c . More explicitly, the Ferrers graph's edges are defined as $E = \{(i, j) | i, j \in X_{\mathbf{n}}, i < j\}$. $A(\mathcal{M})$ and $B(\mathcal{M})$ represent the elements in Y and Y^c that are involved in the matching $\mathcal{M}$, respectively.

We then show that the above expression can be computed by using the polynomial method introduced in Sec. VIB 1. More precisely, we show that Eq. (86) can be written as a loop hafnian of a matrix K which has a low-rank structure. After that, since the matrix C has a low rank, which turns out to be relevant to the low-rank structure of the matrix K , we invoke the following lemma, which states that a loop hafnian of a matrix with a low-rank structure is easy to compute [64]:

Lemma 7 (Loop hafnian of a matrix with low-rank structure [63, 64]). *Let Σ be an $n \times n$ symmetric matrix*

with rank r and A be a matrix constructed by filling Σ 's diagonal matrix with arbitrary elements. Then the loop hafnian of the matrix A can be computed in $O(n \binom{2n+r-1}{r-1})$. Thus, when r is fixed, the cost is polynomial in n and when $r = O(\log n)$, the cost is quasipolynomial in n .

Another observation to make this calculation easier is that the number of non-zero squeezing parameters is at most $2L$, so that the term $\langle \mathbf{r} | \dots | 0 \rangle$ in Eq. (86) can be efficiently computed using Lemma 5. In short, we write Eq. (86) as a polynomial of indeterminates, the number of which is at most $(Mn_{\max} + 1)^{16L}$, which makes it easy to compute when $L = O(1)$. We note that while the degree of the polynomial is quite large at this moment, we expect that it may be reduced, which we leave open. Also, if we restrict our attention to linear-optical circuits, the degree of the polynomial reduces to $(Mn_{\max} + 1)^{2L}$ (see Appendix D).

VII. CONCLUSION

In this work, we presented classical algorithms for solving the quantum mean-value problem in Gaussian circuits, as well as in Gaussian circuits augmented by (i) photon-number-resolving measurements with Gaussian feedforward and (ii) Gaussian measurements with Gaussian feedforward. To support these results, we also developed algorithms for computing amplitudes of low-mode states and marginal probabilities of number-basis measurements, which may be of independent interest and connect to Gurvits' second algorithm.

Our results reveal several conceptual insights. First, low-mode and low-rank structures play a central role in making certain bosonic computations classically tractable. Second, we highlight an important contrast between sampling problems and the quantum mean-value problems: while non-Gaussian resources typically induce classical hardness in sampling, mean-value estimation can remain efficiently simulatable even in the presence of highly non-Gaussian inputs, provided the number of adaptive measurements is bounded. This distinction illustrates a richer landscape of classical-quantum complexity for bosonic systems.

Taken together, these findings not only provide concrete classical algorithms but also clarify where the boundaries of quantum advantage may lie in Gaussian and non-Gaussian regimes. We anticipate that these tools and perspectives will aid future studies of bosonic circuits, both as a benchmark for quantum experiments and as a stepping stone toward understanding the computational power of non-Gaussian resources.

On the other hand, since our results emphasize the role of adaptive measurements in the quantum mean-value problem, it is natural to ask what role adaptive measurements play in the corresponding sampling tasks. In our setting, increasing the amount of adaptivity

leads to an easy-to-hard transition in the complexity of the mean-value problem, whereas in the non-adaptive regime sampling is already believed to be hard due to boson sampling. It is therefore unclear whether, and in what sense, additional rounds of adaptive (or non-Gaussian) operations change the complexity of the sampling problem. There are related studies that add non-linear operations to boson sampling [40], but neither our results nor these works currently provide a satisfactory complexity-theoretic understanding of how sampling interpolates between non-universal boson sampling and universal photonic quantum computation.

While we generalized the classical algorithm for quantum mean-value problem in Ref. [77], the latter provides another classical algorithm that computes the transition amplitude of a quantum state under linear-optical circuits. We believe that it is an interesting open question to extend this algorithm to the adaptive setting due to its close relation to various applications of bosonic circuits (e.g., quantum kernel methods [44, 45]).

Finally, we note that our generalized Gurvits' second algorithm takes polynomial time in the number of modes M when the number of measurements for feedforward is at most constant, i.e., $L = O(1)$, and the degree of the polynomial is not high for linear-optical circuits, as

discussed above. Hence, our algorithm is expected to be practically efficient to simulate recent experiments, e.g., the one in Ref. [45]. On the other hand, while our generalized Gurvits' second algorithm for general Gaussian circuits also takes polynomial time when $L = O(1)$, the degree of the polynomial is quite high, which may make it less practical. Hence, improving the practical running time is an important open question. More importantly, whether our algorithm can be improved further to be efficient even when L is logarithmic in the system size is another open question.

Appendix A: Quantum mean-value problem proofs

In this Appendix, we provide detailed proofs for classical algorithms for quantum mean-value problems.

1. Quantum mean-value problem in Gaussian circuits without feedforward

We provide the full proof of Theorem 1, which is restated here:

Theorem 5 (Theorem 1 restated). *Consider an M -mode Gaussian circuit $\hat{G}$, an arbitrary product input state $|\psi\rangle$, and an M -mode product operator $\hat{O} = \hat{O}_A \otimes \hat{1}_B$. The expectation value $\langle\psi|\hat{G}^\dagger\hat{O}\hat{G}|\psi\rangle$ can be approximated within additive error ϵ with probability $1 - \delta$ in running time*

$$O\left(\frac{M^2\|\hat{O}_A\|_2^2 \text{Tr}[\hat{\rho}_A^2] \log(1/\delta)}{\epsilon^2}\right), \quad (\text{A1})$$

where $\hat{\rho}_A \equiv \text{Tr}_B[\hat{G}|\psi\rangle\langle\psi|\hat{G}^\dagger]$ is the reduced density matrix on the system A .

Proof. Let us consider a general Gaussian unitary circuit $\hat{G}$ and a general product input state $|\psi\rangle$. Then, the expectation value of a product observable $\hat{O} = \hat{O}_A \otimes \hat{1}_B$ can be rewritten as

$$\langle\psi|\hat{G}^\dagger(\hat{O}_A \otimes \hat{1}_B)\hat{G}|\psi\rangle = \frac{1}{\pi^l} \int d^{2l}\alpha_A \text{Tr}[\hat{O}_A \hat{D}(\alpha_A)] \text{Tr}[(\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B)\hat{G}|\psi\rangle\langle\psi|\hat{G}^\dagger] \quad (\text{A2})$$

$$= \frac{1}{\pi^l} \int d^{2l}\alpha_A \text{Tr}[\hat{O}_A \hat{D}(\alpha_A)] \text{Tr}[\hat{D}^\dagger(\alpha_A)\hat{\rho}_A] \quad (\text{A3})$$

$$= \frac{1}{\pi^l} \int d^{2l}\alpha_A \chi_{\hat{O}_A}(\alpha_A) \chi_{\hat{\rho}_A}^*(\alpha_A) \quad (\text{A4})$$

$$= \int d^{2l}\alpha_A \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2} \frac{\chi_{\hat{\rho}_A}^*(\alpha_A) \|\hat{O}_A\|_2^2}{\chi_{\hat{O}_A}^*(\alpha_A)} \quad (\text{A5})$$

$$\equiv \int d^{2l}\alpha_A p(\alpha_A) X(\alpha_A), \quad (\text{A6})$$

where we defined the reduced density matrix, a probability distribution, and a random variable

$$\hat{\rho}_A \equiv \text{Tr}_B[\hat{G}|\psi\rangle\langle\psi|\hat{G}^\dagger], \quad p(\alpha_A) = \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2}, \quad X(\alpha_A) = \frac{\chi_{\hat{\rho}_A}^*(\alpha_A) \|\hat{O}_A\|_2^2}{\chi_{\hat{O}_A}^*(\alpha_A)}. \quad (\text{A7})$$

Here, using the property of the displacement operator, we have

$$\frac{1}{\pi^l} \int d^{2l}\alpha_A |\chi_{\hat{O}_A}(\alpha_A)|^2 = \text{Tr}[\hat{O}_A^\dagger \hat{O}_A] = \|\hat{O}_A\|_2^2, \quad (\text{A8})$$

which shows that $p(\alpha_A)$ is a proper probability distribution. Thus, the above expression allows us to use the median-of-means estimator for estimating the mean value.

We now analyze the complexity. First of all, sampling α_A from $p(\alpha_A)$ is easy due to the product structure of $\hat{O}_A$:

$$p(\alpha_A) = \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2} = \prod_{i \in A} \frac{|\chi_{\hat{O}_i}(\alpha_i)|^2}{\pi \|\hat{O}_i\|_2^2}, \quad (\text{A9})$$

which takes $O(l)$ time to compute. Also, the random variable $X(\alpha_A)$ is easy to compute because $\|\hat{O}_A\|_2^2$ is easy to compute due to the product structure and $\chi_{\hat{O}_A}^*(\alpha_A)$ is easy to compute as shown above and

$$\chi_{\hat{\rho}_A}^*(\alpha_A) = \text{Tr}[\hat{D}^\dagger(\alpha_A) \hat{\rho}_A] = \text{Tr}[(\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B) \hat{G}|\psi\rangle\langle\psi| \hat{G}^\dagger] = \langle\psi| \hat{D}^\dagger(\alpha') |\psi\rangle = \prod_{i=1}^M \langle\psi_i| \hat{D}^\dagger(\alpha'_i) |\psi_i\rangle, \quad (\text{A10})$$

where we used the property of displacement operators and Gaussian unitary circuits,

$$\hat{D}^\dagger(\alpha') = \hat{G}^\dagger(\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B) \hat{G}. \quad (\text{A11})$$

Here, α' has a linear relation with α_A so that computing α' takes at most $O(lM)$ time. Therefore, the random variable can be rewritten as

$$X(\alpha_A) = \frac{\chi_{\hat{\rho}_A}^*(\alpha_A) \|\hat{O}_A\|_2^2}{\chi_{\hat{O}_A}^*(\alpha_A)} = \chi_{\hat{\rho}_A}^*(\alpha_A) \prod_{i \in A} \frac{\|\hat{O}_i\|_2^2}{\chi_{\hat{O}_i}^*(\alpha_i)} = \text{Tr}[\hat{G}|\psi\rangle\langle\psi| \hat{G}^\dagger \hat{D}(\alpha_A)]^* \prod_{i \in A} \frac{\|\hat{O}_i\|_2^2}{\chi_{\hat{O}_i}^*(\alpha_i)} \quad (\text{A12})$$

$$= \text{Tr}[\langle\psi| \hat{D}(\alpha'_A) |\psi\rangle]^* \prod_{i \in A} \frac{\|\hat{O}_i\|_2^2}{\chi_{\hat{O}_i}^*(\alpha_i)} = \prod_{i=1}^M \chi_{\psi_i}^*(\alpha'_i) \prod_{i \in A} \frac{\|\hat{O}_i\|_2^2}{\chi_{\hat{O}_i}^*(\alpha_i)}, \quad (\text{A13})$$

and computing this takes at most $O(l + M)$ cost.

Finally, we find the upper bound on the variance of the random variable:

$$\text{Var}(X) \leq \int d^{2l} \alpha_A p(\alpha_A) |X(\alpha_A)|^2 = \int d^{2l} \alpha_A \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2} \frac{|\chi_\psi(\alpha')|^2 \|\hat{O}_A\|_2^4}{|\chi_{\hat{O}_A}(\alpha_A)|^2} = \|\hat{O}_A\|_2^2 \int d^{2l} \alpha_A \frac{|\chi_\psi(\alpha')|^2}{\pi^l} \quad (\text{A14})$$

$$= \|\hat{O}_A\|_2^2 \|\hat{\rho}_A\|_2^2, \quad (\text{A15})$$

where, for the last equality, we used

$$\int d^{2l} \alpha_A \frac{|\chi_\psi(\alpha')|^2}{\pi^l} = \int d^{2l} \alpha_A \frac{|\langle\psi| \hat{G}^\dagger(\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B) \hat{G} |\psi\rangle|^2}{\pi^l} = \int d^{2l} \alpha_A \frac{|\chi_{\hat{\rho}_A}(\alpha_A)|^2}{\pi^l} = \|\hat{\rho}_A\|_2^2. \quad (\text{A16})$$

Hence, the median-of-means estimator can estimate the mean value with the sampling complexity $O(\|\hat{O}_A\|_2^2 \|\hat{\rho}_A\|_2^2 \log(1/\delta)/\epsilon^2)$. Thus, combining all the complexities, the total running time is given as $O(Ml \|\hat{O}_A\|_2^2 \|\hat{\rho}_A\|_2^2 \log(1/\delta)/\epsilon^2)$. $\square$

2. Quantum mean-value problem in Gaussian circuits with photon-number measurements and Gaussian feedforward

We provide the full proof of Theorem 3, which is restated here:

Theorem 6 (Theorem 3 restated). *Consider an arbitrary product input state and a Gaussian circuit, augmented by photon-number measurements and Gaussian feedforward, which outputs an M -mode quantum state. If the number of photon-number measurements used for feedforward is $L = O(1)$, then the expectation value of an M -mode observable $\hat{O} = \hat{O}_A \otimes \hat{1}_B$ can be approximated within additive error ϵ and success probability $1 - \delta$ in running time*

$$O\left(\frac{\text{poly}(M) \|\hat{O}_A\|_2^2 \mathbb{E}_{\mathbf{n}}[\text{Tr}(\hat{\rho}_{\mathbf{n}}^2)] \log(1/\delta)}{\epsilon^2}\right), \quad (\text{A17})$$

where $\hat{\rho}_{\mathbf{n}}$ is the reduced density matrix on the system A when the photon-number measurement outcome is $\mathbf{n}$ and $\mathbb{E}_{\mathbf{n}}[\text{Tr}(\hat{\rho}_{\mathbf{n}}^2)]$ is the average purity.

Proof. Consider a general product input $|\psi\rangle$. First of all, when the measurement outcomes are $\mathbf{n}$, the corresponding post-measurement output state is (up to normalization) (see Sec. V B)

$$\langle \mathbf{n} | \hat{G}_{\mathbf{n}} | \psi \rangle, \quad (\text{A18})$$

with probability

$$p(\mathbf{n}) = \langle \psi | \hat{G}_{\mathbf{n}}^\dagger (\hat{\mathbb{1}}_M \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) \hat{G}_{\mathbf{n}} | \psi \rangle = \langle \psi_{\mathbf{n}} | (\hat{\mathbb{1}}_M \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle. \quad (\text{A19})$$

Thus, the expectation value when the outcome is $\mathbf{n}$ is

$$\frac{\langle \psi_{\mathbf{n}} | (\hat{O}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle}{\langle \psi_{\mathbf{n}} | (\hat{\mathbb{1}}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle}. \quad (\text{A20})$$

Since the measurement $\mathbf{n}$ is obtained with probability $p(\mathbf{n})$, we take the average over all possible outcomes in the middle:

$$\langle \hat{O} \rangle = \sum_{\mathbf{n}} \langle \psi_{\mathbf{n}} | (\hat{O}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle \quad (\text{A21})$$

$$= \frac{1}{\pi^l} \int d^{2l} \alpha \sum_{\mathbf{n}} \langle \psi_{\mathbf{n}} | (\hat{D}^\dagger(\alpha_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle \chi_{\hat{O}_A}(\alpha_A) \quad (\text{A22})$$

$$= \int d^{2l} \alpha_A \sum_{\mathbf{n}} p(\mathbf{n}) q(\alpha_A) \frac{\|\hat{O}_A\|_2^2 \langle \psi_{\mathbf{n}} | (\hat{D}^\dagger(\alpha_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle}{p(\mathbf{n}) \chi_{\hat{O}_A}^*(\alpha_A)} \quad (\text{A23})$$

$$= \int d^{2l} \alpha_A \sum_{\mathbf{n}} p(\mathbf{n}) q(\alpha_A) X(\mathbf{n}, \alpha_A), \quad (\text{A24})$$

where we defined the probability distribution and the random variable

$$q(\alpha_A) \equiv \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2}, \quad X(\mathbf{n}, \alpha_A) \equiv \frac{\|\hat{O}_A\|_2^2 \langle \psi_{\mathbf{n}} | (\hat{D}^\dagger(\alpha_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle}{p(\mathbf{n}) \chi_{\hat{O}_A}^*(\alpha_A)}. \quad (\text{A25})$$

Now, we analyze the complexity. First, to upper-bound the error of the estimator, we compute the second moment:

$$\int d^{2l} \alpha_A \sum_{\mathbf{n}} p(\mathbf{n}) q(\alpha_A) \frac{\|\hat{O}_A\|_2^4 |\langle \psi_{\mathbf{n}} | (\hat{D}^\dagger(\alpha_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle|^2}{p(\mathbf{n})^2 |\chi_{\hat{O}_A}(\alpha_A)|^2} \quad (\text{A26})$$

$$= \frac{\|\hat{O}_A\|_2^2}{\pi^l} \int d^{2l} \alpha_A \sum_{\mathbf{n}} \frac{|\langle \psi_{\mathbf{n}} | (\hat{D}^\dagger(\alpha_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle \mathbf{n}|) | \psi_{\mathbf{n}} \rangle|^2}{p(\mathbf{n})} \quad (\text{A27})$$

$$= \frac{\|\hat{O}_A\|_2^2}{\pi^l} \int d^{2l} \alpha_A \sum_{\mathbf{n}} p(\mathbf{n}) |\chi_{\hat{\rho}_{\mathbf{n}}}(\alpha_A)|^2 \quad (\text{A28})$$

$$= \|\hat{O}_A\|_2^2 \sum_{\mathbf{n}} p(\mathbf{n}) \text{Tr}[\hat{\rho}_{\mathbf{n}}^2], \quad (\text{A29})$$

where $\hat{\rho}_{\mathbf{n}}$ is the reduced density matrix on the system A when the measurement outcome is $\mathbf{n}$. Thus, the variance is upper-bounded by the Hilbert-Schmidt norm of the operator $\hat{O}_A$ multiplied by the average purity of the reduced state on the observable's Hilbert space. Hence, the sample complexity for the median-of-means estimator is given as $O(\|\hat{O}_A\|_2^2 \mathbb{E}_{\mathbf{n}}[\text{Tr}[\hat{\rho}_{\mathbf{n}}^2]] \log(1/\delta)/\epsilon^2)$.

Meanwhile, we need to be able to sample from $p(\beta)$ and $q(\alpha_A)$. Sampling from $q(\alpha_A)$ can be efficiently done because of the product structure:

$$q(\alpha_A) = \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2} = \prod_{i \in A} \frac{|\chi_{\hat{O}_i}(\alpha_i)|^2}{\pi \|\hat{O}_i\|_2^2}, \quad (\text{A30})$$

which takes at most $O(l)$. Also, $p(\mathbf{n})$ can be easily sampled if the number of modes in $|\mathbf{n}\rangle$ is not too large by Lemma 1. More specifically, when the number of modes in $|\mathbf{n}\rangle$ is $L = O(1)$, sampling from $p(\mathbf{n})$ takes at most polynomial in M .

Also, in computing the random variable $X(\mathbf{n}, \boldsymbol{\alpha}_A)$, $\|\hat{O}_A\|_2^2 = \prod_{i \in A} \|\hat{O}_i\|_2^2$ is easy to compute, and $p(\mathbf{n})$ is the same as the above. Also, $\chi_{\hat{O}_A}(\boldsymbol{\alpha}_A)$ is easy to compute due to the product structure of $\hat{O}_A$ (see Eq. (A9)). Finally,

$$\langle \psi_{\mathbf{n}} | (\hat{D}^\dagger(\boldsymbol{\alpha}_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) | \psi_{\mathbf{n}} \rangle = \langle \psi | \hat{G}_{\mathbf{n}}^\dagger (\hat{D}^\dagger(\boldsymbol{\alpha}_A) \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) \hat{G}_{\mathbf{n}} | \psi \rangle = \langle \psi | \hat{D}^\dagger(\boldsymbol{\alpha}') \hat{G}_{\mathbf{n}}^\dagger (\hat{\mathbb{1}}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) \hat{G}_{\mathbf{n}} | \psi \rangle \quad (\text{A31})$$

$$= \langle \phi | \hat{G}_{\mathbf{n}}^\dagger (\hat{\mathbb{1}}_A \otimes \hat{\mathbb{1}}_B \otimes |\mathbf{n}\rangle\langle\mathbf{n}|) \hat{G}_{\mathbf{n}} | \psi \rangle \quad (\text{A32})$$

where we used

$$\hat{G}_{\mathbf{n}}^\dagger \hat{D}^\dagger(\boldsymbol{\alpha}_A) \hat{G}_{\mathbf{n}} = \hat{D}^\dagger(\boldsymbol{\alpha}'). \quad (\text{A33})$$

Here, computing $\boldsymbol{\alpha}'$ takes at most $O(Ml)$ and again by using Lemma 1, we can compute this quantity in polynomial time when $L = O(1)$. Therefore, the total running time is at most

$$O\left(\frac{\text{poly}(M) \|\hat{O}_A\|_2^2 \mathbb{E}_{\mathbf{n}}[\text{Tr}(\hat{\rho}_{\mathbf{n}}^2)] \log(1/\delta)}{\epsilon^2}\right), \quad (\text{A34})$$

which completes the proof. $\square$

3. Quantum mean-value problem in Gaussian circuit augmented by Gaussian measurement and Gaussian feedforward

We provide the full proof of Theorem 4, which is restated here:

Theorem 7 (Theorem 4 restated). *Consider an arbitrary product input and a Gaussian circuit, augmented by Gaussian measurements and Gaussian feedforward, which outputs an M -mode quantum state. If the number of Gaussian measurements for feedforward is at most constant, i.e., $L = O(1)$, the expectation value of an M -mode product observable $\hat{O} \equiv \hat{O}_A \otimes \hat{\mathbb{1}}_B$ can be approximated within additive error ϵ with probability $1 - \delta$ in running time,*

$$O\left(\frac{\text{poly}(M) \|\hat{O}_A\|_2^2 \mathbb{E}_{\boldsymbol{\beta}}[\text{Tr}(\hat{\rho}_{\boldsymbol{\beta}}^2)] \log(1/\delta)}{\epsilon^2}\right), \quad (\text{A35})$$

where $\hat{\rho}_{\boldsymbol{\beta}}$ is the reduced density matrix on the system A when the Gaussian measurement outcome is $\boldsymbol{\beta}$ and $\mathbb{E}_{\boldsymbol{\beta}}[\text{Tr}(\hat{\rho}_{\boldsymbol{\beta}}^2)]$ is the average purity.

Proof. Consider a general product input $|\psi\rangle$ and Gaussian measurement POVMs:

$$\frac{1}{\pi^L} \hat{D}(\boldsymbol{\beta}) |\psi_G\rangle \langle \psi_G| \hat{D}^\dagger(\boldsymbol{\beta}). \quad (\text{A36})$$

First of all, when the measurement outcomes are $\boldsymbol{\beta}$, the probability of obtaining $\boldsymbol{\beta}$ is

$$p(\boldsymbol{\beta}) = \frac{1}{\pi^L} \langle \psi | \hat{G}_{\boldsymbol{\beta}}^\dagger (\hat{\mathbb{1}}_M \otimes \hat{D}(\boldsymbol{\beta}) | \psi_G\rangle \langle \psi_G| \hat{D}^\dagger(\boldsymbol{\beta})) \hat{G}_{\boldsymbol{\beta}} | \psi \rangle = \frac{1}{\pi^L} \langle \psi_{\boldsymbol{\beta}} | (\hat{\mathbb{1}}_M \otimes \hat{D}(\boldsymbol{\beta}) | \psi_G\rangle \langle \psi_G| \hat{D}^\dagger(\boldsymbol{\beta})) | \psi_{\boldsymbol{\beta}} \rangle, \quad (\text{A37})$$

and the (unnormalized) post-measurement state is

$$\langle \psi_G | \hat{D}^\dagger(\boldsymbol{\beta}) | \psi_{\boldsymbol{\beta}} \rangle. \quad (\text{A38})$$

Thus, the expectation value when the outcome is $\boldsymbol{\beta}$ is

$$\frac{\langle \psi_{\boldsymbol{\beta}} | (\hat{O}_A \otimes \hat{\mathbb{1}}_B \otimes \hat{\Pi}(\boldsymbol{\beta})) | \psi_{\boldsymbol{\beta}} \rangle}{\langle \psi_{\boldsymbol{\beta}} | (\hat{\mathbb{1}}_A \otimes \hat{\mathbb{1}}_B \otimes \hat{\Pi}(\boldsymbol{\beta})) | \psi_{\boldsymbol{\beta}} \rangle}. \quad (\text{A39})$$

Taking the average over all outcomes β and defining $|\psi_\beta\rangle = \hat{G}_\beta|\psi\rangle$, the expectation value is written as

$$\langle \hat{O} \rangle = \frac{1}{\pi^L} \int d^{2L} \beta \langle \psi_\beta | (\hat{O}_A \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle \quad (\text{A40})$$

$$= \frac{1}{\pi^L} \int \frac{d^{2l} \alpha_A}{\pi^l} d^{2L} \beta \langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle \chi_{\hat{O}_A}(\alpha_A) \quad (\text{A41})$$

$$= \frac{1}{\pi^L} \int d^{2l} \alpha_A d^{2L} \beta \frac{\|\hat{O}_A\|_2^2 \langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle}{\chi_{\hat{O}_A}^*(\alpha_A)} \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2} \quad (\text{A42})$$

$$= \int d^{2l} \alpha_A d^{2L} \beta p(\beta) \frac{\|\hat{O}\|_2^2 \langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle}{\pi^L p(\beta) \chi_{\hat{O}_A}^*(\alpha_A)} q(\alpha_A) \quad (\text{A43})$$

$$= \int d^{2l} \alpha_A d^{2L} \beta p(\beta) q(\alpha_A) X(\beta, \alpha_A), \quad (\text{A44})$$

where we defined a probability distribution and a random variable

$$q(\alpha_A) \equiv \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2}, \quad X(\beta, \alpha) = \frac{\|\hat{O}_A\|_2^2 \langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle}{\pi^L p(\beta) \chi_{\hat{O}_A}^*(\alpha_A)}. \quad (\text{A45})$$

Hence, the quantum mean value can be written as

$$\langle \hat{O} \rangle = \int d^{2l} \alpha_A d^{2L} \beta p(\beta) q(\alpha_A) X(\beta, \alpha_A), \quad (\text{A46})$$

which implies that the average of the random variable $X(\beta, \alpha_A)$ over the probability distribution $p(\beta)q(\alpha_A)$ is equal to the mean value. If we use the median-of-means estimator, we can upper-bound the error of the estimator by finding the upper bound on the second moment:

$$\int d^{2l} \alpha_A d^{2L} \beta p(\beta) q(\alpha_A) \frac{\|\hat{O}_A\|_2^4 \langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle^2}{\pi^{2L} p(\beta)^2 |\chi_{\hat{O}_A}(\alpha_A)|^2} \quad (\text{A47})$$

$$= \frac{\|\hat{O}_A\|_2^2}{\pi^{2L} \pi^l} \int d^{2l} \alpha_A d^{2L} \beta \frac{|\langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle|^2}{p(\beta)} \quad (\text{A48})$$

$$= \frac{\|\hat{O}_A\|_2^2}{\pi^l} \int d^{2l} \alpha_A d^{2L} \beta \frac{|\langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle|^2}{\langle \psi_\beta | (\hat{1}_A \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle} \quad (\text{A49})$$

$$= \frac{\|\hat{O}_A\|_2^2}{\pi^l} \int d^{2l} \alpha_A d^{2L} \beta p(\beta) |\chi_{\hat{\rho}_\beta}(\alpha_A)|^2 \quad (\text{A50})$$

$$= \|\hat{O}_A\|_2^2 \int d^{2L} \beta p(\beta) \text{Tr}[\hat{\rho}_\beta^2]. \quad (\text{A51})$$

Thus, the variance is upper-bounded by the Hilbert-Schmidt norm of the operator $\hat{O}_A$ multiplied by the average purity of the reduced state when tracing out the observable's Hilbert space. Thus, the sample complexity for the estimator is given as $O(\|\hat{O}_A\|_2^2 \mathbb{E}_\beta[\text{Tr}[\hat{\rho}_\beta^2]] \log(1/\delta)/\epsilon^2)$.

Meanwhile, we need to be able to sample from $p(\beta)$ and $q(\alpha_A)$. Sampling from $q(\alpha_A)$ can be efficiently done because of the product structure:

$$q(\alpha_A) = \frac{|\chi_{\hat{O}_A}(\alpha_A)|^2}{\pi^l \|\hat{O}_A\|_2^2} = \prod_{i \in A} \frac{|\chi_{\hat{O}_i}(\alpha_i)|^2}{\pi \|\hat{O}_i\|_2^2}, \quad (\text{A52})$$

which takes at most $O(M)$. Also, $p(\beta)$ can also be easily sampled if the number of modes L in $|\beta\rangle$ is not too large:

$$p(\beta) = \frac{1}{\pi^L} \langle \psi | \hat{G}_\beta^\dagger (\hat{1}_M \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) \hat{G}_\beta | \psi \rangle = \frac{1}{\pi^L} \langle \psi | \hat{G}_\beta^\dagger \hat{D}^\dagger(\beta) (\hat{1}_M \otimes |\mathbf{0}\rangle \langle \mathbf{0}|) \hat{D}(\beta) \hat{G}_\beta | \psi \rangle \quad (\text{A53})$$

$$= \frac{1}{\pi^L} \langle \psi | \hat{D}^\dagger(\beta') \hat{G}_\beta^\dagger (\hat{1}_M \otimes |\mathbf{0}\rangle \langle \mathbf{0}|) \hat{G}_\beta \hat{D}(\beta') | \psi \rangle = \frac{1}{\pi^L} \langle \psi' | \hat{G}_\beta^\dagger (\hat{1}_M \otimes |\mathbf{0}\rangle \langle \mathbf{0}|) \hat{G}_\beta | \psi' \rangle, \quad (\text{A54})$$

where we used the property of the displacement operator.

$$\hat{D}^\dagger(\alpha') = \hat{G}_\beta^\dagger \hat{D}^\dagger(\alpha) \hat{G}_\beta. \quad (\text{A55})$$

More specifically, when $L = O(1)$, by Lemma 1, we can sample from $p(\beta)$ in polynomial time.

Finally, we analyze the complexity of computing the random variable X :

$$X(\beta, \alpha) = \frac{\|\hat{O}_A\|_2^2 \langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes |\beta\rangle\langle\beta|) | \psi_\beta \rangle}{\pi^L p(\beta) \chi_{\hat{O}_A}^*(\alpha_A)}. \quad (\text{A56})$$

The difficult part in computing the random variable is

$$\langle \psi_\beta | (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) | \psi_\beta \rangle = \langle \psi | \hat{G}^\dagger(\beta) (\hat{D}^\dagger(\alpha_A) \otimes \hat{1}_B \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) \hat{G}(\beta) | \psi \rangle \quad (\text{A57})$$

$$= \langle \psi | \hat{G}^\dagger(\beta) (\hat{1} \otimes \hat{D}(\beta) | \psi_G \rangle \langle \psi_G | \hat{D}^\dagger(\beta)) \hat{G}(\beta) \hat{D}(\alpha'_A) | \psi \rangle = \langle \psi | \hat{G}^\dagger(\beta) (\hat{1} \otimes |\mathbf{0}\rangle\langle\mathbf{0}|) \hat{G}(\beta) | \psi' \rangle, \quad (\text{A58})$$

but this can also be computed by using Lemma 1 when $L = O(1)$. Thus, the total running time is given as

$$O\left(\frac{\text{poly}(M) \|\hat{O}_A\|_2^2 \mathbb{E}_\beta[\text{Tr}(\hat{\rho}_\beta^2)] \log(1/\delta)}{\epsilon^2}\right), \quad (\text{A59})$$

which completes the proof. $\square$

Appendix B: Derivation of $\tilde{G}(k)$

In this Appendix, we provide a derivation of the following relationship between $\tilde{G}(k)$ and $G(\Omega)$ in Eqs. (55) and (56) [64]:

$$\tilde{G}(k) \equiv \langle \phi | \hat{G}_0^\dagger e^{-ik\theta \hat{\mathbf{n}} \cdot \boldsymbol{\omega}} \hat{G}_0 | \psi \rangle, \quad (\text{B1})$$

$$G(\Omega) \equiv \sum_{\mathbf{n}=0}^{\infty} q(\mathbf{n}) \delta(\Omega - \boldsymbol{\omega} \cdot \mathbf{n}) = \frac{1}{\Omega_{\max} + 1} \sum_{k=0}^{\Omega_{\max}} \tilde{G}(k) e^{ik\Omega}, \quad (\text{B2})$$

where $\theta = 2\pi/(\Omega_{\max} + 1)$ and

$$q(\mathbf{n}) \equiv \langle \phi | \hat{G}_0^\dagger | \mathbf{n} \rangle \langle \mathbf{n} | \hat{G}_0 | \psi \rangle. \quad (\text{B3})$$

Let us compute the Fourier transform of $G(\Omega)$:

$$\sum_{\Omega=0}^{\Omega_{\max}} G(\Omega) e^{-ik\theta\Omega} = \sum_{\Omega=0}^{\Omega_{\max}} \sum_{\mathbf{n}=0}^{\infty} q(\mathbf{n}) \delta(\Omega - \boldsymbol{\omega} \cdot \mathbf{n}) e^{-ik\theta\Omega} = \frac{1}{\Omega_{\max} + 1} \sum_{\Omega=0}^{\Omega_{\max}} \sum_{\mathbf{n}=0}^{\infty} q(\mathbf{n}) \sum_{l=0}^{\Omega_{\max}} e^{il\theta(\Omega - \boldsymbol{\omega} \cdot \mathbf{n}) - ik\theta\Omega} \quad (\text{B4})$$

$$= \frac{1}{\Omega_{\max} + 1} \sum_{l=0}^{\Omega_{\max}} \sum_{\mathbf{n}=0}^{\infty} q(\mathbf{n}) e^{-il\theta \boldsymbol{\omega} \cdot \mathbf{n}} \sum_{\Omega=0}^{\Omega_{\max}} e^{i(l-k)\theta\Omega} = \sum_{\mathbf{n}=0}^{\infty} q(\mathbf{n}) e^{-ik\theta \boldsymbol{\omega} \cdot \mathbf{n}} = \sum_{\mathbf{n}=0}^{\infty} \langle \phi | \hat{G}_0^\dagger | \mathbf{n} \rangle \langle \mathbf{n} | \hat{G}_0 | \psi \rangle e^{-ik\theta \boldsymbol{\omega} \cdot \mathbf{n}} \quad (\text{B5})$$

$$= \langle \phi | \hat{G}_0^\dagger e^{-ik\theta \hat{\mathbf{n}} \cdot \boldsymbol{\omega}} \hat{G}_0 | \psi \rangle = \tilde{G}(k). \quad (\text{B6})$$

Hence, $\tilde{G}(k)$ is the Fourier transformation of $G(\Omega)$, which enables us to compute the marginal probabilities of q .

Appendix C: Low-rank structure in Gaussian circuits

In this Appendix, we provide an explicit derivation of the transformation of bosonic annihilation operators through the Gaussian unitary circuit $\hat{G}_0^\dagger \hat{P}(\boldsymbol{\varphi}) \hat{G}_0$. To be more specific, we prove Lemma 6:

Lemma 8 (Lemma 6 restated). *Consider a general Gaussian unitary circuit $\hat{G}_0$ and phase-shifter operator $\hat{P}(\boldsymbol{\varphi})$ with $\boldsymbol{\varphi} = (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$. Then, $\hat{G}_0^\dagger \hat{P}(\boldsymbol{\varphi}) \hat{G}_0$ can be decomposed into a linear-optical circuit, at most $2L$ non-zero squeezing operators, and another linear-optical circuit.*

Proof. First of all, the bosonic annihilation operator transforms under $\hat{G}_0 = \hat{U}\hat{S}(\mathbf{s})\hat{V}$ as

$$\hat{G}_0\hat{a}_i\hat{G}_0^\dagger = \hat{U}\hat{S}\hat{V}\hat{a}_i\hat{V}^\dagger\hat{S}^\dagger\hat{U}^\dagger = \hat{U}\hat{S}\left(\sum_{j=1}^M V_{ji}^*\hat{a}_j\right)\hat{S}^\dagger\hat{U}^\dagger = \hat{U}\left(\sum_{j=1}^M V_{ji}^*(\cosh s_j\hat{a}_j - \sinh s_j\hat{a}_j^\dagger)\right)\hat{U}^\dagger \quad (C1)$$

$$= \sum_{j,k=1}^M V_{ji}^*(\cosh s_j U_{kj}^*\hat{a}_k - \sinh s_j U_{kj}\hat{a}_k^\dagger) = \sum_{k=1}^M \left(A_{ik}\hat{a}_k + B_{ik}\hat{a}_k^\dagger\right), \quad (C2)$$

where we used

$$\hat{U}^\dagger\hat{a}_i\hat{U} = \sum_{j=1}^M U_{ij}\hat{a}_j, \quad \hat{U}\hat{a}_i\hat{U}^\dagger = \sum_{j=1}^M U_{ji}^*\hat{a}_j, \quad \hat{S}^\dagger(s)\hat{a}_i\hat{S}(s) = \cosh s\hat{a}_i + \sinh s\hat{a}_i^\dagger, \quad \hat{S}(s)\hat{a}_i\hat{S}^\dagger(s) = \cosh s\hat{a}_i - \sinh s\hat{a}_i^\dagger. \quad (C3)$$

and we defined

$$A_{ik} \equiv \sum_{j=1}^M V_{ji}^* \cosh s_j U_{kj}^*, \quad B_{ik} \equiv - \sum_{j=1}^M V_{ji}^* \sinh s_j U_{kj}, \quad (C4)$$

which characterize the Gaussian transformation. Here, we emphasize that the number of non-zero squeezing parameters decides the rank of the matrix B . More precisely, if the number of non-zero squeezing parameters is L , then the rank of the matrix B is at most L .

For the transformation under $\hat{G}_0^\dagger$, we similarly have

$$\hat{G}_0^\dagger\hat{a}_i\hat{G}_0 = \hat{V}^\dagger\hat{S}^\dagger\hat{U}^\dagger\hat{a}_i\hat{U}\hat{S}\hat{V} = \hat{V}^\dagger\hat{S}^\dagger\left(\sum_{j=1}^M U_{ij}\hat{a}_j\right)\hat{S}\hat{V} = \hat{V}^\dagger\left(\sum_{j=1}^M U_{ij}(\cosh s_j\hat{a}_j + \sinh s_j\hat{a}_j^\dagger)\right)\hat{V} \quad (C5)$$

$$= \sum_{j,k=1}^M U_{ij}(\cosh s_j V_{jk}\hat{a}_k + \sinh s_j V_{jk}^*\hat{a}_k^\dagger) = \sum_{k=1}^M \left((A^\dagger)_{ik}\hat{a}_k - (B^T)_{ik}\hat{a}_k^\dagger\right). \quad (C6)$$

Because of the unitarity, after the transformation under $\hat{G}_0$ and then $\hat{G}_0^\dagger$, i.e., the identity operation,

$$\hat{a}_i \rightarrow \sum_{j=1}^M A_{ij}\hat{a}_j + \sum_{j=1}^M B_{ij}\hat{a}_j^\dagger \rightarrow \sum_{j,k=1}^M A_{ij} \left((A^\dagger)_{jk}\hat{a}_k - (B^T)_{jk}\hat{a}_k^\dagger\right) + \sum_{j,k=1}^M B_{ij} \left((A^\dagger)_{jk}^*\hat{a}_k^\dagger - (B^T)_{jk}^*\hat{a}_k\right) \quad (C7)$$

$$= \sum_{j,k=1}^M \left[(A_{ij}(A^\dagger)_{jk} - B_{ij}(B^\dagger)_{jk})\hat{a}_k + (-A_{ij}(B^T)_{jk} + B_{ij}(A^T)_{jk})\hat{a}_k^\dagger \right], \quad (C8)$$

the matrices A and B must satisfy the following conditions:

$$AA^\dagger - BB^\dagger = \mathbb{1}, \quad AB^T = BA^T. \quad (C9)$$

Let $C \equiv A^\dagger$ and $D = -B^T$. After the entire process, including the phase shifter $\hat{P}(\boldsymbol{\varphi})$, the annihilation operator transforms as

$$\hat{a}_i \rightarrow \sum_{j=1}^M A_{ij}\hat{a}_j + \sum_{j=1}^M B_{ij}\hat{a}_j^\dagger \rightarrow \sum_{j=1}^M e^{i\varphi_j} A_{ij}\hat{a}_j + \sum_{j=1}^M e^{-i\varphi_j} B_{ij}\hat{a}_j^\dagger \quad (C10)$$

$$\rightarrow \sum_{j,k=1}^M e^{i\varphi_j} A_{ij} \left(C_{jk}\hat{a}_k + D_{jk}\hat{a}_k^\dagger\right) + \sum_{j,k=1}^M e^{-i\varphi_j} B_{ij} \left(C_{jk}^*\hat{a}_k^\dagger + D_{jk}^*\hat{a}_k\right) \quad (C11)$$

$$= \sum_{j,k=1}^M e^{i\varphi_j} A_{ij} C_{jk}\hat{a}_k + \sum_{j,k=1}^M e^{i\varphi_j} A_{ij} D_{jk}\hat{a}_k^\dagger + \sum_{j,k=1}^M e^{-i\varphi_j} B_{ij} C_{jk}^*\hat{a}_k^\dagger + \sum_{j,k=1}^M e^{-i\varphi_j} B_{ij} D_{jk}^*\hat{a}_k. \quad (C12)$$

Here, by assuming that $\varphi_j = 0$ for $j > L$, without loss of generality, and using Eq. (C9), we can simplify the expression as

$$\sum_{j,k=1}^M e^{i\varphi_j} A_{ij} C_{jk} \hat{a}_k + \sum_{j,k=1}^M e^{i\varphi_j} A_{ij} D_{jk} \hat{a}_k^\dagger + \sum_{j,k=1}^M e^{-i\varphi_j} B_{ij} C_{jk}^* \hat{a}_k^\dagger + \sum_{j,k=1}^M e^{-i\varphi_j} B_{ij} D_{jk}^* \hat{a}_k \quad (\text{C13})$$

$$= \sum_{j=1}^M \sum_{k=1}^M \left(A_{ij} C_{jk} \hat{a}_k + B_{ij} D_{jk}^* \hat{a}_k + A_{ij} D_{jk} \hat{a}_k^\dagger + B_{ij} C_{jk}^* \hat{a}_k^\dagger \right) \quad (\text{C14})$$

$$+ \sum_{j=1}^L \sum_{k=1}^M \left((e^{i\varphi_j} - 1) A_{ij} C_{jk} \hat{a}_k + (e^{-i\varphi_j} - 1) B_{ij} D_{jk}^* \hat{a}_k + (e^{i\varphi_j} - 1) A_{ij} D_{jk} \hat{a}_k^\dagger + (e^{-i\varphi_j} - 1) B_{ij} C_{jk}^* \hat{a}_k^\dagger \right) \quad (\text{C15})$$

$$= \hat{a}_i + \sum_{j=1}^L \sum_{k=1}^M \left((e^{i\varphi_j} - 1) A_{ij} C_{jk} \hat{a}_k + (e^{-i\varphi_j} - 1) B_{ij} D_{jk}^* \hat{a}_k + (e^{i\varphi_j} - 1) A_{ij} D_{jk} \hat{a}_k^\dagger + (e^{-i\varphi_j} - 1) B_{ij} C_{jk}^* \hat{a}_k^\dagger \right) \quad (\text{C16})$$

$$= \hat{a}_i + \sum_{k=1}^M \left(W_{ik} \hat{a}_k + Z_{ik} \hat{a}_k^\dagger \right), \quad (\text{C17})$$

where we defined

$$W_{ik} \equiv \sum_{j=1}^L \left((e^{i\varphi_j} - 1) A_{ij} C_{jk} + (e^{-i\varphi_j} - 1) B_{ij} D_{jk}^* \right) = \sum_{j=1}^L \left((e^{i\varphi_j} - 1) A_{ij} A_{kj}^* - (e^{-i\varphi_j} - 1) B_{ij} B_{kj}^* \right), \quad (\text{C18})$$

$$Z_{ik} \equiv \sum_{j=1}^L \left((e^{i\varphi_j} - 1) A_{ij} D_{jk} + (e^{-i\varphi_j} - 1) B_{ij} C_{jk}^* \right) = \sum_{j=1}^L \left(-(e^{i\varphi_j} - 1) A_{ij} B_{kj} + (e^{-i\varphi_j} - 1) B_{ij} A_{kj} \right), \quad (\text{C19})$$

and hence each of the terms has a low-rank structure. More specifically, W and Z 's ranks are at most $2L$. Thus,

$$W = \sum_{j=1}^{2L} u^{(j)} v^{(j)\text{T}}, \quad Z = \sum_{j=1}^{2L} w^{(j)} z^{(j)\text{T}}. \quad (\text{C20})$$

Here, note that $W + I$ and Z form a Gaussian transform. The low-rankness of the matrix Z implies that the Gaussian transform has a structure in which its squeezing parameters are nonzero only for $2L$ modes. $\square$

Appendix D: Generalized Gurvits' second algorithm for linear-optical circuits

In this Appendix, we present a generalized version of Gurvits' second algorithm for linear-optical circuits with an arbitrary product input, generalizing it from Fock states:

$$\langle \phi | \hat{V} | \psi \rangle = \sum_{\mathbf{n}, \mathbf{m}} a_{\mathbf{m}} b_{\mathbf{n}}^* \langle \mathbf{n} | \hat{V} | \mathbf{m} \rangle, \quad (\text{D1})$$

where $|\psi\rangle$ and $|\phi\rangle$ are arbitrary product states, which are written as

$$|\psi\rangle = \bigotimes_{i=1}^M \left(\sum_{m_i=0}^{n_{\max}} a_{m_i}^{(i)} |m_i\rangle \right), \quad |\phi\rangle = \bigotimes_{i=1}^M \left(\sum_{n_i=0}^{n_{\max}} b_{n_i}^{(i)} |n_i\rangle \right). \quad (\text{D2})$$

Here, $\mathbf{n} = (n_1, \dots, n_M)$ and $\mathbf{m} = (m_1, \dots, m_M)$ and we are interested in a linear-optical circuit $\hat{V}$ whose corresponding unitary matrix V has a low-rank structure such that $V = W + I$ with a low-rank matrix W . More precisely, let us assume that the rank of W is L , so that it can be written as

$$W_{ij} = \sum_{k=1}^L u_i^{(k)} v_j^{(k)}. \quad (\text{D3})$$

To do that, let us first focus on a simpler case

$$\langle \mathbf{n} | \hat{V} | \mathbf{m} \rangle, \quad (\text{D4})$$

which is still a more general form than that of Gurvits' algorithm because $|\mathbf{n}\rangle$ is not equal to $|\mathbf{m}\rangle$ in general. Here, because the linear-optical unitary circuit preserves the photon number, we assume that $|\mathbf{n}| = |\mathbf{m}|$; otherwise, it becomes zero. Let us introduce a notation $X_{\mathbf{n}}$ to represent a multiset corresponding to $\mathbf{n}$, which is composed of n_i times of i 's. For example, for $\mathbf{n} = (2, 1, 0)$, $X_{\mathbf{n}} = \{1, 1, 2\}$.

First of all, we have

$$\langle \mathbf{n} | \hat{V} | \mathbf{m} \rangle = \frac{1}{\sqrt{\mathbf{n}!}} \langle 0 | \left(\prod_{i \in X_{\mathbf{n}}} \hat{a}_i \right) \hat{V} | \mathbf{m} \rangle = \frac{1}{\sqrt{\mathbf{n}!}} \langle 0 | \prod_{i \in X_{\mathbf{n}}} \left(\hat{a}_i + \sum_{k=1}^M W_{ik} \hat{a}_k \right) | \mathbf{m} \rangle \equiv \frac{1}{\sqrt{\mathbf{n}!}} \langle 0 | \prod_{i \in X_{\mathbf{n}}} (\hat{a}_i + \hat{b}_i) | \mathbf{m} \rangle \quad (\text{D5})$$

$$= \frac{1}{\sqrt{\mathbf{n}!}} \langle 0 | \left[\sum_{X \subset X_{\mathbf{n}}} \prod_{x \in X} \hat{a}_x \prod_{x \in X^c} \hat{b}_x \right] | \mathbf{m} \rangle = \frac{1}{\sqrt{\mathbf{n}!}} \sum_{X \subset X_{\mathbf{n}}} \langle 0 | \left[\prod_{x \in X} \hat{a}_x \prod_{x \in X^c} \hat{b}_x \right] | \mathbf{m} \rangle \quad (\text{D6})$$

$$= \frac{1}{\sqrt{\mathbf{n}!}} \sum_{l \leq \mathbf{n}, \mathbf{m}} \binom{\mathbf{n}}{l} \frac{\sqrt{\mathbf{m}!}}{\sqrt{(\mathbf{m}-l)!}} \langle 0 | \left[\prod_{x \in X_{\mathbf{n}-l}} \sum_{j=1}^M W_{xj} \hat{a}_j^\dagger \right] | \mathbf{m}-l \rangle \quad (\text{D7})$$

$$= \frac{\sqrt{\mathbf{m}!}}{\sqrt{\mathbf{n}!}} \sum_{l \leq \mathbf{n}, \mathbf{m}} \binom{\mathbf{n}}{l} \frac{1}{(\mathbf{m}-l)!} \langle 0 | \left[\prod_{x \in X_{\mathbf{n}-l}} \sum_{j=1}^M W_{xj} \hat{a}_j^\dagger \right] \left[\prod_{x \in X_{\mathbf{m}-l}} \hat{a}_x^\dagger \right] | 0 \rangle, \quad (\text{D8})$$

where

$$\langle 0 | \left[\prod_{x \in X_{\mathbf{n}-l}} \sum_{j=1}^M W_{xj} \hat{a}_j^\dagger \right] \left[\prod_{x \in X_{\mathbf{m}-l}} \hat{a}_x^\dagger \right] | 0 \rangle \quad (\text{D9})$$

$$= \sum_{\sigma \in S_{|X_{\mathbf{n}-l}|} : X_{\mathbf{n}-l} \rightarrow X_{\mathbf{m}-l}} \prod_{x \in X_{\mathbf{n}-l}} W_{x, \sigma(x)} \quad (\text{D10})$$

$$= \sum_{\sigma \in S_{|X_{\mathbf{n}-l}|} : X_{\mathbf{n}-l} \rightarrow X_{\mathbf{m}-l}} \prod_{x \in X_{\mathbf{n}-l}} \sum_{k=1}^L u_x^{(k)} v_{\sigma(x)}^{(k)} \quad (\text{D11})$$

$$= \sum_{\sigma \in S_{|X_{\mathbf{n}-l}|} : X_{\mathbf{n}-l} \rightarrow X_{\mathbf{m}-l}} \sum_{k_1, \dots, k_{|X_{\mathbf{n}-l}|}=1}^L \prod_{i=1}^{|X_{\mathbf{n}-l}|} u_{X_{\mathbf{n}-l}(i)}^{(k_i)} v_{X_{\mathbf{m}-l}(i)}^{(k_{\sigma(i)})} \quad (\text{D12})$$

$$= \sum_{s_u(X_{\mathbf{n}-l})} \sum_{s_v(X_{\mathbf{m}-l})} \delta([s_u(X_{\mathbf{n}-l})] = [s_v(X_{\mathbf{m}-l})]) \prod_{i=1}^{|X_{\mathbf{n}-l}|} u_{X_{\mathbf{n}-l}(i)}^{(s_u(i))} v_{X_{\mathbf{m}-l}(i)}^{(s_v(i))} \prod_{i=1}^L k_i! \quad (\text{D13})$$

$$= \sum_{s_u(X_{\mathbf{n}-l})} \sum_{s_v(X_{\mathbf{m}-l})} \delta([s_u(X_{\mathbf{n}-l})] = [s_v(X_{\mathbf{m}-l})]) \prod_{x \in X_{\mathbf{n}-l}} u_x^{(s_u(x))} \prod_{x \in X_{\mathbf{m}-l}} v_x^{(s_v(x))} \prod_{i=1}^L k_i!, \quad (\text{D14})$$

where the summation over $s(X)$ is interpreted as the summation of a tuple from $[L]^{|X|}$ and $[s(X)]$ denotes the multiset of the elements of $s(X)$, and k_i 's denote the multiplicity of i in the multiset $[s_u(X)]$, which arises because of the redundancy.

At this moment, let us ignore the delta function and the multiplicity factor $\prod_i k_i!$, which will be taken care of later. The full expression is then rewritten as

$$\frac{\sqrt{\mathbf{m}!}}{\sqrt{\mathbf{n}!}} \sum_{l \leq \mathbf{n}, \mathbf{m}} \binom{\mathbf{n}}{l} \frac{1}{(\mathbf{m}-l)!} \sum_{s_u(X_{\mathbf{n}-l})} \sum_{s_v(X_{\mathbf{m}-l})} \prod_{x \in X_{\mathbf{n}-l}} u_x^{(s_u(x))} \prod_{x \in X_{\mathbf{m}-l}} v_x^{(s_v(x))} \quad (\text{D15})$$

$$= \frac{\sqrt{\mathbf{m}!}}{\sqrt{\mathbf{n}!}} \sum_{l \leq \mathbf{n}, \mathbf{m}} \binom{\mathbf{n}}{l} \frac{1}{(\mathbf{m}-l)!} \left(\prod_{x \in X_{\mathbf{n}-l}} \sum_{s=1}^L u_x^{(s)} \right) \left(\prod_{x \in X_{\mathbf{m}-l}} \sum_{s=1}^L v_x^{(s)} \right) \quad (\text{D16})$$

$$= \frac{\sqrt{\mathbf{m}!}}{\sqrt{\mathbf{n}!}} \prod_{i=1}^M \sum_{l \leq \min(n_i, m_i)} \binom{n_i}{l} \frac{1}{(m_i-l)!} \left(\sum_{s=1}^L u_i^{(s)} \right)^{n_i-l} \left(\sum_{s=1}^L v_i^{(s)} \right)^{m_i-l}. \quad (\text{D17})$$

Now, to take care of the delta function, we introduce the indeterminates $\{a_u^{(s)}\}_{s=1}^L$ and $\{a_v^{(s)}\}_{s=1}^L$ and write the expression as

$$\prod_{i=1}^M \frac{\sqrt{m_i!}}{\sqrt{n_i!}} \sum_{l \leq \min(n_i, m_i)} \binom{n_i}{l} \frac{1}{(m_i - l)!} \left(\sum_{s=1}^L a_u^{(s)} u_x^{(s)} \right)^{n_i - l} \left(\sum_{s=1}^L a_v^{(s)} v_i^{(s)} \right)^{m_i - l} \quad (\text{D18})$$

and keep the coefficients of the monomials in which $a_u^{(s)}$ and $a_v^{(s)}$'s degrees match each other (e.g., $(a_u^{(1)})^2 (a_u^{(2)})^3 (a_v^{(1)})^2 (a_v^{(2)})^3$). Finally, to take care of the multiplicity factor $\prod_i k_i$, we then multiply the factorial of degrees of $a_u^{(s)}$ (or equivalently $a_v^{(s)}$).

Now, for arbitrary product input states $|\psi\rangle$ and $|\phi\rangle$, we have

$$\langle \phi | \hat{V} | \psi \rangle = \sum_{\mathbf{n}, \mathbf{m}} a_{\mathbf{m}} b_{\mathbf{n}}^* \langle \mathbf{n} | \hat{V} | \mathbf{m} \rangle \quad (\text{D19})$$

$$\rightarrow \sum_{\mathbf{n}, \mathbf{m}} a_{\mathbf{m}} b_{\mathbf{n}}^* \prod_{i=1}^M \frac{\sqrt{m_i!}}{\sqrt{n_i!}} \sum_{l \leq \min(n_i, m_i)} \binom{n_i}{l} \frac{1}{(m_i - l)!} \left(\sum_{s=1}^L a_u^{(s)} u_i^{(s)} \right)^{n_i - l} \left(\sum_{s=1}^L a_v^{(s)} v_i^{(s)} \right)^{m_i - l} \quad (\text{D20})$$

$$\rightarrow \prod_{i=1}^M \sum_{n_i, m_i=0}^{n_{\max}} a_{m_i}^{(i)} b_{n_i}^{(i)*} \frac{\sqrt{m_i!}}{\sqrt{n_i!}} \sum_{l \leq \min(n_i, m_i)} \binom{n_i}{l} \frac{1}{(m_i - l)!} \left(\sum_{s=1}^L a_u^{(s)} u_i^{(s)} \right)^{n_i - l} \left(\sum_{s=1}^L a_v^{(s)} v_i^{(s)} \right)^{m_i - l}. \quad (\text{D21})$$

Let us now analyze the complexity. The number of indeterminates we introduce is $2L$, and each indeterminate may have degree at most $Mn_{\max}$. Thus, the number of coefficients we must keep track of is $(Mn_{\max} + 1)^{2L}$. Since there are M product, the total number of operations is $O(M(Mn_{\max} + 1)^{2L})$.

Appendix E: Antinormal ordering

The goal of this Appendix is to find the antinormal ordering of the following term:

$$\prod_{i=1}^N (\hat{A}_i + \hat{B}_i^\dagger), \quad (\text{E1})$$

where the commutation relations of the operators are given as $[\hat{A}_i, \hat{A}_j] = 0$, $[\hat{B}_i^\dagger, \hat{B}_j^\dagger] = 0$, and $[\hat{A}_i, \hat{B}_j^\dagger] = C_{ij}$. This Appendix is based on Ref. [92]. To find its antinormal ordering, i.e., express the above by operators in which $\hat{A}_i$'s always appear on the left and $\hat{B}_i^\dagger$'s always appear on the right, we consider each term after expanding it, such as $\hat{A}_1 \hat{B}_2^\dagger \hat{A}_3 \hat{A}_4 \hat{B}_5^\dagger \hat{A}_6$. Now, we move all the creation operators $\hat{B}_i^\dagger$'s to the right by using the commutation relation. First, we denote Y as the indices of the annihilation operators $\hat{A}_i$ and Y^c as those of the creation operators $\hat{B}_i^\dagger$. For example, for $\hat{A}_1 \hat{B}_2^\dagger \hat{A}_3 \hat{A}_4 \hat{B}_5^\dagger \hat{A}_6$, $Y = \{1, 3, 4, 6\}$ and $Y^c = \{2, 5\}$. We then move $\hat{B}_i^\dagger$ for $i \in Y^c$ one by one using the commutation relation. First of all, note that when we move $\hat{B}_j^\dagger$ to the right, it only interacts with $\hat{A}_i$ with $i > j$.

Let us start with the largest $j \in Y^c$, say 5 for the above example. Using $\hat{B}_5^\dagger \hat{A}_6 = [\hat{B}_5^\dagger, \hat{A}_6] + \hat{A}_6 \hat{B}_5^\dagger = -C_{65} + \hat{A}_6 \hat{B}_5^\dagger$, we now have two terms

$$\hat{A}_1 \hat{B}_2^\dagger \hat{A}_3 \hat{A}_4 \hat{B}_5^\dagger \hat{A}_6 = -C_{65} \hat{A}_1 \hat{B}_2^\dagger \hat{A}_3 \hat{A}_4 + \hat{A}_1 \hat{B}_2^\dagger \hat{A}_3 \hat{A}_4 \hat{A}_6 \hat{B}_5^\dagger. \quad (\text{E2})$$

Thus, when we use the commutation relation between $\hat{A}_i$ and $\hat{B}_j^\dagger$, the associated term is split into two terms: one that changes $\hat{A}_i \hat{B}_j^\dagger$ to $-C_{ij}$ and the other that simply changes $\hat{A}_i \hat{B}_j^\dagger$ to $\hat{B}_j^\dagger \hat{A}_i$. Using this property, one can easily see that for a given Y and Y^c , its antinormal ordering is simply written as

$$\sum_{\mathcal{M} \in \text{Match}(F_N; Y \rightarrow Y^c)} (-1)^{|\mathcal{M}|} \prod_{(i,j) \in \mathcal{M}} C_{ij} \prod_{i \in Y \setminus A(\mathcal{M})} \hat{A}_i \prod_{j \in Y^c \setminus B(\mathcal{M})} \hat{B}_j^\dagger, \quad (\text{E3})$$

where the Match is the possible matches in F_N , which is the Ferrers graph whose edge set is $E = \{(i, j) | 1 \leq j < i \leq N\}$ [93], and $A(\mathcal{M})$ and $B(\mathcal{M})$ represent the elements in Y and Y^c that are involved in the matching $\mathcal{M}$, respectively.

Since we need to take into account all possible pairs Y and Y^c , we have

$$\prod_{i=1}^N (\hat{A}_i + \hat{B}_i^\dagger) = \sum_{Y \subset [N]} \sum_{\mathcal{M} \in \text{Match}(F_N; Y \rightarrow Y^c)} (-1)^{|\mathcal{M}|} \prod_{(i,j) \in \mathcal{M}} C_{ij} \prod_{i \in Y \setminus A(\mathcal{M})} \hat{A}_i \prod_{j \in Y^c \setminus B(\mathcal{M})} \hat{B}_j^\dagger. \quad (\text{E4})$$

Appendix F: Generalized Gurvits' second algorithm for Gaussian circuits

In this Appendix, we provide a classical algorithm that computes the following using a low-rank property of the relevant matrices,

$$\langle \phi | \hat{G} | \psi \rangle = \sum_{\mathbf{n}, \mathbf{m}} a_{\mathbf{m}} b_{\mathbf{n}}^* \langle \mathbf{n} | \hat{G} | \mathbf{m} \rangle, \quad (\text{F1})$$

where $|\psi\rangle$ and $|\phi\rangle$ are arbitrary product states, which are written due to the product structure as

$$|\psi\rangle = \bigotimes_{i=1}^M \left(\sum_{m_i=0}^{n_{\max}} a_{m_i}^{(i)} |m_i\rangle \right), \quad |\phi\rangle = \bigotimes_{i=1}^M \left(\sum_{n_i=0}^{n_{\max}} b_{n_i}^{(i)} |n_i\rangle \right). \quad (\text{F2})$$

Also, $\hat{G}$ is a Gaussian unitary circuit, and in particular, we are interested in a Gaussian unitary circuit generated by $\hat{G}_0^\dagger \hat{P}(\boldsymbol{\varphi}) \hat{G}_0$, where $\hat{G}_0$ is an arbitrary Gaussian unitary circuit and $\hat{P}(\boldsymbol{\varphi})$ is a phase shifter with phases $\boldsymbol{\varphi}$ whose nonzero elements are a few, i.e., $\boldsymbol{\varphi} = (\varphi_1, \dots, \varphi_L, 0, \dots, 0)$. Hence, we prove Lemma 3:

Lemma 9 (Lemma 3 restated). *Consider an M -mode bosonic system. Let $\hat{G}_0$ be a Gaussian unitary circuit and $\hat{P}(\boldsymbol{\varphi})$ be the phase shifter with phase $\boldsymbol{\varphi}$ and $|\psi\rangle$ and $|\phi\rangle$ be product states. If the number of non-zero elements in $\boldsymbol{\varphi}$ is $L = O(1)$,*

$$\langle \phi | \hat{G}_0^\dagger \hat{P}(\boldsymbol{\varphi}) \hat{G}_0 | \psi \rangle \quad (\text{F3})$$

can be exactly computed in polynomial time in M .

Proof. Before we derive the full expression and the classical algorithm, let us first focus on $\langle \mathbf{n} | \hat{G} | \mathbf{m} \rangle$ and then generalize, where $\hat{G} \equiv \hat{G}_0^\dagger \hat{P}(\boldsymbol{\varphi}) \hat{G}_0$. Let $X_{\mathbf{n}}$ be the multiset representation of $\mathbf{n}$, which is composed of n_i times of i . For example, when $\mathbf{n} = (2, 1, 4)$, $X_{\mathbf{n}} = \{1, 1, 2, 3, 3, 3, 3\}$. $X_{\mathbf{m}}$ is similar. Let $\hat{G} = \hat{U} \hat{S}(\mathbf{r}) \hat{V}$ be the Bloch-Messiah decomposition of $\hat{G}$, following Appendix C. Then,

$$\langle \mathbf{n} | \hat{G} | \mathbf{m} \rangle = \frac{1}{\sqrt{\mathbf{n}!}} \langle 0 | \hat{G} \hat{G}^\dagger \left(\prod_{i \in X_{\mathbf{n}}} \hat{a}_i \right) \hat{G} | \mathbf{m} \rangle = \frac{1}{\sqrt{\mathbf{n}!}} \langle 0 | \hat{G} \left[\prod_{i \in X_{\mathbf{n}}} \left(\hat{a}_i + \sum_{k=1}^M (W_{ik} \hat{a}_k + Z_{ik} \hat{a}_k^\dagger) \right) \right] | \mathbf{m} \rangle \quad (\text{F4})$$

$$= \frac{1}{\sqrt{\mathbf{n}!}} \langle \mathbf{r} | \hat{V} \left[\prod_{i \in X_{\mathbf{n}}} \left(\hat{a}_i + \sum_{k=1}^M (W_{ik} \hat{a}_k + Z_{ik} \hat{a}_k^\dagger) \right) \right] | \mathbf{m} \rangle = \frac{1}{\sqrt{\mathbf{n}!}} \langle \mathbf{r} | \hat{V} \left[\prod_{i \in X_{\mathbf{n}}} (\hat{A}_i + \hat{B}_i^\dagger) \right] | \mathbf{m} \rangle, \quad (\text{F5})$$

where we defined

$$\hat{A}_i = \hat{a}_i + \sum_{k=1}^M W_{ik} \hat{a}_k, \quad \hat{B}_i^\dagger = \sum_{k=1}^M Z_{ik} \hat{a}_k^\dagger, \quad C_{ij} = [\hat{A}_i, \hat{B}_j^\dagger] = Z_{ji} + \sum_{k=1}^M W_{ik} Z_{jk}. \quad (\text{F6})$$

Note that, as shown in Appendix C, W , Z , and C 's ranks are at most $2L$ and that only at most $2L$ r_i 's are nonzero. Without loss of generality, we set $r_i = 0$ for $i > 2L$.

By using the antinormal ordering [92] (see Appendix E), let us expand it and move all the creation operators to the right,

$$\frac{1}{\sqrt{\mathbf{n}! \mathbf{m}!}} \sum_{Y \subset X_{\mathbf{n}}} \sum_{\mathcal{M} \in \text{Match}(F_{X_{\mathbf{n}}}; Y \rightarrow Y^c)} (-1)^{|\mathcal{M}|} \left(\prod_{(i,j) \in \mathcal{M}} C_{ij} \right) \langle \mathbf{r} | \hat{V} \left(\prod_{i \in Y \setminus A(\mathcal{M})} \hat{A}_i \right) \left(\prod_{i \in Y^c \setminus B(\mathcal{M})} \hat{B}_i^\dagger \right) \prod_{i \in X_{\mathbf{m}}} \hat{a}_i^\dagger | 0 \rangle, \quad (\text{F7})$$

where Y and $Y^c \equiv X_{\mathbf{n}} \setminus Y$ are multisets that are subsets of $X_{\mathbf{n}}$ and the Match is the possible matches in $F_{X_{\mathbf{n}}}$, which is the Ferrers graph whose edge set is $E = \{(i, j) \in X_{\mathbf{n}} \times X_{\mathbf{n}} | j < i\}$. Also, $A(\mathcal{M})$ and $B(\mathcal{M})$ are the elements that are involved in M from Y and Y^c , respectively. That means that $Y \setminus A(\mathcal{M})$ and $Y^c \setminus B(\mathcal{M})$ are vertices that are not involved in the matching $\mathcal{M}$. Here,

$$\langle \mathbf{r} | \hat{V} \left(\prod_{i \in Y \setminus A(\mathcal{M})} \hat{A}_i \right) \left(\prod_{i \in Y^c \setminus B(\mathcal{M})} \hat{B}_i^\dagger \right) \prod_{i \in X_{\mathbf{m}}} \hat{a}_i^\dagger | 0 \rangle \quad (\text{F8})$$

$$= \langle \mathbf{r} | \hat{V} \sum_{X \subset Y \setminus A(\mathcal{M})} \prod_{i \in X} \hat{a}_i \left(\prod_{i \in Y \setminus A(\mathcal{M}) \setminus X} \sum_{k=1}^M W_{ik} \hat{a}_k \right) \left(\prod_{i \in Y^c \setminus B(\mathcal{M})} \sum_{k=1}^M Z_{jk} \hat{a}_k^\dagger \right) \left(\prod_{i \in X_{\mathbf{m}}} \hat{a}_i^\dagger \right) | 0 \rangle. \quad (\text{F9})$$

Thus, let us first simplify the following:

$$\langle \mathbf{r} | \hat{V} \prod_{i \in A} \hat{a}_i \prod_{i \in B} \hat{b}_i \prod_{i \in C} \hat{c}_i^\dagger \prod_{i \in D} \hat{a}_i^\dagger | 0 \rangle, \quad (\text{F10})$$

where $A \iff X, B \iff Y \setminus A(\mathcal{M}) \setminus X, C \iff Y^c \setminus B(\mathcal{M}), D \iff X_m$. Here,

$$\prod_{i \in A} \hat{a}_i \prod_{i \in B} \hat{b}_i \prod_{i \in C} \hat{c}_i^\dagger \prod_{i \in D} \hat{a}_i^\dagger | 0 \rangle \quad (\text{F11})$$

$$= \prod_{i \in A} \hat{a}_i \prod_{i \in B} \sum_{j=1}^M W_{ij} \hat{a}_j \prod_{i \in C} \sum_{j=1}^M Z_{ij} \hat{a}_j^\dagger \prod_{i \in D} \hat{a}_i^\dagger | 0 \rangle \quad (\text{F12})$$

$$= \sum_{j_{B(1)}, \dots, j_{B(|B|)}=1}^M \sum_{j'_{C(1)}, \dots, j'_{C(|C|)}=1}^M \prod_{i \in B} W_{ij_i} \prod_{i \in C} Z_{ij'_i} \prod_{i \in A} \hat{a}_i \prod_{i \in B} \hat{a}_{j_i} \prod_{i \in C} \hat{a}_{j'_i}^\dagger \prod_{i \in D} \hat{a}_i^\dagger | 0 \rangle. \quad (\text{F13})$$

To simplify this expression, we first need to match all A and B to C and D first, and then the remaining elements in C and D will be matched with the squeezed state $\langle \mathbf{r} | \hat{V}$. Here, $a \in A$ matches with $a = d_a \in D$ and $b \in B$ with $d_b \in D \setminus a$, and $A \setminus a$ with $c_a \in C$ and $B \setminus b$ with c_b . Thus,

$$\begin{aligned} & \prod_{i \in A} \hat{a}_i \prod_{i \in B} \hat{a}_{j_i} \prod_{i \in C} \hat{a}_{j'_i}^\dagger \prod_{i \in D} \hat{a}_i^\dagger | 0 \rangle \quad (\text{F14}) \\ &= \sum_{a \in A \cap D} \sum_{b \in B} \sum_{c_a, c_b \in C} \sum_{d_b \in D \setminus d_a} \sum_{\sigma \in S_{|a|}: a \rightarrow d_a} \prod_{i \in a} \delta_{i, \sigma(i)} \sum_{\sigma \in S_{|a^c|}: a^c \rightarrow c_a} \prod_{i \in a^c} \delta_{i, j'_{\sigma(i)}} \sum_{\sigma \in S_{|b|}: b \rightarrow d_b} \prod_{i \in b} \delta_{j_i, \sigma(i)} \sum_{\sigma \in S_{|B \setminus b|}: B \setminus b \rightarrow c_b} \prod_{i \in B \setminus b} \delta_{j_i, j'_{\sigma(i)}} \\ & \times \prod_{i \in C \setminus (c_a \cup c_b)} \hat{a}_{j'_i}^\dagger \prod_{i \in D \setminus (d_a \cup d_b)} \hat{a}_i^\dagger | 0 \rangle. \quad (\text{F15}) \end{aligned}$$

Hence, we have

$$\langle \mathbf{r} | \hat{V} \sum_{j_{B(1)}, \dots, j_{B(|B|)}=1}^M \sum_{j'_{C(1)}, \dots, j'_{C(|C|)}=1}^M \prod_{i \in B} W_{ij_i} \prod_{i \in C} Z_{ij'_i} \prod_{i \in A} \hat{a}_i \prod_{i \in B} \hat{a}_{j_i} \prod_{i \in C} \hat{a}_{j'_i}^\dagger \prod_{i \in D} \hat{a}_i^\dagger | 0 \rangle \quad (\text{F16})$$

$$\begin{aligned} &= \sum_{a \in A \cap D} \sum_{b \in B} \sum_{c_a, c_b \in C} \sum_{d_b \in D \setminus d_a} \sum_{\sigma \in S_{|a^c|}: a^c \rightarrow c_a} \prod_{i \in a^c} Z_{i, \sigma(i)} \sum_{\sigma \in S_{|b|}: b \rightarrow d_b} \prod_{i \in b} W_{i, \sigma(i)} \sum_{\sigma \in S_{|B \setminus b|}: B \setminus b \rightarrow c_b} \prod_{i \in B \setminus b} (W Z^T)_{i, \sigma(i)} \\ & \times \langle \mathbf{r} | \hat{V} \prod_{i \in C \setminus (c_a \cup c_b)} \sum_{j'_i=1}^M Z_{ij'_i} \hat{a}_{j'_i}^\dagger \prod_{i \in D \setminus (d_a \cup d_b)} \hat{a}_i^\dagger | 0 \rangle \quad (\text{F17}) \end{aligned}$$

$$\begin{aligned} &= \sum_{a \in A \cap D} \sum_{b \in B} \sum_{c_a, c_b \in C} \sum_{d_b \in D \setminus d_a} \sum_{\sigma \in S_{|a^c|}: a^c \rightarrow c_a} \prod_{i \in a^c} Z_{i, \sigma(i)} \sum_{\sigma \in S_{|b|}: b \rightarrow d_b} \prod_{i \in b} W_{i, \sigma(i)} \sum_{\sigma \in S_{|B \setminus b|}: B \setminus b \rightarrow c_b} \prod_{i \in B \setminus b} (W Z^T)_{i, \sigma(i)} \\ & \times \langle \mathbf{r} | \prod_{i \in C \setminus (c_a \cup c_b)} \sum_{j'_i=1}^M Z_{ij'_i} V_{k, j'_i} \hat{a}_k^\dagger \prod_{i \in D \setminus (d_a \cup d_b)} \sum_{k=1}^M V_{k, i} \hat{a}_k^\dagger | 0 \rangle \quad (\text{F18}) \end{aligned}$$

$$\begin{aligned} &= \sum_{a \in A \cap D} \sum_{b \in B} \sum_{c_a, c_b \in C} \sum_{d_b \in D \setminus d_a} \sum_{\sigma \in S_{|a^c|}: a^c \rightarrow c_a} \prod_{i \in a^c} Z_{i, \sigma(i)} \sum_{\sigma \in S_{|b|}: b \rightarrow d_b} \prod_{i \in b} W_{i, \sigma(i)} \sum_{\sigma \in S_{|B \setminus b|}: B \setminus b \rightarrow c_b} \prod_{i \in B \setminus b} (W Z^T)_{i, \sigma(i)} \\ & \times \langle \mathbf{r} | \prod_{i \in C \setminus (c_a \cup c_b)} \sum_{k=1}^M (Z V^T)_{i, k} \hat{a}_k^\dagger \prod_{i \in D \setminus (d_a \cup d_b)} \sum_{k=1}^M (V^T)_{i, k} \hat{a}_k^\dagger | 0 \rangle, \quad (\text{F19}) \end{aligned}$$

where $c_a \cap c_b = \emptyset$ and $d_a \cap d_b = \emptyset$. Here, using the low-rank structure of W and Z , we simplify the expression further

as

$$\sum_{\sigma \in \mathcal{S}_{|a^c|}: a^c \rightarrow c_a} \prod_{i \in a^c} Z_{i, \sigma(i)} \sum_{\sigma \in \mathcal{S}_{|b|}: b \rightarrow d_b} \prod_{i \in b} W_{i, \sigma(i)} \sum_{\sigma \in \mathcal{S}_{|B \setminus b|}: B \setminus b \rightarrow c_b} \prod_{i \in B \setminus b} (W Z^T)_{i, \sigma(i)} \quad (\text{F20})$$

$$= \sum_{\sigma \in \mathcal{S}_{|a^c|}: a^c \rightarrow c_a} \prod_{i \in a^c} \sum_{l=1}^{2L} u_i^{(l)} v_{\sigma(i)}^{(l)} \sum_{\rho \in \mathcal{S}_{|b|}: b \rightarrow d_b} \prod_{i \in b} \sum_{k=1}^{2L} w_i^{(k)} x_{\rho(i)}^{(k)} \sum_{\omega \in \mathcal{S}_{|B \setminus b|}: B \setminus b \rightarrow c_b} \prod_{i \in B \setminus b} \sum_{m=1}^{2L} y_i^{(m)} z_{\omega(i)}^{(m)} \quad (\text{F21})$$

$$= \sum_{\sigma \in \mathcal{S}_{|a^c|}: a^c \rightarrow c_a} \sum_{l_{a^c(1)}, \dots, l_{a^c(|a^c|)}=1}^{2L} \prod_{i \in a^c} u_i^{(l_i)} v_{\sigma(i)}^{(l_i)} \sum_{\rho \in \mathcal{S}_{|b|}: b \rightarrow d_b} \sum_{k_{b(1)}, \dots, k_{b(|b|)}=1}^{2L} \prod_{i \in b} w_i^{(k_i)} x_{\rho(i)}^{(k_i)} \quad (\text{F22})$$

$$\times \sum_{\omega \in \mathcal{S}_{|B \setminus b|}: B \setminus b \rightarrow c_b} \sum_{m_{(B \setminus b)(1)}, \dots, m_{(B \setminus b)(|B \setminus b|)}=1}^{2L} \prod_{i \in B \setminus b} y_i^{(m_i)} z_{\omega(i)}^{(m_i)} \quad (\text{F23})$$

$$= \sum_{\sigma \in \mathcal{S}_{|a^c|}: a^c \rightarrow c_a} \sum_{\rho \in \mathcal{S}_{|b|}: b \rightarrow d_b} \sum_{\omega \in \mathcal{S}_{|B \setminus b|}: B \setminus b \rightarrow c_b} \sum_{l_1, \dots, l_{|a^c|}=1}^{2L} \sum_{k_1, \dots, k_{|b|}=1}^{2L} \sum_{m_1, \dots, m_{|B \setminus b|}=1}^{2L} \prod_{i \in [a^c]} u_{c_a(i)}^{(l_i)} v_{a^c(i)}^{(l_{\sigma(i)})} \prod_{i \in [b]} w_{b(i)}^{(k_{\rho(i)})} x_{d_b(i)}^{(k_i)} \quad (\text{F24})$$

where the summation over $s(X)$ is interpreted as the summation of a tuple from $[L]^{|X|}$ and k_i, k'_i, k''_i represent the multiplicity of u, w, y , respectively. Thus, ignoring the delta functions and the multiplicity factors, which will be taken care of later, we can rewrite the expression as

$$\sum_{a \subset A \cap D} \sum_{b \subset B} \sum_{c_a, c_b \subset C} \sum_{d_b \subset D \setminus a} \sum_{s_u(c_a), s_v(a^c)} \sum_{s_w(b), s_x(d_b)} \sum_{s_z(B \setminus b), s_y(c_b)} \prod_{i \in [a^c]} u_{c_a(i)}^{(l_{s_u(i)})} v_{a^c(i)}^{(s_v(i))} \prod_{i \in [b]} w_{b(i)}^{(s_w(i))} x_{d_b(i)}^{(k_{s_x(i)})} \prod_{i \in [B \setminus b]} y_{c_b(i)}^{(s_z(i))} z_{(B \setminus b)(i)}^{(s_y(i))} \quad (\text{F25})$$

$$= \sum_{a \subset A \cap D} \sum_{b \subset B} \sum_{c_a, c_b \subset C} \sum_{d_b \subset D \setminus a} \prod_{i \in c_a} \sum_{s=1}^{2L} u_i^{(s)} a_u^{(s)} \prod_{i \in a^c} \sum_{s=1}^{2L} v_i^{(s)} a_v^{(s)} \prod_{i \in b} \sum_{s=1}^{2L} w_i^{(s)} a_w^{(s)} \prod_{i \in d_b} \sum_{s=1}^{2L} x_i^{(s)} a_x^{(s)} \prod_{i \in c_b} \sum_{s=1}^{2L} y_i^{(s)} a_y^{(s)} \prod_{i \in B \setminus b} \sum_{s=1}^{2L} z_i^{(s)} a_z^{(s)} \quad (\text{F26})$$

$$= \sum_{a \subset A \cap D} \sum_{b \subset B} \sum_{c_a, c_b \subset C} \sum_{d_b \subset D \setminus a} \prod_{i \in c_a} f_1(i) \prod_{i \in a^c} f_2(i) \prod_{i \in b} f_3(i) \prod_{i \in d_b} f_4(i) \prod_{i \in c_b} f_5(i) \prod_{i \in B \setminus b} f_6(i), \quad (\text{F27})$$

where we introduced the indeterminates $a_u^{(s)}, a_v^{(s)}, a_w^{(s)}, a_x^{(s)}, a_y^{(s)}, a_z^{(s)}$ to take care of the delta functions and defined

$$f_1(i) = \sum_{s=1}^{2L} u_i^{(s)} a_u^{(s)}, f_2(i) = \sum_{s=1}^{2L} v_i^{(s)} a_v^{(s)}, f_3(i) = \sum_{s=1}^{2L} w_i^{(s)} a_w^{(s)}, f_4(i) = \sum_{s=1}^{2L} x_i^{(s)} a_x^{(s)}, f_5(i) = \sum_{s=1}^{2L} y_i^{(s)} a_y^{(s)}, f_6(i) = \sum_{s=1}^{2L} z_i^{(s)} a_z^{(s)}. \quad (\text{F28})$$

In addition, to take care of the remaining creation operators, we replace them with indeterminates x_k 's as in

Sec. VIB 2:

$$\begin{aligned} & \sum_{a \subset A \cap D} \sum_{b \subset B} \sum_{c_a, c_b \subset C} \sum_{d_b \subset D \setminus a} \prod_{i \in c_a} f_1(i) \prod_{i \in a^c} f_2(i) \prod_{i \in b} f_3(i) \prod_{i \in d_b} f_4(i) \prod_{i \in c_b} f_5(i) \prod_{i \in B \setminus b} f_6(i) \\ & \times \langle \mathbf{r} | \prod_{i \in C \setminus (c_a \cup c_b)} \sum_{k=1}^M (ZV^T)_{i,k} \hat{a}_k^\dagger \prod_{i \in D \setminus (d_a \cup d_b)} \sum_{k=1}^M (V^T)_{i,k} \hat{a}_k^\dagger | 0 \rangle \end{aligned} \quad (\text{F29})$$

$$\begin{aligned} & \rightarrow \sum_{a \subset A \cap D} \sum_{b \subset B} \sum_{c_a, c_b \subset C} \sum_{d_b \subset D \setminus a} \prod_{i \in c_a} f_1(i) \prod_{i \in a^c} f_2(i) \prod_{i \in b} f_3(i) \prod_{i \in d_b} f_4(i) \prod_{i \in c_b} f_5(i) \prod_{i \in B \setminus b} f_6(i) \\ & \times \prod_{i \in C \setminus (c_a \cup c_b)} \sum_{k=1}^{2L} (ZV^T)_{i,k} x_k \prod_{i \in D \setminus (d_a \cup d_b)} \sum_{k=1}^{2L} (V^T)_{i,k} x_k \end{aligned} \quad (\text{F30})$$

$$\begin{aligned} & \rightarrow \sum_{a \subset A \cap D} \sum_{b \subset B} \sum_{c_a, c_b \subset C} \sum_{d_b \subset D \setminus a} \prod_{i \in c_a} f_1(i) \prod_{i \in a^c} f_2(i) \prod_{i \in b} f_3(i) \prod_{i \in d_b} f_4(i) \prod_{i \in c_b} f_5(i) \prod_{i \in B \setminus b} f_6(i) \prod_{i \in C \setminus (c_a \cup c_b)} g_1(i) \prod_{i \in D \setminus (d_a \cup d_b)} g_2(i), \end{aligned} \quad (\text{F31})$$

where we defined

$$g_1(i) = \sum_{k=1}^{2L} (ZV^T)_{i,k} x_k, \quad g_2(i) = \sum_{k=1}^{2L} (V^T)_{i,k} x_k. \quad (\text{F32})$$

The squeezed states' coefficients will be taken care of later by using the indeterminates x_k 's.

Now we simplify the expression. Using

$$\sum_{b \subset B} \left(\prod_{i \in b} f_3(i) \prod_{i \in B \setminus b} f_6(i) \right) = \prod_{i \in B} (f_3(i) + f_6(i)), \quad (\text{F33})$$

$$\sum_{c_a, c_b \subset C} \left(\prod_{i \in c_a} f_1(i) \prod_{i \in c_b} f_5(i) \prod_{i \in C \setminus (c_a \cup c_b)} g_1(i) \right) = \prod_{i \in C} (f_1(i) + f_5(i) + g_1(i)), \quad (\text{F34})$$

$$\sum_{a \subset A \cap D} \sum_{d_b \subset D \setminus a} \left(\prod_{i \in A \setminus a} f_2(i) \prod_{i \in d_b} f_4(i) \prod_{i \in (D \setminus a) \setminus d_b} g_2(i) \right) \quad (\text{F35})$$

$$= \prod_{i \in A \setminus D} f_2(i) \sum_{a \subset A \cap D} \prod_{i \in (A \cap D) \setminus a} f_2(i) \sum_{d_b \subset D \setminus a} \left(\prod_{i \in d_b} f_4(i) \prod_{i \in (D \setminus a) \setminus d_b} g_2(i) \right) \quad (\text{F36})$$

$$= \prod_{i \in A \setminus D} f_2(i) \sum_{a \subset A \cap D} \prod_{i \in (A \cap D) \setminus a} f_2(i) \prod_{i \in D \setminus a} (f_4(i) + g_2(i)) \quad (\text{F37})$$

$$= \prod_{i \in A \setminus D} f_2(i) \prod_{i \in D \setminus A} (f_4(i) + g_2(i)) \sum_{a \subset A \cap D} \prod_{i \in (A \cap D) \setminus a} f_2(i) \prod_{i \in (A \cap D) \setminus a} (f_4(i) + g_2(i)) \quad (\text{F38})$$

$$= \prod_{i \in A \setminus D} f_2(i) \prod_{i \in D \setminus A} (f_4(i) + g_2(i)) \prod_{i \in A \cap D} [1 + f_2(i)(f_4(i) + g_2(i))], \quad (\text{F39})$$

the expression is simplified as

$$\prod_{i \in A \setminus D} f_2(i) \prod_{i \in D \setminus A} (f_4(i) + g_2(i)) \prod_{i \in A \cap D} [1 + f_2(i)(f_4(i) + g_2(i))] \prod_{i \in B} (f_3(i) + f_6(i)) \prod_{i \in C} (f_1(i) + f_5(i) + g_1(i)). \quad (\text{F40})$$

And recalling

$$A \iff X, \quad B \iff Y \setminus A(\mathcal{M}) \setminus X, \quad C \iff Y^c \setminus B(\mathcal{M}), \quad D \iff X_m, \quad (\text{F41})$$

the full expression becomes

$$\prod_{i \in X \setminus X_m} F_i \prod_{i \in X_m \setminus X} E_i \prod_{i \in X \cap X_m} D_i \prod_{i \in Y \setminus A(\mathcal{M}) \setminus X} A_i \prod_{i \in Y^c \setminus B(\mathcal{M})} B_i, \quad (\text{F42})$$

where we defined

$$A_i = f_3(i) + f_6(i), \quad B_i = f_1(i) + f_5(i) + g_1(i), \quad D_i = 1 + f_2(i)(f_4(i) + g_2(i)), \quad E_i = f_4(i) + g_2(i), \quad F_i = f_2(i). \quad (\text{F43})$$

Thus, we can simplify the expression as a loop hafnian:

$$\sum_{Y \subset X_{\mathbf{n}}} \sum_{\mathcal{M} \in \text{Match}(F_{X_{\mathbf{n}}}; Y \rightarrow Y^c)} \sum_{X \subset Y \setminus A(\mathcal{M})} \times (-1)^{|\mathcal{M}|} \left(\prod_{(i,j) \in \mathcal{M}} C_{ij} \right) \left(\prod_{i \in X \setminus X_{\mathbf{m}}} F_i \right) \left(\prod_{i \in X_{\mathbf{m}} \setminus X} E_i \right) \left(\prod_{i \in X \cap X_{\mathbf{m}}} D_i \right) \left(\prod_{i \in Y \setminus A(\mathcal{M}) \setminus X} A_i \right) \left(\prod_{i \in Y^c \setminus B(\mathcal{M})} B_i \right) \quad (\text{F44})$$

$$= \sum_{Y \subset X_{\mathbf{n}}} \sum_{\mathcal{M} \in \text{Match}(F_{X_{\mathbf{n}}}; Y \rightarrow Y^c)} \prod_{(i,j) \in \mathcal{M}} (-C_{ij}) \prod_{i \in Y \setminus A(\mathcal{M}) \setminus X_{\mathbf{m}}} (A_i + F_i) \prod_{i \in X_{\mathbf{m}}} (E_i A_i + D_i) \prod_{i \in Y^c \setminus B(\mathcal{M})} B_i \quad (\text{F45})$$

$$= \prod_{i \in X_{\mathbf{m}}} (E_i A_i + D_i) \text{lhaf}(\tilde{K}), \quad (\text{F46})$$

where $\tilde{K}$ is a $|X_{\mathbf{n}}| \times |X_{\mathbf{n}}|$ matrix whose elements are given as

$$\tilde{K}_{ij} = \begin{cases} -C_{ij} & \text{if } i < j \text{ and} \\ A_i + B_i + F_i & \text{if } i = j \text{ and } i \notin X_{\mathbf{m}}, \\ B_i + 1 & \text{if } i = j \text{ and } i \in X_{\mathbf{m}} \end{cases} \quad (\text{F47})$$

where $i, j \in X_{\mathbf{n}}$. Hence, the low-rank structure of C may be used. Let us also define a matrix K as the symmetrized version of $\tilde{K}$, i.e.,

$$K_{ij} = \begin{cases} -C_{ij} & \text{if } i \neq j \text{ and} \\ A_i + B_i + F_i & \text{if } i = j \text{ and } i \notin X_{\mathbf{m}}, \\ B_i + 1 & \text{if } i = j \text{ and } i \in X_{\mathbf{m}} \end{cases} \quad (\text{F48})$$

and note that $\text{lhaf}(K) = \text{lhaf}(\tilde{K})$ if we define the loop hafnian to depend only on the upper triangular matrix (see Appendix G). To exploit this low-rank structure, we can then invoke the following lemma:

Lemma 10 (Loop hafnian of a matrix with low-rank structure [64]). *Let Σ be an $n \times n$ symmetric matrix with rank r and A be a matrix constructed by filling Σ 's diagonal matrix with arbitrary elements. Then the loop hafnian of the matrix A can be computed in $O(n^{\binom{2n+r-1}{r-1}})$. Thus, when r is fixed, the cost is polynomial in n and when $r = O(\log n)$, the cost is quasipolynomial in n .*

As an example, let us first consider the case that $\mathbf{n} = \mathbf{m} = (1, \dots, 1)$, i.e., $X_{\mathbf{n}} = X_{\mathbf{m}} = [M]$. Then, the matrix K can be treated as a matrix constructed by replacing the diagonal matrix of matrix C with $B_i + 1$. Hence, we can use the lemma, and the complexity is $O(M^{\binom{2M+2L-1}{2L-1}})$. (See Appendix G for the algorithm.) More specifically, since C has a rank $2L$, we find a decomposition $C = GG^T$, where G is an $M \times 2L$ matrix and then construct the polynomial

$$g(y_1, \dots, y_{2L}) = \prod_{i=1}^M \left(\sum_{j=1}^{2L} G_{ij} y_j + B_i + 1 \right) (E_i A_i + D_i), \quad (\text{F49})$$

and multiply appropriate prefactors to obtain the loop hafnian.

Now, let us consider more general $\mathbf{n}$ and $\mathbf{m}$. In this case, the matrix K is constructed by repeating rows and columns of the matrix C according to $X_{\mathbf{n}}$ and filling the matrix's the diagonal elements according to the definition of K . Hence, this matrix still has a low-rank structure that enables us to invoke the above lemma. One may then observe that if we let $l_i \equiv \min(n_i, m_i)$, define a polynomial

$$g(y_1, \dots, y_{2L}) = \frac{1}{\sqrt{\mathbf{n}! \mathbf{m}!}} \prod_{i=1}^M \left[\left(\sum_{j=1}^{2L} G_{ij} y_j + B_i + 1 \right)^{l_i} \left(\sum_{j=1}^{2L} G_{ij} y_j + A_i + B_i + F_i \right)^{\max(0, n_i - l_i)} (E_i A_i + D_i)^{m_i} \right], \quad (\text{F50})$$

and multiply appropriate prefactors, we obtain the loop hafnian. The final expression is a polynomial of $\{x_i\}_{i=1}^{2L}$ and $\{y_i\}_{i=1}^{2L}$ and $\{a_u^{(i)}\}_{i=1}^{2L}$, $\{a_v^{(i)}\}_{i=1}^{2L}$, $\{a_w^{(i)}\}_{i=1}^{2L}$, $\{a_x^{(i)}\}_{i=1}^{2L}$, $\{a_y^{(i)}\}_{i=1}^{2L}$, and $\{a_z^{(i)}\}_{i=1}^{2L}$. Finally, to deal with the squeezed states, we replace x_i with the corresponding coefficients of the squeezed states. To be more explicit, x_i is replaced with $\cosh^{-1/2} r \tanh^{i/2} r \sqrt{i!}/(2^{i/2}(i/2)!)$ for even i and with 0 for odd i , where r is the squeezing parameter for each. Then, y_i 's are taken care of using the method in Appendix G, and $\{a_u^{(i)}\}_{i=1}^{2L}$, $\{a_v^{(i)}\}_{i=1}^{2L}$, $\{a_w^{(i)}\}_{i=1}^{2L}$, $\{a_x^{(i)}\}_{i=1}^{2L}$, $\{a_y^{(i)}\}_{i=1}^{2L}$, and $\{a_z^{(i)}\}_{i=1}^{2L}$ are taken care of as explained above.

Finally, let us now consider the general case:

$$\langle \phi | \hat{G} | \psi \rangle = \sum_{\mathbf{n}, \mathbf{m}} a_{\mathbf{m}} b_{\mathbf{n}}^* \langle \mathbf{n} | \hat{G} | \mathbf{m} \rangle, \quad (\text{F51})$$

which is the goal of this Appendix. Then, we define a polynomial

$$g(y_1, \dots, y_{2L}) = \prod_{i=1}^M \sum_{n_i, m_i=0}^{n_{\max}} \frac{a_{m_i}^{(i)} b_{n_i}^{(i)*}}{\sqrt{n_i! m_i!}} \left[\left(\sum_{j=1}^{2L} G_{ij} y_j + B_i + 1 \right)^{l_i} \left(\sum_{j=1}^{2L} G_{ij} y_j + A_i + B_i + F_i \right)^{\max(0, n_i - l_i)} (E_i A_i + D_i)^{m_i} \right]. \quad (\text{F52})$$

Then, by multiplying appropriate prefactors as above for squeezed states' coefficients, we obtain $\langle \phi | \hat{G} | \psi \rangle$ by appropriately selecting coefficients of the monomials as above.

Let us now analyze the complexity. Note that we have introduced indeterminates $\{x_i\}_{i=1}^{2L}$ and $\{y_i\}_{i=1}^{2L}$ and $\{a_u^{(i)}\}_{i=1}^{2L}$, $\{a_v^{(i)}\}_{i=1}^{2L}$, $\{a_w^{(i)}\}_{i=1}^{2L}$, $\{a_x^{(i)}\}_{i=1}^{2L}$, $\{a_y^{(i)}\}_{i=1}^{2L}$, and $\{a_z^{(i)}\}_{i=1}^{2L}$. Thus, the number of indeterminates we introduced is $16L$. All these indeterminates can have a degree at most $3Mn_{\max}$ due to the quadratic form of $E_i A_i$ in the expression and $D_i = 1 + f_2(i)(f_4(i) + g_2(i))$. Thus, the number of coefficients we need to keep track of is $(3Mn_{\max} + 1)^{16L}$. Therefore, when $L = O(1)$, it can be computed in polynomial time. $\square$

Appendix G: Low-rank loop hafnian

For completeness, we provide the details of a classical algorithm that computes the loop hafnian of a matrix with a low-rank structure, which was proposed in Ref. [64] by generalizing the algorithm for hafnian [63].

Let us first recall the definition of the loop hafnian of an $n \times n$ matrix A . Consider the graph G whose adjacency matrix is A . Here, the diagonal elements of A represent the loops from a vertex to itself. Then, the loop hafnian can be written as

$$\text{lhaf}(A) \equiv \sum_{\mathcal{M} \in \text{SPM}} \prod_{(i,j) \in \mathcal{M}} A_{ij}, \quad (\text{G1})$$

where SPM is the set of all possible matchings of a graph G , including loops. In many cases, as the hafnian, we assume A to be a symmetric matrix because of the undirectedness of the graph. However, one may define the loop hafnian of a matrix that is not symmetric by always considering a match (i, j) as either $i \leq j$ or $i \geq j$. Then, the loop hafnian depends only on the upper or lower triangular part, respectively. This property was used in Ref. [63] and is used below to employ the low-rank structure for computing the loop hafnian.

Before we present the algorithm, let us define the loop hafnian in a different way. Let $X \equiv [n]$. Then, the loop hafnian can be written as

$$\text{lhaf}(A) = \sum_{Y \subset X} \sum_{\mathcal{M} \in \text{Match}(F_X; Y \rightarrow Y^c)} \prod_{(i,j) \in \mathcal{M}} A_{ij} \prod_{i \in Y \setminus A(\mathcal{M})} A_{ii}/2 \prod_{i \in Y^c \setminus B(\mathcal{M})} A_{ii}/2. \quad (\text{G2})$$

Here, F_X is the Ferrers graph, i.e., its edges are $E = \{(i, j) : j < i\}$ and $1/2$ factor is introduced to cancel out the redundancy, and $A(\mathcal{M})$ and $B(\mathcal{M})$ represent the elements in Y and Y^c that are involved in the matching $\mathcal{M}$, respectively. Hence, this is consistent with the argument regarding the lower triangular matrix above. Thus, the first product corresponds to the matches between distinct vertices, and the last two products correspond to the loops. We may generalize this expression to

$$\sum_{Y \subset X} \sum_{\mathcal{M} \in \text{Match}(F_X; Y \rightarrow Y^c)} \prod_{(i,j) \in \mathcal{M}} C_{ij} \prod_{i \in Y \setminus A(\mathcal{M})} A_i \prod_{i \in Y^c \setminus B(\mathcal{M})} B_i, \quad (\text{G3})$$

and this is equivalent to

$$\text{lhaf}(W), \quad (\text{G4})$$

where the matrix W 's off-diagonal elements are equal to C_{ij} and diagonal elements are $A_i + B_i$.

We now provide the classical algorithm that takes advantage of the low-rank structure [64]. Consider a symmetric matrix Σ and another symmetric matrix A which is obtained by replacing Σ 's diagonal elements by μ . When Σ has rank r , it can be decomposed as $\Sigma = GG^T$, where G is an $n \times r$ matrix. Then, we can compute the loop hafnian of the matrix as

$$\text{lhaf}(A) = \sum_{\mathcal{M} \in \text{SPM}} \prod_{(i,j) \in \mathcal{M}} A_{ij} = \sum_{a \subset [n]: |a|: \text{even}} \text{haf}(A_{a,a}) \prod_{i \in a^c} \mu_i = \sum_{\sigma \in \text{PMP}(|a|)} \prod_{i=1}^{|a|} A_{a(\sigma(2i-1)), a(\sigma(2i))} \prod_{i \in a^c} \mu_i \quad (\text{G5})$$

$$\rightarrow \prod_{i=1}^n \left(\sum_{j=1}^r G_{ij} x_j + \mu_i \right), \quad (\text{G6})$$

where PMP is the set of perfect matchings without loops, and we introduced a polynomial with indeterminates x_i 's. Let $\mathcal{P}_{2s,r}$ be the set of integer r -partitions of $2s$, i.e., tuples $(p_1, p_2, \dots, p_r)$ such that $p_i \geq 0$ for all i and $\sum_i p_i = 2s$, and let $\mathcal{E}_{2s,r}$ be the subset of $\mathcal{P}_{s,r}$ such that p_i is even for all i . We then expand the polynomial and identify the coefficients λ_p as

$$q(x_1, \dots, x_r) = \sum_{s=0}^{\lfloor n/2 \rfloor} \sum_{p=(p_1, \dots, p_{2s}) \in \mathcal{P}_{2s,r}} \lambda_p \prod_{i=1}^r x_i^{p_i}, \quad (\text{G7})$$

where we dropped a polynomial composed of an odd number of x_i 's from the polynomial, Eq. (G6), because it is not relevant to the loop hafnian. Since

$$|\mathcal{P}_{2s,r}| = \binom{2s+r-1}{r-1}, \quad |\mathcal{E}_{2s,r}| = \binom{s+r-1}{r-1}, \quad (\text{G8})$$

the coefficients λ_p can be found in $O(n|\mathcal{P}_{2n,r}|)$ running time because there are $|\mathcal{P}_{2n,r}|$ monomials whose coefficients are kept track of and we have n multiplications. Meanwhile, the loop hafnian can be written as

$$\text{lhaf}(A) = \sum_{s=0}^{\lfloor n/2 \rfloor} \sum_{e \in \mathcal{E}_{2s,r}} \lambda_e \prod_{i=1}^r (e_i - 1)!!. \quad (\text{G9})$$

Therefore, by expanding the polynomial (G7) and identifying the coefficients, we can compute the loop hafnian in $O(n|\mathcal{P}_{2n,r}|)$ and when r is fixed, in $O(n^r)$.

Universal Entanglement Detection with Geometrically Optimal Witnesses

Abstract. Constructing optimal entanglement witnesses for arbitrary quantum systems remains a formidable challenge, hindered by the structural complexity of high-dimensional quantum state spaces. In this work, we overcome this barrier by introducing a unified framework for constructing geometrically optimal witnesses capable of identifying arbitrary entanglement structures. By leveraging the geometric properties of a target quantum state relative to a specific entanglement structure in Hilbert-Schmidt space, these witnesses are constructed in an efficient and effective manner. Among all nontrivial witnesses, they provide maximal distinguishability between the target state and the set of states without the desired entanglement structure. As a result, our approach enables the universal detection of bipartite, multipartite, and high-dimensional entanglement. To demonstrate its experimental feasibility, we apply the framework to a four-qubit nuclear spin quantum system. Compared to existing methods, our approach offers enhanced noise robustness, broader detection universality, and improved construction efficiency, providing a powerful and versatile tool for advancing the characterization and understanding of entanglement in quantum systems.

Keywords: entanglement detection, entanglement witnesses, geometric optimization

1 Motivation and Contribution

Entanglement is a central resource for quantum teleportation, quantum computation, quantum simulation, and quantum metrology [1, 2, 3, 4]. Certifying it, however, remains a persistent theoretical and experimental challenge [5, 6, 7]. Entanglement witnesses (EWs) offer a practical route because they can certify entanglement without full state tomography [8, 9, 10]. They have also been extended beyond ordinary bipartite entanglement to richer structures, including multipartite and high-dimensional entanglement [11, 12, 13, 14, 15, 16, 17, 18]. Nevertheless, existing constructions are often tied either to particular separability criteria, such as PPT or CCNR [19, 20, 21], or to state families with special structure. This lack of a unified construction reflects the geometric difficulty of characterizing high-dimensional convex sets such as the separable

set [22, 23].

Geometric entanglement witnesses (GEWs) provide a natural route to optimal witnesses by using the closest point geometry of quantum state space [24, 25, 26, 27]. Earlier GEW works mainly focused on ordinary entanglement detection: the relevant set was the separable set, and the central task was to find the nearest separable state to a target entangled state. These results were largely limited to special states or highly symmetric settings, even though separating hyperplanes are guaranteed abstractly by convex geometry [28].

In this work, we extend the closest point construction from the separable set to the convex set associated with an arbitrary entanglement structure [29, 30, 31, 32]. This single framework covers separability, biseparability, low Schmidt number, and finer multipartite partitions. We prove geometric optimality, develop the dynamic refinement of extremes approximation model (DREAM) to compute the witnesses efficiently, and demonstrate the resulting witnesses experimentally on a four-qubit

Figure 1: Schematic diagram of GEWs for detecting arbitrary entanglement structures. The convex, compact set $\mathcal{C}$ denotes the set of states without the desired entanglement structure. A GEW is constructed from the nearest state $\sigma \in \mathcal{C}$ to the target state ρ in the Hilbert-Schmidt space, and the corresponding hyperplane separates ρ from $\mathcal{C}$, thereby certifying the entanglement structure of the target state.

nuclear spin system. As a result, it certifies bound entanglement [33], multipartite entanglement [34], and high-dimensional entanglement [35, 36, 37].

2 Main Ideas

The construction is illustrated in Fig. 1. The set $\mathcal{C}$ is a convex body in Hilbert-Schmidt space: it may be the separable set, the biseparable set, or the set of states below a target Schmidt number. If the target state ρ lies outside $\mathcal{C}$, the nearest point σ on the boundary determines a supporting hyperplane. This hyperplane is the GEW, specified by an observable W . A negative measured expectation value places the prepared state outside $\mathcal{C}$ and therefore certifies the desired entanglement structure.

This geometry gives a precise optimality statement. Among all nontrivial witnesses with the same natural normalization, the GEW maximizes the expectation-value gap between the target state and the whole set $\mathcal{C}$. We call this gap the maximal distinguishability. It is exactly equal to the Hilbert-Schmidt distance from the target state to $\mathcal{C}$, namely the Hilbert-Schmidt measure. Thus the geometric measure is not only a distance measure; it is also the best witness separation achievable within this normalized witness class.

The same viewpoint explains robustness. Under depolarizing noise, the state moves from the target

state toward the maximally mixed state. The GEW detects the noisy state until this trajectory reaches the supporting hyperplane. We prove that the corresponding visibility threshold is upper bounded by an expression determined only by the Hilbert-Schmidt measure of the target state and its purity. This connects noise tolerance directly to geometry: the distance controls the certified separation, while the purity captures the orientation of the depolarizing trajectory. Using this relation, we prove that for every entangled bipartite pure state the GEW has a strictly lower visibility threshold than the standard fidelity witness. When a specific noise model is known, we further propose a Newton-like refinement that iteratively reconstructs the witness at successive transition states along the noise trajectory. This improves the certified threshold monotonically and can, in principle, approach the optimal threshold for that noise model.

The remaining challenge is computation: even deciding separability is hard in general [38]. DREAM addresses this by representing $\mathcal{C}$ as a dynamic convex hull of structured extreme points. These are product states for separability, product states across bipartitions for biseparability, and states with low Schmidt rank for Schmidt number certification. Rather than sampling a large fixed hull, DREAM parameterizes a modest number of extreme points and their convex weights, then optimizes them directly. Caratheodory's theorem guarantees that finite convex decompositions are sufficient in principle [39], and in practice the dynamic hull concentrates resources near the boundary region relevant to the target state.

3 Applications

Bound entanglement. Bound entanglement is a demanding test case because PPT entangled states cannot be detected by decomposable witnesses [40, 41]. For the Horodecki $3 \otimes 3$ family, GEWs recover the transition between separable, bound entangled, and free entangled regions. For the Tiles bound entangled state [42], DREAM finds a closer separable approximation than a Gilbert algorithm benchmark [43]. It also gives an explicit convex decomposition of the nearest separable state, revealing a previously hidden symmetry in this closest state structure. The resulting witness tolerates lower visibility under depolarizing noise than the operator Schmidt decomposition witness [44].

High-dimensional entanglement. Taking $\mathcal{C}$ to be the set of states with Schmidt number less than k

gives Schmidt number witnesses [45]. For isotropic states, the GEW reduces analytically to the known fidelity form, which provides a benchmark. For less symmetric states, where fidelity witnesses can fail, DREAM directly constructs witnesses for higher Schmidt number. In a $4 \otimes 4$ example of Schmidt number three, the GEW detects three-dimensional entanglement down to visibility $p \simeq 0.75$, compared with about 0.83 for the CCNR benchmark reported in Ref. [44].

Multipartite entanglement. For multipartite systems, the choice of $\mathcal{C}$ can be adapted to the desired structure. Taking $\mathcal{C}$ as the fully separable set gives a benchmark for complete multipartite entanglement: for n -qubit GHZ states, DREAM reproduces the known analytical Hilbert-Schmidt measure with maximum relative error about 0.0124% from $n = 3$ to $n = 11$, and remains computationally manageable on a standard laptop [43]. For n -qubit W states, where no closed form nearest fully separable state is known, the method still converges efficiently. For genuine multipartite entanglement, $\mathcal{C}$ is instead the convex hull of states separable across at least one bipartition [46, 47]. In this setting, GEWs for three- and four-qubit W states under white noise outperform fidelity witnesses and operator Schmidt decomposition witnesses [44]. With the refinement that incorporates the noise model, the thresholds improve to about 0.478 for $|W_3\rangle$ and 0.470 for $|W_4\rangle$, matching or slightly improving fully decomposable witness benchmarks [48].

4 Experimental Demonstration

We realize the framework on a four-qubit nuclear magnetic resonance quantum processor based on ^{13}C -labeled crotonic acid. The same four physical qubits are used in different encodings: as two qutrits for the Horodecki bound entanglement family, as a $4 \otimes 4$ bipartite system for Schmidt number certification, and as three- or four-qubit registers for multipartite W states. Target states are prepared by temporal averaging or coherent optimal control pulses [49]. The GEWs are computed from the intended target states and then measured through local Pauli decompositions. The measured witness values agree with theoretical predictions and certify the intended entanglement structures without using full tomography to construct the witnesses.

5 Impact

The broader significance is that entanglement certification is recast as one geometric task: choose the

convex set of states without the desired entanglement structure, find the closest point, and measure the supporting hyperplane. This unifies witness constructions that are usually treated separately, gives an intrinsic optimality guarantee through maximal distinguishability, and makes noise robustness a consequence of geometry. Because the method only assumes convexity of the free set, it can also be adapted to other quantum resources such as coherence, magic, and nonclassicality. It therefore provides both a practical certification tool for near term quantum experiments and a conceptual bridge between resource theories, geometric optimization, and quantum information certification.

Constructing optimal entanglement witnesses for arbitrary quantum systems remains a formidable challenge, hindered by the structural complexity of high-dimensional quantum state spaces. In this work, we overcome this barrier by introducing a unified framework for constructing geometrically optimal witnesses capable of identifying arbitrary entanglement structures. By leveraging the geometric properties of a target quantum state relative to a specific entanglement structure in Hilbert-Schmidt space, these witnesses are constructed in an efficient and effective manner. Among all non-trivial witnesses, they provide maximal distinguishability between the target state and the set of states without the desired entanglement structure. As a result, our approach enables the universal detection of bipartite, multipartite, and high-dimensional entanglement. To demonstrate its experimental feasibility, we apply the framework to a 4-qubit nuclear spin quantum system. Compared to existing methods, our approach offers enhanced noise robustness, broader detection universality, and improved construction efficiency, providing a powerful and versatile tool for advancing the characterization and understanding of entanglement in quantum systems.

Introduction.— Over the past decades, entanglement has been recognized as a fundamental resource for various quantum information processing tasks, including quantum teleportation [1], quantum computing [2, 3], and quantum metrology [4]. A key challenge in both theoretical and experimental contexts lies in the detection of entanglement [5–7]. Entanglement witnesses (EWs) [8, 9], which circumvent the need for full state tomography [10], are widely employed for entanglement detection. Their construction can be derived from separability criteria, such as the positive partial transpose (PPT) [11] and the computable cross norm or realignment (CCNR) [12, 13]. EWs have been further extended to detect more complex entanglement structures, including multipartite entanglement [14–18] and high-dimensional entanglement [19–21]. However, the construction of optimal EWs is fundamentally hindered, e.g., by the intricate geometry of the separable state set [22, 23].

Geometric entanglement witnesses (GEWs) provide an intuitive framework for optimal entanglement detection by leveraging the geometry of separable states in a metric space, such as Hilbert-Schmidt space [24–27]. GEWs offer maximal distinguishability between the target state and separable states, which yields intrinsic robustness to noise models such as depolarizing noise. The existence of corresponding GEWs is guaranteed by the Hahn-Banach separation theorem [28]. However, due to the intrinsic complexity of separability characterization, prior studies have only succeeded in determining GEWs for specific quantum states with particular symmetries. The construction of GEWs for general states remains a significant challenge. Moreover, the generalization of GEWs

for detecting diverse entanglement structures has yet to be systematically explored.

FIG. 1. Schematic diagram of GEWs for detecting arbitrary entanglement structures. The convex, compact set $\mathcal{C}$ denotes the set of states without the desired entanglement structure. For example, for genuine multipartite entanglement detection, $\mathcal{C}$ can be chosen as the set of biseparable states. A GEW is constructed based on the nearest state $\sigma \in \mathcal{C}$ to the target entangled state ρ , as determined by the Hilbert-Schmidt distance D . The hyperplane defined by the GEW separates ρ from $\mathcal{C}$, thereby certifying the entanglement structure of ρ .

In this Letter, we present a universal framework for constructing GEWs capable of detecting arbitrary entanglement structures [29–32]. The framework exploits the geometric properties of a target quantum state relative to the given entanglement structure in the Hilbert-Schmidt space, as illustrated in Fig. 1. Crucially, we show that this framework inherently guarantees geometric op-

tinality, maximizing distinguishability for detecting arbitrary entanglement structures. Compared with previous GEW studies, which focused mainly on special states or specific scenarios, our work formulates the closest-state construction for a general convex compact set $\mathcal{C}$ associated with the entanglement structure to be certified. We further develop the dynamic refinement of extremes approximation model (DREAM) to make this construction computationally accessible, and realize the resulting witnesses experimentally on a four-qubit nuclear spin system. We demonstrate this unified framework for bound entanglement [33], multipartite entanglement [34], and high-dimensional entanglement [35–37]. Experimental results show excellent agreement with theoretical predictions, underscoring the advantages of the framework in terms of detection universality, noise resilience, and construction efficiency when compared to existing methods.

Geometric entanglement witnesses.— We begin with the basic definitions in bipartite systems. A bipartite state ρ_{AB} in $\mathcal{H}_A \otimes \mathcal{H}_B$ is separable if it can be expressed as a convex combination of product pure states:

$$\rho_{AB} = \sum_i \lambda_i |\phi_A^{(i)}\rangle\langle\phi_A^{(i)}| \otimes |\phi_B^{(i)}\rangle\langle\phi_B^{(i)}|, \quad (1)$$

where $0 < \lambda_i \leq 1$ and $\sum_i \lambda_i = 1$. Otherwise, ρ_{AB} is entangled. An EW is a Hermitian operator W satisfying $\langle W \rangle_\sigma = \text{Tr}[W\sigma] \geq 0$ for all separable states σ , with at least one entangled state ρ such that $\langle W \rangle_\rho < 0$. If there exists a separable state σ_0 such that $\langle W \rangle_{\sigma_0} = 0$, then W is called an optimal EW. Geometrically, this implies that the hyperplane defined by W is tangent to the set of separable states.

One type of optimal EWs for detecting a given entangled state ρ can be constructed by calculating the Hilbert-Schmidt (HS) measure $D(\rho) = \min_{\sigma \in \text{SEP}} D(\rho, \sigma)$, where the HS distance $D(\rho, \sigma) = \|\rho - \sigma\| = \sqrt{\text{Tr}[(\rho - \sigma)^2]}$ [38], and subsequently identifying the nearest separable state σ^* to ρ . The corresponding EW is called GEW, given by:

$$W(\sigma^*) = \frac{(\sigma^* - \rho) - \text{Tr}[\sigma^*(\sigma^* - \rho)]I}{\|\sigma^* - \rho\|}. \quad (2)$$

Importantly, for a target state on a d -dimensional Hilbert space, GEWs provide maximal distinguishability among all non-trivial EWs: under a trace-free norm constraint, they maximize the expectation-value gap between the target state and the separable set, i.e.,

$$W(\sigma^*) = \arg \max_{\|W\|_{\text{tf}} \leq 1} \left(\min_{\sigma \in \text{SEP}} \langle W \rangle_\sigma - \langle W \rangle_\rho \right), \quad (3)$$

where the trace-free norm constraint, $\|W\|_{\text{tf}} = \|W - \text{Tr}[W]I/d\| \leq 1$, prevents trivial scaling. Furthermore, it can be shown that the maximal distinguishability is directly related to the HS measure of the given state [27], i.e., $\langle W(\sigma^*) \rangle_\rho = -D(\rho)$.

As a result, the maximal distinguishability of GEWs establishes their intrinsic robustness in detecting noisy entangled states. For example, when the effect of depolarizing noise is considered, the visibility threshold of GEWs is determined by the following theorem, with the proof provided in the End Matter:

Theorem 1 (Robustness of GEWs). *Consider a target state ρ affected by depolarizing noise, described as $\mathcal{N}_p(\rho) = p\rho + (1-p)\frac{I}{d}$. The visibility threshold p_{th} for a witness is the minimum visibility such that all noisy states with $p > p_{\text{th}}$ can be detected as entangled. For the GEW constructed for the target state ρ , the visibility threshold is given by*

$$p_{\text{GEW}} = \frac{\text{Tr}[\sigma^*(\rho - \sigma^*)]}{\text{Tr}[\rho(\rho - \sigma^*)]} \leq 1 - \frac{D(\rho)}{\sqrt{\gamma(\rho)}}, \quad (4)$$

where σ^* is the nearest separable state to ρ under the HS distance, $D(\rho)$ is the HS measure of ρ , and $\gamma(\rho)$ denotes the purity of ρ .

This theorem establishes a direct link between the geometric measure and noise tolerance, providing a sufficient visibility threshold for entanglement detection under depolarizing noise. The following corollary further shows that, for bipartite pure states, the GEW is strictly more robust than the fidelity-based witness, with the proof provided in the End Matter.

Corollary 1. *For detecting entanglement in any bipartite pure state, the GEW is strictly more robust than the fidelity-based witness under depolarizing noise.*

The above results extend to the detection of general entanglement structures, as illustrated in Fig. 1 and discussed further in the End Matter.

Construction of GEWs.— In this work, we introduce a highly efficient and robust algorithm for computing the HS measure and identifying the nearest separable state σ^* , leveraging a dynamic characterization of separable states.

For the set of separable states described in Eq. (1), we decompose it into three components: (i) the probability distribution $\{\lambda_i\}$, (ii) the local states $\{|\phi_A^{(i)}\rangle\}$, and (iii) the local states $\{|\phi_B^{(i)}\rangle\}$. A natural approach is to reformulate the constrained optimization problem over separable states into an unconstrained optimization problem by introducing a set of free parameters $\vec{\theta}$ to parameterize the separable states. This allows the distance to be expressed as $D(\rho) = \min_{\vec{\theta}} \|\rho - \sigma(\vec{\theta})\|$, where $\sigma(\vec{\theta})$ represents the parameterized separable state.

The probability distribution $\{\lambda_i\}$ resides on a probability simplex, which can be conveniently parameterized using the softmax function [39]:

$$\lambda_i = \frac{e^{\theta_i}}{\sum_j e^{\theta_j}}, \quad i = 1, 2, \dots, n, \quad (5)$$

where $\{\theta_i\}$ are the free real parameters.

The local states $\{|\phi_A^{(i)}\rangle\}$ and $\{|\phi_B^{(i)}\rangle\}$ are constrained to the unit spheres in their respective Hilbert spaces. These states can be parameterized by complex vectors normalized to unit length:

$$|\phi\rangle = \frac{|\tilde{\phi}\rangle}{\sqrt{\langle\tilde{\phi}|\tilde{\phi}\rangle}}, \quad |\tilde{\phi}\rangle = \sum_{k=0}^{d-1} (\theta_{2k} + i\theta_{2k+1})|k\rangle, \quad (6)$$

where d is the local dimension of the subsystem, and $\{\theta_{2k}, \theta_{2k+1}\}$ represent the free parameters of the unnormalized state vector $|\tilde{\phi}\rangle$.

For an n -entry separable state in a $d_A \otimes d_B$ composite system, where d_A and d_B denote the local dimensions, the total number of free parameters required is $(2(d_A + d_B) + 1)n$. Here, the number n for any separable state can be upper bounded by $d_A^2 d_B^2$ due to Carathéodory's theorem [40], ensuring that the optimization process involves polynomial parameter complexity.

Once the parameterization is established, a dynamic convex hull approximation (CHA) of the separable states is constructed. This approach provides a substantial improvement in efficiency compared to previous CHA methods, which relied on the random sampling of a large number of product states [41, 42]. To further refine the approximation, gradient-based optimization techniques are employed to minimize the distance and identify the closest separable state σ^* . Notably, our approach can be seamlessly generalized to locate the nearest state within any other convex compact sets $\mathcal{C}$, enabling the detection of arbitrary entanglement structures, which we refer to as the dynamic refinement of extremes approximation model (DREAM). More optimization details are provided for different scenarios in Supplemental Material (SM) [43].

Experimental realization.—With the construction of GEWs, we employ them to experimentally detect target entangled states on a 4-qubit nuclear magnetic resonance (NMR) platform [44–48]. The sample used is ^{13}C -labeled trans-crotonic acid dissolved in d_6 -acetone, where four ^{13}C nuclear spins constitute a 4-qubit quantum system. The internal Hamiltonian of the system is described as

$$\mathcal{H}_{\text{NMR}} = - \sum_{i=1}^4 \pi \nu_i \sigma_z^i + \sum_{i<j}^4 \pi \frac{J_{ij}}{2} \sigma_z^i \sigma_z^j, \quad (7)$$

where ν_i denotes the chemical shift of each spin, and J_{ij} represents the coupling strength between spins i and j . Single-qubit gates are implemented using radio-frequency (RF) pulses with tailored shapes, while two-qubit gates are achieved via the natural coupling between qubits. To prepare the target quantum states in our experiments, shaped RF pulses were optimized using gradient ascent pulse engineering [49]. The GEWs are computed from the intended target states specified by these preparation

protocols, rather than reconstructed from tomography of unknown experimental states. The expectation values of the GEW on the target state were then measured through local Pauli measurements. All experiments were performed on a Bruker 300-MHz spectrometer at room temperature. Additional experimental details can be found in the SM [43].

Bound entanglement.— We first demonstrate the detection of bound entanglement, a special type of entanglement that cannot be distilled into Bell states via local operations and classical communication. It is well established that PPT entangled states are bound entangled [33, 50] and cannot be detected by fidelity-based witnesses [51]. Here, we consider a one-parameter $3 \otimes 3$ quantum state ρ_b introduced by the Horodecki family [52]. It is known that ρ_b is separable for $2 \leq b \leq 3$, bound entangled for $1 \leq b < 2$ and $3 < b \leq 4$, and free entangled for $0 \leq b < 1$ and $4 < b \leq 5$ [53].

We apply our method to compute the HS measure $D(\rho_b)$ numerically and obtain the expectation values of the GEWs from the experimental data. As shown in Fig. 2, our method accurately identifies the boundary between the bound entangled region and the separable states, exhibiting strong alignment between the numerical and experimental results. This demonstrates the capability of the method to detect such subtle entanglement structures.

FIG. 2. Numerical and experimental results for the Horodecki states ρ_b . A positive value indicates the presence of entanglement. The dashed line represents the numerical results of the HS measure. Dots denote the mean expectation values of the GEWs, multiplied by a negative sign, from repeated experiments, while the error bars represent the standard deviations. The bound entangled state (BES) regions are shaded in gray.

We can further compare our method with the Gilbert algorithm in detecting bound entangled states constructed from the unextendible product basis [54]. For the Tiles bound entangled state ρ_{Tiles} , the HS measure computed by our method is around 0.043455, whereas Ref. [55] reports $D^2 \simeq 0.002177$ for the Gilbert algorithm, equivalently $D \simeq 0.046658$. Under the same distance convention, our result gives a smaller HS distance. This implies that our method can identify a closer separa-

ble state to the target state, thereby constructing a more effective EW. Additionally, our numerical results reveal some novel symmetries of the nearest separable state to ρ_{Tiles} in SM [43].

We also compare the noise tolerance of our GEW with that of the OSD witness [56] by introducing depolarizing noise to ρ_{Tiles} . According to Theorem 1, the GEW demonstrates a higher robustness to noise, tolerating a lower visibility ($p_{\text{GEW}} \approx 0.8687$) compared to the OSD witness ($p_{\text{OSD}} \approx 0.8908$). Notably, this robustness is achieved without incorporating the noise model into the optimization process, unlike the OSD witness, which explicitly accounts for it.

High-dimensional entanglement.— The entanglement dimensionality of a bipartite state ρ is quantified by its Schmidt number [8]:

$$\text{SN}(\rho) = \min_{\{\lambda_i, |\psi_i\rangle\}} \max_i \text{SR}(|\psi_i\rangle), \quad (8)$$

where $\text{SR}(|\psi_i\rangle)$ denotes the Schmidt rank of the pure state $|\psi_i\rangle$, and $\rho = \sum_i \lambda_i |\psi_i\rangle\langle\psi_i|$ represents the possible convex decomposition of ρ .

To identify k -entangled states whose Schmidt numbers are at least k , one can construct a Schmidt number witness W_k , which generalizes the concept of an EW. Specifically, W_k satisfies the condition $\langle W_k \rangle_\sigma \geq 0$ for all states σ with Schmidt number less than k , while there exists at least one k -entangled state ρ such that $\langle W_k \rangle_\rho < 0$.

In this scenario, the convex set $\mathcal{C}$ can be chosen as the set of all states with a Schmidt number less than k to construct GEWs. The parameterization can be performed analogously by replacing the product pure states with states that have Schmidt ranks less than k [43].

Here, we first consider the $d \otimes d$ isotropic states, which are defined as follows [57]:

$$\rho_I(F) = F |\Psi_d^+\rangle\langle\Psi_d^+| + (1-F) \frac{I - |\Psi_d^+\rangle\langle\Psi_d^+|}{d^2 - 1}, \quad (9)$$

where $|\Psi_d^+\rangle = \frac{1}{\sqrt{d}} \sum_{i=0}^{d-1} |ii\rangle$ is the maximally entangled state in $d \otimes d$ systems. We find that GEWs for isotropic states are in the form of fidelity-based witnesses, with the proof left in the End Matter:

Theorem 2 (GEW for isotropic state). *For the isotropic state $\rho_I(F)$ in $d \otimes d$ systems, defined in Eq. (9), its Schmidt number $\text{SN}(\rho_I(F)) = k$ for $F \in (\frac{k-1}{d}, \frac{k}{d}]$, and can be certified by the corresponding GEW:*

$$W_k = c \cdot \left(\frac{k-1}{d} I - |\Psi_d^+\rangle\langle\Psi_d^+| \right), \quad (10)$$

where the coefficient $c = \frac{d}{\sqrt{d^2-1}}$.

We leverage the above analytical results to evaluate the performance of our method across various dimensions. The findings indicate that, for quantum systems

of moderate size, the computation time scales mildly with increasing local dimension and remains exceptionally low. Furthermore, the computational error is consistently maintained below 10^{-9} . These results underscore the efficiency and accuracy of our method in handling quantum systems of moderate size. Detailed results are provided in the SM [43].

It is worth noting that for general states lacking such high symmetry, fidelity-based witnesses fail to detect their Schmidt numbers. For example, the following state in a $4 \otimes 4$ system [58]:

$$\varrho = \frac{1}{2} |\Psi_3^+\rangle\langle\Psi_3^+| + \frac{1}{2} \left(\frac{|23\rangle + |32\rangle}{\sqrt{2}} \right) \left(\frac{\langle 23| + \langle 32|}{\sqrt{2}} \right), \quad (11)$$

whose Schmidt number equals three but cannot be certified by fidelity-based witnesses. Although OSD witnesses can detect its Schmidt number, the efficient construction of OSD witnesses for arbitrary Schmidt numbers remains unsolved. In contrast, our method provides a more intuitive and straightforward approach to constructing GEWs for Schmidt number witnesses, making it significantly easier to detect states with higher Schmidt numbers.

FIG. 3. Numerical and experimental results for the state ϱ in Eq. (11) under depolarizing noise with different visibility p . Here, W_k represents the constructed GEW for the target state ϱ , and a negative value of $\langle W_k \rangle$ indicates the presence of k -entangled states. The dashed lines correspond to the numerical results, while the dots denote the experimental results obtained from repeated experiments. The blue and orange regions indicate the areas of different k -entangled states detected by the GEW.

To demonstrate the capabilities of our method, we investigate the noise tolerance of our GEWs in detecting the Schmidt number of the aforementioned state ϱ under depolarizing noise $\mathcal{N}_p$. As shown in Fig. 3, numerical and experimental results clearly demonstrate the transition from separable states to 2-entangled states and subsequently to 3-entangled states as the visibility p increases. Our GEWs exhibit significantly better noise tolerance compared to the CCNR witness. Specifically, our

GEWs can detect 3-entangled states at a much lower visibility threshold ($p_{\text{GEW}} \approx 0.75$) than the CCNR witness ($p_{\text{CCNR}} \approx 0.83$), as reported in [56]. This enhanced robustness highlights the practical advantages of our method in detecting high-dimensional entanglement under realistic noise conditions.

Multipartite entanglement.— GEWs can also be applied to detect multipartite entanglement. Here, we focus on the detection of genuinely entangled states that cannot be expressed as a convex combination of biseparable states across different bipartitions. To detect genuine entanglement, we can choose the convex set $\mathcal{C}$ as the set of all biseparable states. The parameterization can be done similarly by replacing the product pure states with biproduct pure states under various bipartitions [43].

FIG. 4. Numerical and experimental results for the noisy state $\mathcal{N}_p(|\psi\rangle) = p|\psi\rangle\langle\psi| + (1-p)\frac{I}{2^n}$ for (a) three-qubit W state and (b) four-qubit W state. A negative expectation value of the witness indicates the presence of genuine entanglement. The dashed lines represent the numerical results, while dots denote the experimental results from repeated experiments. The solid black and blue lines are the visibility thresholds given by fidelity-based witnesses and OSD witnesses, while the orange ones represent the thresholds from GEWs.

We consider the following n -qubit states under depolarizing noise defined as $\mathcal{N}_p(|\psi\rangle) = p|\psi\rangle\langle\psi| + (1-p)\frac{I}{2^n}$, where p denotes the visibility and I is the identity operator in the 2^n -dimensional Hilbert space. The states investigated include the three-qubit W state $|W_3\rangle$ and the four-qubit W state $|W_4\rangle$. As shown in Fig. 4, for each state, the visibility threshold given by GEWs is lower than that of the fidelity-based witnesses and OSD witnesses [56]. Moreover, when the depolarizing noise model is explicitly incorporated into the optimization [43], the visibility threshold of the three-qubit W state is further

reduced from 0.541 to 0.478, saturating the theoretical optimum reported in Ref. [59].

Besides the bipartition of multipartite states, GEWs can also be applied to finer partitions, such as the detection of completely entangled states. In this scenario, the convex set $\mathcal{C}$ is chosen as the set of fully separable states under the given partition. The further results are provided in SM [43].

Conclusion.— We propose a universal method for constructing GEWs that can detect arbitrary entanglement structures of target states while achieving maximal distinguishability among all nontrivial witnesses. This enhanced distinguishability improves the noise tolerance of our detection method, as demonstrated for depolarizing noise, compared to existing approaches.

In addition to its theoretical strengths, our approach demonstrates practical feasibility in quantum experiments, providing a versatile tool for entanglement detection in real-world scenarios. Furthermore, the proposed method can be extended to detect other quantum resources [60, 61], highlighting its broad applicability in quantum information science. The relevant algorithm and data supporting this work are publicly available in our repository [62].

End Matter

Proof of Theorem 1

Proof. For the target state ρ , the corresponding GEW has the following form:

$$W = \frac{(\sigma^* - \rho) - \text{Tr}[\sigma^*(\sigma^* - \rho)]I}{\|\sigma^* - \rho\|},$$

where σ^* is the nearest separable state to ρ under the HS measure. The visibility threshold p_{GEW} satisfies

$$\text{Tr} \left[W \left(p_{\text{GEW}} \rho + (1 - p_{\text{GEW}}) \frac{I}{d} \right) \right] = 0.$$

From the above equations, we can derive that

$$p_{\text{GEW}} = \frac{\text{Tr}[\frac{W}{d}]}{\text{Tr}[\frac{W}{d}] - \text{Tr}[W\rho]} = \frac{\text{Tr}[\sigma^*(\rho - \sigma^*)]}{\text{Tr}[\rho(\rho - \sigma^*)]}.$$

For simplicity, we denote the inner product of two matrices as $\langle A, B \rangle = \text{Tr}[A^\dagger B]$, so that

$$p_{\text{GEW}} = 1 - \frac{\text{Tr}[(\rho - \sigma^*)^2]}{\text{Tr}[\rho(\rho - \sigma^*)]} = 1 - \frac{\|\rho - \sigma^*\|^2}{\langle \rho, \rho - \sigma^* \rangle}.$$

Since $\langle A, B \rangle \leq \|A\| \cdot \|B\|$, we obtain that

$$p_{\text{GEW}} \leq 1 - \frac{\|\rho - \sigma^*\|}{\|\rho\|} = 1 - \frac{D(\rho)}{\sqrt{\gamma(\rho)}},$$

where $D(\rho)$ is the HS measure of ρ and $\gamma(\rho) = \text{Tr}[\rho^2]$ is the purity of ρ . $\square$

Proof of Corollary 1

Proof. For any bipartite pure state $|\psi\rangle$ in $d_A \otimes d_B$, the resulting state after depolarizing channel is $\mathcal{N}_p(|\psi\rangle) = p|\psi\rangle\langle\psi| + (1-p)\frac{I}{d}$, where $d = d_A d_B$ is the total dimension. The corresponding fidelity-based witness is given by

$$W = \mu_1(|\psi\rangle)^2 I - |\psi\rangle\langle\psi|,$$

where μ_1 denotes the largest Schmidt coefficient of $|\psi\rangle$. Then it is easy to derive that the visibility threshold is

$$p_{\text{FID}} = \frac{\mu_1^2 - \frac{1}{d}}{1 - \frac{1}{d}} = 1 - \frac{1 - \mu_1^2}{1 - \frac{1}{d}}.$$

Next, we aim to prove that $D(|\psi\rangle) > \frac{1 - \mu_1^2}{1 - \frac{1}{d}}$, such that

$$p_{\text{GEW}} \leq 1 - D(|\psi\rangle) < p_{\text{FID}}.$$

First, it is easy to prove that $\max_{\sigma \in \text{SEP}} \text{Tr}[\rho_\psi \sigma] = \max_{\sigma \in \text{SEP}} \langle \psi | \sigma | \psi \rangle = \mu_1^2$. Then for any $\sigma \in \text{SEP}$, we have

$$\text{Tr}[(\rho_\psi - \frac{I}{d})(\rho_\psi - \sigma)] = 1 - \text{Tr}[\rho_\psi \sigma] \geq 1 - \mu_1^2.$$

On the other hand, by Cauchy-Schwarz inequality for the Hilbert-Schmidt inner product, we have

$$\begin{aligned} \text{Tr}[(\rho_\psi - \frac{I}{d})(\rho_\psi - \sigma)] &\leq \|\rho_\psi - \frac{I}{d}\| \cdot \|\rho_\psi - \sigma\| \\ &= \sqrt{1 - \frac{1}{d}} \|\rho_\psi - \sigma\|. \end{aligned}$$

Finally, we obtain that

$$D(|\psi\rangle) = \min_{\sigma \in \text{SEP}} \|\rho_\psi - \sigma\| \geq \frac{1 - \mu_1^2}{\sqrt{1 - \frac{1}{d}}} > \frac{1 - \mu_1^2}{1 - \frac{1}{d}}.$$

$\square$

Proof of Theorem 2

Proof. For simplicity, here, we denote the set of states with Schmidt number no larger than k as S_k and the inner product of two operators A and B as $\langle A, B \rangle = \text{Tr}[A^\dagger B]$.

From Ref. [19], $\text{SN}(\rho_I(F)) = k$ for $\frac{k-1}{d} < F \leq \frac{k}{d}$. This suggests that the nearest state in S_{k-1} to $\rho_I(F)$ under the HS distance is $\rho_I(\frac{k-1}{d})$. It is therefore sufficient to prove that the following witness constructed from Eq. (2)

$$W_k = \frac{(\rho_I(\frac{k-1}{d}) - \rho_I(F)) - \langle \rho_I(\frac{k-1}{d}), \rho_I(\frac{k-1}{d}) - \rho_I(F) \rangle I}{\|\rho_I(\frac{k-1}{d}) - \rho_I(F)\|} \quad (12)$$

is effective [25] for $F > \frac{k-1}{d}$. Using the following results:

$$\begin{aligned} \langle \rho_I(F_1), \rho_I(F_2) \rangle &= F_1 F_2 + \frac{(1 - F_1)(1 - F_2)}{d^2 - 1}, \\ \|\rho_I(F_1) - \rho_I(F_2)\| &= \frac{d}{\sqrt{d^2 - 1}} |F_1 - F_2|, \end{aligned}$$

we can simplify the witness in Eq. (12) to the following form:

$$W_k = \frac{d}{\sqrt{d^2 - 1}} \left(\frac{k-1}{d} I - |\Psi_d^+\rangle\langle\Psi_d^+| \right).$$

For isotropic states $\rho_I(F)$ with $F > \frac{k-1}{d}$, we can obtain that

$$\text{Tr}[W_k \rho_I(F)] = -\frac{d}{\sqrt{d^2 - 1}} \left(F - \frac{k-1}{d} \right) < 0,$$

while for quantum states $\sigma \in S_{k-1}$, according to Lemma 1 from Ref. [19], we have

$$\text{Tr}[W_k \sigma] = \frac{k-1}{\sqrt{d^2 - 1}} \left(1 - \frac{d}{k-1} \langle \Psi_d^+ | \sigma | \Psi_d^+ \rangle \right) \geq 0.$$

Thus, we prove that the corresponding witness is effective. $\square$

Detection of Arbitrary Entanglement Structure

Here, we define the HS measure for a quantum state ρ with respect to a convex and compact set $\mathcal{C}$ as

$$D_{\mathcal{C}}(\rho) = \min_{\sigma \in \mathcal{C}} \|\rho - \sigma\|. \quad (13)$$

In this framework, a witness $W_{\mathcal{C}}$ for detecting states outside the set $\mathcal{C}$ is defined as a Hermitian operator satisfying $\langle W_{\mathcal{C}} \rangle_{\sigma} \geq 0$ for all states $\sigma \in \mathcal{C}$, with the additional property that there exists at least one state $\rho \notin \mathcal{C}$ such that $\langle W_{\mathcal{C}} \rangle_{\rho} < 0$. The witness is termed optimal if there exists a state $\sigma_0 \in \mathcal{C}$ such that $\langle W_{\mathcal{C}} \rangle_{\sigma_0} = 0$.

For any state ρ outside the set $\mathcal{C}$, the Hahn-Banach separation theorem ensures the existence of a witness [28]:

Theorem 3. *Given a convex and compact subset $\mathcal{C}$ of the quantum state space, for any state $\rho \notin \mathcal{C}$, there exists a valid witness $W_{\mathcal{C}}$ for detecting it.*

The maximal distinguishability of a target state ρ from the set $\mathcal{C}$ is defined as

$$B_{\mathcal{C}}(\rho) = \max_{\|W_{\mathcal{C}} - \text{Tr}[W_{\mathcal{C}}]I/d\| \leq 1} (\min_{\sigma \in \mathcal{C}} \langle W_{\mathcal{C}} \rangle_{\sigma} - \langle W_{\mathcal{C}} \rangle_{\rho}), \quad (14)$$

where d is the Hilbert-space dimension. This quantity is the maximum gap between the minimum expectation value of $W_{\mathcal{C}}$ over all states in $\mathcal{C}$ and the expectation value of $W_{\mathcal{C}}$ for the state ρ . The norm constraint on the trace-free part of $W_{\mathcal{C}}$ prevents trivial scaling. For optimal witnesses, it reduces to the simpler form

$$B_{\mathcal{C}}(\rho) = \max_{\|W_{\mathcal{C}} - \text{Tr}[W_{\mathcal{C}}]I/d\| \leq 1} -\langle W_{\mathcal{C}} \rangle_{\rho}. \quad (15)$$

The following theorem establishes the alignment between the HS measure and the maximal distinguishability. Furthermore, this theorem provides a geometric approach to constructing an optimal witness with such maximal distinguishability.

Theorem 4. *For any convex compact set $\mathcal{C}$ and quantum state $\rho \notin \mathcal{C}$, the following relation holds:*

$$D_{\mathcal{C}}(\rho) = B_{\mathcal{C}}(\rho), \quad (16)$$

and the optimal witness $W_{\mathcal{C}}$ that achieves the maximum in $B_{\mathcal{C}}(\rho)$ is given by

$$W_{\mathcal{C}}(\sigma^*) = \frac{(\sigma^* - \rho) - \text{Tr}[\sigma^*(\sigma^* - \rho)]I}{\|\sigma^* - \rho\|}, \quad (17)$$

where $\sigma^* = \arg \min_{\sigma \in \mathcal{C}} \|\rho - \sigma\|$ is the nearest state in $\mathcal{C}$ to ρ under the HS distance.

Proof. For simplicity, we denote the inner product of two operators A and B as $\langle A, B \rangle = \text{Tr}[A^\dagger B]$ and ignore the subscript $\mathcal{C}$ in $D_{\mathcal{C}}(\rho)$, $W_{\mathcal{C}}$ and $B_{\mathcal{C}}(\rho)$ in the following proof.

From the maximization, we know that for any $\rho' \in \mathcal{C}$:

$$B(\rho) \geq \min_{\sigma \in \mathcal{C}} \langle \frac{\rho' - \rho}{\|\rho' - \rho\|}, \sigma - \rho \rangle,$$

where we choose $W = \frac{\rho' - \rho}{\|\rho' - \rho\|}$. On the other hand, from the minimization, we know that for any $\rho' \in \mathcal{C}$:

$$\begin{aligned} B(\rho) &\leq \max_{\|W - \text{Tr}[W]I/d\| \leq 1} \langle W, \rho' - \rho \rangle \\ &= \max_{\|W - \text{Tr}[W]I/d\| \leq 1} \langle W - \text{Tr}[W]I/d, \rho' - \rho \rangle \\ &\leq \|\rho' - \rho\|. \end{aligned}$$

Therefore, for any $\rho' \in \mathcal{C}$,

$$\min_{\sigma \in \mathcal{C}} \langle \frac{\rho' - \rho}{\|\rho' - \rho\|}, \sigma - \rho \rangle \leq B(\rho) \leq \|\rho' - \rho\|.$$

Here, we denote the nearest state in $\mathcal{C}$ under the HS distance as σ^* , then let $\rho' = \sigma^*$ so that $B(\rho) \leq \|\sigma^* - \rho\| = D(\rho)$ and

$$B(\rho) \geq \min_{\sigma \in \mathcal{C}} \langle \frac{\sigma^* - \rho}{\|\sigma^* - \rho\|}, \sigma - \rho \rangle = \|\sigma^* - \rho\| = D(\rho),$$

where the first equality follows from the variational condition for the nearest point in the convex compact set $\mathcal{C}$. The above inequalities are saturated when $D(\rho) = B(\rho)$, with the corresponding optimal witness

$$W_{\text{opt}} = \frac{(\sigma^* - \rho) - \langle \sigma^*, \sigma^* - \rho \rangle I}{\|\sigma^* - \rho\|},$$

where the part $\langle \sigma^*, \sigma^* - \rho \rangle I$ ensures the optimality $\text{Tr}[W_{\text{opt}} \sigma^*] = 0$. $\square$

Dynamic Refinement of Extremes Approximation Model (DREAM)

Overview of the optimization procedure

Here, we consider the general HS measure of a target state ρ with respect to a convex, compact set $\mathcal{C}$:

$$D_{\mathcal{C}}(\rho) = \min_{\sigma \in \mathcal{C}} \|\rho - \sigma\| = \min_{\sigma \in \mathcal{C}} \sqrt{\text{Tr}[(\rho - \sigma)^2]}.$$

The key step in this optimization is the parameterization of the convex set $\mathcal{C}$. Due to the convexity of $\mathcal{C}$, it can be expressed as the convex hull of all its extreme points. These extreme points, corresponding to pure states $\{|\psi_i\rangle\}$ with specific properties, allow us to approximate $\mathcal{C}$ using a convex hull with limited extreme points. A traditional convex hull approximation involves sampling a large number of extreme points and constructing the convex hull [1, 2]. However, this method can be highly inefficient and inaccurate, as most of the sampled extreme points may be irrelevant to the computation of $D_{\mathcal{C}}$. While one could attempt to improve the approximation by sampling additional extreme points and discarding those with low probability weights, such a randomness-based updating scheme provides limited improvement.

FIG. S1. Schematic diagram of convex hull approximation (CHA): (a) Traditional CHA: Random sampling of a large number of extreme points. (b) Dynamic CHA: A small number of extreme points characterized by variational parameters.

Alternatively, Carathéodory's theorem [3] guarantees that any state within a convex subset of the quantum state space can be expressed as a finite convex combination of extreme points, with the number of terms upper-bounded by D^2 , where D is the total dimension of the quantum system. This insight enables the use of parametrized extreme points to construct a dynamic convex hull approximation, which requires significantly fewer extreme points compared to random sampling, see Fig. S1. Consequently, the computation of the HS measure can be reformulated as:

$$D_C(\rho) = \min_{\vec{\alpha}, \vec{\beta}} \left\| \rho - \left(\sum_{i=1}^n \lambda_i (\vec{\alpha}) |\psi_i(\vec{\beta})\rangle \langle \psi_i(\vec{\beta})| \right) \right\|, \quad (\text{S1})$$

where $\vec{\alpha}$ and $\vec{\beta}$ are real parameters characterizing $\{\lambda_i\}$ and $\{|\psi_i\rangle\}$, respectively. Here, the number of terms $n \leq D^2$ is a hyperparameter in the optimization procedure. Numerical experiments indicate that using several multiples of D typically provides satisfactory results for most quantum states, which aligns with the previous studies [4–6].

To solve the resulting unconstrained optimization problem, we employ the PyTorch deep learning framework to construct a computational graph for the objective function. This allows automatic differentiation via backpropagation to compute gradients efficiently. For optimization, we utilize the classical L-BFGS algorithm. As the problem is inherently non-convex, convergence to the global minimum is not guaranteed. To improve numerical precision, we perform multiple runs with random initializations.

Parameterization

The parameterization of the probability distribution has been mentioned in the main text. Here, we focus on the parameterization of extreme points $\{|\psi_i\rangle\}$ in different entanglement detection tasks.

High-dimensional entanglement.— In this scenario, $\{|\psi_i\rangle\}$ represents the set of states with Schmidt ranks no larger than $k - 1$, defined as follows:

$$|\psi\rangle = \frac{|\tilde{\psi}\rangle}{\sqrt{\langle \tilde{\psi} | \tilde{\psi} \rangle}}, \quad |\tilde{\psi}\rangle = \sum_{j=1}^{k-1} s_j |\phi_A^{(j)}\rangle \otimes |\phi_B^{(j)}\rangle, \quad (\text{S2})$$

where $\{s_j\}$ are positive coefficients. The parameterization of the local states $\{\phi_A^{(j)}\}$ and $\{\phi_B^{(j)}\}$ is detailed in the main text. For the coefficients $\{s_j\}$, we employ the SoftPlus function, a commonly used activation function in machine learning:

$$s_j = \ln(1 + e^{\theta_j}) \in \mathbb{R}^+, \quad (\text{S3})$$

where $\{\theta_j\}$ are real-valued parameters.

Genuine entanglement.— For the detection of genuine entanglement, $\{|\psi_i\rangle\}$ is chosen as the set of product pure states under different bipartitions. For example, consider a tripartite quantum state in the composite Hilbert space $\mathcal{H}_A \otimes \mathcal{H}_B \otimes \mathcal{H}_C$. The possible bipartitions are $A|BC$, $B|CA$, and $C|AB$. Consequently, the set of extreme points for the set of biseparable states can be expressed as:

$$\{|\psi_i\rangle\} = \{|\phi_A^{(j)}\rangle \otimes |\phi_{BC}^{(j)}\rangle\} \cup \{|\phi_B^{(k)}\rangle \otimes |\phi_{CA}^{(k)}\rangle\} \cup \{|\phi_C^{(l)}\rangle \otimes |\phi_{AB}^{(l)}\rangle\}. \quad (\text{S4})$$

For each product pure state under a given bipartition, the parameterization follows the same procedure as in the bipartite case.

Complete entanglement.— For the detection of completely entangled states, $\{|\psi_i\rangle\}$ is chosen as the set of fully product states under the given partitions. For a partition $A_1, A_2, \dots, A_n$, the fully product state takes the form:

$$|\psi\rangle = |\phi_{A_1}\rangle \otimes |\phi_{A_2}\rangle \otimes \dots \otimes |\phi_{A_n}\rangle, \quad (\text{S5})$$

where $|\phi_{A_j}\rangle$ represents the local pure state in the j -th subsystem. The parameterization of these local states is detailed in the main text.

Computational efficiency and accuracy

Since the HS measure coincides with maximal distinguishability, the computational error of a GEW can be quantified as

$$|\delta(\text{Tr}[W\rho])| = \delta(D(\rho)) = \|\rho - \sigma\| - \|\rho - \sigma^*\|, \quad (\text{S6})$$

where σ is the nearest state obtained from the algorithm, while σ^* denotes the exact nearest state.

Here, we consider the $d \otimes d$ isotropic states, which are defined in the main text as

$$\rho_I(F) = F|\Psi_d^+\rangle\langle\Psi_d^+| + (1-F)\frac{I - |\Psi_d^+\rangle\langle\Psi_d^+|}{d^2 - 1}. \quad (\text{S7})$$

The corresponding HS measure is

$$D(\rho_I(F)) = \begin{cases} 0, & 0 \leq F \leq \frac{1}{d}, \\ \frac{d}{\sqrt{d^2-1}}(F - \frac{1}{d}), & \frac{1}{d} < F \leq 1. \end{cases} \quad (\text{S8})$$

We uniformly sampled one hundred entangled isotropic states from the range $F \in (\frac{1}{d}, 1]$ with varying local dimensions d , and applied our proposed method to compute their HS measures. For each data point, we calculated the average computational time and error, as presented in Fig. S2. The results demonstrate that, even for quantum systems of moderate size, the proposed method achieves satisfactory accuracy within a reasonable computational time.

FIG. S2. Average computational time and error for calculating the HS measure of isotropic states with different local dimensions. Each data point represents the average over one hundred selected entangled isotropic states. All computations were performed on a MacBook Pro with an M1 Pro chip.

The analysis can also be extended to multipartite states. As a benchmark, we consider the HS measure of the n -qubit GHZ state,

$$|\text{GHZ}_n\rangle = \frac{1}{\sqrt{2}}(|0\rangle^{\otimes n} + |1\rangle^{\otimes n}). \quad (\text{S9})$$

Here, the HS measure is computed with respect to the set of fully separable states. Although the GHZ and W states considered here are pure, their nearest fully separable states under the HS distance are generally *mixed*: they lie on the boundary of the convex hull of fully product pure states and can involve nontrivial convex combinations of rank-deficient density matrices, as shown explicitly by σ^* below. The optimization is therefore not reduced to a pure-product-state overlap problem, but still involves the mixed-state separable boundary. Ref. [7] provides an analytical solution for the nearest fully separable state σ^* to n -qubit GHZ states:

$$\sigma^* = x\sigma_1 + (1-x)\sigma_2, \quad x = \frac{(2^n - 2)^2}{4 + 4^n - 2^{n+1}}, \quad (\text{S10})$$

and

$$\sigma_1 = \frac{1}{2} \begin{pmatrix} 1 & 0 & \dots & 0 & 0 \\ 0 & 0 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & 0 & 0 \\ 0 & 0 & \dots & 0 & 1 \end{pmatrix}, \quad \sigma_2 = \frac{1}{2^n} \begin{pmatrix} 1 & 0 & \dots & 0 & 1 \\ 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & 1 & 0 \\ 1 & 0 & \dots & 0 & 1 \end{pmatrix}. \quad (\text{S11})$$

This gives the HS measure of n -qubit GHZ states as

$$D(|\text{GHZ}_n\rangle) = \sqrt{\frac{(2^n - 2)}{-4 + 2^{3-n} + 2^{n+1}}}. \quad (\text{S12})$$

Figure S3 shows the numerical results obtained from our method for n -qubit GHZ states. Compared with the analytical solution, the maximum relative error from $n = 3$ to $n = 11$ is about 0.0124%. Although the computational time increases with the number of qubits, it remains manageable up to $n = 11$ qubits on a standard laptop. We also compute the HS measure of n -qubit W states,

$$|W_n\rangle = \frac{1}{\sqrt{n}}(|00 \dots 001\rangle + |00 \dots 010\rangle + \dots + |10 \dots 000\rangle). \quad (\text{S13})$$

Although no closed-form expression is known for the nearest fully separable state to n -qubit W states, our method still converges efficiently in this regime, as shown in the right panel of Fig. S3.

FIG. S3. HS measure of n -qubit GHZ states (left) and n -qubit W states (right) with respect to fully separable states. Blue curves show the numerical HS measures, while red curves show the computational times. All computations were performed on a MacBook Pro with an M1 Pro chip.

Enhanced Noise Robustness from Newton-like Method

In the main text, the visibility threshold for a target state is obtained directly using its corresponding GEW. In most cases, the performance already surpasses that of previous methods. However, if a specific noise model is incorporated into the construction of GEWs, an even better threshold can be achieved.

For instance, a Newton-like method can be employed to iteratively update our GEWs for improved noise resilience, as illustrated in Fig. S4. The key idea is that, starting from the current GEW $W^{(n)}$, we identify the next transition state $\rho^{(n+1)}$ by solving $\text{Tr}[W^{(n)}\rho^{(n+1)}] = 0$, which gives

$$\rho^{(n+1)} = \frac{\text{Tr}[W^{(n)}]\rho - \text{Tr}[W^{(n)}\rho] \cdot I}{\text{Tr}[W^{(n)}] - d \cdot \text{Tr}[W^{(n)}\rho]}, \quad (\text{S14})$$

where $\rho = \rho^{(0)}$ is the initial target state with total dimension d . Using our method, we then find the nearest separable state $\sigma^{(n+1)}$ to $\rho^{(n+1)}$ and construct the updated GEW $W^{(n+1)}$ accordingly. Owing to the convexity of the set $\mathcal{C}$, this iterative procedure is guaranteed to improve the visibility threshold with each iteration.

FIG. S4. Schematic diagram of Newton-like method for constructing GEWs with better noise resilience against depolarizing noise.

For example, in the main text, the visibility thresholds p_{GEW} for the three-qubit W state and the four-qubit W state are 0.5414 and 0.6667, respectively. After applying iterative optimization, these thresholds are improved to 0.4777 and 0.4701. As shown in Fig. S5, the visibility thresholds converge to near-optimal values after only a few iterations.

FIG. S5. Improved visibility thresholds achieved through iterative optimization.

We further compare the improved visibility thresholds with existing methods for the following standard genuinely multipartite entangled (GME) states:

$$\begin{aligned}
 |W_3\rangle &= \frac{1}{\sqrt{3}}(|001\rangle + |010\rangle + |100\rangle), \\
 |W_4\rangle &= \frac{1}{2}(|0001\rangle + |0010\rangle + |0100\rangle + |1000\rangle), \\
 |D_4\rangle &= \frac{1}{\sqrt{6}}(|0011\rangle + |1100\rangle + |0110\rangle + |1001\rangle + |1010\rangle + |0101\rangle), \\
 |Cl_4\rangle &= \frac{1}{2}(|0000\rangle + |0011\rangle + |1100\rangle - |1111\rangle), \\
 |\Psi_4\rangle &= \frac{1}{\sqrt{3}}(|0011\rangle + |1100\rangle - \frac{1}{2}(|01\rangle + |10\rangle) \otimes (|01\rangle + |10\rangle))
 \end{aligned} \tag{S15}$$

TABLE S1. Improved visibility thresholds for GEWs compared with other methods. FID denotes fidelity-based witnesses, OSD denotes operator-Schmidt-decomposition witnesses, and FUL denotes fully-decomposable witnesses. The FID and OSD values are taken from Ref. [8], while the FUL values are taken from Ref. [9]. The lowest (best) threshold for each state is highlighted in bold.

State	Visibility p_{FID}	Visibility p_{OSD}	Visibility p_{FUL}	Visibility p_{GEW}
$ W_3\rangle$	0.619	0.556	0.479	0.478
$ W_4\rangle$	0.733	0.714	0.474	0.470
$ D_4\rangle$	0.644	0.540	0.461	0.459
$ Cl_4\rangle$	0.467	0.463	0.385	0.383
$ \Psi_4\rangle$	0.733	0.572	0.447	0.446

The numerical gap between p_{GEW} and p_{FUL} is small for most of the states considered above, but the GEW threshold is consistently no worse than, and slightly below, the fully-decomposable benchmark. More importantly, the two constructions differ in principle. Fully-decomposable witnesses are restricted to decomposable operators and therefore cannot detect PPT-entangled bound entangled states. In contrast, a GEW based on the HS distance is constructed directly from the geometry of the target state relative to the relevant separable set, and can detect entanglement beyond the decomposable-witness class, as illustrated by the Horodecki and Tiles bound entangled states in the main text. Thus, Table S1 shows consistent tightening on standard GME states, while the broader detection power of GEWs comes from this geometric construction.

Supplementary Results

Tiles bound entangled state

A bound entangled state (BES) can be constructed from the Tiles unextendible product basis (UPB) $\{|\psi_i\rangle\}$ as follows [10],

$$\rho_{\text{Tiles}} = \frac{1}{4} \left(I - \sum_{i=0}^3 |\psi_i\rangle\langle\psi_i| \right), \quad (\text{S16})$$

where the UPB states are

$$\begin{aligned} |\psi_0\rangle &= \frac{1}{\sqrt{2}}|0\rangle(|0\rangle - |1\rangle), & |\psi_1\rangle &= \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)|2\rangle, \\ |\psi_2\rangle &= \frac{1}{\sqrt{2}}|2\rangle(|1\rangle - |2\rangle), & |\psi_3\rangle &= \frac{1}{\sqrt{2}}(|1\rangle - |2\rangle)|0\rangle, \\ |\psi_4\rangle &= \frac{1}{3}(|0\rangle + |1\rangle + |2\rangle)(|0\rangle + |1\rangle + |2\rangle). \end{aligned} \quad (\text{S17})$$

By computing the HS measure of Tiles BES, we find that its nearest separable state is a mixture of ten product pure states as the following form:

$$\begin{aligned} \sigma = & p_0 (\rho_a \otimes \rho_b + \rho_b \otimes \rho_{\bar{a}} + \rho_{\bar{b}} \otimes \rho_a + \rho_{\bar{a}} \otimes \rho_{\bar{b}}) \\ & + p_1 (\rho_c \otimes \rho_d + \rho_d \otimes \rho_{\bar{c}} + \rho_{\bar{d}} \otimes \rho_c + \rho_{\bar{c}} \otimes \rho_{\bar{d}}) \\ & + p_2 (\rho_e \otimes \rho_f + \rho_f \otimes \rho_e), \end{aligned} \quad (\text{S18})$$

where $\rho_x := |x\rangle\langle x|$ with $|x\rangle := x_0|0\rangle + x_1|1\rangle + x_2|2\rangle$ and $\rho_{\bar{x}} := |\bar{x}\rangle\langle\bar{x}|$ with $|\bar{x}\rangle := x_2|0\rangle + x_1|1\rangle + x_0|2\rangle$. The numerical values of these vectors are provided below:

$$\begin{aligned} p &= (0.0757194884, 0.1304440066, 0.08767301), \\ a &= (0.8229256532, 0.5311820912, 0.2015910597), \\ b &= (0.4803621975, 0.3840458715, -0.7885181849), \\ c &= (0.7069251656, 0.7070735048, -0.0174318434), \\ d &= (0.1899793832, 0.4370482044, -0.8791454379), \\ e &= (0.0217550144, 0.9995266073, 0.0217550144), \\ f &= (0.2725406432, -0.9227367965, 0.2725406432). \end{aligned}$$

Four-qubit Smolin state

Here, we consider the four-qubit Smolin state [11]:

$$\rho_S = \frac{1}{16} (I + \sigma_x^{\otimes 4} + \sigma_y^{\otimes 4} + \sigma_z^{\otimes 4}), \quad (\text{S19})$$

where σ_x , σ_y , and σ_z are the Pauli matrices. The HS measure of a state under a specific partition $\mathcal{P}$ is defined as

$$D(\rho) = \min_{\sigma \in \text{SEP}(\mathcal{P})} \|\rho - \sigma\|, \quad (\text{S20})$$

where $\text{SEP}(\mathcal{P})$ denotes the set of separable states under the partition $\mathcal{P}$. Due to the symmetry of the Smolin state, it suffices to consider the bipartitions $\{1\} : \{2, 3, 4\}$ and $\{1, 2\} : \{3, 4\}$, the tripartition $\{1\} : \{2\} : \{3, 4\}$, and the four-partition $\{1\} : \{2\} : \{3\} : \{4\}$.

The Smolin state has been proven to be entangled for all partitions except $\{1, 2\} : \{3, 4\}$ [11]. Furthermore, when white noise is added, the noisy state

$$\mathcal{N}_p(\rho_S) = p\rho_S + (1-p)\frac{I}{16} \quad (\text{S21})$$

remains entangled for $p > \frac{1}{3}$ [12]. A natural conjecture is that

$$D(\mathcal{N}_p(\rho_S)) = \begin{cases} 0, & p \in [0, \frac{1}{3}], \\ \|\mathcal{N}_p(\rho_S) - \mathcal{N}_{\frac{1}{3}}(\rho_S)\|, & p \in (\frac{1}{3}, 1], \end{cases} \quad (\text{S22})$$

which simplifies to

$$D(\mathcal{N}_p(\rho_S)) = \begin{cases} 0, & p \in [0, \frac{1}{3}], \\ \frac{\sqrt{3}}{4} (p - \frac{1}{3}), & p \in (\frac{1}{3}, 1]. \end{cases} \quad (\text{S23})$$

Our numerical results strongly support this conjecture, as illustrated in Fig. S6. The corresponding GEWs for detecting entanglement in the range $p \in (\frac{1}{3}, 1]$ across any partition can be constructed directly from the state $\mathcal{N}_{\frac{1}{3}}(\rho_S)$:

$$W = \frac{(\mathcal{N}_{\frac{1}{3}}(\rho_S) - \rho_S) - \text{Tr}[\mathcal{N}_{\frac{1}{3}}(\rho_S)(\mathcal{N}_{\frac{1}{3}}(\rho_S) - \rho_S)]I}{\|\mathcal{N}_{\frac{1}{3}}(\rho_S) - \rho_S\|}. \quad (\text{S24})$$

FIG. S6. HS measure of noisy Smolin states $\mathcal{N}_p(\rho_S) = p\rho_S + (1-p)\frac{I}{16}$ under different partitions.

Experimental Realization

Experimental system

Our experiments are performed on a nuclear magnetic resonance (NMR) quantum processor using a Bruker 300-MHz NMR spectrometer. The sample is ^{13}C -labeled crotonic acid dissolved in d_6 -acetone. The molecular structure is shown in Fig. S7(a). This molecule hosts four coupled ^{13}C nuclear spins— C_1 , C_2 , C_3 , and C_4 —which together constitute a four-qubit quantum processor. All hydrogen spins, including H_1 , H_2 , and the methyl group M_H , are fully decoupled throughout the experiments.

The internal dynamics of the system are governed by the Hamiltonian [13]

$$\mathcal{H}_{\text{NMR}} = -\sum_{i=1}^4 \frac{\omega_i}{2} \sigma_z^i + \frac{\pi}{2} \sum_{i<j}^4 J_{ij} \sigma_z^i \sigma_z^j, \quad (\text{S25})$$

where σ_z denotes the Pauli matrix, and $\omega_i = 2\pi\nu_i$ is the Larmor frequency associated with the chemical shift ν_i of the i th spin. The scalar coupling strengths J_{ij} quantify the interactions between spins i and j . These parameters are extracted from the thermal-equilibrium NMR spectrum and summarized in Fig. S7(b), with diagonal elements showing Larmor frequencies and off-diagonal elements representing coupling constants. Controlled two-spin interactions are implemented by letting the system evolve naturally under this Hamiltonian.

FIG. S7. Molecular structure and system parameters.

Control of each individual spin is achieved using radio-frequency (rf) pulses described by

$$H_{\text{rf}} = -\sum_k \gamma_k B_1 [\cos(\omega_{\text{rf}} t + \phi) \sigma_x^k + \sin(\omega_{\text{rf}} t + \phi) \sigma_y^k], \quad (\text{S26})$$

where B_1 , ϕ , and ω_{rf} are the amplitude, phase, and frequency of the rf field, respectively, and γ_k is the gyromagnetic ratio of spin k . By designing appropriate sequences of rf pulses, arbitrary single-spin rotations can be implemented. Combined with the intrinsic spin-spin couplings, these controls provide universal manipulation over the entire four-spin system.

State preparation

Because the system's natural Gibbs state does not match the initial states required for our experiments, a dedicated preparation procedure is employed. To test the witnesses introduced in the main text, we prepare states of specific forms. This section describes how these states are generated. The overall preparation begins with the creation of a pseudo-pure state (PPS) via spatial averaging. The target states are then generated either by temporal averaging for predefined mixed states or by coherent unitary preparation for W states.

We begin by generating the PPS from the thermal equilibrium state. In NMR quantum computing, a PPS is a mixed state that behaves effectively as a pure state. For our four-spin system, the PPS is defined as

$$\rho_{\text{PPS}} = \frac{1-\epsilon}{16} I + \epsilon |0000\rangle \langle 0000|, \quad (\text{S27})$$

where I is the 16×16 identity matrix and the polarization under experimental conditions is $\epsilon \sim 10^{-5}$. The identity term does not influence observable signals or typical NMR dynamics (rf pulses or free evolution). Thus, up to a global scaling factor, the PPS behaves as the pure state $|0000\rangle \langle 0000|$. We employ spatial averaging to obtain this PPS from the thermal state [14].

FIG. S8. Circuit for PPS preparation.

Spatial averaging relies on applying magnetic-field gradients to suppress unwanted off-diagonal terms in the density matrix. All experiments are carried out at room temperature. The thermal state of the four-spin system is

$$\rho_{eq} = \frac{I}{2^4} + \epsilon \sum_{k=1}^4 \sigma_z^k. \quad (\text{S28})$$

Using the pulse sequence shown in Fig. S8, and ignoring the identity component, the deviation density operator evolves as

$$\begin{aligned} \sigma_z^1 + \sigma_z^2 + \sigma_z^3 + \sigma_z^4 &\xrightarrow{U_{p1,Gz}} \sigma_z^1 + \frac{1}{2}\sigma_z^2 + \frac{1}{4}\sigma_z^3 + \frac{1}{8}\sigma_z^4 \\ &\xrightarrow{U_{p2,Gz}} \frac{1}{2}(\sigma_z^1\sigma_z^2\sigma_z^3 + \sigma_z^1\sigma_z^2\sigma_z^3\sigma_z^4) + \frac{1}{4}(\sigma_z^2\sigma_z^3 + \sigma_z^2\sigma_z^3\sigma_z^4) + \frac{1}{8}(\sigma_z^3\sigma_z^4 + \sigma_z^4) \\ &\xrightarrow{U_{p3,Gz}} \frac{1}{4}(\sigma_z^1\sigma_z^2\sigma_z^3 + \sigma_z^1\sigma_z^2 + \sigma_z^1\sigma_z^2\sigma_z^3\sigma_z^4 + \sigma_z^1\sigma_z^2\sigma_z^4) \\ &\quad + \frac{1}{8}(\sigma_z^2 + \sigma_z^2\sigma_z^3 + \sigma_z^2\sigma_z^3\sigma_z^4 + \sigma_z^2\sigma_z^4 + \sigma_z^3 + \sigma_z^3\sigma_z^4 + \sigma_z^4) \\ &\xrightarrow{U_{p4,Gz}} \frac{1}{8}(\sigma_z^1\sigma_z^2\sigma_z^3 + \sigma_z^1\sigma_z^3 + \sigma_z^1\sigma_z^2 + \sigma_z^1 + \sigma_z^1\sigma_z^2\sigma_z^3\sigma_z^4 + \sigma_z^1\sigma_z^3\sigma_z^4 \\ &\quad + \sigma_z^1\sigma_z^2\sigma_z^4 + \sigma_z^1\sigma_z^4 + \sigma_z^2 + \sigma_z^2\sigma_z^3 + \sigma_z^2\sigma_z^3\sigma_z^4 + \sigma_z^2\sigma_z^4 \\ &\quad + \sigma_z^3 + \sigma_z^3\sigma_z^4 + \sigma_z^4). \end{aligned} \quad (\text{S29})$$

The resulting deviation operator is proportional to the traceless part of

$$\bigotimes_{k=1}^4 \frac{I + \sigma_z^k}{2} = |0000\rangle \langle 0000|,$$

which corresponds to the desired PPS up to an irrelevant identity component and a global scaling factor.

For the high-dimensional-entanglement experiment, the bipartite $4 \otimes 4$ Hilbert space is encoded into the same four-qubit NMR register by grouping two physical qubits into one subsystem and the other two physical qubits into the second subsystem. Specifically, we take (C_1, C_2) as subsystem A and (C_3, C_4) as subsystem B . The local computational basis of each four-dimensional subsystem is defined as

$$|0\rangle \equiv |00\rangle, \quad |1\rangle \equiv |01\rangle, \quad |2\rangle \equiv |10\rangle, \quad |3\rangle \equiv |11\rangle.$$

Under this encoding, the four-qubit Hilbert space is identified with a bipartite $4 \otimes 4$ system used to realize the high-dimensional entangled states in the Schmidt-number-witness experiment.

For the Horodecki bound-entanglement experiment shown in Fig. 2 of the main text, the target states are bipartite $3 \otimes 3$ states. They are encoded into the same four-qubit NMR register by grouping two physical qubits as subsystem

A and the other two physical qubits as subsystem B . For each subsystem, we use a three-dimensional subspace of the two-qubit Hilbert space as the qutrit computational basis,

$$|0\rangle \equiv |00\rangle, \quad |1\rangle \equiv |01\rangle, \quad |2\rangle \equiv |10\rangle,$$

while the remaining level $|11\rangle$ is not used in this encoding. Under this mapping, the Horodecki states ρ_b are embedded into a nine-dimensional subspace of the four-qubit Hilbert space.

We then prepare the predefined mixed states required for our experiment. This includes the Horodecki bound-entangled states ρ_b and the high-dimensional target states used in the Schmidt-number-witness experiment. Since these target states cannot be obtained from the pure state $|0000\rangle$ through unitary evolution alone, we employ the temporal averaging technique commonly used in NMR. In this approach, we repeatedly generate the individual pure-state components that constitute the desired mixed state. Each component can be prepared from the PPS using appropriate unitary operations, which are implemented experimentally through tailored pulse sequences [15, 16]. These pulses are designed using an optimal-control algorithm, yielding simulated fidelities above 99.5% with a total pulse duration of 20 ms. After preparing all components, we combine them with the proper weights to obtain the final target mixed states.

For the multipartite-entanglement experiments, the three- and four-qubit W states are pure states prepared coherently from the PPS by unitary operations. The logical preparation circuit for the four-qubit W state is shown in Fig. S9.

FIG. S9. Logical circuit for preparing the four-qubit W state.

The four-qubit target state is

$$|W_4\rangle = \frac{1}{2} (|1000\rangle + |0100\rangle + |0010\rangle + |0001\rangle).$$

Starting from $|0000\rangle$, a y -axis rotation with angle $\pi/2$ first creates a single excitation. The subsequent controlled rotations, implemented by the rotation pairs θ_j and $-\theta_j$ together with CNOT gates, sequentially redistribute the excitation amplitude over the four spins, following the standard controlled-rotation state-preparation strategy [17]. With the convention $R_y(\theta) = e^{-i\sigma_y\theta}$, the rotation angles for preparing $|W_4\rangle$ are chosen as

$$\cos(2\theta_1^{(4)}) = \frac{1}{2}, \quad \cos(2\theta_2^{(4)}) = \frac{1}{\sqrt{3}}, \quad \cos(2\theta_3^{(4)}) = \frac{1}{\sqrt{2}},$$

which gives equal amplitudes for the four single-excitation basis states.

The three-qubit W state is prepared in the subspace of the first three spins, while the fourth spin is kept in $|0\rangle$. The target state is therefore

$$|W_3\rangle \otimes |0\rangle = \frac{1}{\sqrt{3}} (|1000\rangle + |0100\rangle + |0010\rangle).$$

Its preparation follows the same sequential-amplitude-distribution procedure as in Fig. S9, but only the first two controlled-rotation blocks are used. The final redistribution between the third and fourth spins is omitted, so that the fourth spin remains in $|0\rangle$. The corresponding angles are chosen as

$$\cos(2\theta_1^{(3)}) = \frac{1}{\sqrt{3}}, \quad \cos(2\theta_2^{(3)}) = \frac{1}{\sqrt{2}}.$$

These logical preparation circuits are compiled into shaped radio-frequency pulses using the same GRAPE-based optimal-control procedure described above.

Readout

The signal produced by an individual molecule is too weak to detect directly, so the NMR sample contains a macroscopic ensemble of identical molecules. All measurements therefore produce ensemble-averaged signals, from which the quantum state of an individual molecule can be inferred.

During detection, the nuclear spins precess around the static magnetic field B_0 along the z -axis and gradually relax back to thermal equilibrium. This precession induces an oscillating transverse (in the x - y plane) electromagnetic signal, which is captured by the surrounding rf detection coils. The resulting time-domain signal, known as the free induction decay (FID), can be expressed as [18]

$$A(t) = \text{Tr} \left[e^{-i\mathcal{H}_{\text{NMR}}t} \rho e^{i\mathcal{H}_{\text{NMR}}t} \sum_k (\sigma_x^k - i\sigma_y^k) e^{-\lambda_k t} \right], \quad (\text{S30})$$

where ρ is the density matrix of the system and $\lambda_k = 1/T_2$ accounts for transverse relaxation. The real and imaginary parts correspond to the measured signals along the x and y axes, respectively. A typical real-part FID for the thermal state of crotonic acid is shown in Fig. S10(a).

FIG. S10. Direct results obtained in the NMR experiment.

Given the Hamiltonian in Eq. S25, the FID can be decomposed into a sum of single-frequency components determined by the Larmor frequencies and coupling constants. These components can be resolved through a Fourier transform.

Consider a single-spin example with Hamiltonian $H_{\text{single}} = \frac{\omega_s}{2} \sigma_z$, where ω_s is the Larmor frequency. The density matrix can be expanded in the Pauli basis as

$$\rho_{\text{single}} = \frac{I_2 + \alpha_1 \sigma_x + \alpha_2 \sigma_y + \alpha_3 \sigma_z}{2}. \quad (\text{S31})$$

The corresponding FID signal is

$$A_{\text{single}}(t) = \frac{1}{2} \text{Tr} \left[e^{-i\omega_s \sigma_z t/2} (I_2 + \alpha_1 \sigma_x + \alpha_2 \sigma_y + \alpha_3 \sigma_z) e^{i\omega_s \sigma_z t/2} (\sigma_x - i\sigma_y) e^{-\lambda_k t} \right]. \quad (\text{S32})$$

Because $\text{Tr}(\sigma_x) = \text{Tr}(\sigma_y) = 0$, the terms I_2 and $\alpha_3 \sigma_z$ do not contribute. Separating into real and imaginary parts yields

$$\begin{aligned} \text{Re}[A_{\text{single}}(t)] &= \frac{1}{2} \text{Tr} \left[e^{-i\omega_s \sigma_z t/2} (\alpha_1 \sigma_x + \alpha_2 \sigma_y) e^{i\omega_s \sigma_z t/2} \sigma_x \right] e^{-\lambda_k t}, \\ \text{Im}[A_{\text{single}}(t)] &= \frac{1}{2} \text{Tr} \left[e^{-i\omega_s \sigma_z t/2} (\alpha_1 \sigma_x + \alpha_2 \sigma_y) e^{i\omega_s \sigma_z t/2} \sigma_y \right] e^{-\lambda_k t}. \end{aligned} \quad (\text{S33})$$

Neglecting relaxation, the expressions simplify to

$$\begin{aligned} \text{Re}[A_{\text{single}}(t)] &= \frac{\alpha_1 \cos \omega_s t - \alpha_2 \sin \omega_s t}{2}, \\ \text{Im}[A_{\text{single}}(t)] &= \frac{\alpha_2 \cos \omega_s t + \alpha_1 \sin \omega_s t}{2}. \end{aligned} \quad (\text{S34})$$

After Fourier transformation,

$$\begin{aligned} \text{Re}[A_{\text{single}}(\omega)] &= \frac{\alpha_1 + \alpha_2}{2} \delta(\omega - \omega_s), \\ \text{Im}[A_{\text{single}}(\omega)] &= \frac{\alpha_2 - \alpha_1}{2} \delta(\omega - \omega_s). \end{aligned} \quad (\text{S35})$$

Thus, the amplitudes of the spectral peaks encode the coefficients of the Pauli operators, allowing us to reconstruct these coefficients from the observed spectrum.

Since the NMR spectrometer directly detects only transverse components (σ_x and σ_y), accessing longitudinal information (σ_z) requires an additional rotation. We apply a $\pi/2$ rotation about the y -axis, $R_y(\pi/2)$, which maps σ_z to σ_x , allowing σ_z components to be measured.

This analysis generalizes to multi-spin systems by incorporating spin-spin couplings. For the four-spin crotonic acid system, the spectrum contains 32 distinct spectral lines [Fig. S10(b)], enabling the extraction of a large set of Pauli coefficients from a single measurement.

The GEWs studied in this work are constructed from a geometric optimization, rather than from a preselected set of experimentally convenient observables. More precisely, a GEW is determined by the nearest state in the desired set to the target state under the HS distance, and hence corresponds to the supporting hyperplane obtained from this closest-state geometry. The number of local measurement settings is therefore not an input constraint in our optimization. Imposing a fixed set or number of measurement settings would restrict the allowed witnesses to a smaller, experimentally tailored class; such witnesses may be useful in practice, but they are not generally guaranteed to be geometrically optimal in the sense considered here.

After a GEW has been obtained, its experimental implementation is handled as a separate step. The witness is decomposed into local Pauli operators, and compatible Pauli terms are grouped into common local measurement settings. Consequently, the required number of settings depends on the Pauli structure of the resulting GEW and on the grouping strategy used in the experiment. When a noise model is explicitly incorporated to improve the visibility threshold, the optimized witness may acquire a different Pauli structure; therefore, the measurement cost need not scale monotonically with the threshold. We therefore distinguish between the construction of the geometrically optimal GEW and the subsequent Pauli decomposition and grouping used for implementation.

To experimentally detect entanglement, we evaluate the expectation value of the corresponding witness operator W . The witness is first embedded into the four-qubit Hilbert space according to the encoding of the target state and then decomposed into the local Pauli basis. Importantly, the witness evaluation itself does not require full quantum state tomography; only the Pauli components with nonzero coefficients in the witness decomposition need to be measured.

$$\langle W \rangle_{\text{exp}} = \text{Tr}(W\rho) = \text{Tr} \left(\sum_i w_i \sigma_{4,i} \rho \right) = \sum_i w_i \langle \sigma_{4,i} \rangle_{\text{exp}}, \quad (\text{S36})$$

where $\sigma_{4,i}$ denotes a four-qubit Pauli operator and w_i is the corresponding coefficient in the witness expansion. Thus, the experimentally required measurements are determined by the nonzero Pauli terms appearing in W .

For the Horodecki bound-entanglement experiment shown in Fig. 2 of the main text, a geometrically optimal witness W_b is constructed for each target state ρ_b by finding the nearest separable state under the Hilbert–Schmidt distance. The resulting $3 \otimes 3$ witness is embedded into the four-qubit Hilbert space using the qutrit encoding described in the state-preparation section. We then decompose the embedded witness into local Pauli operators and evaluate $\langle W_b \rangle_{\text{exp}}$ from the measured Pauli expectations according to the equation above.

As for multipartite entangled states, the construction of GEWs follows a similar approach. For example, the GEW for the three-qubit W state $|W_3\rangle$ can be expressed as

$$\begin{aligned} W \approx & 0.473 \cdot IIII + 0.053 \cdot \sigma_z^1 \sigma_z^2 \sigma_z^3 + 0.017 \cdot (I \sigma_z^2 \sigma_z^3 + \sigma_z^1 I \sigma_z^3 + \sigma_z^1 \sigma_z^2 I) \\ & - 0.096 \cdot (I \sigma_x^2 \sigma_x^3 + \sigma_x^1 I \sigma_x^3 + \sigma_x^1 \sigma_x^2 I + I \sigma_y^2 \sigma_y^3 + \sigma_y^1 I \sigma_y^3 + \sigma_y^1 \sigma_y^2 I) \\ & - 0.105 \cdot (\sigma_z^1 \sigma_x^2 \sigma_x^3 + \sigma_x^1 \sigma_z^2 \sigma_x^3 + \sigma_x^1 \sigma_x^2 \sigma_z^3 + \sigma_z^1 \sigma_y^2 \sigma_y^3 + \sigma_y^1 \sigma_z^2 \sigma_y^3 + \sigma_y^1 \sigma_y^2 \sigma_z^3). \end{aligned} \quad (\text{S37})$$

The witness measurements described above are sufficient for entanglement detection. Separately, to assess the quality of the experimentally prepared states, we reconstruct the full density matrices via quantum state tomography. Complete tomography of a four-qubit state requires determining $4^4 - 1 = 255$ independent parameters, where the identity component $IIII$ in the Pauli expansion is fixed by normalization and is not independently measured.

In the NMR implementation, the following strings denote the readout rotation settings used in the state-interrogation tomography protocol, rather than independently measured Pauli-basis operators. Here, I indicates that no readout rotation is applied to the corresponding spin. Thus, the setting $IIII$ corresponds to direct acquisition without additional readout rotations. Following the standard state-interrogation method for NMR quantum-information processing [19], complete tomography of a four-qubit state can be achieved with $2^4 + 1 = 17$ readout experiments.

We use the following 17 readout rotation settings:

$$\begin{aligned} & IIII, \sigma_x^1 \sigma_x^2 \sigma_x^3 \sigma_x^4, II \sigma_y^3 \sigma_y^4, \sigma_y^1 \sigma_y^2 \sigma_x^3 \sigma_x^4, III \sigma_y^4, \sigma_x^1 \sigma_y^2 \sigma_x^3 \sigma_x^4, \sigma_y^1 \sigma_x^2 \sigma_y^3 I, \\ & I \sigma_x^2 \sigma_y^3 I, III \sigma_x^4, \sigma_x^1 I \sigma_y^3 \sigma_y^4, \sigma_y^1 \sigma_x^2 II, \sigma_y^1 \sigma_y^2 \sigma_x^3 \sigma_y^4, \sigma_x^1 \sigma_y^2 \sigma_x^3 I, \\ & II \sigma_y^3 \sigma_x^4, I \sigma_x^2 I \sigma_y^4, II \sigma_x^3 I, I \sigma_y^2 I \sigma_y^4. \end{aligned}$$

In this protocol, each readout rotation maps a specific set of density-matrix elements onto observable single-quantum coherences in the NMR spectrum. Therefore, settings such as $II \sigma_y^3 \sigma_y^4$ and $III \sigma_y^4$ are distinct readout settings, rather than lower-weight marginals obtained from another setting.

Combining the data from these experiments yields the full reconstructed density matrix. As an example of state-quality characterization, Fig. S11 shows the real and imaginary parts of the experimentally reconstructed density matrix of the bound entangled state ρ_b with $b = 1$. Here, the original $3 \otimes 3$ state is embedded into the four-qubit Hilbert space using the qutrit encoding described in the state-preparation section, with the unused level $|11\rangle$ in each two-qubit subsystem lying outside the encoded qutrit subspace.

FIG. S11. Four-qubit quantum state tomography result for the embedded Horodecki state ρ_b with $b = 1$.

To quantify the state preparation accuracy, we compute the fidelity

$$F(\rho_{\text{the}}, \rho_{\text{exp}}) = \text{Tr} \left(\sqrt{\rho_{\text{the}}^{1/2} \rho_{\text{exp}} \rho_{\text{the}}^{1/2}} \right), \quad (\text{S38})$$

where ρ_{the} is the ideal theoretical state and ρ_{exp} is the experimentally reconstructed density matrix. All prepared states in our experiments achieve fidelities above 98%.

The target states in this work are specified by the preparation protocol and are therefore known theoretically before the experiment. The corresponding GEWs are computed from these known target states by finding the nearest state in the relevant convex set, such as the separable, biseparable, or low-Schmidt-number set. The experimental task is then to measure the expectation value of the precomputed witness on the actually prepared state. Thus, tomography of an unknown target state is not required for constructing the witness; in our implementation, tomography is used only as an independent characterization of the preparation quality.

Abstract. Achieving practical quantum advantage on near-term noisy hardware is a central goal of quantum computation. However, without efficient pre-execution diagnostics, circuit design and scheme selection often rely on costly hardware-in-the-loop trial-and-error, inflating experimental overhead and impeding progress. To address this challenge, we introduce 2MC-OBPPP, a polynomial-time classical estimator that, for parameterized quantum circuits, jointly estimates trainability, expressibility, and robustness to noise. For example, our approach visually demonstrates that moderate amplitude damping alleviates barren plateaus (improving trainability) while decreasing expressibility. Moreover, the method produces a spatiotemporal “noise-hotspot” map that pinpoints the most noise-sensitive qubits/gates, enabling targeted noise suppression. In a representative circuit, interventions on fewer than 2% qubits reduce the error up to 90%. Together, before execution, our approach provides an efficient diagnostic benchmark for circuit/scheme design, and in deployment, guides for targeted interventions that substantially reduce the cost of error suppression.

Keywords: quantum circuit, pre-execution diagnostics, quantum benchmarking, error suppression

1 Motivation

Near-term quantum algorithms rely heavily on parameterized quantum circuits (PQCs), which underlie variational quantum algorithms and quantum machine learning. Yet a PQC that looks reasonable as an ansatz can still fail for at least three distinct reasons: its output can be too sensitive to hardware noise, its gradients can concentrate near zero and become untrainable, or its ensemble can be insufficiently expressive for the target task. These criteria are coupled in subtle ways. For example, noise can damage the output accuracy, but certain non-unital noise processes can also make deep circuits behave effectively shallower and thereby temporarily improve trainability.

Directly diagnosing these effects on hardware is expensive: one must choose a circuit, run it many times, train or benchmark it, and then redesign it if the result is poor. This hardware-in-the-loop process is especially wasteful when only a small subset of gates or qubits dominates the performance loss. An efficient classical diagnostic should therefore answer two questions before deployment. First, does the circuit have the basic properties needed for the

intended computation? Second, if noise is the main obstacle, where should limited error-suppression resources be spent?

We address these questions with *2-moment Monte Carlo using observable’s back-propagation on Pauli paths* (2MC-OBPPP). The framework estimates three two-moment diagnostics: the mean-squared error between ideal and noisy expectation values, the variance of parameter gradients, and a second-moment expressibility measure given by deviation from the Haar ensemble. It also produces a sensitivity map for the circuit, revealing noise bottlenecks that are natural targets for quantum error mitigation or improved control.

2 Method

Consider an n -qubit PQC $\mathcal{C}(\theta) = U_{N_g}(\theta_{N_g}) \cdots U_1(\theta_1)$, where each parameterized gate is a Pauli rotation followed by a Clifford gate. Real devices are modeled by inserting local noise channels after gates. We work with the class of Pauli column-wise sum at most one (PCS1) channels: in the Pauli transfer matrix of such a channel, each column has absolute sum at most one. This class includes common models such as depolarizing noise, Pauli error channels, amplitude damping, thermal relaxation, and mid-circuit Pauli

*weizhaohui@gmail.com

†liuzhengwei@mail.tsinghua.edu.cn

Figure 1: Noise bottleneck diagnosis. (a) Qubit sensitivity map for a 435-qubit, 75-layer circuit. (b) Bottleneck-first mitigation reduces the mean-squared error by about one order of magnitude after suppressing noise on seven selected qubits.

feed-forward processes.

The key observation is that the robustness, trainability, and expressibility diagnostics considered here are determined by the circuit’s two-fold channel. For Pauli rotations, the average over continuous angles can be replaced by an average over the Clifford-compatible set $\{0, \pi/2, \pi, 3\pi/2\}^{N_g}$. After this reduction, each diagnostic can be written as an average of bounded functions over sampled angle configurations.

2MC-OBPPP estimates this average with two nested Monte Carlo procedures. The outer layer samples the discrete angles. For each sample, the inner layer starts from Pauli terms in the measured observable and back-propagates them through the circuit in the Heisenberg picture. At each noisy component, a Pauli transition is sampled according to the local PCS1 channel, producing an unbiased Pauli-path estimator. For local PCS1 noise, the cost of estimating the diagnostics to additive accuracy ε with high probability scales linearly in the number of qubits and circuit depth, up to the polynomial dependence on $1/\varepsilon$ and logarithmic confidence factors. For common observables such as Pauli measurements or computational-basis projectors, this gives a scalable pre-execution benchmark for large PQC.

3 Noise Bottlenecks

The same estimator can be differentiated with respect to local noise strengths. For a qubit or gate indexed by (i, j) with noise parameter $\lambda_{i,j}$, the sensitivity $|\partial \text{MSE} / \partial \lambda_{i,j}|$ quantifies how strongly that el-

ement affects the final observable error. Large sensitivity identifies a noise bottleneck. This information is directly actionable: rather than applying error mitigation or pulse improvement uniformly, one can spend resources where they most reduce the output error.

We demonstrate this strategy on a 75-layer, 435-qubit circuit composed of R_X , R_Z , and R_{ZZ} gates on a chip-like architecture. Under qubit-wise depolarizing noise with rate $\lambda = 0.007$, comparable to the fitted noise scale of IBM Eagle devices, the sensitivity map is highly inhomogeneous. Suppressing the noise rate to $\lambda = 0.001$ on only seven qubits, fewer than 2% of all qubits, reduces the mean-squared error by roughly a factor of ten. This shows that the diagnostic is not merely descriptive: it turns a large noisy circuit into a prioritized intervention list.

4 Trainability and Expressibility

Trainability is diagnosed through the variance of parameter gradients. When this variance decays exponentially with system size or depth, random initializations almost always produce near-zero gradients, which is the barren plateau phenomenon. Expressibility is diagnosed through a second-moment deviation from the Haar ensemble; smaller deviation means the circuit ensemble is closer to a unitary 2-design. Both quantities fit naturally into the same two-moment estimator, so they can be compared under a shared noise model.

Amplitude damping illustrates why such joint diagnosis matters. In our numerical experiments, increasing the damping strength first suppresses the

Figure 2: Trainability and expressibility under amplitude damping. (a) The total gradient variance can increase at moderate damping strengths, indicating partial alleviation of barren plateaus. (b) The same damping drives the circuit ensemble farther from a unitary 2-design, revealing a tradeoff between trainability and expressibility.

gradient variance, then increases it over an intermediate range, and finally suppresses it again when decoherence becomes too strong. The intermediate increase agrees with the noise-induced shallow-circuit picture: moderate damping reduces the effective depth and can partially alleviate barren plateaus. However, the expressibility diagnostic moves in the opposite direction over the same range, showing that the circuit ensemble becomes less Haar-like. Thus, noise can improve one useful property while degrading another, and 2MC-OBPPP exposes this tradeoff before a costly hardware run.

5 Impact

The proposed framework provides a scalable classical toolkit for circuit and scheme design. Before execution, it compares candidate ansatzes, depths, observables, and noise models using the same diagnostic language. During deployment, it identifies the gates or qubits where targeted noise suppression should have the largest effect. This is particularly relevant because general quantum error mitigation can have rapidly growing sampling overhead; a bottleneck-first strategy can reduce the number of components that require expensive mitigation or calibration.

More broadly, 2MC-OBPPP supports noise-aware co-design of quantum algorithms and hardware. It applies beyond Pauli noise and Clifford circuits, captures robustness, trainability, and expressibility within one estimator, and converts global performance questions into local sensitivity maps. ² *Department of Physics, Yonsei University*

Abstract. In this work, we investigate the convergence and stability of QKD for the one-dimensional Hubbard model with periodic boundary conditions. Using noiseless simulations, we analyze the interplay between Krylov dimension, time-evolution parameters, and Trotter discretization, identifying distinct stable and unstable convergence regimes. We further study the effects of system size, interaction strength, and singular-value truncation on the accuracy of ground-state energy estimation. Benchmark comparisons with iterative quantum phase estimation (IQPE) demonstrate that QKD achieves comparable or improved accuracy using substantially shallower circuits. Our results provide practical guidelines for implementing Krylov-based quantum algorithms on near-term quantum hardware.

Keywords: Quantum Krylov Diagonalization, Quantum Simulation, Quantum Computing

1 Introduction

Quantum simulation of strongly correlated many-body systems is expected to be one of the most important applications of quantum computers [1, 2]. However, conventional approaches such as quantum phase estimation (QPE) [3, 4] generally require deep quantum circuits beyond the capability of current noisy intermediate-scale quantum (NISQ) devices. Variational quantum eigensolvers [5] provide an alternative framework, but their performance is often limited by optimization difficulties and large measurement overheads.

Recently, Krylov-based quantum algorithms have emerged as a promising alternative for near-term quantum simulation [6, 7, 8]. In particular, quantum Krylov diagonalization (QKD) constructs a low-dimensional Krylov subspace from time-evolved quantum states and solves a reduced generalized eigenvalue problem classically. This hybrid strategy combines shallow quantum circuits with efficient classical post-processing and has recently been demonstrated experimentally for several many-body Hamiltonians [8].

Despite recent progress in Krylov-based quantum algorithms, a systematic understanding of their convergence, numerical stability, and practical parameter selection for strongly correlated fermionic systems remains limited. In this work, we address these issues through a comprehensive study of QKD applied to the one-dimensional Hubbard model. Specifically, we identify stable and unstable convergence regimes governed by the interplay between Krylov dimension, evolution time, and Trotter discretization; analyze the dependence on system size and interaction strength; and investigate the role of singular-value truncation (SVT).

2 Quantum Krylov Diagonalization

In QKD, the Krylov basis is generated from repeated applications of the unitary time-evolution operator $U (= e^{-i\mathcal{H}t})$ to an initial reference state $|\psi_0\rangle$ [8],

$$|\psi_j\rangle = U^j|\psi_0\rangle = e^{-i\mathcal{H}jt}|\psi_0\rangle, \quad j = 0, 1, \dots, D-1 \quad (1)$$

where t denotes the evolution time step and D is the Krylov dimension. The projected Hamiltonian and overlap matrices are defined as

$$\tilde{\mathcal{H}}_{jk} = \langle\psi_j|\mathcal{H}|\psi_k\rangle, \quad \tilde{S}_{jk} = \langle\psi_j|\psi_k\rangle. \quad (2)$$

The approximate energy eigenvalues E are obtained by solving the generalized eigenvalue equation

$$\tilde{\mathcal{H}}\mathbf{c} = E\tilde{S}\mathbf{c}, \quad (3)$$

where the vector $\mathbf{c}$ contains the expansion coefficients of the Krylov basis states defining the approximate eigenstate.

The matrix elements are evaluated using Hadamard-test circuit (see Fig. 1) [8] together with Trotterized real-time evolution. Owing to the Toeplitz structure of the Krylov matrices (e.g., $\tilde{S}_{j,k} = \tilde{S}_{j+1,k+1}$), only matrix elements corresponding to distinct time differences must be measured, reducing the measurement overhead from quadratic to linear scaling in the Krylov dimension.

We apply this framework to the 1D Hubbard Hamiltonian,

$$\mathcal{H} = -\gamma_0 \sum_{\langle i,j \rangle, \sigma} (c_{i\sigma}^\dagger c_{j\sigma} + c_{j\sigma}^\dagger c_{i\sigma}) + \mathcal{U}_0 \sum_i n_{i\uparrow} n_{i\downarrow}, \quad (4)$$

using the Jordan-Wigner transformation to map fermionic operators onto qubits. Throughout this work, we consider a chain of L lattice sites with periodic boundary conditions at half-filling ($N_e = L$) and set $\gamma_0 = 1$. Besides, the reference state $|\psi_0\rangle$ is taken to be a Slater determinant state, an eigenstate of noninteracting fermions with $\mathcal{U}_0 = 0$.

Figure 1: Circuit used to evaluate the real and imaginary components of the matrix element $\langle \psi_0 | P | \psi_{k-j} \rangle = \langle \psi_0 | P U^{k-j} | \psi_0 \rangle$ within the Krylov framework. The sub-circuit labeled ψ_0 -prep prepares the reference state $|\psi_0\rangle$ from the computational basis, while U^{k-j} denotes the time-evolution operator. An ancillary qubit, initialized in $|0\rangle$ and rotated by a Hadamard gate $\hat{H}$, enables the Hadamard test for extracting the desired expectation values.

Figure 2: (a) Absolute error in the GSE, $|E_{\text{QKD}} - E_{\text{exact}}|$, as a function of the Krylov subspace dimension D , for different time-step sizes t_{evol} as indicated in the figure. Results are shown for the weakly interacting case $\mathcal{U}_0 = 2$ with $N_{\text{trot}} = 100$. (b) Absolute error corresponding to the Δt_o time evolution in panel (a), for different Trotter numbers. The reference time step Δt_o is defined as $\Delta t_o = \pi / \|\mathcal{H}\| \approx 0.28$, where $\|\mathcal{H}\|$ denotes the spectral norm of the Hamiltonian.

Figure 3: Convergence of the QKD energy error as a function of the Krylov dimension D for different lattice sizes L . For each system size, the time-evolution parameter t_{evol} and the number of Trotter steps N_{trot} are chosen relative to the reference time scale Δt_o to ensure comparable dynamical resolution across systems.

3 Numerical Results

3.1 Time-step dependence and Krylov convergence

We first investigate the convergence of QKD for a six-site Hubbard chain under noiseless statevector simulations. Figure 2(a) shows the absolute ground-state energy (GSE) error as a function of the Krylov dimension D for several evolution times t_{evol} .

Two distinct convergence regimes emerge. For sufficiently small evolution times, namely $t_{\text{evol}} = \Delta t_o/6$ and $t_{\text{evol}} = \Delta t_o/8$, the energy error decreases smoothly and monotonically with increasing Krylov dimension. In this regime, the Trotter error is strongly suppressed, and the remaining error is primarily limited by the finite Krylov subspace. In contrast, larger time steps, $t_{\text{evol}} = \Delta t_o$ and $t_{\text{evol}} = \Delta t_o/2$, lead to strong fluctuations and eventual breakdown of convergence at large D . The error saturates and may even increase as the Krylov dimension grows, indicating that the accuracy becomes limited by time-discretization errors rather than the Krylov approximation itself.

To clarify the origin of this instability, we vary the number of Trotter steps N_{trot} while keeping the evolution time fixed $t_{\text{evol}} = \Delta t_o$ as shown in Fig 2(b). Increasing N_{trot} systematically stabilizes the convergence and shifts the onset of instability toward larger Krylov dimensions. These results demonstrate that the observed breakdown primarily originates from Trotter errors accumulated during long-time evolution.

3.2 System-size dependence

We next investigate the scalability of the QKD approach for system sizes ranging from $L = 2$ to $L = 10$ (see Fig. 3). The results are obtained using $t_{\text{evol}} \in [\Delta t_o/6, 2\Delta t_o]$, depending on the system size.

For most lattice sizes, the QKD error decreases systematically with increasing Krylov dimension, although convergence becomes progressively slower for larger systems due to the increasing complexity of the many-body spectrum. Interestingly, the cases $L = 4$ and $L = 8$ exhibit anomalously slow convergence compared to neighboring system sizes. This behavior is consistent with the general perspective of real-time Krylov methods, whose efficiency depends strongly on the spectral structure of the Hamiltonian [6, 7]. For these two lattice sizes, the relevant low-energy spectrum exhibits small spectral gaps, reducing the rate at which dynamical phases accumulate. Consequently, longer evolution times are required to distinguish nearby eigenstates, so the Krylov basis acquires information about the low-energy subspace more gradually, leading to slower convergence.

3.3 Interaction strength and SVT

We further study the effect of interaction strength $\mathcal{U}_0$ on the performance of the QKD method for a ten-site Hubbard chain as shown in Fig. 4. For weak interactions $\mathcal{U}_0 = 2-4$, the energy error decreases rapidly with increasing Krylov dimension. However, stronger interac-

Figure 4: Absolute error in the GSE as a function of D for different interaction strengths $\mathcal{U}_0 = 2-8$ at fixed system size $L = 10$. The time evolution is performed with $t_{\text{evol}} = 2\Delta t_o$ for each $\mathcal{U}_0$, using $N_{\text{trout}} = 200$ Trotter steps. The inset shows the fidelity between the reference state and the true ground state as a function of $\mathcal{U}_0$.

Figure 5: Absolute error in the GSE as a function of D for different SVT thresholds δ_{SVT} . The number of chain is $L = 10$ and $\mathcal{U}_0 = 3$. The time evolution is performed with $2\Delta t_o = 0.28$ using $N_{\text{trout}} = 200$ Trotter steps.

Figure 6: Absolute GSE error as a function of D for QKD (blue) compared with IQPE (red dashed) for the six-site Hubbard model ($L = 6$, $\mathcal{U}_0 = 3$). The IQPE result corresponds to the parameters $m = 5$ binary digits and $N_{\text{trout}} = 10$ Trotter steps.

tions lead to slower convergence and larger residual errors. This behavior can be understood from the changing character of the ground state. The reference state employed throughout this work is the noninteracting Slater determinant, which provides an excellent approximation in the weakly correlated regime. As $\mathcal{U}_0$ increases, the exact ground state becomes increasingly correlated, reducing its overlap with the reference state. This trend is confirmed by the fidelity shown in the inset of Fig. 4, which decreases monotonically with increasing $\mathcal{U}_0$.

We additionally examine the role of SVT in stabilizing the generalized eigenvalue problem. As shown in Fig. 5, large truncation thresholds discard physically relevant Krylov components and degrade accuracy, whereas excessively small thresholds retain nearly linearly dependent basis vectors and amplify numerical instabilities.

3.4 Comparison with IQPE

To benchmark the efficiency of QKD, we compare its performance against IQPE [9] for the six-site Hubbard model at $\mathcal{U}_0 = 3$, as shown in Fig. 6. Under noiseless conditions, IQPE achieves an energy error of approximately 7×10^{-3} , whereas QKD reaches accuracies on the order of 10^{-3} – 10^{-4} at moderate Krylov dimensions.

Importantly, this improvement is achieved with substantially shallower circuits. IQPE requires deep controlled time evolutions whose depth exceeds 2×10^5 gates for high-precision iterations, while the QKD circuit depth remains approximately 6×10^3 and independent of the Krylov dimension. This demonstrates the practical advantage of QKD for near-term quantum hardware, where circuit depth and two-qubit gate noise remain major limitations.

3.5 Conclusion

We have systematically investigated the performance and numerical stability of QKD for the one-dimensional Hubbard model under noiseless simulations. Our results reveal that the accuracy of the method is governed by a delicate interplay between the Krylov dimension, the evolution time, and the Trotter discretization. While increasing the evolution time initially improves the efficiency of the Krylov basis construction, excessively large values introduce time-discretization errors that ultimately limit the achievable accuracy. We further demonstrate that, with appropriate parameter choices, QKD achieves higher accuracy than IQPE while requiring substantially shallower quantum circuits, highlighting its potential as a practical approach for near-term quantum simulation of strongly correlated systems.

Extensions to realistic noisy simulations and implementations on superconducting quantum processors are currently in progress to further assess the practical performance of the method on NISQ hardware.

Abstract. Parameterized quantum circuits are central to near-term quantum algorithms, but their optimization is often obstructed by barren plateaus. We introduce modified parameterized quantum circuits (MPQCs), a hardware-efficient framework that inserts simple quantum-channel gadgets into an arbitrary PQC. The resulting circuit is at least as expressive as the original one, preserves classical-simulation hardness in both worst-case and average-case senses whenever the original family is hard to simulate, and admits polynomial lower bounds on loss and gradient variance under mild locality conditions. MPQCs can also activate any chosen parameter and remain robust under realistic noise.

Keywords: barren plateaus, parameterized quantum circuits, variational quantum algorithms, trainability, expressibility

1 Motivation and contribution

Parameterized quantum circuits (PQCs) are a basic primitive in variational quantum algorithms, but their optimization can be obstructed by barren plateaus: for a loss function $L(\theta)$, one often has

$$\text{Var}_{\theta}[\partial_{\theta_i} L(\theta)] \leq O(b^{-n})$$

for a constant $b > 1$, so useful gradients become exponentially unlikely [1, 2]. Existing remedies often rely on shallow circuits, restrictive symmetry, or architectures whose dynamics may become easier to simulate classically [3–5]. We address the following question: *can one make an arbitrary PQC trainable without sacrificing expressibility or classical hardness?*

Our answer is affirmative. We introduce *modified parameterized quantum circuits* (MPQCs), obtained by inserting a local layer of trainable quantum-channel gadgets into an arbitrary PQC; see Fig. 1. The construction is modular and hardware-efficient: each gadget uses one ancilla qubit initialized in $|0\rangle$, one single-qubit operation op , and three two-qubit rotations R_{XX}, R_{YY}, R_{ZZ} . We prove that MPQCs (i) are at least as expressive as the original PQCs, (ii) preserve classical-simulation hardness whenever the original circuit family is hard to simulate, in both worst-case and average-case senses, (iii) are free from barren plateaus under mild locality assumptions, (iv) can *activate* an arbitrary chosen

original parameter, and (v) remain trainable under realistic local noise.

2 Construction and main guarantees

Let $\Phi_{\mathcal{C}}(\theta, \theta_G)$ denote the channel implemented by the MPQC obtained from a PQC $\mathcal{C}(\theta)$. Because the gadget parameters can be set to zero, the original circuit is embedded as

$$\mathcal{C}(\theta)\rho\mathcal{C}(\theta)^\dagger = \Phi_{\mathcal{C}}(\theta, \mathbf{0})(\rho).$$

Hence the output ensemble of the original PQC is a subset of that of the MPQC, so expressibility is never reduced. The same embedding also gives a worst-case hardness-preservation statement: any classical simulator for the MPQC would immediately simulate the original PQC by restricting to the slice $\theta_G = \mathbf{0}$. Thus the gadget layer does not replace the original quantum dynamics by a classically tractable ansatz; it only enlarges the model around the original circuit.

We also prove an average-case version, which is important because the special slice $\theta_G = \mathbf{0}$ has measure zero. Informally, if a polynomial-time classical algorithm estimated local-observable expectation values of arbitrary MPQCs with small mean-squared error over their parameters, then one could estimate the corresponding expectation values of the original PQC for a $1 - 1/\text{poly}(n)$ fraction of its parameters. The reduction samples gadget angles in a small hypercube around zero and uses

Figure 1: Main idea of the construction. **(a)** An MPQC is obtained by inserting a gadget layer $\mathcal{G}(\theta_G)$ into an arbitrary PQC $\mathcal{C}(\theta)$. **(b)** By enlarging one gadget inside the backward light cone of a relevant observable term, we obtain a T -activating MPQC that specifically makes a chosen original parameter trainable. **(c)** Numerical illustration: for thermal-state-preparation ansatzes, the MPQC removes the severe variance decay observed in the original PQC.

Lipschitz continuity of the MPQC loss to transfer the average-case guarantee back to the original circuit. In short, average-case simulation of MPQCs would imply average-case simulation of arbitrary PQCs. This distinguishes MPQCs from approaches that eliminate barren plateaus by imposing a low-complexity circuit structure: here trainability is improved without assuming that the underlying PQC has an efficiently classically describable evolution.

The key trainability result uses Pauli back-propagation through the gadget layer. For a local observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$, assume that the backward light cone of each Pauli term P_{α} intersects at most $K = O(\log n)$ gadgets. Then the MPQC loss

$$L^{\mathcal{C}}(\theta, \theta_G) = \text{tr}[O \Phi_{\mathcal{C}}(\theta, \theta_G)(\rho)]$$

obeys

$$\begin{aligned} \text{Var}_{\theta, \theta_G}[L^{\mathcal{C}}(\theta, \theta_G)] \\ \geq \sum_{\alpha} c_{\alpha}^2 \left(\frac{\tau}{4}\right)^K = \Omega\left(\frac{1}{\text{poly}(n)}\right), \end{aligned}$$

where $\tau > 0$ depends only on the one-qubit operation op . Thus the loss does not concentrate exponentially, ruling out barren plateaus in the relevant variance sense.

We further prove parameter-level trainability. For any parameter θ_j located *after* the gadget layer, if it influences the loss then

$$\text{Var}_{\theta, \theta_G}[\partial_{\theta_j} L^{\mathcal{C}}(\theta, \theta_G)] \geq \Omega\left(\frac{1}{\text{poly}(n)}\right).$$

For any parameter θ_j located *before* the gadget layer, the MPQC retains at least the original trainability up to a polynomial factor:

$$\begin{aligned} \text{Var}_{\theta, \theta_G}[\partial_{\theta_j} L^{\mathcal{C}}(\theta, \theta_G)] \\ \geq \Omega\left(\frac{1}{\text{poly}(n)}\right) \text{Var}_{\theta}[\partial_{\theta_j} L(\theta)]. \end{aligned}$$

This corrects a common tradeoff in the literature: parameters before the gadget layer keep their useful gradients when they were already trainable, and the circuit need not be made shallow to obtain such guarantees.

3 Activation, robustness, and impact

A parameter before the gadget layer may nevertheless be nearly untrainable in the unmodified PQC. This is the situation addressed by Fig. 1(b): we introduce a targeted *activation* procedure. For any chosen original rotation $T = R_{P_T}(\theta_T)$, we locally enlarge one gadget inside the backward light cone of a relevant observable term, obtaining a T -activating MPQC. The resulting circuit satisfies

$$\text{Var}[\partial_{\theta_T} L(\theta)] \geq \Omega\left(\frac{1}{\text{poly}(n)}\right),$$

so an arbitrary target parameter can be made trainable without redesigning the entire ansatz. Operationally, the enlarged gadget in Fig. 1(b) is inserted locally in the backward light cone of the target gate, while all newly introduced parameters can be initialized to zero so that optimization continues from the same loss value.

The guarantees are robust to realistic local Pauli noise. If each original gate and gadget gate is followed by noise of strength $\gamma < 1/2$, then the lower bounds degrade only by a factor $(1 - 2\gamma)^{O(\log n)} = \Omega(1/\text{poly}(n))$. Therefore, the MPQC remains free from barren plateaus under these noise models.

Numerically, we benchmark MPQCs on thermal-state-preparation circuits and end-to-end ground-state-energy optimization tasks. Figure 1(c) summarizes the thermal-state-preparation benchmark: the original PQC exhibits exponential concentration of the loss and gradients, whereas the MPQC removes this decay and remains trainable in simulations up to 100 qubits and 2400 layers. In end-to-end variational experiments, MPQCs consistently outperform the corresponding PQCs, including cases where the original ansatz fails to train. Overall, the work provides a conceptually simple route to *simultaneously* improving trainability, preserving expressibility, and retaining the potential classical hardness of variational quantum circuits. Conceptually, the result separates two issues that are often conflated: barren-plateau avoidance does not have to come from restricting the accessible Hilbert space or from making the circuit shallow. Instead, the gadget layer injects non-vanishing signal into the backward propagation of observables while keeping the original hard-to-simulate forward computation embedded in the model.

Technical version

A full technical version with proofs, additional constructions, and numerical details is appended after this extended abstract in the single-file submission.

Quantum algorithms based on parameterized quantum circuits (PQCs) have enabled a wide range of applications on near-term quantum devices. However, existing PQC architectures face several challenges, among which the “barren plateaus” phenomenon is particularly prominent. In such cases, the loss function concentrates exponentially with increasing system size, thereby hindering effective parameter optimization. To address this challenge, we propose a general and hardware-efficient method for eliminating barren plateaus in an arbitrary PQC. Specifically, our approach achieves this by inserting a layer of easily implementable quantum channels into the original PQC, each channel requiring only one ancilla qubit and four additional gates, yielding a modified PQC (MPQC) that is provably at least as expressive as the original PQC and, under mild assumptions, is guaranteed to be free from barren plateaus. Furthermore, by appropriately adjusting the structure of MPQCs, we rigorously prove that any parameter in the original PQC can be made trainable. Importantly, the absence of barren plateaus in MPQCs is robust against realistic noise, making our approach directly applicable to near-term quantum hardware. Numerical simulations demonstrate that MPQC effectively eliminates barren plateaus in PQCs for preparing thermal states of systems with up to 100 qubits and 2400 layers. Furthermore, in end-to-end simulations, MPQC significantly outperforms PQC in finding the ground-state energy of a complex Hamiltonian.

Parameterized quantum circuits (PQCs) play a central role in a wide range of quantum algorithms, including those for quantum machine learning [1–5], quantum optimization [6–8] and quantum chemistry [9–11]. A typical application of PQCs is in the framework of variational quantum algorithms (VQAs) [12, 13]: one defines a class of PQCs (also referred to as ansatz), encodes the target problem into a loss function expressed as an observable expectation value measured on the outputs of the PQCs, and then iteratively updates the circuit parameters using a classical optimization algorithm to minimize the loss function. Parameter updates are often based on gradient information, which can be evaluated using the parameter shift rule [14, 15].

However, the optimization of many PQCs suffers from the problem known as “barren plateaus” [16–18], where the landscape of the loss function becomes exponentially concentrated. Mathematically, a PQC is said to exhibit a barren plateau if its loss function $L(\theta)$, with $\theta = (\theta_1, \theta_2, \dots)$, satisfies that for all θ , the variance of its partial derivative decays exponentially with the system size n , i.e.,

$$\text{Var}_{\theta} [\partial_{\theta_i} L(\theta)] \leq F(n), \quad \text{with} \quad F(n) \in \mathcal{O}\left(\frac{1}{b^n}\right),$$

where $b > 0$ is some constant. By Chebyshev’s inequality, $P_{\theta}(|\partial_{\theta_i} L(\theta)| \geq \epsilon) \leq \frac{\text{Var}_{\theta}[\partial_{\theta_i} L(\theta)]}{\epsilon^2} \leq \mathcal{O}\left(\frac{1}{\epsilon^2 b^n}\right)$. Thus,

the probability of encountering a nontrivial gradient decreases exponentially with system size. As a consequence, the designed PQC is not trainable.

To overcome this problem, various strategies have been proposed, such as the use of shallow circuits [18–22], correlated parameter initialization schemes [23–27], restrictions of the circuit dynamics to small Lie algebras [28–31], and non-unitary constructions [32–34]. However, most of these PQCs circumvent barren plateaus at the cost of expressibility—typically defined as the ability of a PQC to explore the Hilbert space [35–37]—or by embedding symmetries into the circuit architecture. Consequently, such barren-plateau-free constructions often make the circuit dynamics efficiently simulable on a classical computer [38, 39]. This situation naturally raises a fundamental question: can we design a class of PQCs that achieves high expressibility and trainability simultaneously, while remaining classically intractable?

In this work, we provide an affirmative answer to this question through the construction of *modified parameterized quantum circuits* (MPQCs), which incorporate trainable quantum channels—referred to as gadgets $\mathcal{G}(\theta)$ —into the original PQC, as illustrated in Fig. 1(a). Starting from an arbitrary PQC that may exhibit barren plateaus, an MPQC is constructed by inserting a layer of gadgets $\mathcal{G}(\theta)$ acting on each qubit. It turns out that the resulting circuit architecture is guaranteed to be at least as expressive as the original PQC. Moreover, we prove that classically simulating the MPQC is at least as hard as simulating the original PQC, in both the worst case and the average case, implying that typical MPQCs remain classically intractable.

Crucially, through rigorous analysis we prove that the

‡ weizhaohui@gmail.com

MPQC is free from barren plateaus when the gadget layer is properly configured. Furthermore, we show that the introduction of gadgets universally enhances the trainability of PQCs. Specifically, the gradient variance of parameters following the gadget layer is always lower bounded by $\Omega(1/\text{poly}(n))$, while for the remaining parameters, the gradient variance retains at least its original scaling. Given that some of the latter may remain untrainable, we introduce a practical strategy to activate them to be trainable, thereby enabling the optimization of all the parameters in the circuit (see Fig. 1(b)). Notably, we further prove that the trainability of MPQCs is robust to noise, meaning that they work well even in the presence of realistic noise.

We perform numerical simulations to demonstrate the effectiveness of our approach in eliminating barren plateaus. Using a specific PQC ansatz for thermal-state preparation [40–42], we estimate both the variance of the loss function and that of the gradient in both the original PQC and the MPQC via the Monte Carlo method [43]. The results show that our approach successfully eliminates barren plateaus even for circuits with up to 100 qubits and 2400 layers, in sharp contrast to the exponential gradient decay observed in the original PQC. Lastly, we emphasize that when applying MPQC to various variational quantum algorithms in an end-to-end fashion, we consistently observe improved performance compared with the original PQCs.

RESULTS

Modified Parameterized Quantum Circuits (MPQCs)

A PQC $\mathcal{C}(\boldsymbol{\theta}) = U_m(\theta_m) \cdots U_1(\theta_1)$ consists of a sequence of unitaries $U_i(\theta_i)$ parameterized by $\boldsymbol{\theta} = (\theta_1, \theta_2, \dots, \theta_m)$, where each $\theta_i \in [0, 2\pi)$ specifies a rotation angle and m denotes the number of parameters. In this work, each unitary $U_i(\theta_i)$ is taken to be a Pauli rotation of the form $e^{-i\frac{\theta_i}{2}P}$, where $P \in \{\mathbb{I}, X, Y, Z\}^{\otimes n}$ with n being the number of qubits, followed by a non-parameterized Clifford gate C_i . We do not impose any restriction on the form of the input state ρ of $\mathcal{C}(\boldsymbol{\theta})$, meaning that it can be a noisy or mixed state. In practice, ρ is typically chosen as the state $|0^n\rangle\langle 0^n|$. The parameters $\boldsymbol{\theta}$ are optimized by minimizing a loss function of the form $L(\boldsymbol{\theta}) = \text{tr}\{OC(\boldsymbol{\theta})\rho\mathcal{C}(\boldsymbol{\theta})^\dagger\}$ with O being an observable.

To mitigate barren plateaus, a gadget layer is inserted at a chosen position of the PQC (the location will be specified later). This layer consists of n gadgets and can be written as $\bigotimes_{i=1}^n \mathcal{G}_i(\boldsymbol{\theta}_{\mathcal{G}_i})$, where each gadget contains one single-qubit operation op and three two-qubit rotation gates, parameterized by $\boldsymbol{\theta}_{\mathcal{G}_i} = (\theta_{\mathcal{G}_{i,1}}, \theta_{\mathcal{G}_{i,2}}, \theta_{\mathcal{G}_{i,3}})$, as illustrated in Fig. 1(a). The single-qubit operation op can be any quantum operation that satisfies the following condition: there exists a constant $\tau > 0$ such that:

$$\text{tr}\{op(|0\rangle\langle 0|)P\}^2 \geq \tau, \quad \forall P \in \{X, Y, Z\}. \quad (1)$$

In Supplementary Information A, we present two constructions of op using single-qubit gates. The first is a fixed unitary gate that achieves the maximal value of τ , while the second introduces two parameterized single-qubit rotation gates, rendering op trainable.

It is straightforward to verify that the expressibility of an MPQC is at least as large as that of the original PQC. Let $\Phi^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ denote the channel corresponding to the MPQC obtained by augmenting $\mathcal{C}(\boldsymbol{\theta})$ with a gadget layer, where $\boldsymbol{\theta}_{\mathcal{G}} = (\boldsymbol{\theta}_{\mathcal{G}_1}, \boldsymbol{\theta}_{\mathcal{G}_2}, \dots, \boldsymbol{\theta}_{\mathcal{G}_n})$ collects the parameters of the n gadgets. For an arbitrary input state ρ , we have $\mathcal{C}(\boldsymbol{\theta})\rho\mathcal{C}^\dagger(\boldsymbol{\theta}) = \Phi^{\mathcal{C}}(\boldsymbol{\theta}, \mathbf{0})(\rho)$. Hence, the output state ensemble generated by $\mathcal{C}(\boldsymbol{\theta})$ is a subset of that generated by $\Phi^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$.

Absence of barren plateaus in MPQC

We now establish the following theorem, which demonstrates that introducing a gadget layer can eliminate barren plateaus in arbitrary PQCs, thereby restoring their trainability. The proof is sketched in *Methods*, with the full version deferred to Supplementary Information E.

Theorem 1. [informal] For an arbitrary $\mathcal{C}(\boldsymbol{\theta})$, if the corresponding MPQC $\Phi^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ satisfies the following conditions:

- The observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$ is local, i.e., O is the sum of Pauli words $\{P_{\alpha}\}_{\alpha}$ with each nontrivially acting on at most $\mathcal{O}(1)$ qubits.
- For each Pauli term P_{α} in O , the support size of its backward light cone at the gadget layer, i.e., the number of qubits in the layer whose perturbations can affect the measurement outcome of P_{α} , is upper bounded by $K = \mathcal{O}(\log n)$.

Then the variance of its loss function $L^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) := \text{tr}\{\Phi^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})(\rho)O\}$ admits the lower bound:

$$\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})} [L^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})] \geq \sum_{\alpha} c_{\alpha}^2 \left(\frac{\tau}{4}\right)^K = \Omega\left(\frac{1}{\text{poly}(n)}\right). \quad (2)$$

As a consequence, according to Ref. [44], Eq. (2) ensures the absence of barren plateaus in $\Phi^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$.

Later in this section, we will show that the support-size condition can be easily satisfied by appropriately placing the gadget layer. Although MPQCs are inherently free from barren plateaus, the trainability of individual parameters needs further investigation. Here, we address this issue by examining $\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})} \left[\frac{\partial L^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})}{\partial \theta_j} \right]$. The results are summarized in the following theorem, with a proof sketch provided in *Methods* and the full proof presented in Supplementary Information F.

Theorem 2. Consider an MPQC $\Phi^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ and a local observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$. If the support-size condition

Figure 1: (a) Structure of an MPQC, where a layer of gadgets $\mathcal{G}(\theta)$ (outlined by the red dashed box) is inserted into the original PQC $\mathcal{C}(\theta)$ (indicated by the light-blue region). Each gadget $\mathcal{G}(\theta)$ (highlighted in light purple) contains an ancilla qubit initialized in $|0\rangle$, one single-qubit unitary op , and three two-qubit rotation gates R_{XX} , R_{YY} , and R_{ZZ} . The symbol $\dashv|$ denotes the ancilla is discarded. (b) Structure of a T -activating MPQC. The gates denoted by “...” represent those in the original PQC located between T and the gadget layer. In this MPQC, we specifically enlarge the gadget $\mathcal{G}(\theta)$ acting on the same qubit as T , transforming it into $\mathcal{G}'_T(\theta)$. (c) Top: Ansatz circuit for thermal state preparation, where the number of blocks equals the number of qubits n . Bottom: Variance comparison between PQCs and MPQCs for thermal state preparation, where the MPQCs are formed by inserting a gadget layer before the final block. Yellow and blue curves show the cost-function variances of PQCs and MPQCs, respectively, estimated via the method in Ref. [43]. The blue curve is omitted for $n > 21$, as its values are extremely close to zero in this regime. The inset presents the gradient variance of parameters located after the gadget layer for $n = 20$.

in Theorem 1 holds, and for each P_α the segment of its backward light cone from P_α to the gadget layer contains at most $\mathcal{O}(\log n)$ parameters in gates, then $L^C(\theta, \theta_{\mathcal{G}})$ satisfies the following properties:

- For parameter θ_j located after the gadget layer, if $\text{Var}_{\theta} \left[\frac{\partial L^C(\theta)}{\partial \theta_j} \right] \neq 0$, then we have:

$$\text{Var}_{(\theta, \theta_{\mathcal{G}})} \left[\frac{\partial L^C(\theta, \theta_{\mathcal{G}})}{\partial \theta_j} \right] \geq \Omega \left(\frac{1}{\text{poly}(n)} \right). \quad (3)$$

- For parameter θ_j located before the gadget layer, there is:

$$\text{Var}_{(\theta, \theta_{\mathcal{G}})} \left[\frac{\partial L^C(\theta, \theta_{\mathcal{G}})}{\partial \theta_j} \right] \geq \Omega \left(\frac{1}{\text{poly}(n)} \right) \text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right]. \quad (4)$$

Theorem 2 implies that modifying an original PQC into an MPQC necessarily improves its trainability. Specifically, Eq. (3) guarantees the trainability of parameters located after the gadget layer, while Eq. (4) ensures that the resulting circuit is not effectively restricted to a shallow architecture: The parameters before the gadget layer remain trainable whenever they are trainable in the original PQC. Crucially, as demonstrated by our subsequent numerical simulations, MPQC significantly outperforms shallow circuits, indicating that these parameters continue to play an essential role during training.

To satisfy the conditions of Theorem 2, the placement of the gadget layer can be determined according to the

geometric structure of the circuit. In Supplementary Information G, we provide an explicit construction for a broad class of PQCs defined on (hyper)cubic lattices. As a specific example, for a one-dimensional brick-wall PQC, the gadget layer should be placed at a distance of order $\mathcal{O}((\log n)^{1/2})$ from the final measurement layer.

Strategy to activate untrainable parameters

Note that Theorem 2 does not guarantee that parameters located before the gadget layer have nonvanishing gradients. In the worst case, one may still encounter a single-qubit rotation gate $T = R_{P_T}(\theta_T)$ before the gadget layer whose gradient variance is nearly zero. To address this issue, we present a targeted procedure to “activate” T , which is a strategy that significantly increases the trainability of T .

As illustrated in Fig. 1(b), this is accomplished by inserting an additional gadget $\mathcal{G}(\theta)$ immediately before the target gate T and enlarging one gadget in the gadget layer through the following procedure: we first move the op operation of this gadget layer to the same layer as T , and then append three two-qubit parameterized rotation gates— R_{XX} , R_{YY} , and R_{ZZ} —immediately after op and T , thereby transforming it into a new type of gadget, denoted as $\mathcal{G}'_T(\theta)$. The position of the enlarged $\mathcal{G}(\theta)$ can be selected flexibly to suit physical implementation convenience. In fact, any $\mathcal{G}(\theta)$ located within the backward light cone of some Pauli term P_α in O qualifies as a valid candidate, as elaborated in Supplementary Infor-

mation H.

We refer to the resulting circuit as the T -activating MPQC. Let the corresponding quantum channel be $\Phi_T^C(\theta, \theta_G, \theta_{G'_T})$, where $\theta_{G'_T}$ collects the parameters in the enlarged gadget $\mathcal{G}'_T(\theta)$, and θ_G collects the parameters in all the $\mathcal{G}(\theta)$ gadgets, including the one inserted before T . We define its loss function as $L_T^C(\theta, \theta_G, \theta_{G'_T}) := \text{tr}\{\Phi_T^C(\theta, \theta_G, \theta_{G'_T})(\rho)O\}$. The following theorem guarantees that θ_T is trainable, and the proof is given in Supplementary Information H.

Theorem 3. *Consider a T -activating MPQC $\Phi_T^C(\theta, \theta_G, \theta_{G'_T})$, evaluated with respect to a local observable O . Suppose that the conditions stated in Theorem 2 hold. Let $T = R_{P_T}(\theta_T)$ denote the single-qubit rotation gate to be activated. Then, we have*

$$\text{Var}_{(\theta, \theta_G, \theta_{G'_T})} \left[\frac{\partial L_T^C(\theta, \theta_G, \theta_{G'_T})}{\partial \theta_T} \right] \geq \Omega \left(\frac{1}{\text{poly}(n)} \right). \quad (5)$$

In practice, Theorem 3 provides a strategy to adaptively modify the MPQC architecture, enabling the training of all the parameters in the circuit. The procedure can be implemented as follows. We first train the MPQC $\Phi^C(\theta, \theta_G)$ to minimize the loss function. As stated before, certain parameters before the gadget layer may remain untrainable. If such a parameter is identified, we can apply the activation strategy to make it trainable. Moreover, by initializing the newly introduced parameters in $\Phi_T^C(\theta, \theta_G, \theta_{G'_T})$ to zero, the loss function retains the same value as that of $\Phi^C(\theta, \theta_G)$. This enables us to further minimize the loss function. If multiple untrainable parameters are identified, the same activation procedure can be successively applied.

Furthermore, this strategy can naturally extend to multi-qubit rotation gate and multiple parameters: by inserting several $\mathcal{G}(\theta)$ and several gadgets of the form $\mathcal{G}'_T(\theta)$, multiple parameters can be simultaneously activated within a single MPQC. Details of the construction for this strategy and its application can be found in Supplementary Information I and Supplementary Information M, respectively.

Noise robustness

MPQCs and its variants still work well even in the presence of noise on quantum devices, making them an applicable tool for quantum machine learning in the NISQ era. This property is formalized in the following theorem, with the complete proof provided in Supplementary Information J.

Theorem 4 (informal). *Suppose the MPQC is subject to Pauli noise of strength at most $\gamma < 1/2$ after each $U_i(\theta_i)$ and every gate within the gadgets. Then, the lower bounds on the (gradient) variance of the loss function established in Theorems 1 to 3 deteriorate by at most a multiplicative factor of $(1 - 2\gamma)^{\mathcal{O}(\log n)} = \Omega \left(\frac{1}{\text{poly}(n)} \right)$.*

As a consequence of Theorem 4, the variance and the gradient variance of the loss function of the noisy MPQCs are still lower bounded by $\Omega \left(\frac{1}{\text{poly}(n)} \right)$, implying the merits hold for the MPQC even in the noisy setting. It is worth noting, however, that MPQCs (and, more generally, arbitrary PQCs) with a constant noise rate are classically simulable in an average sense [45]; that is, over the MPQC loss function landscape, outputs corresponding to most parameter settings are classically predictable. Nevertheless, some specific parameter configurations of noisy MPQCs may still retain quantum advantage, indicating their potential value for deployment on near-term quantum devices. Similar discussions can also be seen in Ref. [32].

Numerical simulations

We provide numerical evidence showing that MPQCs can effectively eliminate barren plateaus in PQCs. More importantly, we demonstrate that the MPQCs we construct for quite a few variational algorithms outperform the original PQCs significantly. These results highlight that MPQC is a promising approach for constructing trainable and expressive variational parameterized quantum circuits.

Evidence that MPQC Eliminates Barren Plateaus

We first conduct numerical experiments that compare the variances of the loss function and those of the parameter gradients between PQCs and MPQCs. The numerical study focuses on PQCs for thermal state preparation, a task known to be NP-hard [46]. We consider the 2-local transverse field Ising model

$$H_{\text{TFI}} = - \sum_{j=1}^n X_j X_{j+1} - h \sum_{j=1}^n Z_j \quad (6)$$

defined on a periodic 1D chain with system sizes ranging from $n = 10$ to 100 qubits, where h denotes the transverse-field strength controlling the relative weight of the single-qubit field term [47, 48], and is fixed to be $h = 1/2$ in this case. The circuits architecture is shown in Fig. 1(c). Following Ref. [49], which reports the small preparation errors when the number of blocks equals n , we set the number of blocks to be n . To eliminate the barren plateaus present in such a PQC, we construct an MPQC by inserting a gadget layer after the $(n - 1)$ -th block, followed by an additional block.

We employ the numerical method of Ref. [43], which offers efficient classical method to estimate both the variance and the gradient variance of the loss function of arbitrary PQCs, to compare the trainability of the PQC and that of the corresponding MPQC. As shown in Fig. 1(c), we first see that the variance of the loss function for the

Figure 2: Performance of PQC and MPQC in variational quantum algorithms. All results are obtained from ten independent random parameter initializations. Shaded regions indicate the min-max envelope of the loss across different initializations, and lines represent the corresponding mean values. (a) Variational training of a poorly designed PQC and the corresponding MPQC for H_{TFI} with $h = 0.01$ and $h = 0.5$. In both cases, MPQC converges to the ground energy, whereas the original PQC fails. (b) Left: Performance of two-dimensional PQCs with different numbers of repeated blocks in approximating the ground-state energy of H_G . As the number of blocks increases, the lowest achievable energy first decreases and then increases. Right: Comparison between the best-performing PQC in the left plot and the corresponding MPQC. During the first 2000 epochs, MPQC is trained without activation, followed by 1000 epochs with activation, where newly introduced parameters are initialized to zero. The final energy achieved by MPQC is lower than that of the best-performing PQC by 0.39.

original PQC (blue curve) decreases rapidly as the number of qubits increases. Our numerical results show that it becomes negligibly small when $n > 21$, indicating the onset of barren plateaus. In stark contrast, the variance of the loss function for the MPQC (yellow curve) remains stable (approximately 1) and even exhibits a slight increase with the number of qubits. This behavior demonstrates that the MPQC effectively avoids barren plateaus and preserves trainability across increasing system sizes in this case.

Furthermore, for $n = 20$, we evaluate the gradient variances of the gradients associated with the parameters located after the gadget layer. The results are shown in the inset of Fig. 1(c), where all the red points corresponding to the MPQC have gradient variances of the order of 10^{-2} , whereas the blue points for the original PQC fall below 10^{-4} . Collectively, these numerical results provide strong evidence that MPQCs are highly effective in enhancing the trainability of PQCs.

Evidence that MPQC outperforms original PQC in variational algorithms

We next demonstrate, through comprehensive numerical simulations across all stages, that MPQC can substantially improve the performance of PQCs in variational quantum algorithms. Owing to the limitations of classical numerical simulation and the additional ancilla qubits required by MPQC, our simulations are restricted to systems of up to 24 qubits. At these system sizes, gradients that vanish exponentially with the number of qubits may not yet be extremely small. Nevertheless, even for medium-size PQCs, the cost-function gradient can still be close to zero when the ansatz is poorly

designed, which leads to severe training difficulties and gives us chance to test the performance of MPQC.

For this, we first construct a deliberately unfavorable ansatz to approximate the ground-state energy of the Hamiltonian in Eq. (6). For this ansatz, the corresponding PQC becomes untrainable when the transverse field strength h is close to zero. By inserting a gadget layer into the circuit, we obtain the corresponding MPQC. In this example, we let $n = 6$ (the number of qubits) and consider two representative values of h , which are $h = 0.01$ and $h = 0.5$. Details of the circuit construction and the training procedure are provided in Supplementary Information M.

As shown in Fig. 2(a), when $h = 0.01$, even the shallow PQC cannot be trained properly, indicating the presence of vanishing gradients. Moreover, increasing the field strength to $h = 0.5$ does not resolve this issue: the poorly designed PQC still fails to converge to the ground-state energy, as illustrated by the blue and orange curves. In contrast, for the both values of h , MPQC consistently converges to the exact ground-state energy up to a small error of 0.01. These results demonstrate that MPQC remains effective even when the underlying ansatz is improperly designed.

To provide further evidence that MPQC can outperform the original PQC, we next consider the task of approximating the ground-state energy of a more complex Hamiltonian H_G discussed in [50], which is QMA-complete. Here, G specifies the underlying geometry of the Hamiltonian. To generate the ground state, we construct a family of two-dimensional ansätze on 12 qubits, composed of repeated circuit blocks, with the number of blocks ranging from 1 to 8. The corresponding MPQC is constructed by inserting a gadget layer after the fourth block of the PQC consisting of eight blocks. In addition,

we employ the activation strategy to further enhance the performance of MPQC, which doubles the qubit number. For a fair comparison, all the PQCs are trained for 3000 epochs, and the MPQC is trained for 2000 epochs without activations, followed by 1000 more epochs with activations, resulting in the same total number of optimization steps. Details on the Hamiltonian H_G , the two-dimensional PQC ansatz, the construction of MPQC, and the training process are provided in Supplementary Information M.

As shown in the left panel of Fig. 2(b), the final energy obtained by the original PQC initially decreases as the number of blocks increases, reflecting the improved expressibility of deeper circuits. However, when the number of blocks exceeds five, the performance deteriorates, indicating the onset of severe trainability issue.

As a sharp comparison, the right panel of Fig. 2(b) shows that the MPQC addresses the trainability issue very well and significantly outperforms the original PQC at all depths considered here. Moreover, its loss function decreases more rapidly and reaches much lower values than those achieved by the best-performing PQC (with five blocks). We further observe that the activation strategy enables additional optimization progress: without activation, the MPQC loss remains nearly constant after approximately 2000 training epochs, whereas activating additional parameters allows the loss function to decrease further.

CONCLUSIONS AND DISCUSSIONS

In this work, we have introduced a novel, easily implementable, and universal strategy to improve the trainability of an arbitrary PQC. By inserting a layer of gadgets, we transform the PQC into an MPQC that is at least as expressive as the original PQC and, importantly, is provably free of barren plateaus. We further analyze the trainability of parameters in the MPQC, showing that our construction consistently enhances trainability: parameters following the gadget layer are guaranteed to be trainable, whereas the others retain the same learning behavior as in the original PQC. Moreover, we further propose a targeted strategy to render these remaining parameters trainable, ensuring that all the parameters can be effectively optimized.

The improvement in trainability brought by constructing MPQCs is supported by our numerical experiments. Focusing on a PQC for thermal state preparation, we find that barren plateaus are absent in the MPQC even for deep circuits with up to 100 qubits and 2400 layers, whereas the original PQC becomes untrainable when the system size reaches 20 qubits. Furthermore, by end-to-end numerical simulations we show that MPQC can substantially enhance the performance of the original PQC in variational quantum algorithms. In particular, in some cases we see that MPQC is able to converge to the optimal solution even when the corresponding PQC cannot

be trained at all.

Our theoretical analysis and numerical verifications position MPQCs as a promising circuit architecture for PQC-based quantum algorithms. However, several interesting questions remain. First, we have shown that the set of the output state of an MPQC subsumes that of the original PQC, implying that classical simulation of the MPQC is at least as hard as that of the original PQC. Actually, we have also theoretically demonstrated that the average-case classical simulation of the MPQC leads to that of the original PQC (see Supplementary Information L for details). These results may shed new light on the relationship between average-case classical simulation complexity and barren plateaus, as recently discussed in Ref. [38]. Second, as highlighted in Ref. [32], the absence of barren plateaus alone does not guarantee that a quantum algorithm will converge to the optimal solution, since the loss landscape can still exhibit significant complexity. In future work, we will investigate the internal mechanisms of MPQCs to examine their effects on the loss function landscape, with the aim of understanding the convergence behavior of training MPQCs.

METHODS

Theoretical Framework for Variance Analysis

The variance of the loss function and that of the gradient can be expressed as:

$$\begin{aligned} \text{Var}_{\theta} [L(\theta)] &= \mathbb{E}_{\theta} [L(\theta)^2] - (\mathbb{E}_{\theta} [L(\theta)])^2 \\ \text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] &= \mathbb{E}_{\theta} \left[\left(\frac{\partial L(\theta)}{\partial \theta_j} \right)^2 \right] - \left(\mathbb{E}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] \right)^2, \end{aligned} \quad (7)$$

where each θ_i is sampled uniformly from $[0, 2\pi)$. Writing P_{α} as the Pauli expansion of the observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$, the loss function can be expressed in the Pauli path integral formalism [45, 51–53]:

$$\begin{aligned} L(\theta) &= \langle O \rangle \\ &= \sum_{\alpha, \vec{s}} c_{\alpha} \text{tr}\{P_{\alpha} s_m\} \text{tr}\{s_0 \rho\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^{\dagger}\} \\ &= \sum_{\alpha, \vec{s}} c_{\alpha} f(\vec{s}, \theta, P_{\alpha}, \rho), \end{aligned} \quad (8)$$

where $\vec{s} = (s_0, s_1, \dots, s_m)$ is a Pauli path, which is a sequence of normalized Pauli operators $s_i \in \{\frac{\mathbb{I}}{\sqrt{2}}, \frac{X}{\sqrt{2}}, \frac{Y}{\sqrt{2}}, \frac{Z}{\sqrt{2}}\}^{\otimes n}$, and $f(\vec{s}, \theta, P_{\alpha}, \rho) := \text{tr}\{P_{\alpha} s_m\} \text{tr}\{s_0 \rho\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^{\dagger}\}$ denotes the contribution of a specific Pauli path $\vec{s}$ to the expectation value $\langle O \rangle$.

As shown in Refs. [43, 54, 55], when calculating the two quantities in Eq. (7), the uniform distribution over $[0, 2\pi)$ can be replaced by a discrete uniform distribution over the set $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$. In particular, when the rotation angles satisfy $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$, each

$U_i(\theta_i)$ belongs to the Clifford group. Consequently, for any fixed s_i , there exists a unique s_{i-1} such that $\text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^\dagger\} \neq 0$. Therefore, starting from $s_m \propto P_\alpha$, there exists a unique Pauli path $\vec{s}^{(\theta, \alpha)}$ satisfying $\text{tr}\{P_\alpha s_m\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^\dagger\} \neq 0$.

Using the above expression, and assuming the PQC architecture satisfies a mild structural condition (shown in Ref. [45] to be met by most PQCs and also holding for arbitrary MPQCs), we can express the variance of the loss function and that of its gradient in a simplified form.

Lemma 1. *Let $O = \sum_\alpha c_\alpha P_\alpha$ be an observable, and $C(\theta)$ be a PQC with parameters $\theta \in [0, 2\pi)^m$. Suppose the following orthogonality condition holds:*

$$\mathbb{E}_\theta [f(\vec{s}, \theta, P_\alpha, \rho) f(\vec{s}', \theta, P_\beta, \rho)] = 0, \quad \forall \alpha \neq \beta, \vec{s}, \vec{s}', \quad (9)$$

and each $\langle P_\alpha \rangle$ is not a non-zero constant function of θ . Then the variance of the loss function and the variance of its gradient can be expressed as:

$$\text{Var}_\theta [L(\theta)] = \frac{1}{4^m} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_\alpha c_\alpha^2 f(\vec{s}^{(\theta, \alpha)}, \theta, P_\alpha, \rho)^2 \quad (10)$$

$$\text{Var}_\theta \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] = \frac{1}{4^m} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \{P_j, s_j^{(\theta, \alpha)}\} = 0}} \sum_\alpha c_\alpha^2 f(\vec{s}^{(\theta, \alpha)}, \theta, P_\alpha, \rho)^2, \quad (11)$$

where P_j denotes the Pauli operator in the elementary rotation $e^{-i\frac{\theta_j}{2} P_j}$ of the circuit, and $\vec{s}^{(\theta, \alpha)}$ is the unique normalized Pauli operator sequence such that $\text{tr}\{P_\alpha s_m\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^\dagger\} \neq 0$.

Notably, it can be observed that $\text{Var}_\theta \left[\frac{\partial L(\theta)}{\partial \theta_j} \right]$ corresponds to a subset of the terms in $\text{Var}_\theta [L(\theta)]$, which allows us to analyze their scaling using the same techniques. The detailed proof of Lemma 1 is provided in Supplementary Information C.

Moreover, as shown in the proof provided in Supplementary Information D, both Eq. (9) and non-constant condition hold for arbitrary MPQCs, thereby enabling the application of Lemma 1 in our analysis.

The above lemma shows that, to analyze the properties of the gradient of the MPQC loss function, it suffices to restrict parameters (θ, θ_G) to the discrete set $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{m+3n}$. Moreover, owing to the special structure of the MPQC, the cross terms of the variance vanish. Namely, for any $\alpha \neq \beta$ we have

$$\mathbb{E}_{(\theta, \theta_G)} \text{tr}\{P_\alpha \Phi^C(\theta, \theta_G)\} \text{tr}\{P_\beta \Phi^C(\theta, \theta_G)\} = 0.$$

This implies that sign ambiguities do not arise in the variance analysis. Consequently, in the Pauli path integral framework, one can focus on operator evolution without being affected by sign issues.

Proof sketch of Theorem 1

Proof Sketch. The proof consists of two parts. First, we present how the gadget affects the backward propagation of Pauli operators. We begin by extending the MPQC to a $2n$ -qubit unitary, where the first n qubits are ancillas and the remaining n qubits correspond to the original system. Since the ancilla qubits in the gadgets are never measured, any Pauli operator that back-propagates to a gadget has the form $I \otimes P$.

We then analyze how the three two-qubit rotation gates in the gadget, with angles restricted to $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$, transform $I \otimes P$ into other Pauli operators, denoted by P_1 . Among the $4^3 = 64$ possible angle configurations, the outcomes are:

- If $P = I$, then $P_1 = I \otimes I$ for all 64 choices of parameter configurations.
- If $P \neq I$, the backward operator becomes

$$P_1 = \begin{cases} P \otimes I, & \text{for 16 parameter configurations,} \\ I \otimes P, & \text{for 16 parameter configurations,} \\ Q_1 \otimes Q_2, & \text{for 16 parameter configurations,} \\ Q_2 \otimes Q_1, & \text{for 16 parameter configurations,} \end{cases} \quad (12)$$

where $\{Q_1, Q_2, P\}$ equals $\{X, Y, Z\}$.

As shown in the first case of Eq. (12), for any $I \otimes P$ ($P \neq I$) propagating backward into a gadget $\mathcal{G}(\theta_{\mathcal{G}_i})$, there exist 16 angle choices $\theta_{\mathcal{G}_i}$ that swap the non-trivial Pauli from the system qubit to the ancilla. By assumption in Eq. (1), this yields an ancilla contribution of at least τ .

Next we lower bound $\text{Var}_{(\theta, \theta_G)} [L^C(\theta, \theta_G)]$ via Eq. (10), by taking a partial sum over discrete angles $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ and $\theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}$. If the backward light cone of arbitrary Pauli word P_α in O at the gadget layer has size at most $K = \mathcal{O}(\text{poly}(\log n))$, the number of θ_G such that the first case of Eq. (12) holds is at least $16^K 64^{n-K}$. In these cases, the remaining operators on the system qubits are all I , so these terms survive, since $\text{tr}\{I\rho\} = 1$, for arbitrary input state ρ and for arbitrary $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$. Evaluating these terms gives the lower bound for $\text{Var}_\theta [L^C(\theta, \theta_G)]$:

$$\begin{aligned} & \sum_\alpha \frac{c_\alpha^2}{4^{m+3n}} 16^K 64^{n-K} 4^m \tau^K \\ &= \sum_\alpha c_\alpha^2 \left(\frac{\tau}{4}\right)^K = \Omega\left(\frac{1}{\text{poly}(n)}\right). \end{aligned} \quad (13)$$

□

Proof sketch of Theorem 2

Proof Sketch. For a parameter θ_j located after the gadget layer, Eq. (11) implies that the summation retains only

those angle configurations satisfying $\{P_j, s_j^{(\theta, \alpha)}\} = 0$. Since $\text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] \neq 0$, There must exist a P_β contained in O and a specific $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that $\{P_j, s_j^{(\theta, \beta)}\} = 0$ holds.

Denote by $f_{j,O}^c$ the number of parameters that may influence $s_j^{(\theta, \beta)}$. It is straightforward to observe that $f_{j,O}^c = \mathcal{O}(\log n)$. By selecting gate angles such that $\{P_j, s_j^{(\theta, \beta)}\} = 0$ holds, and choosing $\theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}$ to ensure that the first case in Eq. (12) holds, we guarantee that the corresponding term in the summation does not vanish. Consequently, we obtain the lower bound for Eq. (11) as

$$\begin{aligned} & \frac{c_\beta^2}{4^{m+3n}} 16^K 64^{n-K} 4^{m-f_{j,O}^c} 2^{f_{j,O}^c} \tau^K \\ &= c_\beta^2 \left(\frac{1}{2}\right)^{f_{j,O}^c} \left(\frac{\tau}{4}\right)^K = \Omega\left(\frac{1}{\text{poly}(n)}\right). \end{aligned} \quad (14)$$

For parameters located before the gadget layer, one can instead choose another set of angles θ_G to guarantee that the second case in Eq. (12) holds, in which these angle configurations do not alter the back-propagation of the Pauli operator. Similarly, for any given θ , there exist at least $16^K 64^{n-K}$ angle configurations of θ_G such that the above condition holds. Under this choice, the contributions of such terms in Eq. (11) remain unchanged,

leading to the following lower bound:

$$\begin{aligned} & \frac{16^K 64^{n-K}}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \{P_j, s_j^{(\theta, \alpha)}\} = 0}} \sum_{\alpha} c_\alpha^2 f(\bar{s}^{(\theta, \alpha)}, \theta, P_\alpha, \rho)^2 \\ &= \left(\frac{1}{4}\right)^K \sum_{\alpha} c_\alpha^2 f(\bar{s}^{(\theta, \alpha)}, \theta, P_\alpha, \rho)^2 \\ &\geq \Omega\left(\frac{1}{\text{poly}(n)}\right) \text{Var} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right]. \quad \square \end{aligned}$$

Supplementary Information A: Circuit architectures

1. Parameterized quantum circuit (PQC)

A typical n -qubit PQC, denoted as $\mathcal{C}(\theta)$, consists of a sequence of Pauli rotation gates and non-parameterized Clifford gates. The Pauli rotation gates are represented as $e^{-i\frac{\theta}{2}P}$, where $P \in \{\mathbb{I}, X, Y, Z\}^{\otimes n}$. The Clifford gates are the unitary operators that normalize the Pauli group $Cl_n := \{C \in U_{2^n} \mid C\mathcal{P}_n C^\dagger = \mathcal{P}_n\}$, where $\mathcal{P}_n$ is the Pauli group on n qubits. Any unitary operator $U \in Cl_n$ is equivalent to a circuit generated using Hadamard, CNOT, and phase gates S [56].

Without loss of generality, we assume that PQCs follow the form:

$$\mathcal{C}(\theta) = U_m(\theta_m) \cdots U_1(\theta_1), \quad (\text{A1})$$

where $\theta = (\theta_1, \dots, \theta_m)$ are rotation angles and m is the number of the parameters. Each unitary $U_i(\theta_i) := R_{P_i}(\theta_i)C_i$ comprises a Clifford operator C_i and a rotation $R_{P_i}(\theta_i) := \exp(-i\frac{\theta_i}{2}P_i)$ on Pauli operator $P_i \in \{\mathbb{I}, X, Y, Z\}^{\otimes n}$ with angle θ_i .

In this context, the quantum circuit $\mathcal{C}(\theta)$ is applied to an initial state ρ , and what we are interested in is the expectation value of an observable O , which is given by

$$\langle O \rangle = \text{tr}\{O\mathcal{C}(\theta)\rho\mathcal{C}(\theta)^\dagger\}. \quad (\text{A2})$$

Without loss of generality, we assume that the observable is traceless, i.e., $\text{tr}\{O\} = 0$, otherwise we can replace O with $O - \frac{\text{tr}\{O\}}{2^n}I$.

Moreover, we restrict the number of Pauli words constituting the observable O is $\mathcal{O}(\text{poly}(n))$, since measuring an exponential number of expectation values is experimentally infeasible. This assumption is satisfied for a wide range of variational quantum algorithms (VQAs), such as the Variational Quantum Eigensolver (VQE) [57] and the Quantum Approximate Optimization Algorithm (QAOA) [58]. Consequently, for $O = \sum_\alpha c_\alpha P_\alpha$, we have

$$\sum_\alpha c_\alpha^2 \leq \max_\alpha \{c_\alpha^2\} \sum_\alpha 1 = \mathcal{O}(\text{poly}(n)). \quad (\text{A3})$$

2. Modified parameterized quantum circuit (MPQC)

By introducing some gadgets to any PQC in form of (A1), we obtain a corresponding modified parameterized quantum circuit (MPQC). A schematic illustration of the MPQC is shown in Fig. A.3.

Figure A.3: An example of an MPQC, where gadgets $\mathcal{G}(\theta)$ drawn in purple are inserted into the original PQC. The gadget contains an ancilla qubit $|0\rangle$, one single qubit gate op and three 2-qubit rotation gates R_{XX}, R_{YY}, R_{ZZ} .

In Fig. A.3, the single qubit gate op in gadget $\mathcal{G}(\theta)$ satisfies the following condition:

$$\min \left\{ \text{tr}\{op(|0\rangle\langle 0|)X\}^2, \text{tr}\{op(|0\rangle\langle 0|)Y\}^2, \text{tr}\{op(|0\rangle\langle 0|)Z\}^2 \right\} = \tau > 0. \quad (\text{A4})$$

In the next subsection, we present a construction of op such that Eq. (A4) holds with maximum τ when op is a unitary. Moreover, we provide an alternative construction that keeps op trainable. It is easy to see inserting $\mathcal{G}(\theta)$ to the original PQC will not decrease expressibility, because if the rotation angles in these three 2-qubit gates equal 0, the PQC in Fig. A.3 is exactly the original PQC.

We assume that all gadgets $\mathcal{G}(\boldsymbol{\theta})$ are inserted after the l -th layer of the original circuit, as illustrated in Fig. A.4. Also for further simplify the proof, we restrict that the gadget layer is placed after the L -th block of the PQC, i.e.:

$$\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) = \mathcal{U}_m(\theta_m) \circ \mathcal{U}_{m-1}(\theta_{m-1}) \cdots \circ \mathcal{U}_{L+1}(\theta_{L+1}) \circ \bigotimes_{i=1}^n \mathcal{G}_i(\boldsymbol{\theta}_{G_i}) \circ \mathcal{U}_L(\theta_L) \cdots \circ \mathcal{U}_1(\theta_1), \quad (\text{A5})$$

where $\mathcal{U}_i(\theta_i)$ is the channel representation corresponding to the unitary operation $U_i(\theta_i)$, each gadget is parameterized by three angles $\boldsymbol{\theta}_{G_i} = (\theta_{G_{i,1}}, \theta_{G_{i,2}}, \theta_{G_{i,3}})$, and “ $\circ$ ” denotes the composition of quantum channels.

Figure A.4: One construction of the MPQC: all gadgets $\mathcal{G}(\boldsymbol{\theta})$ are inserted in parallel after the l -th layer of the original circuit.

3. Constructions of op

We now present two constructions of op . The first achieves the maximal value of τ using a single unitary gate. The second employs two parameterized single-qubit Pauli rotation gates, offering a hardware-efficient implementation compatible with current quantum devices.

a. Single qubit unitary Suppose op is a unitary gate U such that

$$U|0\rangle = \cos\psi|0\rangle + \sin\psi e^{i\phi}|1\rangle.$$

Then we have

$$\begin{aligned} \text{tr}\{U(|0\rangle\langle 0|)U^\dagger X\}^2 &= (\cos\psi \sin\psi)^2 (e^{i\phi} + e^{-i\phi})^2 = \sin^2 2\psi (\text{real}(e^{i\phi}))^2 \\ \text{tr}\{U(|0\rangle\langle 0|)U^\dagger Y\}^2 &= (\cos\psi \sin\psi)^2 (ie^{i\phi} - ie^{-i\phi})^2 = \sin^2 2\psi (\text{Im}(e^{i\phi}))^2 \\ \text{tr}\{U(|0\rangle\langle 0|)U^\dagger Z\}^2 &= (\cos^2\psi - \sin^2\psi)^2 = \cos^2 2\psi \\ \tau &= \min\{\sin^2 2\psi (\text{real}(e^{i\phi}))^2, \sin^2 2\psi (\text{Im}(e^{i\phi}))^2, \cos^2 2\psi\}. \end{aligned} \quad (\text{A6})$$

It is straightforward to verify that when $2\psi = \arcsin \sqrt{2/3}$ and $\phi = \pi/4$, the value of τ attains its maximum of $1/3$.

b. Trainable construction We can further allow op to be trainable. Here, we provide a construction that employs two additional parameterized single-qubit rotation gates, in which op is defined as follows:

Figure A.5: Trainable construction of op , in which we allow parameters θ_1 and θ_2 to be trainable.

In Appendix K, we further show that the favorable properties of MPQCs still hold when op is trainable. In the proofs of the main theorems, we assume that the condition in Eq. (A4) holds.

Supplementary Information B: Technical preliminaries

In this section, we introduce the mathematical tools used to analyze the variance and gradient variance of parameterized quantum circuits.

1. 2-design of parameterized rotation gates

Let $R_P(\theta) = \exp(-i\frac{\theta}{2}P) = \cos(\frac{\theta}{2})\mathbb{I} - i\sin(\frac{\theta}{2})P$, it is not hard to see that the set $\{R_P(\theta)\}_{\theta \in [0, 2\pi)}$ forms a group, which is a subgroup of the n -qubit unitary group $\mathbb{U}(2^n)$. Similar to unitary t -design, here we consider the t -design over the group $\{R_P(\theta)\}_{\theta \in [0, 2\pi)}$, which we call the *quantum rotation t -design*.

Definition A.1. A set of unitary matrices $\{A_i\}_{i=1}^K$ is called a quantum rotation t -design with respect to $R_P(\theta)$, if

$$\frac{1}{K} \sum_{i=1}^K (A_i \otimes A_i^\dagger)^{\otimes t} = \frac{1}{2\pi} \int_0^{2\pi} (R_P(\theta) \otimes R_P(-\theta))^{\otimes t} d\theta. \quad (\text{B1})$$

We now prove that the following gate set forms a quantum rotation 2-design.

Theorem A.5. $\{R_P(\theta)\}_{\theta=0, \pi/2, \pi, 3\pi/2}$ is a quantum rotation 2-design with respect to $\{R_P(\theta)\}_{\theta \in [0, 2\pi)}$.

Proof. Utilizing the relations

$$\begin{aligned} \frac{1}{2\pi} \int_0^{2\pi} \cos^4 \frac{\theta}{2} d\theta &= \frac{1}{2\pi} \int_0^{2\pi} \sin^4 \frac{\theta}{2} d\theta = \frac{3}{8}, \\ \frac{1}{2\pi} \int_0^{2\pi} \cos \frac{\theta}{2} \sin^3 \frac{\theta}{2} d\theta &= \frac{1}{2\pi} \int_0^{2\pi} \cos^3 \frac{\theta}{2} \sin \frac{\theta}{2} d\theta = 0, \\ \frac{1}{2\pi} \int_0^{2\pi} \cos^2 \frac{\theta}{2} \sin^2 \frac{\theta}{2} d\theta &= \frac{1}{8}, \end{aligned}$$

we have

$$\begin{aligned} & \frac{1}{2\pi} \int_0^{2\pi} R_P(\theta)^{\otimes 2} \otimes R_P(-\theta)^{\otimes 2} d\theta \\ &= \sum_{i_1, \dots, i_4=0}^1 \frac{1}{2\pi} \int_0^{2\pi} i^{-i_1-i_2+i_3+i_4} \left(\cos \frac{\theta}{2}\right)^{4-\sum_j i_j} \left(\sin \frac{\theta}{2}\right)^{\sum_j i_j} \times \left(\bigotimes_{j=1}^4 P^{i_j}\right) d\theta \\ &= \frac{3}{8} I^{\otimes 4} + \frac{3}{8} P^{\otimes 4} + \frac{1}{8} \sum_{\substack{i_1, \dots, i_4=0 \\ i_1+\dots+i_4=2}}^1 i^{-i_1-i_2+i_3+i_4} \bigotimes_{j=1}^4 P^{i_j}. \end{aligned}$$

Meanwhile, it can be verified that

$$\begin{aligned} & \frac{1}{4} \sum_{k=0}^3 R_P\left(\frac{k\pi}{2}\right)^{\otimes 2} \otimes R_P\left(\frac{-k\pi}{2}\right)^{\otimes 2} \\ &= \frac{1}{4} \left(1 + \frac{1}{4} + \frac{1}{4}\right) I^{\otimes 4} + \frac{1}{4} \left(1 + \frac{1}{4} + \frac{1}{4}\right) P^{\otimes 4} + \frac{1}{4} \left(\frac{1}{4} + \frac{1}{4}\right) \sum_{\substack{i_1, \dots, i_4=0 \\ i_1+\dots+i_4=2}}^1 i^{-i_1-i_2+i_3+i_4} \bigotimes_{j=1}^4 P^{i_j} \\ &= \frac{3}{8} I^{\otimes 4} + \frac{3}{8} P^{\otimes 4} + \frac{1}{8} \sum_{\substack{i_1, \dots, i_4=0 \\ i_1+\dots+i_4=2}}^1 i^{-i_1-i_2+i_3+i_4} \bigotimes_{j=1}^4 P^{i_j}, \end{aligned}$$

which concludes the proof. $\square$

Thus for arbitrary operators A, B, C, D , we have the following corollary:

Corollary A.1. For any n -qubit operators A, B, C, D , the following equation holds:

$$\mathbb{E}_\theta \text{tr}\{AR_P(\theta)BR_P(-\theta)\} \text{tr}\{CR_P(\theta)DR_P(-\theta)\} = \frac{1}{4} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}} \text{tr}\{AR_P(\theta)BR_P(-\theta)\} \text{tr}\{CR_P(\theta)DR_P(-\theta)\}. \quad (\text{B2})$$

Proof. The proof is straightforward by using the definition of the quantum rotation 2-design in Eq. (B1) and the fact of Thm. A.5, we have:

$$\mathbb{E}_\theta R_P(\theta) \otimes R_P(-\theta) \otimes R_P(\theta) \otimes R_P(-\theta) = \frac{1}{4} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}} R_P(\theta) \otimes R_P(-\theta) \otimes R_P(\theta) \otimes R_P(-\theta). \quad (\text{B3})$$

The left-hand side of Eq. (B2) can be expressed as:

$$\begin{aligned} & \mathbb{E}_\theta \text{tr}\{AR_P(\theta)BR_P(-\theta)\} \text{tr}\{CR_P(\theta)DR_P(-\theta)\} \\ &= \mathbb{E}_\theta \left(\sum_{i,j} \langle i | AR_P(\theta)B | j \rangle \langle j | R_P(-\theta) | i \rangle \right) \left(\sum_{k,l} \langle k | CR_P(\theta)D | l \rangle \langle l | R_P(-\theta) | k \rangle \right) \\ &= \mathbb{E}_\theta \left(\sum_{i,j} \langle i | \otimes \langle j | \cdot (AR_P(\theta)B) \otimes R_P(-\theta) \cdot | j \rangle \otimes | i \rangle \right) \left(\sum_{k,l} \langle k | \otimes \langle l | \cdot (CR_P(\theta)D) \otimes R_P(-\theta) \cdot | l \rangle \otimes | k \rangle \right) \\ &= \mathbb{E}_\theta \left(\sum_{i,j,k,l} \langle i | \otimes \langle j | \otimes \langle k | \otimes \langle l | \cdot (AR_P(\theta)B) \otimes R_P(-\theta) \otimes (CR_P(\theta)D) \otimes R_P(-\theta) \cdot | j \rangle \otimes | i \rangle \otimes | l \rangle \otimes | k \rangle \right) \\ &= \mathbb{E}_\theta \left(\sum_{i,j,k,l} \langle i | A \otimes \langle j | \otimes \langle k | C \otimes \langle l | \cdot R_P(\theta) \otimes R_P(-\theta) \otimes R_P(\theta) \otimes R_P(-\theta) \cdot B | j \rangle \otimes | i \rangle \otimes D | l \rangle \otimes | k \rangle \right) \quad (\text{B4}) \\ &= \sum_{i,j,k,l} \langle i | A \otimes \langle j | \otimes \langle k | C \otimes \langle l | \cdot \mathbb{E}_\theta (R_P(\theta) \otimes R_P(-\theta) \otimes R_P(\theta) \otimes R_P(-\theta)) \cdot B | j \rangle \otimes | i \rangle \otimes D | l \rangle \otimes | k \rangle \\ &= \sum_{i,j,k,l} \langle i | A \otimes \langle j | \otimes \langle k | \cdot \frac{1}{4} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}} (C \otimes \langle k | R_P(\theta) \otimes R_P(-\theta) \otimes R_P(\theta) \otimes R_P(-\theta)) \cdot B | j \rangle \otimes | i \rangle \otimes D | l \rangle \otimes | k \rangle \\ &= \frac{1}{4} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}} \left(\sum_{i,j} \langle i | AR_P(\theta)B | j \rangle \langle j | R_P(-\theta) | i \rangle \right) \left(\sum_{k,l} \langle k | CR_P(\theta)D | l \rangle \langle l | R_P(-\theta) | k \rangle \right) \\ &= \frac{1}{4} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}} \text{tr}\{AR_P(\theta)BR_P(-\theta)\} \text{tr}\{CR_P(\theta)DR_P(-\theta)\}. \end{aligned}$$

□

2. Pauli path integral

A Pauli path is a sequence $\vec{s} = (s_0, \dots, s_m) \in \mathbf{P}_n^{m+1}$, where $\mathbf{P}_n = \{\mathbb{I}/\sqrt{2}, X/\sqrt{2}, Y/\sqrt{2}, Z/\sqrt{2}\}^{\otimes n}$ represents the set of all normalized n -qubit Pauli words. Using the fact that the normalized n -qubit Pauli group $\mathbf{P}_n$ forms a basis of the 2^n -dimensional Hilbert space, we can express any operator A as a linear combination of elements in $\mathbf{P}_n$:

$$A = \sum_{s \in \mathbf{P}_n} \text{tr}\{As\} s, \quad (\text{B5})$$

Iteratively applying the Pauli operator decomposition, we can express the expectation value of O as the sum of contributions from all Pauli paths:

$$\begin{aligned}
\langle O \rangle &= \sum_{s_m} \text{tr}\{O s_m\} \text{tr}\{s_m \mathcal{C}(\boldsymbol{\theta}) \rho \mathcal{C}(\boldsymbol{\theta})^\dagger\} \\
&= \sum_{s_m} \text{tr}\{O s_m\} \text{tr}\left\{s_m U_m(\theta_m) \cdots U_1(\theta_1) \rho U_1^\dagger(\theta_1) \cdots U_m^\dagger(\theta_m)\right\} \\
&= \sum_{s_m, s_{m-1}} \text{tr}\{O s_m\} \text{tr}\{s_m U_m(\theta_m) s_{m-1} U_m^\dagger(\theta_m)\} \text{tr}\left\{s_{m-1} U_{m-1}(\theta_{m-1}) \cdots U_1(\theta_1) \rho U_1^\dagger(\theta_1) \cdots U_{m-1}^\dagger(\theta_{m-1})\right\} \\
&\vdots \\
&= \sum_{s_m, s_{m-1}, \dots, s_0} \text{tr}\{O s_m\} \text{tr}\{s_m U_m(\theta_m) s_{m-1} U_m^\dagger(\theta_m)\} \cdots \text{tr}\left\{s_1 U_1(\theta_1) s_0 U_1^\dagger(\theta_1)\right\} \text{tr}\{s_0 \rho\} \\
&= \sum_{s_m, s_{m-1}, \dots, s_0} \text{tr}\{O s_m\} \text{tr}\{s_0 \rho\} \prod_{i=1}^m \text{tr}\left\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\right\} \\
&= \sum_{\vec{s}} f(\vec{s}, \boldsymbol{\theta}, O, \rho),
\end{aligned} \tag{B6}$$

where

$$f(\vec{s}, \boldsymbol{\theta}, O, \rho) := \text{tr}\{O s_m\} \text{tr}\{s_0 \rho\} \prod_{i=1}^m \text{tr}\left\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\right\} \tag{B7}$$

is the contribution of a specific Pauli path $\vec{s} = (s_0, \dots, s_m)$ to the expectation value $\langle O \rangle$.

For the contribution of Pauli path $f(\vec{s}, \boldsymbol{\theta}, O, \rho)$, we have the following lemma:

Lemma A.2. *For the Pauli path $\vec{s}$ and $\vec{s}'$, and for arbitrary observable O_1 and O_2 , the contribution $f(\vec{s}, \boldsymbol{\theta}, O_1, \rho)$ and $f(\vec{s}', \boldsymbol{\theta}, O_2, \rho)$ satisfy the following equation:*

$$\mathbb{E}_{\boldsymbol{\theta}} f(\vec{s}, \boldsymbol{\theta}, O_1, \rho) f(\vec{s}', \boldsymbol{\theta}, O_2, \rho) = \frac{1}{4^m} \sum_{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} f(\vec{s}, \boldsymbol{\theta}, O_1, \rho) f(\vec{s}', \boldsymbol{\theta}, O_2, \rho), \tag{B8}$$

where $\boldsymbol{\theta} = \{\theta_1, \dots, \theta_m\}$ is the set of rotation angles and m is number of rotation gates.

Proof. The proof is straightforward by using Corollary A.1, we have:

$$\begin{aligned}
&\mathbb{E}_{\boldsymbol{\theta}} f(\vec{s}, \boldsymbol{\theta}, O_1, \rho) f(\vec{s}', \boldsymbol{\theta}, O_2, \rho) \\
&= \text{tr}\{O_1 s_m\} \text{tr}\{O_2 s'_m\} \text{tr}\{s_0 \rho\} \text{tr}\{s'_0 \rho\} \prod_{i=1}^m \mathbb{E}_{\theta_i} \text{tr}\left\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\right\} \text{tr}\left\{s'_i U_i(\theta_i) s'_{i-1} U_i^\dagger(\theta_i)\right\}
\end{aligned} \tag{B9}$$

For terms $\mathbb{E}_{\theta_i} \text{tr}\left\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\right\} \text{tr}\left\{s'_i U_i(\theta_i) s'_{i-1} U_i^\dagger(\theta_i)\right\}$, using Eq. (B2), we have:

$$\mathbb{E}_{\theta_i} \text{tr}\left\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\right\} \text{tr}\left\{s'_i U_i(\theta_i) s'_{i-1} U_i^\dagger(\theta_i)\right\} = \frac{1}{4} \sum_{\theta_i \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}} \text{tr}\left\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\right\} \text{tr}\left\{s'_i U_i(\theta_i) s'_{i-1} U_i^\dagger(\theta_i)\right\}. \tag{B10}$$

Therefore, we have:

$$\begin{aligned}
&\mathbb{E}_{\boldsymbol{\theta}} f(\vec{s}, \boldsymbol{\theta}, O_1, \rho) f(\vec{s}', \boldsymbol{\theta}, O_2, \rho) \\
&= \text{tr}\{O_1 s_m\} \text{tr}\{O_2 s'_m\} \text{tr}\{s_0 \rho\} \text{tr}\{s'_0 \rho\} \prod_{i=1}^m \frac{1}{4} \sum_{\theta_i \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}} \text{tr}\left\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\right\} \text{tr}\left\{s'_i U_i(\theta_i) s'_{i-1} U_i^\dagger(\theta_i)\right\} \\
&= \frac{1}{4^m} \sum_{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} f(\vec{s}, \boldsymbol{\theta}, O_1, \rho) f(\vec{s}', \boldsymbol{\theta}, O_2, \rho).
\end{aligned} \tag{B11}$$

□

Next we study the evolution of the Pauli operator s under the operator $U_i(\theta_i) = \exp(-i\frac{\theta_i}{2}P_i)C_i$, which is given by

$$U_i(\theta_i)s_{i-1}U_i^\dagger(\theta_i) = \exp\left(-i\frac{\theta_i}{2}P_i\right)\underbrace{C_is_{i-1}C_i^\dagger}_{Q_i}\exp\left(i\frac{\theta_i}{2}P_i\right), \quad (\text{B12})$$

where $Q_i = C_is_{i-1}C_i^\dagger$ is the transformed Pauli operator after applying the Clifford gate C_i to s_{i-1} . The above equation shows that the factor $\text{tr}\{s_iU_i(\theta_i)s_{i-1}U_i^\dagger(\theta_i)\}$ in $f(\vec{s}, \boldsymbol{\theta}, O, \rho)$ can be expressed as:

$$\begin{aligned} \text{tr}\{s_iU_i(\theta_i)s_{i-1}U_i^\dagger(\theta_i)\} &= \text{tr}\left\{s_i\exp\left(-i\frac{\theta_i}{2}P_i\right)Q_i\exp\left(i\frac{\theta_i}{2}P_i\right)\right\} \\ &= \text{tr}\left\{\exp\left(i\frac{\theta_i}{2}P_i\right)s_i\exp\left(-i\frac{\theta_i}{2}P_i\right)Q_i\right\} \\ &= \begin{cases} \text{tr}\{s_iQ_i\}, & [P_i, s_i] = 0, \\ \cos(\theta_i)\text{tr}\{s_iQ_i\} - i\sin(\theta_i)\text{tr}\{s_iP_iQ_i\}, & \{P_i, s_i\} = 0. \end{cases} \end{aligned} \quad (\text{B13})$$

Because of $Q_i = C_is_{i-1}C_i^\dagger$, and C_i is Clifford operator, the operator Q_i is also a Pauli operator in $\mathbf{P}_n$. Then, if $[P_i, s_i] = 0$, we have $Q_i = s_i$, which contributes a term $\text{tr}\{s_iQ_i\}$ to the corresponding $f(\vec{s}, \boldsymbol{\theta}, O, \rho)$. On the other hand, if $\{P_i, s_i\} = 0$, then Q_i may be either s_i or s_iP_i , leading to terms of the form $\cos(\theta_i)\text{tr}\{s_iQ_i\}$ or $-i\sin(\theta_i)\text{tr}\{s_iP_iQ_i\}$ in $f(\vec{s}, \boldsymbol{\theta}, O, \rho)$, respectively.

Specifically, if the rotation angle θ_i takes the value in $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$, the Pauli rotation $\exp(-i\frac{\theta_i}{2}P_i)$ falls into the set of Clifford gates, and the factor $\text{tr}\{s_iU_i(\theta_i)s_{i-1}U_i^\dagger(\theta_i)\}$ in Eq. (B13) can be expressed as:

$$\begin{aligned} \text{tr}\{s_iU_i(\theta_i)s_{i-1}U_i^\dagger(\theta_i)\} &= \begin{cases} \text{tr}\{s_iQ_i\}, & [P_i, s_i] = 0, \\ \cos(\theta_i)\text{tr}\{s_iQ_i\} - i\sin(\theta_i)\text{tr}\{s_iP_iQ_i\}, & \{P_i, s_i\} = 0. \end{cases} \\ &= \begin{cases} 0, & [P_i, s_i] = 0, Q_i \neq s_i \\ 1, & [P_i, s_i] = 0, Q_i = s_i \\ \pm 1, & \{P_i, s_i\} = 0, Q_i = s_i \end{cases} \text{ when } \theta_i \in \{0, \pi\} \quad \text{or} \quad \begin{cases} 0, & [P_i, s_i] = 0, s_i \neq Q_i \\ 1, & [P_i, s_i] = 0, Q_i = s_i \\ \pm 1, & \{P_i, s_i\} = 0, Q_i = is_iP_i. \end{cases} \text{ when } \theta_i \in \{\frac{\pi}{2}, \frac{3\pi}{2}\}, \end{aligned} \quad (\text{B14})$$

Here, we ignore the sign $\pm$ in front of the Pauli operator Q_i in the above equation. As shown in (B14), if $[P_i, s_i] = 0$, then Q_i must be equal to s_i . If instead $\{P_i, s_i\} = 0$, then $Q_i = s_i$ when $\theta_i \in \{0, \pi\}$, and $Q_i = is_iP_i$ when $\theta_i \in \{\frac{\pi}{2}, \frac{3\pi}{2}\}$. This observation will play an important role in the subsequent analysis.

Supplementary Information C: Variance and gradient variance of the loss function of PQC

In this section, we express and simplify the variance of the loss function and the gradient variance of PQCs using the formalisms of the Pauli path integral and quantum rotation 2-design, which form the foundation of our theoretical analysis.

1. Simplified expression via the orthogonality condition of Pauli paths

For an arbitrary PQC $\mathcal{C}(\boldsymbol{\theta})$ and observable O , let its loss function be defined as $L(\boldsymbol{\theta}) = \text{tr}\{O\mathcal{C}(\boldsymbol{\theta})\rho\mathcal{C}(\boldsymbol{\theta})^\dagger\}$. According to this definition, the variance of the loss function and that of its gradient can be expressed as follows:

$$\begin{aligned} \text{Var}_{\boldsymbol{\theta}}[L(\boldsymbol{\theta})] &= \mathbb{E}_{\boldsymbol{\theta}}[L(\boldsymbol{\theta})^2] - (\mathbb{E}_{\boldsymbol{\theta}}[L(\boldsymbol{\theta})])^2 \\ \text{Var}_{\boldsymbol{\theta}}\left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j}\right] &= \mathbb{E}_{\boldsymbol{\theta}}\left[\left(\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j}\right)^2\right] - \left(\mathbb{E}_{\boldsymbol{\theta}}\left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j}\right]\right)^2, \end{aligned} \quad (\text{C1})$$

where each θ_i is sampled uniformly from $[0, 2\pi)$. Writing P_α as the Pauli expansion of the observable $O = \sum_\alpha c_\alpha P_\alpha$,

the loss function can be expressed in the Pauli path integral formalism according to Eq. (B6):

$$\begin{aligned}
L(\boldsymbol{\theta}) &= \langle O \rangle \\
&= \sum_{\alpha, \vec{s}} c_{\alpha} \text{tr}\{P_{\alpha} s_m\} \text{tr}\{s_0 \rho\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^{\dagger}\} \\
&= \sum_{\alpha, \vec{s}} c_{\alpha} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho),
\end{aligned} \tag{C2}$$

where $\vec{s} = (s_0, s_1, \dots, s_m)$ is a Pauli path, which is a sequence of normalized Pauli operators $s_i \in \{\frac{I}{\sqrt{2}}, \frac{X}{\sqrt{2}}, \frac{Y}{\sqrt{2}}, \frac{Z}{\sqrt{2}}\}^{\otimes n}$, and $f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) := \text{tr}\{P_{\alpha} s_m\} \text{tr}\{s_0 \rho\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^{\dagger}\}$ denotes the contribution of a specific Pauli path $\vec{s}$ to the expectation value $\langle O \rangle$.

In particular, when the rotation angles satisfy $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$, each $U_i(\theta_i)$ belongs to the Clifford group. Consequently, for any fixed s_i , there exists a unique s_{i-1} such that $\text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^{\dagger}\} \neq 0$. Therefore, starting from $s_m \propto P_{\alpha}$, there exists a unique Pauli path $\vec{s}^{(\boldsymbol{\theta}, \alpha)}$ satisfying $\text{tr}\{P_{\alpha} s_m\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^{\dagger}\} \neq 0$.

Using the above expression, and assuming the PQC architecture satisfies a mild structural condition (shown in Ref. [45] to be met by most PQCs and also holding for arbitrary MPQCs which will be proved in Appendix D), we can express the variance of the loss function and that of its gradient in a simplified form.

Lemma A.3. *Let $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$ be an observable, and $\mathcal{C}(\boldsymbol{\theta})$ be a PQC with parameters $\boldsymbol{\theta} \in [0, 2\pi)^m$. Suppose the following orthogonality condition holds:*

$$\mathbb{E}_{\boldsymbol{\theta}} [f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) f(\vec{s}', \boldsymbol{\theta}, P_{\beta}, \rho)] = 0, \quad \forall \alpha \neq \beta, \vec{s}, \vec{s}', \tag{C3}$$

and each $\langle P_{\alpha} \rangle$ is not a non-zero constant function of $\boldsymbol{\theta}$. Then the variance of the loss function and the variance of its gradient can be expressed as:

$$\text{Var}_{\boldsymbol{\theta}} [L(\boldsymbol{\theta})] = \frac{1}{4^m} \sum_{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\alpha} c_{\alpha}^2 f(\vec{s}^{(\boldsymbol{\theta}, \alpha)}, \boldsymbol{\theta}, P_{\alpha}, \rho)^2 \tag{C4}$$

$$\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] = \frac{1}{4^m} \sum_{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\substack{\alpha \\ \{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\} = 0}} c_{\alpha}^2 f(\vec{s}^{(\boldsymbol{\theta}, \alpha)}, \boldsymbol{\theta}, P_{\alpha}, \rho)^2, \tag{C5}$$

where P_j denotes the Pauli operator in the elementary rotation $e^{-i\frac{\theta_j}{2}P_j}$ of the circuit, and $\vec{s}^{(\boldsymbol{\theta}, \alpha)}$ is the unique normalized Pauli operator sequence such that $\text{tr}\{P_{\alpha} s_m\} \prod_{i=1}^m \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i(\theta_i)^{\dagger}\} \neq 0$.

Notably, it can be observed that $\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right]$ corresponds to a subset of the terms in $\text{Var}_{\boldsymbol{\theta}} [L(\boldsymbol{\theta})]$, which allows us to analyze their scaling using the same techniques. In the following two subsections, we prove Eq. (C4) and Eq. (C5), respectively.

2. Proof of Eq. (C4)

We begin by expanding the variance of $L(\boldsymbol{\theta})$ in the language of Pauli path integral:

$$\begin{aligned}
\text{Var}_{\boldsymbol{\theta}} [L(\boldsymbol{\theta})] &= \mathbb{E}_{\boldsymbol{\theta}} [\langle O \rangle^2] - \mathbb{E}_{\boldsymbol{\theta}} [\langle O \rangle]^2 \\
&= \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha, \beta} c_{\alpha} c_{\beta} \langle P_{\alpha} \rangle \langle P_{\beta} \rangle \right] - \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha} c_{\alpha} \langle P_{\alpha} \rangle \right]^2 \\
&= \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha, \vec{s}} \sum_{\beta, \vec{s}'} c_{\alpha} c_{\beta} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) f(\vec{s}', \boldsymbol{\theta}, P_{\beta}, \rho) \right] - \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha, \vec{s}} c_{\alpha} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) \right]^2.
\end{aligned} \tag{C6}$$

Next, we show that for any P_α , the following holds:

$$\mathbb{E}_\theta [\langle P_\alpha \rangle] = \mathbb{E}_\theta \left[\sum_{\vec{s}} f(\vec{s}, \theta, P_\alpha, \rho) \right] = 0. \quad (\text{C7})$$

In the conditions of Lemma A.3, we require that $\langle P_\alpha \rangle$ is not a non-zero constant, which means that $\langle P_\alpha \rangle$ can either be zero or a non-trivial function of θ . If $\langle P_\alpha \rangle = 0$, then Eq. (C7) holds trivially. Now we suppose that $\langle P_\alpha \rangle$ is not a constant. We consider the evolution of the Pauli path in the Heisenberg picture, as described in Eq. (B13). Initially, starting from the observable, we have $s_m = P_\alpha / \sqrt{2^n}$. If $[P_m, s_m] = 0$, then $Q_m = C_m s_{m-1} C_m^\dagger = s_m$, which implies that the parameter θ_m has no effect on $\langle P_\alpha \rangle$. If this commutation relation persists throughout the circuit, i.e., $[P_i, s_i] = 0$ for all i , then each Q_i is uniquely determined, and none of the parameters affects $\langle P_\alpha \rangle$. This contradicts our assumption that P_α is a nontrivial observable with respect to $\mathcal{C}(\theta)$.

Therefore, for each non-vanishing term $f(\vec{s}, \theta, P_\alpha, \rho) \neq 0$, there must exist at least one index $i \in [m]$ such that the corresponding contribution contains a term of the form

$$\cos(\theta_i) \text{tr}\{s_i Q_i\} \quad \text{or} \quad i \sin(\theta_i) \text{tr}\{s_i P_i Q_i\}.$$

Since $\mathbb{E}_{\theta_i} [\cos(\theta_i)] = \mathbb{E}_{\theta_i} [\sin(\theta_i)] = 0$, we obtain

$$\mathbb{E}_{\theta_i} [\cos(\theta_i) \text{tr}\{s_i Q_i\}] = \mathbb{E}_{\theta_i} [-i \sin(\theta_i) \text{tr}\{s_i P_i Q_i\}] = 0.$$

This completes the proof of Eq. (C7).

Next, we compute $\mathbb{E}_\theta [\langle O \rangle^2]$. We first prove that for any fixed α , the following orthogonality condition holds:

$$\mathbb{E}_\theta [f(\vec{s}, \theta, P_\alpha, \rho) f(\vec{s}', \theta, P_\alpha, \rho)] = 0, \quad \forall \vec{s} \neq \vec{s}'. \quad (\text{C8})$$

Since the observable is the Pauli operator P_α , the final Pauli path elements s_m and s'_m must both equal $P_\alpha / \sqrt{2^n}$; otherwise, both $f(\vec{s}, \theta, P_\alpha, \rho)$ and $f(\vec{s}', \theta, P_\alpha, \rho)$ vanish.

Let i be the largest index such that $s_i \neq s'_i$. According to the analysis following Eq. (B13), we must have $\{P_{i+1}, s_{i+1} (= s'_{i+1})\} = 0$; otherwise, we would have $Q_{i+1} = Q'_{i+1} = s_{i+1}$. Since $Q_{i+1} = C_{i+1} s_i C_{i+1}^\dagger$ and $Q'_{i+1} = C_{i+1} s'_i C_{i+1}^\dagger$, this implies $s_i = s'_i$, contradicting our assumption.

Therefore, $\{P_{i+1}, s_{i+1}\} = 0$, and without loss of generality, we assume that $Q_{i+1} = s_{i+1}$ and $Q'_{i+1} = i s_{i+1} P_{i+1}$. This results in a product of terms in $f(\vec{s}, \theta, P_\alpha, \rho) f(\vec{s}', \theta, P_\alpha, \rho)$ that includes $\cos \theta_{i+1} \sin \theta_{i+1}$. However, since $\mathbb{E}_{\theta_{i+1}} [\cos \theta_{i+1} \sin \theta_{i+1}] = 0$, the cross term $\mathbb{E}_\theta [f(\vec{s}, \theta, P_\alpha, \rho) f(\vec{s}', \theta, P_\alpha, \rho)]$ vanishes. Hence, we conclude the proof for Eq. (C8).

Combining Eq. (C8) with the orthogonality condition:

$$\mathbb{E}_\theta [f(\vec{s}, \theta, P_\alpha, \rho) f(\vec{s}', \theta, P_\beta, \rho)] = 0, \quad \forall \alpha \neq \beta, \vec{s}, \vec{s}', \quad (\text{C9})$$

we obtain

$$\begin{aligned} \text{Var}_\theta [L(\theta)] &= \mathbb{E}_\theta \left[\sum_{\alpha, \vec{s}} \sum_{\beta, \vec{s}'} c_\alpha c_\beta f(\vec{s}, \theta, P_\alpha, \rho) f(\vec{s}', \theta, P_\beta, \rho) \right] \\ &= \mathbb{E}_\theta \left[\sum_{\alpha, \vec{s}} c_\alpha^2 f(\vec{s}, \theta, P_\alpha, \rho)^2 \right] \\ &= \frac{1}{4^m} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\alpha} c_\alpha^2 f(\vec{s}^{(\theta, \alpha)}, \theta, P_\alpha, \rho)^2, \end{aligned} \quad (\text{C10})$$

where the last equality uses the property of quantum rotation 2-design, as proven in Lemma A.2. $\square$

3. Proof of Eq. (C5)

Eq. (C5) expresses the variance of the gradient with respect to each parameter in terms of the Pauli path integral and quantum rotation 2-design. Similarly, we first express the gradient with respect to a given parameter θ_j in the form of a Pauli path integral:

$$\begin{aligned}
\frac{\partial \langle O \rangle}{\partial \theta_j} &= \sum_{s_m} \text{tr}\{O s_m\} \frac{\partial \text{tr}\{s_m \mathcal{C}(\boldsymbol{\theta}) \rho \mathcal{C}(\boldsymbol{\theta})^\dagger\}}{\partial \theta_j} \\
&= \sum_{\vec{s}} \frac{\partial f(\vec{s}, \boldsymbol{\theta}, O, \rho)}{\partial \theta_j} \\
&= \sum_{s_m, s_{m-1}, \dots, s_0} \text{tr}\{s_0 \rho\} \text{tr}\{O s_m\} \prod_{i \neq j}^L \text{tr}\{s_i U_i(\theta_i) s_{i-1} U_i^\dagger(\theta_i)\} \frac{\partial}{\partial \theta_j} \left(\text{tr}\{s_j U_j(\theta_j) s_{j-1} U_j^\dagger(\theta_j)\} \right).
\end{aligned} \tag{C11}$$

According to the parameter-shift rule [15], there is $\frac{\partial \langle O \rangle}{\partial \theta_j} = \frac{1}{2}(\langle O \rangle_{\theta_j + \frac{\pi}{2}} - \langle O \rangle_{\theta_j - \frac{\pi}{2}})$, where $\langle O \rangle_{\theta_j + \frac{\pi}{2}}$ and $\langle O \rangle_{\theta_j - \frac{\pi}{2}}$ are the expectation values of the observable O when the parameter θ_j is shifted by $\frac{\pi}{2}$ and $-\frac{\pi}{2}$, respectively. Therefore, we have $\mathbb{E}_{\boldsymbol{\theta}} \left(\frac{\partial \langle O \rangle}{\partial \theta_j} \right) = 0$, and apply the property of quantum rotation 2-design (as in Lemma A.2) to $\frac{\partial f(\vec{s}, \boldsymbol{\theta}, O, \rho)}{\partial \theta_j}$, we have

$$\begin{aligned}
\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] &= \mathbb{E}_{\boldsymbol{\theta}} \left[\left(\frac{\partial \langle O \rangle}{\partial \theta_j} \right)^2 \right] = \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\vec{s}, \vec{s}'} \frac{\partial f(\vec{s}, \boldsymbol{\theta}, O, \rho)}{\partial \theta_j} \frac{\partial f(\vec{s}', \boldsymbol{\theta}, O, \rho)}{\partial \theta_j} \right] \\
&= \frac{1}{4^m} \sum_{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\vec{s}, \vec{s}'} \frac{\partial f(\vec{s}, \boldsymbol{\theta}, O, \rho)}{\partial \theta_j} \frac{\partial f(\vec{s}', \boldsymbol{\theta}, O, \rho)}{\partial \theta_j}.
\end{aligned} \tag{C12}$$

A detailed proof of Eq. (C12) is also provided in Appendix G of Ref. [43]. We now evaluate $\left[\frac{\partial}{\partial \theta} \left(\text{tr}\{s_j U_j(\theta) s_{j-1} U_j^\dagger(\theta_j)\} \right) \right]$ when $\theta_j \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$:

$$\begin{aligned}
\left[\frac{\partial}{\partial \theta} \left(\text{tr}\{s_j U_j(\theta) s_{j-1} U_j^\dagger(\theta_j)\} \right) \right] &= \begin{cases} 0, & [P_j, s_j] = 0, \\ -\sin(\theta_j) \text{tr}\{s_j Q_j\} - i \cos(\theta_j) \text{tr}\{s_j P_j Q_j\}, & \{P_j, s_j\} = 0. \end{cases} \\
&= \begin{cases} \pm 1, & \{P_j, s_j\} = 0, Q_j = i s_j P_j, \text{ when } \theta_j \in \{0, \pi\} \\ 0, & \text{others.} \end{cases} \text{ or } = \begin{cases} \pm 1, & \{P_j, s_j\} = 0, Q_j = s_j, \text{ when } \theta_j \in \{\frac{\pi}{2}, \frac{3\pi}{2}\}. \\ 0, & \text{others.} \end{cases}
\end{aligned} \tag{C13}$$

It turns out that this term is closely related to the undifferentiated term $\text{tr}\{s_j U_j(\theta_j) s_{j-1} U_j^\dagger(\theta_j)\}$ when $\theta_j \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$. To formalize this connection, we recall the value of such term

$$\begin{aligned}
\text{tr}\{s_j U_j(\theta_j) s_{j-1} U_j^\dagger(\theta_j)\} &= \begin{cases} \text{tr}\{s_j Q_j\}, & [P_j, s_j] = 0, \\ \cos(\theta_j) \text{tr}\{s_j Q_j\} - i \sin(\theta_j) \text{tr}\{s_j P_j Q_j\}, & \{P_j, s_j\} = 0. \end{cases} \\
&= \begin{cases} \pm 1, & \{P_j, s_j\} = 0, Q_j = i s_j P_j \\ 1, & [P_j, s_j] = 0, Q_j = s_j \text{ when } \theta_j \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \\ 0, & \text{others.} \end{cases} \text{ or } = \begin{cases} \pm 1, & \{P_j, s_j\} = 0, Q_j = s_j \\ 1, & [P_j, s_j] = 0, Q_j = s_j \text{ when } \theta_j \in \{0, \pi\}. \\ 0, & \text{others} \end{cases}
\end{aligned} \tag{C14}$$

It is easy to verify that Eq. (C13) and Eq. (C14) become equivalent if we exchange the assignments $\theta_j \in \{0, \pi\}$ and

$\theta_j \in \{\frac{\pi}{2}, \frac{3\pi}{2}\}$, while excluding the case where $[P_j, s_j] = 0$ in Eq. (C14). Then we have

$$\begin{aligned}
\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] &= \frac{1}{4^m} \sum_{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\vec{s}, \vec{s}'} \frac{\partial f(\vec{s}, \boldsymbol{\theta}, O, \rho)}{\partial \theta_j} \frac{\partial f(\vec{s}', \boldsymbol{\theta}, O, \rho)}{\partial \theta_j} \\
&= \frac{1}{4^m} \sum_{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\substack{\vec{s}: \{P_j, s_j\}=0 \\ \vec{s}': \{P_j, s'_j\}=0}} f(\vec{s}, \boldsymbol{\theta}, O, \rho) f(\vec{s}', \boldsymbol{\theta}, O, \rho) \\
&= \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\substack{\vec{s}: \{P_j, s_j\}=0 \\ \vec{s}': \{P_j, s'_j\}=0}} f(\vec{s}, \boldsymbol{\theta}, O, \rho) f(\vec{s}', \boldsymbol{\theta}, O, \rho) \right] \\
&= \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\substack{\vec{s}: \{P_j, s_j\}=0 \\ \vec{s}': \{P_j, s'_j\}=0}} \sum_{\alpha, \beta} c_{\alpha} c_{\beta} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) f(\vec{s}', \boldsymbol{\theta}, P_{\beta}, \rho) \right] \\
&= \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\vec{s}: \{P_j, s_j\}=0} \sum_{\alpha} c_{\alpha}^2 f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho)^2 \right] \\
&= \frac{1}{4^m} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\}=0}} \sum_{\alpha} c_{\alpha}^2 f(\boldsymbol{\theta}, P_{\alpha}, \vec{s}^{(\boldsymbol{\theta}, \alpha)}, \rho)^2.
\end{aligned} \tag{C15}$$

The second-to-last inequality holds due to the orthogonality condition, and the last equality follows from the property of the quantum rotation 2-design, as proven in Lemma A.2. $\square$

Also, according to the proof of Eq. (11), it is easily to derive the upper bound of the variance $\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right]$ when the orthogonality condition may not be satisfied:

Corollary A.2. *For an arbitrary PQC $\mathcal{C}(\boldsymbol{\theta})$ and any parameter $\theta_j \in \boldsymbol{\theta}$, the variance of the gradient with respect to θ_j can be upper bounded as*

$$\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] \leq \left(\frac{\|O\|_{HS}}{\|O\|_{\min}} \right)^2 \frac{1}{4^m} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\}=0}} \sum_{\alpha} c_{\alpha}^2 f(\boldsymbol{\theta}, P_{\alpha}, \vec{s}^{(\boldsymbol{\theta}, \alpha)}, \rho)^2, \tag{C16}$$

where $\|O\|_{HS} := \sqrt{\frac{\text{tr}\{O^2\}}{2^n}} = \sqrt{\sum_{\alpha} c_{\alpha}^2}$ denotes as the Hilbert-Schmidt norm of O and $\|O\|_{\min} := \min\{|c_{\alpha}| > 0\}$. Here, the orthogonality condition in Eq. (C3) is not required to hold.

Proof. According to Eq. (C15), for arbitrary PQC $\mathcal{C}(\boldsymbol{\theta})$, when the orthogonality condition in Eq. (C3) may not hold, we have

$$\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] = \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha} c_{\alpha} \sum_{\vec{s}: \{P_j, s_j\}=0} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) \right]^2. \tag{C17}$$

Applying the Cauchy-Schwarz inequality to the summation, the variance of the gradient can be upper bounded as

follows:

$$\begin{aligned}
& \text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] \\
&= \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha} c_{\alpha} \sum_{\vec{s}: \{P_j, s_j\}=0} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) \right]^2 \\
&\leq \mathbb{E}_{\boldsymbol{\theta}} \left[\left(\sum_{\alpha} c_{\alpha}^2 \right) \sum_{\alpha} \left(\sum_{\vec{s}: \{P_j, s_j\}=0} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) \right)^2 \right] \\
&\leq \|O\|_{HS}^2 \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha} \frac{c_{\alpha}^2}{\min\{c_{\alpha}^2\}} \left(\sum_{\vec{s}: \{P_j, s_j\}=0} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) \right)^2 \right] \\
&= \left(\frac{\|O\|_{HS}}{\|O\|_{\min}} \right)^2 \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha} c_{\alpha}^2 \left(\sum_{\vec{s}: \{P_j, s_j\}=0} f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho) \right)^2 \right].
\end{aligned} \tag{C18}$$

Then according to Eq. (C8), the cross terms in Eq. (C18) vanishes, then we have

$$\begin{aligned}
& \text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] \\
&\leq \left(\frac{\|O\|_{HS}}{\|O\|_{\min}} \right)^2 \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{\alpha} \sum_{\vec{s}: \{P_j, s_j\}=0} c_{\alpha}^2 f(\vec{s}, \boldsymbol{\theta}, P_{\alpha}, \rho)^2 \right] \\
&= \left(\frac{\|O\|_{HS}}{\|O\|_{\min}} \right)^2 \frac{1}{4^m} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\}=0}} \sum_{\alpha} c_{\alpha}^2 f(\boldsymbol{\theta}, P_{\alpha}, \vec{s}^{(\boldsymbol{\theta}, \alpha)}, \rho)^2. \\
&= \mathcal{O}(\text{poly}(n)) \frac{1}{4^m} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\}=0}} \sum_{\alpha} c_{\alpha}^2 f(\boldsymbol{\theta}, P_{\alpha}, \vec{s}^{(\boldsymbol{\theta}, \alpha)}, \rho)^2,
\end{aligned} \tag{C19}$$

where the last equality follows from Eq. (A3). $\square$

Supplementary Information D: Variance and gradient variance of the loss function of MPQCs

In this section, we leverage Lemma A.3 to derive analytical expressions for both the variance of the loss function of MPQCs and that of its gradient. To apply this lemma, it is necessary to prove that the Pauli path of MPQC satisfies the orthogonality condition, and that for any P_{α} , the quantity $\text{tr}\{\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})(\rho)P_{\alpha}\}$ is not a non-zero constant function of $(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$.

We first express the variance of the MPQC in terms of the Pauli path integral. Suppose $\mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ denotes the unitary representation of $\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ that includes the ancilla qubits but excludes all *op*. Instead, the operations *op* are treated explicitly as acting on the initial state of the ancilla qubits. Then, the loss function reads

$$\begin{aligned}
L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) &= \text{tr}\{\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})(\rho)O\} \\
&= \text{tr}\left\{ \left[\mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) \left(\text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right) (\mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}))^{\dagger} \right] \cdot [I \otimes O] \right\},
\end{aligned} \tag{D1}$$

Here, the first n qubits are the ancilla qubits, and the last n qubits correspond to the original PQC, which we will refer to as the *system qubits* in the following discussion. The observable operator acting on the ancilla qubits is fixed to be I , according to the definition of the quantum channel.

Next we express $\mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ as the form in Eq. (A1):

$$\mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) = \mathbf{U}_m(\theta_m) \cdots \mathbf{U}_{L+1}(\theta_{L+1}) \prod_{i=1}^n (R_{Z_i Z_{i+n}}(\theta_{\mathcal{G}_{i,1}}) R_{Y_i Y_{i+n}}(\theta_{\mathcal{G}_{i,2}}) R_{X_i X_{i+n}}(\theta_{\mathcal{G}_{i,3}})) \mathbf{U}_L(\theta_L) \cdots \mathbf{U}_1(\theta_1), \tag{D2}$$

where $\mathbf{U}_i(\theta_i)$ denote the unitary operator corresponding to the original circuit acting on $2n$ qubits, i.e. $\mathbf{U}_i(\theta_i) = I \otimes U_i(\theta_i)$. For convenience in the subsequent proof, we denote $R_{i,j}(\theta_{\mathcal{G}_{i,j}})$ as the 2-qubit rotation gate $R_{P(j)iP(j)_{i+n}}(\theta_{\mathcal{G}_{i,j}})$, where $i \in [n], j \in [3]$, and $P(1) = Z, P(2) = Y, P(3) = X$.

Following the procedure in Eq. (B6), we expand the loss function $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ using the Pauli path integral formalism:

$$\begin{aligned}
L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) &= \text{tr} \left\{ \mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \left(\mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) \right)^\dagger I \otimes O \right\} \\
&= \sum_{\alpha, \mathbf{s}_m} c_\alpha \text{tr} \{ I \otimes P_\alpha \mathbf{s}_m \} \text{tr} \left\{ \mathbf{s}_m \mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \left(\mathbf{U}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) \right)^\dagger \right\} \\
&= \sum_{\substack{\alpha, \mathbf{s}_m, \mathbf{s}_{m-1}, \dots, \mathbf{s}_0 \\ \mathbf{s}_{\mathcal{G}_{1,1}}, \mathbf{s}_{\mathcal{G}_{1,2}}, \dots, \mathbf{s}_{\mathcal{G}_{n,3}}}} \text{tr} \{ I \otimes O \mathbf{s}_m \} \text{tr} \left\{ \mathbf{s}_m \mathbf{U}_m(\theta_m) \mathbf{s}_{m-1} \mathbf{U}_m(\theta_m)^\dagger \right\} \cdots \text{tr} \left\{ \mathbf{s}_{L+1} \mathbf{U}_{L+1}(\theta_{L+1}) \mathbf{s}_{\mathcal{G}_{1,1}} \mathbf{U}_{L+1}(\theta_{L+1})^\dagger \right\} \\
&\quad \cdot \text{tr} \{ \mathbf{s}_{\mathcal{G}_{1,1}} R_{11}(\theta_{\mathcal{G}_{11}}) \mathbf{s}_{\mathcal{G}_{1,2}} R_{11}(-\theta_{\mathcal{G}_{11}}) \} \text{tr} \{ \mathbf{s}_{\mathcal{G}_{1,2}} R_{12}(\theta_{\mathcal{G}_{12}}) \mathbf{s}_{\mathcal{G}_{1,3}} R_{12}(-\theta_{\mathcal{G}_{12}}) \} \cdots \text{tr} \{ \mathbf{s}_{\mathcal{G}_{n,3}} R_{n3}(\theta_{\mathcal{G}_{n3}}) \mathbf{s}_L R_{n3}(-\theta_{\mathcal{G}_{n3}}) \} \\
&\quad \cdot \text{tr} \left\{ \mathbf{s}_L \mathbf{U}_L(\theta_L) \mathbf{s}_{L-1} \mathbf{U}_L(\theta_L)^\dagger \right\} \cdots \text{tr} \left\{ \mathbf{s}_1 \mathbf{U}_1(\theta_1) \mathbf{s}_0 \mathbf{U}_1(\theta_1)^\dagger \right\} \text{tr} \{ \mathbf{s}_0 \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \} \\
&= \sum_{\alpha, \vec{\mathbf{s}}} c_\alpha f(\vec{\mathbf{s}}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), I \otimes P_\alpha, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho),
\end{aligned} \tag{D3}$$

where we define $\vec{\mathbf{s}} = (\mathbf{s}_0, \dots, \mathbf{s}_m, \mathbf{s}_{\mathcal{G}_{n,3}}, \mathbf{s}_{\mathcal{G}_{n,2}}, \dots, \mathbf{s}_{\mathcal{G}_{1,1}})$ with each element a normalized $2n$ -qubit Pauli operator and $f(\vec{\mathbf{s}}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), I \otimes P_\alpha, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho)$ as the contribution of Pauli path $\vec{\mathbf{s}}$ to the expectation value. To prove that MPQC satisfies the conditions demanded in Lemma A.3, we need the following Lemma A.4 and Lemma A.5 proved in Ref. [45].

Lemma A.4. Consider a PQC $\mathcal{C}(\boldsymbol{\theta}) = U_m(\theta_m) \cdots U_1(\theta_1)$ measured with observable $O = \sum_\alpha c_\alpha P_\alpha$. Let $\overline{P}_i$ denote the Pauli operator P_i after conjugation by a sequence of Clifford gates, i.e., $\overline{P}_i = C_m \cdots C_i P_i C_i^\dagger \cdots C_m^\dagger$. Then the orthogonality condition Eq. (C3) holds for $\mathcal{C}(\boldsymbol{\theta})$ if the set of Pauli operators $\{\overline{P}_i\}$ can split the Pauli operator set $\{P_\alpha\}$ of O . We say that Pauli set A can split Pauli set B if there exist no two distinct elements in B that exhibit identical anti-commute/commute relation with each element in A .

Lemma A.5. $\{\overline{P}_i\}$ can split the entire n -qubit Pauli $\{\mathbb{I}, X, Y, Z\}^{\otimes n}$ is equivalent to the condition that

$$\langle \{\overline{P}_i\} \rangle / (\langle \{\overline{P}_i\} \rangle \cap \langle \mathbb{I}^{\otimes n} \rangle) = \{\mathbb{I}, X, Y, Z\}^{\otimes n}, \tag{D4}$$

here $\langle \{\overline{P}_i\} \rangle$ denotes to the Pauli subgroup that is generated by set $\{\overline{P}_i\}$, meaning every element in $\langle \{\overline{P}_i\} \rangle$ can be expressed as the finite product of elements in $\{\overline{P}_i\}$.

Next, we prove that two conditions of Lemma A.3 are both satisfied for arbitrary MPQC, which are concluded in the following two lemmas.

Lemma A.6. Consider a MPQC $\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ taking in parameters $(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) \in [0, 2\pi)^{m+3n}$ measured with observable $O = \sum_\alpha c_\alpha P_\alpha$. Then, the orthogonality condition for the Pauli paths in the expansion form of Eq. (D3) always holds.

Proof. We employ Lemma A.4 and Lemma A.5 to prove Lemma A.6. To facilitate the analysis, we first express the Pauli operators generated by the MPQC in Lemma A.4 to act on the full $2n$ -qubit system. Specifically, these operators can be written as

$$\overline{P}_i = \mathbf{C}_m \cdots \mathbf{C}_i \mathbf{P}_i \mathbf{C}_i^\dagger \cdots \mathbf{C}_m^\dagger,$$

where each $\mathbf{C}_i$ denotes a Clifford operator in the original PQC, extended to act on $2n$ qubits.

Recall that each gadget $\mathcal{G}(\boldsymbol{\theta})$ employs three two-qubit rotation gates: R_{XX} , R_{YY} , and R_{ZZ} , acting between a system qubit and an ancilla qubit. For each system qubit, at least one such gadget is applied. Then, the Pauli operator set generated in the gadget layer contains at least the following:

$$\{X_{i_1}^{j_1} Y_{i_2}^{j_2} Z_{i_3}^{j_3} \otimes \tilde{\mathbf{C}}_{L+1} X_{i_1+n}^{j_1} Y_{i_2+n}^{j_2} Z_{i_3+n}^{j_3} \tilde{\mathbf{C}}_{L+1}^\dagger\}_{i_1, i_2, i_3}^{j_1, j_2, j_3} := F,$$

where $i_1, i_2, i_3 \in [n]$, $j_1, j_2, j_3 \in \{0, 1\}$ satisfying $j_1 + j_2 + j_3 = 1$, and $\tilde{\mathbf{C}}_{L+1} := \mathbf{C}_m \cdots \mathbf{C}_{L+1}$. Since the Pauli operator set of the observable of MPQCs takes the form $\{I \otimes P_\alpha\}$, the (anti)commutation relation between any element

$$X_{i_1}^{j_1} Y_{i_2}^{j_2} Z_{i_3}^{j_3} \otimes \tilde{\mathbf{C}}_{L+1} X_{i_1+n}^{j_1} Y_{i_2+n}^{j_2} Z_{i_3+n}^{j_3} \tilde{\mathbf{C}}_{L+1}^\dagger \in F$$

and $I \otimes P_\alpha$ is determined by the (anti)commutation relation between $\tilde{\mathbf{C}}_{L+1} X_{i_1+n}^{j_1} Y_{i_2+n}^{j_2} Z_{i_3+n}^{j_3} \tilde{\mathbf{C}}_{L+1}^\dagger$ and P_α .

This implies that F can split the Pauli operator set $\{I \otimes P_\alpha\}$ if and only if the set $\{\tilde{\mathbf{C}}_{L+1} X_{i_1+n}^{j_1} Y_{i_2+n}^{j_2} Z_{i_3+n}^{j_3} \tilde{\mathbf{C}}_{L+1}^\dagger\}$ can split $\{P_\alpha\}$.

It is straightforward to verify that $\{\tilde{\mathbf{C}}_{L+1} X_{i_1+n}^{j_1} Y_{i_2+n}^{j_2} Z_{i_3+n}^{j_3} \tilde{\mathbf{C}}_{L+1}^\dagger\}$ generates the entire n -qubit Pauli group. By Lemma A.5, we conclude that the operator F already suffices to split the Pauli operator set of any observable O . Consequently, the whole Pauli operator set $\{\bar{\mathbf{P}}_i\}$ of MPQC can split the Pauli operator set of arbitrary O . According to Lemma A.4, we thus conclude that the orthogonality condition holds for all MPQCs. $\square$

Lemma A.7. *For any MPQC and any nontrivial n -qubit Pauli word P , the expectation value $\langle P \rangle$ is not a non-zero constant function of the parameters in MPQC.*

Proof. Suppose there exists an MPQC $\Phi^C(\theta, \theta_G)$ and a nontrivial Pauli operator $P \neq I$ such that $\langle P \rangle = c \neq 0$. Then we have

$$\mathbb{E}_{(\theta, \theta_G)} [\langle P \rangle] = \mathbb{E}_{(\theta, \theta_G)} \left[\sum_{\vec{s}} f(\vec{s}, (\theta, \theta_G), I \otimes P, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho) \right] = c \neq 0. \quad (\text{D5})$$

For arbitrary $\vec{s}$, if there exists some $\{\mathbf{s}_i, \mathbf{P}_i\} = 0$ or some $\{\mathbf{s}_{G_{i,j}}, P(j)_i P(j)_{i+n}\} = 0$, then the corresponding term $\mathbb{E}_{\theta} f(\vec{s}, (\theta, \theta_G), I \otimes P, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho)$ vanishes. This is because, according to (B13), this term must contain one of the following components:

$$\begin{aligned} & \mathbb{E}_{\theta_i} [\cos(\theta_i) \text{tr}\{\mathbf{s}_i \mathbf{C}_i \mathbf{s}_{i-1} \mathbf{C}_i^\dagger\}] \quad \text{or} \quad \mathbb{E}_{\theta_i} [\sin(\theta_i) \text{tr}\{\mathbf{s}_i P_i \mathbf{C}_i \mathbf{s}_{i-1} \mathbf{C}_i^\dagger\}], \quad i \neq L+1 \\ \text{or} \quad & \mathbb{E}_{\theta_{L+1}} [\cos(\theta_{L+1}) \text{tr}\{\mathbf{s}_{L+1} \mathbf{C}_{L+1} \mathbf{s}_{G_{1,1}} \mathbf{C}_{L+1}^\dagger\}] \quad \text{or} \quad \mathbb{E}_{\theta_{L+1}} [\sin(\theta_{L+1}) \text{tr}\{\mathbf{s}_{L+1} P_{L+1} \mathbf{C}_{L+1} \mathbf{s}_{G_{1,1}} \mathbf{C}_{L+1}^\dagger\}], \\ \text{or} \quad & \mathbb{E}_{\theta_{G_{i,j}}} [\cos(\theta_{G_{i,j}}) \text{tr}\{\mathbf{s}_{G_{i,j}} \mathbf{s}_{G_{i,j+1}}\}] \quad \text{or} \quad \mathbb{E}_{\theta_{G_{i,j}}} [\sin(\theta_{G_{i,j}}) \text{tr}\{\mathbf{s}_{G_{i,j}} P(j)_i P(j)_{i+n} \mathbf{s}_{G_{i,j+1}}\}], \quad i \in [n], j \leq 2 \\ \text{or} \quad & \mathbb{E}_{\theta_{G_{i,3}}} [\cos(\theta_{G_{i,3}}) \text{tr}\{\mathbf{s}_{G_{i,3}} \mathbf{s}_{G_{i+1,1}}\}] \quad \text{or} \quad \mathbb{E}_{\theta_{G_{i,3}}} [\sin(\theta_{G_{i,3}}) \text{tr}\{\mathbf{s}_{G_{i,3}} P(3)_i P(3)_{i+n} \mathbf{s}_{G_{i+1,1}}\}], \quad i \leq n-1 \\ \text{or} \quad & \mathbb{E}_{\theta_{G_{n,3}}} [\cos(\theta_{G_{n,3}}) \text{tr}\{\mathbf{s}_{G_{n,3}} \mathbf{s}_L\}] \quad \text{or} \quad \mathbb{E}_{\theta_{G_{n,3}}} [\sin(\theta_{G_{n,3}}) \text{tr}\{\mathbf{s}_{G_{n,3}} P(3)_n P(3)_{2n} \mathbf{C}_{L+1} \mathbf{s}_L\}], \end{aligned} \quad (\text{D6})$$

while all of them equal 0.

Based on this observation, if

$$\mathbb{E}_{(\theta, \theta_G)} \left[\sum_{\vec{s}} f(\vec{s}, (\theta, \theta_G), I \otimes P, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho) \right] = c \neq 0,$$

then there must exist a Pauli path $\vec{s}$ such that each element commutes with the corresponding generator of its associated rotation gate. According to (B13), the following equation must hold:

$$\mathbf{C}_i \mathbf{s}_{i-1} \mathbf{C}_i^\dagger = \mathbf{s}_i, \quad i > L+2. \quad (\text{D7})$$

Here we again we ignore the sign $\pm$ in front of the Pauli operator as we only concern the commutation relation between Pauli operators. By recursively applying (D7) and $\mathbf{C}_{L+1} \mathbf{s}_{G_{1,1}} \mathbf{C}_{L+1}^\dagger = \mathbf{s}_{L+1}$, we obtain

$$\mathbf{s}_{G_{1,1}} = \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger \mathbf{s}_m \mathbf{C}_m \cdots \mathbf{C}_{L+1}. \quad (\text{D8})$$

By applying the same procedure to the Pauli operators of Pauli path that pass through the gadget layers, we obtain that $\mathbf{s}_{G_{i,j}} = \mathbf{s}_{G_{1,1}}$. Due to the commutation condition, this implies that $[\mathbf{s}_{G_{1,1}}, P(j)_i P(j)_{i+n}] = 0$ for all i, j .

Since $\mathbf{s}_{G_{1,1}}$ commutes with all $P(j)_i P(j)_{i+n}$, it follows that

$$\mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger \mathbf{s}_m \mathbf{C}_m \cdots \mathbf{C}_{L+1} P(j)_i P(j)_{i+n} = P(j)_i P(j)_{i+n} \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger \mathbf{s}_m \mathbf{C}_m \cdots \mathbf{C}_{L+1}.$$

This implies

$$\mathbf{s}_m \mathbf{C}_m \cdots \mathbf{C}_{L+1} P(j)_i P(j)_{i+n} \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger = \mathbf{C}_m \cdots \mathbf{C}_{L+1} P(j)_i P(j)_{i+n} \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger \mathbf{s}_m,$$

and hence $\mathbf{s}_m$ commutes with each $\bar{\mathbf{P}}_{i,j} := \mathbf{C}_m \cdots \mathbf{C}_{L+1} P(j)_i P(j)_{i+n} \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger$. Through the same analysis in Lemma A.6, $[\mathbf{s}_m, \bar{\mathbf{P}}_{i,j}] = 0$ if and only if $[P, \mathbf{C}_m \cdots \mathbf{C}_{L+1} P(j)_{i+n} \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger] = 0$. Also since $\{\mathbf{C}_m \cdots \mathbf{C}_{L+1} P(j)_{i+n} \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger\}$ can generate the entire n -qubit Pauli group, by Lemma A.5, the Pauli word can commute with all $\mathbf{C}_m \cdots \mathbf{C}_{L+1} P(j)_{i+n} \mathbf{C}_{L+1}^\dagger \cdots \mathbf{C}_m^\dagger$ must be I . This leads to a contradiction with the assumption that $P \neq I$. $\square$

Lemma A.6 and Lemma A.7 guarantee that the circuit architecture of MPQC always satisfies the conditions required in Lemma A.3. Therefore, according to Lemma A.3 both the variance and the gradient variance of the loss function can be explicitly expressed using the Pauli path integral formulation:

Lemma A.8. Consider a MPQC $\Phi^C(\theta, \theta_G)$ taking in parameters $(\theta, \theta_G) \in [0, 2\pi)^{m+3n}$ measured with observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$. The variance and the gradient variance of the loss function $L^C(\theta, \theta_G)$ under the Pauli path integral formulation can be expressed as

$$\text{Var}_{(\theta, \theta_G)} [L^C(\theta, \theta_G)] = \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}}} \sum_{\alpha} c_{\alpha}^2 f\left(\vec{s}^{((\theta, \theta_G), \alpha)}, (\theta, \theta_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2. \quad (\text{D9})$$

$$\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right] = \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n} \\ \{\mathbf{P}_j, \mathbf{s}_j^{(\theta, \alpha)}\} = 0}} \sum_{\alpha} c_{\alpha}^2 f\left(\vec{s}^{((\theta, \theta_G), \alpha)}, (\theta, \theta_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2, \quad (\text{D10})$$

where $\vec{s}^{((\theta, \theta_G), \alpha)}$ is the unique Pauli path such that $f\left(\vec{s}^{((\theta, \theta_G), \alpha)}, (\theta, \theta_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right) \neq 0$, if $\text{tr}\left\{\mathbf{s}_0 \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right\} \neq 0$.

Supplementary Information E: Proof of Theorem 1

In this section, we prove Theorem 1. The proof consists of two parts. First, we present how the gadget affects the backward propagation of Pauli operators. We then lower bound $\text{Var}_{(\theta, \theta_G)} [L^C(\theta, \theta_G)]$ via Eq.(D9), by taking a partial sum over discrete angles $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ and $\theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}$.

1. Impact of the gadget $\mathcal{G}(\theta)$ on pauli paths

Here, we discuss the impact of $\mathcal{G}(\theta)$ on the Pauli path in the Heisenberg picture. Suppose that the Pauli operator at the output of the gadget $\mathcal{G}(\theta)$ in Fig. A.6 is $I \otimes P$. Then, for certain subsets of angle choices $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$, we can determine the corresponding Pauli operators P_1, P_2 , and P_3 , where θ_1, θ_2 , and θ_3 are the rotation angles for the R_{XX} , R_{YY} , and R_{ZZ} gates, respectively.

Figure A.6: Effect of the gadget $\mathcal{G}(\theta)$ on Pauli paths in the Heisenberg picture.

Analyzing the backward propagation of Pauli path, direct calculation based on (B14) yields that

- $P = I, \theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}, P_1 = P_2 = P_3 = II.$
- $P = X, \{IX, ZZ\} = 0, \theta_3 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_3 = ZY; \{ZY, YY\} = 0, \theta_2 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_2 = XI; [XI, XX] = 0, \theta_1 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_1 = XI.$
- $P = Y, \{IY, ZZ\} = 0, \theta_3 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_3 = ZX; [ZX, YY] = 0, \theta_2 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_2 = ZX; \{ZX, XX\} = 0, \theta_1 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_1 = YI.$
- $P = Z, [IZ, ZZ] = 0, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_3 = IZ; \{IZ, YY\} = 0, \theta_2 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_2 = YX; \{YX, XX\} = 0, \theta_1 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_1 = ZI.$

Here we also ignore the sign $\pm$ in front of the Pauli operator. The above result indicates that, from the perspective of the Heisenberg picture, among the 64 possible combinations of $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$, there exist at least $2 \times 2 \times 4 = 16$ configurations that lead to $P_1 = P \otimes I$.

Moreover, for any given single-qubit Pauli operator P , there exist $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$ such that $P_1 = I \otimes P$. Specifically, we have:

- $P = I$, $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$, $P_1 = P_2 = P_3 = II$.
- $P = X$, $\{IX, ZZ\} = 0$, $\theta_3 \in \{0, \pi\} \rightarrow P_3 = IX$; $\{IX, YY\} = 0$, $\theta_2 \in \{0, \pi\} \rightarrow P_2 = IX$; $[IX, XX] = 0$, $\theta_1 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_1 = IX$.
- $P = Y$, $\{IY, ZZ\} = 0$, $\theta_3 \in \{0, \pi\} \rightarrow P_3 = IY$; $[IY, YY] = 0$, $\theta_2 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_2 = IY$; $\{IY, XX\} = 0$, $\theta_1 \in \{0, \pi\} \rightarrow P_1 = IY$.
- $P = Z$, $[IZ, ZZ] = 0$, $\theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_3 = IZ$; $\{IZ, YY\} = 0$, $\theta_2 \in \{0, \pi\} \rightarrow P_2 = IZ$; $\{IZ, XX\} = 0$, $\theta_1 \in \{0, \pi\} \rightarrow P_1 = IZ$.

Therefore, there also exist 16 choices of $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$ that leave the Pauli path unchanged; that is, the resulting Pauli operator P_1 remains $I \otimes P$.

Next, we analyze the remaining 32 configurations of $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$ when the Pauli operator P is non-trivial. Consider the case $P = X$ as an example. The analysis proceeds as follows:

- $P = X$, $\{IX, ZZ\} = 0$, $\theta_3 \in \{0, \pi\} \rightarrow P_3 = IX$; $\{IX, YY\} = 0$, $\theta_2 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_2 = YZ$; $[YZ, XX] = 0$, $\theta_1 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_1 = YZ$.
- $P = X$, $\{IX, ZZ\} = 0$, $\theta_3 \in \{\frac{\pi}{2}, \frac{3\pi}{2}\} \rightarrow P_3 = ZY$; $\{ZY, YY\} = 0$, $\theta_2 \in \{0, \pi\} \rightarrow P_2 = ZY$; $[ZY, XX] = 0$, $\theta_1 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\} \rightarrow P_1 = ZY$.

Thus, among these 32 configurations, 16 of them transform IX to YZ , while the other 16 transform IX to ZY . Following similar calculations, we find that:

- When $P = Y$, 16 configurations of $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$ map IY to XZ , and 16 to ZX .
- When $P = Z$ 16 configurations of $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$ map IZ to XY , and 16 to YX .

To summarize, among all 64 possible angle combinations with $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$, the operator P_1 has the following possibilities:

- If $P = I$, then $P_1 = II$ for all 64 configurations of $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$.
- $P \neq I$, $P_1 = \begin{cases} PI, & \text{for 16 configurations of } \theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}; \\ IP, & \text{for 16 configurations of } \theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}; \\ Q_1Q_2, & \text{for 16 configurations of } \theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}; \\ Q_2Q_1, & \text{for 16 configurations of } \theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}, \end{cases}$
where $\{Q_1, Q_2, P\} = \{X, Y, Z\}$.

Remark. We analyze the effect of the gadget $\mathcal{G}(\theta)$ on the backward propagation of Pauli paths from an operational perspective. When the three parameters of the gadget are chosen from the discrete set $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$, and $P \neq I$, we find that in 16 out of the 64 possible angle combinations—that is, in a proportion of $1/4$ —the backward-propagated operator IP is transformed via a “swap” operation. In another $1/4$ of the combinations, the Pauli operator remains unchanged during the backward propagation.

Furthermore, on the system qubit, for any given Pauli operator P' , there exists a proportion of $1/4$ among the total angle combinations for which that P' appears after backward propagation when $P \neq I$. This reflects the uniformity of Pauli operator appearances under the action of the gadget when the angles are sampled from the discrete set.

2. Lower bound of the variance of the loss function of MPQC

In this subsection, we derive a lower bound on the variance of the loss function for well-constructed MPQCs. According to Ref. [44], a non-vanishing variance implies the absence of barren plateaus. Hence, our result confirms that MPQCs do not suffer from barren plateau.

The lower bound of the variance can be described by the following theorem:

Theorem A.6. [Theorem 1, formal version] Consider a k -local observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$ (i.e., each Pauli word P_{α} acts non-trivially on at most k qubits) and an MPQC $\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$ which is achieved by inserting a layer of the gadgets after the l -th layer (also, $U_L(\theta_L)$) of the PQC. Suppose for each Pauli word P_{α} , the support size of its backward light cone at the gadget layer is upper bounded by $K = \mathcal{O}(\log n)$. Then the variance of the loss function $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) = \text{tr}\{\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)(\rho)O\}$ is lower bounded by

$$\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)] \geq \left(\frac{\tau}{4}\right)^K \|O\|_{HS}^2 = \Omega\left(\frac{1}{\text{poly}(n)}\right),$$

where $\|O\|_{HS} = \sqrt{\frac{\text{tr}\{O^2\}}{2^n}} = \sqrt{\sum_{\alpha} c_{\alpha}^2}$.

Proof. According to Eq. (D9), the variance of the loss function for the MPQC $\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$ can be written and lower bounded as follows:

$$\begin{aligned} \text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)] &= \frac{1}{4^{m+3n}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}}} \sum_{\alpha} c_{\alpha}^2 f\left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_G), \alpha)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2 \\ &\geq \frac{1}{4^{m+3n}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_G \in M_{\text{swap}}(\boldsymbol{\theta})}} \sum_{\alpha} c_{\alpha}^2 f\left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_G), \alpha)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2. \end{aligned} \quad (\text{E1})$$

Here, we consider a specific subset $M_{\text{swap}}(\boldsymbol{\theta}) \subseteq \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}$, defined as the collection of discrete angle configurations such that, for each $\boldsymbol{\theta}_G \in M_{\text{swap}}(\boldsymbol{\theta})$, all the gadgets transform the backward-propagated operator IP into PI . Here, the input $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ determines the Pauli operators that are backward propagated to the gadget layer. When the backward-propagated operator is nontrivial (i.e., $P \neq I$) on the i -th qubit, which occurs on at most K qubits, we choose the angle combination of $\boldsymbol{\theta}_{G_i}$ according to the first case in Appendix E1, which provides a construction of 16 configurations of $\boldsymbol{\theta}_{G_i} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^3$. On the otherhand, when the backward-propagated operator is I , which holds for at least $n - K$ qubits, any angle combination $\boldsymbol{\theta}_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}$ satisfies the required condition. It implies that for arbitrary $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$,

$$|M_{\text{swap}}(\boldsymbol{\theta})| \geq 4^{3(n-K)} 16^K = 4^{3n} \left(\frac{1}{4}\right)^K. \quad (\text{E2})$$

The effect of choosing $\boldsymbol{\theta}_G \in M_{\text{swap}}(\boldsymbol{\theta})$ on the Pauli path is illustrated in Fig. A.7.

Figure A.7: Pauli path of MPQC propagated from the observable P_α . Each column corresponds to a Pauli operator in the Pauli path, and each circle in the column represents a Pauli operator acting on one specific qubit. Solid circles denote nontrivial Pauli operators (i.e., not equal to I), while dashed circles indicate identity operators. Lines between Pauli operators at adjacent layers represent quantum gates acting on the corresponding qubits. All gates within the gadget layer are grouped into a single layer, as indicated by the purple dashed box. Purple circles represent Pauli operators immediately before and after the gadget layer in the backward propagation. In this example, we choose $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ and $\theta_G \in M_{\text{swap}}(\theta)$, so that the backward-propagated Pauli path is uniquely determined. The configuration $\theta_G \in M_{\text{swap}}(\theta)$ ensures that nontrivial Pauli operators originally acting on system qubits are swapped to the corresponding ancilla qubits.

Since the Pauli operators remaining on the system qubits before the gadget layer are all identities when we choose $\theta_G \in M_{\text{swap}}(\theta)$, the variance of the loss function is lower bounded by

$$\begin{aligned}
\text{Var}_{(\theta, \theta_G)} [L^C(\theta, \theta_G)] &\geq \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in M_{\text{swap}}(\theta)}} \sum_{\alpha} c_{\alpha}^2 f\left(\bar{s}^{((\theta, \theta_G), \alpha)}, (\theta, \theta_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2 \\
&\geq \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in M_{\text{swap}}(\theta)}} \sum_{\alpha} c_{\alpha}^2 \text{tr}\left\{(I \otimes P_{\alpha})^2 / 2^n\right\}^2 \text{tr}\left\{s_L^{((\theta, \theta_G), \alpha)} \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right\}^2 \\
&= \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in M_{\text{swap}}(\theta)}} \sum_{\alpha} c_{\alpha}^2 \text{tr}\left\{s_L^{((\theta, \theta_G), \alpha)}|_{\leq n} \text{op}(|0\rangle\langle 0|)^{\otimes n}\right\}^2 \text{tr}\{I\rho\}^2 \\
&\geq \frac{1}{4^{m+3n}} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} |M_{\text{swap}}(\theta)| \sum_{\alpha} c_{\alpha}^2 \tau^K \\
&\geq \frac{1}{4^{m+3n}} 4^m 4^{3n} \left(\frac{1}{4}\right)^K \sum_{\alpha} c_{\alpha}^2 \tau^K \\
&= \left(\frac{\tau}{4}\right)^K \sum_{\alpha} c_{\alpha}^2 = \left(\frac{\tau}{4}\right)^K \|O\|_{HS}^2 = \Omega\left(\frac{1}{\text{poly}(n)}\right).
\end{aligned} \tag{E3}$$

Here, the first equality holds because $\mathbf{U}_i(\theta_i)$ for $i \leq L$ has no effect on the Pauli path, as all Pauli operators acting on the system qubits are identities. The notation $s_L^{((\theta, \theta_G), \alpha)}|_{\leq n}$ denotes the Pauli operator supported on the first n qubits of $s_L^{((\theta, \theta_G), \alpha)}$. The third inequality holds since $s_L^{((\theta, \theta_G), \alpha)}|_{\leq n}$ contains at most K nontrivial single-qubit Pauli operators, each contributing at least a factor τ .

□

Supplementary Information F: Proof of Theorem 2

In this section, we prove that introducing a gadget layer consistently improves the trainability of a PQC, by establishing a lower bound on the gradient of the variance $\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right]$ for every $\theta_j \in \boldsymbol{\theta}$.

1. Feedforward parameters number of PQCs

Recall that for each θ_j , we prove that for PQC satisfying the conditions of Lemma A.3, $\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right]$ can be express as

$$\text{Var}_{\boldsymbol{\theta}} \left[\frac{\partial L(\boldsymbol{\theta})}{\partial \theta_j} \right] = \frac{1}{4^m} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\} = 0}} \sum_{\alpha} c_{\alpha}^2 f(\boldsymbol{\theta}, P_{\alpha}, \vec{s}^{(\boldsymbol{\theta}, \alpha)}, \rho)^2. \quad (\text{F1})$$

This indicates that, in order to analyze the scaling of this quantity, we need to characterize the number of angle combinations $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ satisfying $\{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\} = 0$. To this end, we introduce the concept of the *feedforward parameter number* $f_{j,O}^{\mathcal{C}}$ associated with the parameter θ_j and the observable O :

Definition A.2 (feedforward parameters number). *For a PQC $\mathcal{C}(\boldsymbol{\theta})$ and an observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$, we consider its parameter θ_j appearing in a rotation gate $R_{P_j}(\theta_j)$. Denote by $\{J_{\alpha}\}_{\alpha}$ the collection of backward light cones of $\{P_{\alpha}\}$ that include $R_{P_j}(\theta_j)$, and let $\{\bar{J}_{\alpha}\}$ represent the portions of these cones that appear after the layer containing $R_{P_j}(\theta_j)$, as illustrated in Fig. A.8. For each region $\bar{J}_{\alpha}$, count the number of rotation gates that contain parameters, resulting in a set $\{\#_R \bar{J}_{\alpha}\}$. The quantity $f_{j,O}^{\mathcal{C}}$ is defined as the maximum value in this set. More precisely,*

$$f_{j,O}^{\mathcal{C}} = \begin{cases} 0, & \text{if } \{\bar{J}_{\alpha}\} = \emptyset \\ \max_{\alpha} \{\#_R \bar{J}_{\alpha}\}, & \text{otherwise} \end{cases} \quad (\text{F2})$$

Figure A.8: Illustration of the feedforward parameters number $f_{j,O}^{\mathcal{C}}$. The yellow region represents the backward light cone J_{α} of a specific Pauli word P_{α} in the observable O . The orange region $\bar{J}_{\alpha}$ denotes the portion of J_{α} that appears after the layer containing the rotation gate $R_{P_j}(\theta_j)$. The quantity $\#_R \bar{J}_{\alpha}$ counts the number of rotation gates with parameters within the region $\bar{J}_{\alpha}$. The support size of the backward light cone at layer l (i.e., the layer where the gadget is inserted in MPQCs) is upper bounded by K .

It is straightforward to observe that in the Heisenberg picture, examining the rotation angles in $\{\bar{J}_{\alpha}\}$ suffices to determine whether $\{P_j, s_j^{(\boldsymbol{\theta}, \alpha)}\} = 0$. This implies that, at most $f_{j,O}^{\mathcal{C}}$ parameters in $\boldsymbol{\theta}$ need to be considered. Then, to characterize the total number of parameters that need to be considered in each Pauli path after the gadget layer, we introduce the following definition.

Definition A.3 (Total number of feedforward parameters after the gadget layer). For a PQC $C(\theta)$ and an observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$, consider its corresponding MPQC $\Phi^C(\theta, \theta_G)$ obtained by inserting a gadget layer. We define the total number of feedforward parameters after the gadget layer, denoted by $f_{G,O}^C$, as the maximum number of parameters contained in the backward light cones of all Pauli terms P_{α} that located after the gadget layer.

It is straightforward to verify that for any parameter θ_j lie after the gadget layer, we have $f_{j,O}^C \leq f_{G,O}^C$.

2. Lower bound of gradient variance of the loss function of MPQCs

We are now ready to present the following theorem, which provides the formal version of Theorem 2:

Theorem A.7 (Theorem 2, formal version). Consider an MPQC $\Phi^C(\theta, \theta_G)$ and a k -local observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$. Suppose the support size of the backward light cone of each P_{α} at the gadget layer is upper bounded by $K = \mathcal{O}(\log n)$ and $f_{G,O}^C = \mathcal{O}(\log n)$. Then, the variance of the gradient with respect to the parameters $\theta \in [0, 2\pi)^m$ in the original PQC satisfies the following properties:

- For parameter θ_j located after the gadget layer, if $\text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] \neq 0$, then $\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right]$ is lower bounded by

$$\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right] \geq \left(\frac{1}{2} \right)^{f_{j,O}^C} \left(\frac{\tau}{4} \right)^K \|O\|_{\min}^2 = \Omega \left(\frac{1}{\text{poly}(n)} \right), \quad (\text{F3})$$

where $\|O\|_{\min} := \min\{|c_{\alpha}| > 0\}$.

- For parameter θ_j located before the gadget layer, θ_j remains trainable if it is already trainable in the original PQC, which is ensured by the following lower bound on the gradient variance $\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right]$:

$$\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right] \geq \left(\frac{1}{4} \right)^K \left(\frac{\|O\|_{\min}}{\|O\|_{HS}} \right)^2 \text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] = \Omega \left(\frac{1}{\text{poly}(n)} \right) \text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right]. \quad (\text{F4})$$

Proof. We first suppose that the gate $R_{P_j}(\theta_j)$ contains parameter θ_j is located after the gadget layer. According to Eq. (D10), the variance of its gradient $\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right]$ can be expressed as

$$\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right] = \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n} \\ \{\mathbf{P}_j, \mathbf{s}_j^{((\theta, \theta_G), \alpha)}\} = 0}} \sum_{\alpha} c_{\alpha}^2 f \left(\vec{s}^{((\theta, \theta_G), \alpha)}, (\theta, \theta_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|^{\otimes n} \otimes \rho) \right)^2. \quad (\text{F5})$$

If $\text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right]$ is nonzero, then there at least exist one Pauli word P_{β} in O and $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that $\{P_j, \vec{s}_j^{(\theta, \beta)}\} = 0$. Since the gadget layer does not affect the Pauli path after l -th layer (in the Heisenberg picture), we have that in the MPQC setting, $\mathbf{P}_j = I \otimes P_j$ and $\mathbf{s}_j^{((\theta, \theta_G), \beta)} = I \otimes \vec{s}_j^{(\theta, \beta)}$ for arbitrary θ_G . It also implies that

$$\{\mathbf{P}_j, \mathbf{s}_j^{((\theta, \theta_G), \beta)}\} = \{I \otimes P_j, I \otimes \vec{s}_j^{(\theta, \beta)}\} = \{P_j, \vec{s}_j^{(\theta, \beta)}\} = 0.$$

This implies that if there exists a parameter configuration $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ and a Pauli word P_{β} in O such that $\{P_j, \vec{s}_j^{(\theta, \beta)}\} = 0$ holds in the original PQC, then one can construct a group of angle combinations (θ, θ_G) such that $\{\mathbf{P}_j, \mathbf{s}_j^{((\theta, \theta_G), \beta)}\} = 0$ holds in the corresponding MPQC.

Employing this property, we now count the number of discrete angle configurations in Eq. (F5) for which the corresponding term does not vanish. Let M_j denote the set of angle configurations of $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ that maximize the number of angle configurations satisfying $\{P_j, \vec{s}_j^{(\theta, \beta)}\} = 0$. Since $\text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] \neq 0$, there exists at least one Pauli word P_{β} in O and one angle configuration $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that $\{P_j, \vec{s}_j^{(\theta, \beta)}\} = 0$. On the other hand, the angle values $\{0, \pi\}$ and $\{\pi/2, 3\pi/2\}$ yield the same effect on the backward propagation of the Pauli path, up to

an overall sign. Therefore, for parameters located in the region $\bar{J}_\beta$, they can be replaced by their corresponding pairs without affecting the commutation relation between $\vec{s}_j^{(\theta, \beta)}$ and P_j . Consequently, there exist at least $2^{\#_R \bar{J}_\beta}$ angle configurations such that $\{P_j, \vec{s}_j^{(\theta, \beta)}\} = 0$ holds.

While for parameters outside $\bar{J}_\beta$, their values do not affect the commutation relation between $\vec{s}_j^{(\theta, \beta)}$ and P_j , and hence can be chosen arbitrarily, yielding $4^{m - \#_R \bar{J}_\beta}$ possible angle configurations.

Therefore, we obtain:

$$|M_j| \geq 2^{\#_R \bar{J}_\beta} 4^{m - \#_R \bar{J}_\beta} = 4^m \left(\frac{1}{2}\right)^{\#_R \bar{J}_\beta}. \quad (\text{F6})$$

Next, we fix the choice of θ_G . We pick $\theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}$ the same as the construction in the proof of Theorem A.6 (corresponding to the first case in Appendix E1). It swaps the non-trivial Pauli operator in the system qubits to the ancillas. We also denote the set of such configurations of θ_G as $M_{\text{swap}}(\theta)$. Since the support size of the backward-propagated Pauli operator at the gadget layer is upper bounded by K , following the same counting argument as in the proof of Theorem A.6, we obtain that for any $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$,

$$|M_{\text{swap}}(\theta)| \geq 4^{3n} \left(\frac{1}{4}\right)^K. \quad (\text{F7})$$

Based on the above constructions of θ and θ_G , we obtain the following lower bound:

$$\begin{aligned} \text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right] &= \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n} \\ \{P_j, \vec{s}_j^{((\theta, \theta_G), \alpha)}\} = 0}} \sum_{\alpha} c_{\alpha}^2 f \left(\vec{s}^{((\theta, \theta_G), \alpha)}, (\theta, \theta_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right)^2 \\ &\geq \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n} \\ \{P_j, \vec{s}_j^{((\theta, \theta_G), \beta)}\} = 0}} c_{\beta}^2 f \left(\vec{s}^{((\theta, \theta_G), \beta)}, (\theta, \theta_G), I \otimes P_{\beta}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right)^2 \\ &\geq \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in M_j \\ \theta_G \in M_{\text{swap}}(\theta)}} c_{\beta}^2 f \left(\vec{s}^{((\theta, \theta_G), \beta)}, (\theta, \theta_G), I \otimes P_{\beta}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right)^2 \\ &\geq \frac{1}{4^{m+3n}} \sum_{\theta \in M_j} |M_{\text{swap}}(\theta)| c_{\beta}^2 \text{tr} \left\{ \mathbf{s}_L |_{\leq n} \text{op}(|0\rangle\langle 0|)^{\otimes n} \right\}^2 \text{tr} \{I\rho\}^2 \\ &\geq \frac{|M_j|}{4^{m+3n}} 4^{3n} \left(\frac{1}{4}\right)^K c_{\beta}^2 \tau^K \\ &\geq \frac{c_{\beta}^2}{4^{m+3n}} 4^m 4^{3n} \left(\frac{1}{2}\right)^{\#_R \bar{J}_\beta} \left(\frac{1}{4}\right)^K \tau^K \\ &= \left(\frac{1}{2}\right)^{\#_R \bar{J}_\beta} \left(\frac{\tau}{4}\right)^K c_{\beta}^2 \\ &\geq \left(\frac{1}{2}\right)^{f_{j,O}^C} \left(\frac{\tau}{4}\right)^K \|O\|_{\min}^2 = \Omega \left(\frac{1}{\text{poly}(n)} \right), \end{aligned} \quad (\text{F8})$$

where the last equation holds because $f_{j,O}^C \leq f_{G,O}^C = \mathcal{O}(\log n)$. This completes the proof of Eq. (F3).

If the parameter θ_j is located before the gadget layer, we again consider a specific construction of $\theta_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}$. In particular, we choose θ_G such that it does not affect the backward propagation of the Pauli path; we denote this the angle configuration as $M_{\text{same}}(\theta)$.

Note that for arbitrary $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ and Pauli word P_{α} in O , at most K nontrivial Pauli operators are propagated backward to the gadget layer. We then select θ_G corresponding to the second case described in Appendix E1

that does not change the Pauli operators on these qubits. There is at least $4^{3(n-K)}16^K$ distinct angle configurations of θ_G that satisfy this requirement. This implies that for any $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ and P_α , we have

$$|M_{\text{same}}(\theta)| \geq 4^{3(n-K)}16^K.$$

By restricting our attention to these configurations, we obtain the following lower bound on the gradient variance with respect to θ_j :

$$\begin{aligned} & \text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^C(\theta, \theta_G)}{\partial \theta_j} \right] \\ & \geq \frac{1}{4^{m+3n}} \sum_{\substack{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \theta_G \in M_{\text{same}}(\theta) \\ \{\mathbf{P}_j, \mathbf{s}_j^{(\theta, \alpha)}\} = 0}} \sum_{\alpha} c_{\alpha}^2 f\left(\vec{s}^{((\theta, \theta_G), \alpha)}, (\theta, \theta_G), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2 \\ & = \frac{1}{4^{m+3n}} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} |M_{\text{same}}(\theta)| \sum_{\alpha} c_{\alpha}^2 \sum_{\substack{\mathbf{s}_m, \mathbf{s}_{m-1}, \dots, \mathbf{s}_0 \\ \{\mathbf{P}_j, \mathbf{s}_j\} = 0}} \text{tr}\{I \otimes P_{\alpha} \mathbf{s}_m\}^2 \prod_{i=i}^m \text{tr}\{\mathbf{s}_i \mathbf{U}_i(\theta_i) \mathbf{s}_{i-1} \mathbf{U}_i(\theta_i)^{\dagger}\}^2 \text{tr}\{\mathbf{s}_0 \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\}^2 \\ & \geq \frac{4^{3(n-K)}16^K}{4^{m+3n}} \sum_{\alpha} \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\substack{\mathbf{s}_m, \mathbf{s}_{m-1}, \dots, \mathbf{s}_0 \\ \{\mathbf{P}_j, \mathbf{s}_j\} = 0}} c_{\alpha}^2 \text{tr}\{I \otimes P_{\alpha} \mathbf{s}_m\}^2 \prod_{i=i}^m \text{tr}\{\mathbf{s}_i \mathbf{U}_i(\theta_i) \mathbf{s}_{i-1} \mathbf{U}_i(\theta_i)^{\dagger}\}^2 \text{tr}\{\mathbf{s}_0 \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\}^2 \\ & = \left(\frac{1}{4}\right)^K \left(\frac{1}{4}\right)^m \sum_{\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m} \sum_{\vec{s}: \{\mathbf{P}_j, \mathbf{s}_j\} = 0} \sum_{\alpha} c_{\alpha}^2 \text{tr}\{P_{\alpha} \mathbf{s}_m\}^2 \prod_{i=i}^m \text{tr}\{\mathbf{s}_i \mathbf{U}_i(\theta_i) \mathbf{s}_{i-1} \mathbf{U}_i(\theta_i)^{\dagger}\}^2 \text{tr}\{\mathbf{s}_0 |0^n\rangle\langle 0^n|\}^2 \\ & \geq \left(\frac{1}{4}\right)^K \left(\frac{\|O\|_{\min}}{\|O\|_{HS}}\right)^2 \text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right] = \Omega\left(\frac{1}{\text{poly}(n)}\right) \text{Var}_{\theta} \left[\frac{\partial L(\theta)}{\partial \theta_j} \right]. \end{aligned} \tag{F9}$$

Here the first equality holds due to the choice $\theta_G \in M_{\text{same}}(\theta)$, under which all the Pauli paths in the gadget layer remain unchanged and equal to $\mathbf{s}_L$, i.e., $\mathbf{s}_{L+1} = \mathbf{s}_{G_{1,1}} = \mathbf{s}_{G_{1,2}} = \dots = \mathbf{s}_{G_{n,3}} = \mathbf{s}_L$. The last inequality employs the conclusion in Corollary A.2. $\square$

Remark. As we can see, the proof of this theorem is rather loose, as three cases in Appendix E 1 were entirely omitted. We believe that introducing the gadget layer enriches the diversity of Pauli paths contributing to the gradient, which can substantially increase the overall gradient variance.

Supplementary Information G: Locating the Gadget Layer via Circuit Geometry

In this section, we demonstrate how to determine the placement of the gadget layer based on the geometric structure of the circuit. Our goal is to determine the appropriate position of the gadget layer—specifically, the value of $D - l$ (where D denotes the depth of the original PQC)—such that both K and $f_{G,O}^C$ are of order $\mathcal{O}(\log n)$, thereby fulfilling the assumptions required by the theorem.

As an example, we consider a class of PQCs defined on (hyper)cubic lattices. These circuits are composed of two-qubit gates, or blocks of gates that effectively act on two qubits, applied along the edges of a lattice such that each qubit participates in exactly one two-qubit gate (or gate block) per layer. We consider circuits embedded in a d -dimensional (hyper)cubic lattice with $d \geq 1$. For simplicity, in the following discussion we assume that each two-qubit gate block consists of a single two-qubit gate. This simplification only affects constant prefactors in the scaling of gate-related quantities and does not alter the asymptotic analysis.

In such uniform architectures, it is natural to characterize the size of backward light cones using the concept of *operator spreading velocity* $v \in [0, 1]$ [59]. According to the analysis in Ref. [60], for a 1-local observable, the number of qubits involved after $D - l$ layers in the Heisenberg picture is given by

$$n_{D-l} = \left(\frac{2v}{d}(D-l)\right)^d.$$

Therefore, for arbitrary k -local Pauli word P_{α} in O , the number of qubits influenced after $D - l$ layers is at most

$$kn_{D-l} = k \left(\frac{2v}{d}(D-l)\right)^d,$$

which is an upper bound of K .

For this type of circuit, the feedforward parameter number can also be tightly upper bounded. Based on the calculation in Ref. [60], the total number of gates involved in the backward light cone of k -local observable after $D-l$ layers is upper bounded by

$$\frac{kn_{D-l}(D-l)}{2(d+1)} = \frac{k2^{d-1}v^d}{(d+1)d^d}(D-l)^{d+1},$$

which serves as an upper bound on $f_{\mathcal{G},O}^{\mathcal{C}}$.

To conclude, for PQCs defined on a d -dimensional cubic lattice and measured with a k -local observable, if the corresponding MPQC is constructed by inserting a gadget layer after the l -th layer of the original circuit, then the following result holds:

$$K \leq kn_{D-l} = k \left(\frac{2v}{d} (D-l) \right)^d \quad (\text{G1})$$

$$f_{\mathcal{G},O}^{\mathcal{C}} \leq \frac{kn_{D-l}(D-l)}{2(d+1)} = \frac{k2^{d-1}v^d}{(d+1)d^d}(D-l)^{d+1}. \quad (\text{G2})$$

Then, by restricting $D-l = \mathcal{O}\left((\log n)^{\frac{1}{d+1}}\right)$ and treating v and d as constants, we can apply Eq. (G1) and Eq. (G2) to obtain the following results:

$$K = \mathcal{O}\left((\log n)^{\frac{d}{d+1}}\right), f_{\mathcal{G},O}^{\mathcal{C}} = \mathcal{O}(\log n). \quad (\text{G3})$$

This implies that the conditions in Theorem A.7 are naturally satisfied when $D-l = \mathcal{O}\left((\log n)^{\frac{1}{d+1}}\right)$. We thus obtain the following corollary:

Corollary A.3. *Let $\mathcal{C}(\boldsymbol{\theta})$ be a PQC defined on a d -dimensional (hyper)cubic lattice, and let its circuit depth be denoted by D . Suppose the corresponding MPQC $\Phi^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ is constructed by inserting a layer of gadgets after the l -th layer of $\mathcal{C}(\boldsymbol{\theta})$. Then, the lower bounds on the gradient variance $\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})} \left[\frac{\partial L^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})}{\partial \theta_j} \right]$ established in Theorem A.7 hold, provided that $D-l = \mathcal{O}\left((\log n)^{\frac{1}{d+1}}\right)$.*

Supplementary Information H: Strategy for activating single parameter

In this section, we provide additional details on the activation of a single parameter, including the construction of the enlarged gadget and the proof of Theorem 3.

1. Selection of the enlarged gadget

Suppose we aim to activate a single-qubit rotation gate $T = R_{P_T}(\theta_T)$, which acts nontrivially on the t -th system qubit and is located before the gadget layer. To achieve this, we insert one extra gadget immediately before T and enlarge one gadget $\mathcal{G}(\boldsymbol{\theta})$ in the gadget layer to obtain a new type of gadget $\mathcal{G}'_T(\boldsymbol{\theta})$, in which three additional two-qubit rotation gates are inserted. The only restriction we impose on the enlarged gadget is that if we choose the i -th gadget $\mathcal{G}_i(\boldsymbol{\theta})$ in the gadget layer, there must exist some P_β in O and $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that $s_L^{(\boldsymbol{\theta}, \beta)}|_i \neq I$. In other words, we require that the i -th Pauli word in the operator arriving at the gadget layer, backward propagated from P_β for some angle configuration $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$, be nontrivial.

Next, we show that such a gadget $\mathcal{G}(\boldsymbol{\theta})$ satisfying the above condition can be efficiently identified. We first randomly select a Pauli word P_β from O , and to determine the Pauli operator that is backward propagated to the gadget layer, it suffices to scan over the angles within the backward light cone of P_β , i.e., at most $f_{\mathcal{G},O}^{\mathcal{C}} = \mathcal{O}(\log n)$ parameters. We assign these angles random values from $\{0, \pi/2, \pi, 3\pi/2\}$ and then compute $s_L^{(\boldsymbol{\theta}, \beta)}$. Since the resulting circuit is Clifford, evaluating $s_L^{(\boldsymbol{\theta}, \beta)}$ can be done efficiently. We then arbitrarily choose one position where $s_L^{(\boldsymbol{\theta}, \beta)}$ acts nontrivially to construct $\mathcal{G}'_T(\boldsymbol{\theta})$. Moreover, since each angle can take four possible values, a large number of distinct $s_L^{(\boldsymbol{\theta}, \beta)}$ can be

generated, implying that almost any gadget within the support of the backward light cone of P_β has a high probability of satisfying the required condition.

Without loss of generality and for the convenience of proof, we make the following reasonable assumption: there exists a Pauli word P_β in observable O and some $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that the backward-propagated Pauli operator $s_L^{(\theta, \beta)}$ reaches the gadget layer and satisfies $s_L^{(\theta, \beta)}|_t \neq I$, where the subscript t denotes the t -th qubit with the target gate T applied. If this condition is not satisfied, one can instead modify another gadget $\mathcal{G}_i(\theta)$ into $\mathcal{G}'_T(\theta)$ with a nontrivial input, thereby activating the gate T —the only difference being that $\mathcal{G}_i(\theta)$ and T act on different system qubits, which is depicted in Fig. A.9. This modification does not affect the validity of the subsequent analysis.

Figure A.9: Construction of $\mathcal{G}'_T(\theta)$ when $\mathcal{G}_i(\theta)$ and T act on different system qubits. The first three two-qubit parameterized gates act on the ancilla qubit and the system qubit on which the target gate T is applied.

2. Proof of Theorem 3

Now we are ready to prove Theorem 3. For clarity, we provide a detailed lower bound on the variance of the partial derivative of the loss function with respect to θ_T , following the notation introduced in the manuscript:

Theorem A.8. Consider a T -activating MPQC $\Phi_T^C(\theta, \theta_G, \theta_{G'_T})$ and a k -local observable $O = \sum_\alpha c_\alpha P_\alpha$. Suppose the conditions in Theorem A.7 still hold. Then, we have

$$\text{Var}_{(\theta, \theta_G, \theta_{G'_T})} \left[\frac{\partial L_T^C(\theta, \theta_G, \theta_{G'_T})}{\partial \theta_T} \right] \geq \left(\frac{1}{2} \right)^{f_{G, O}^C + 8} \left(\frac{\tau}{4} \right)^{K+1} \|O\|_{\min}^2 = \Omega \left(\frac{1}{\text{poly}(n)} \right), \quad (\text{H1})$$

for the loss function of the T -activating MPQC, defined as $L_T^C(\theta, \theta_G, \theta_{G'_T}) := \text{tr}\{\Phi_T^C(\theta, \theta_G, \theta_{G'_T})(\rho)O\}$.

Proof. We begin by expressing the unitary representation of $\Phi_T^C(\theta, \theta_G, \theta_{G'_T})$ when ancilla qubits are included. We denote it as $\mathbf{U}_T^C(\theta, \theta_G, \theta_{G'_T})$. Note that an additional $\mathcal{G}(\theta)$ is inserted before the gate T , so the unitary $\mathbf{U}_T^C(\theta, \theta_G, \theta_{G'_T})$ acts on a $(2n+1)$ -qubit Hilbert space. The loss function of this MPQC can thus be written as

$$\begin{aligned} L_T^C(\theta, \theta_G, \theta_{G'_T}) &= \text{tr}\{\Phi_T^C(\theta, \theta_G, \theta_{G'_T})(\rho)O\} \\ &= \sum_\alpha c_\alpha \text{tr}\left\{ \mathbf{U}_T^C(\theta, \theta_G, \theta_{G'_T}) (op(|0\rangle\langle 0|)^{\otimes(n+1)} \otimes \rho) \mathbf{U}_T^C(\theta, \theta_G, \theta_{G'_T})^\dagger I \otimes P_\alpha \right\}. \end{aligned} \quad (\text{H2})$$

Then we rewrite $\text{Var}_{(\theta, \theta_G, \theta_{G'_T})} \left[\frac{\partial L_T^C(\theta, \theta_G, \theta_{G'_T})}{\partial \theta_T} \right]$ in the language of Pauli path integral and quantum rotation 2-design

according to Eq. (D10):

$$\begin{aligned}
& \text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})} \left[\frac{\partial L_T^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})}{\partial \theta_T} \right] \\
&= \frac{1}{4^{m+3n+6}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_{\mathcal{G}} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n} \\ \boldsymbol{\theta}_{\mathcal{G}'_T} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^6 \\ \{\mathbf{P}_T, \mathbf{s}_T^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \alpha)}\} = 0}} \sum_{\alpha} c_{\alpha}^2 f \left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \alpha)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes(n+1)} \otimes \rho \right)^2 \\
&\geq \frac{1}{4^{m+3n+6}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_{\mathcal{G}} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n} \\ \boldsymbol{\theta}_{\mathcal{G}'_T} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^6 \\ \{\mathbf{P}_T, \mathbf{s}_T^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \beta)}\} = 0}} c_{\beta}^2 f \left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \beta)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), I \otimes P_{\beta}, \text{op}(|0\rangle\langle 0|)^{\otimes(n+1)} \otimes \rho \right)^2,
\end{aligned} \tag{H3}$$

where we fix a specific Pauli word P_{β} in $\mathcal{O}$ such that its backward-propagated Pauli operator $s_L^{(\boldsymbol{\theta}, \beta)}$ satisfies $s_L^{(\boldsymbol{\theta}, \beta)}|_t \neq I$ for some $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$.

We then again derive a lower bound for Eq. (H3) by constructing explicit angle configurations of $\boldsymbol{\theta}$, $\boldsymbol{\theta}_{\mathcal{G}}$, and $\boldsymbol{\theta}_{\mathcal{G}'_T}$, where all angles take values in $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$. For $\boldsymbol{\theta}$, we select configurations such that the Pauli operator backward propagated from P_{β} acts nontrivially on the t -th system qubit when reaching the gadget layer. Let $M_t \subseteq \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ denote the set of such configurations with the maximal cardinality. From the perspective of backward Pauli propagation, only the gates in the backward light cone of P_{β} following the gadget layer affect the Pauli path $s_L^{(\boldsymbol{\theta}, \beta)}$. Therefore, it suffices to fix at most $f_{\mathcal{G}, \mathcal{O}}^{\mathcal{C}}$ angles in $\boldsymbol{\theta}$ to ensure $s_L^{(\boldsymbol{\theta}, \beta)}|_t \neq I$. This implies that

$$|M_t| \geq 4^{m-f_{\mathcal{G}, \mathcal{O}}^{\mathcal{C}}} 2^{f_{\mathcal{G}, \mathcal{O}}^{\mathcal{C}}} = 4^m \left(\frac{1}{2} \right)^{f_{\mathcal{G}, \mathcal{O}}^{\mathcal{C}}}, \tag{H4}$$

where the factor $2^{f_{\mathcal{G}, \mathcal{O}}^{\mathcal{C}}}$ arises from the observation discussed in Appendix F 2, namely that the angle values $\{0, \pi\}$ and $\{\pi/2, 3\pi/2\}$ produce identical effects on the backward propagation of the Pauli path.

Below, we illustrate the choice of $\boldsymbol{\theta}_{\mathcal{G}'_T} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^6$ based on $\boldsymbol{\theta}$ with the aid of the following figure.

Figure A.10: Expansion of $\mathcal{G}'_T(\boldsymbol{\theta})$ in terms of Pauli operators for analyzing its effect on Pauli paths. Both Q_i and P_i represent Pauli operators.

The choice of $\boldsymbol{\theta} \in M_t$ ensures that the backward-propagated Pauli operator P is nontrivial, i.e., $P \neq I$. Then, we set the parameters of $\mathcal{G}'_T(\boldsymbol{\theta})$ to satisfy the condition $\{\mathbf{P}_T, \mathbf{s}_T^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \beta)}\} = 0$. This can be achieved according to the following rules:

- Choose $\theta_4, \theta_5, \theta_6 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^3$ such that $P_1 = P, P_2 = I$.
- Choose $\theta_1, \theta_2, \theta_3 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^3$ such that $\{\mathbf{P}_T, Q_2\} = 0$.

The above requirements can always be fulfilled as follows: we choose $\theta_4, \theta_5, \theta_6$ according to the first case in Appendix E 1, which swaps the operator onto the ancilla qubit and yields 16 possible angle configurations, corresponding

to $P_1 = P$ and $P_2 = I$. Then, we pick $\theta_1, \theta_2, \theta_3$ according to the first, third, and fourth cases in Appendix E1, which allow the resulting operator Q_2 to be any nontrivial Pauli operator. We then select one such configuration to ensure $\{P_T, Q_2\} = 0$, which also yields at least 16 angle combinations. Denote by $M_{\text{anti}}(\boldsymbol{\theta})$ the set of parameter configurations $\theta_1, \dots, \theta_6$ satisfying these two conditions. Then, for any given $\boldsymbol{\theta} \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ (which determines the Pauli operator P), we have

$$|M_{\text{anti}}(\boldsymbol{\theta})| \geq 16^2 = 4^4. \quad (\text{H5})$$

For $\boldsymbol{\theta}_{\mathcal{G}}$, we adopt the same configuration as in the proof of Theorem A.6, which transforms the operator IP into PI . We denote this set of configurations as $M_{\text{swap}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}'_T})$. Here, $\boldsymbol{\theta}_{\mathcal{G}'_T}$ is treated as an input, since it determines the angle configuration of the gadget $\mathcal{G}(\boldsymbol{\theta})$ placed before T . Following a similar argument to that in the proof of Theorem A.6, we obtain that for any $\boldsymbol{\theta} \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ and $\boldsymbol{\theta}_{\mathcal{G}'_T} \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^6$,

$$|M_{\text{swap}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}'_T})| \geq 4^{3(n-K-1)} 16^K = 4^{3n} \left(\frac{1}{4}\right)^{K+3}. \quad (\text{H6})$$

From a geometric perspective, when choosing $\boldsymbol{\theta} \in M_t$, $\boldsymbol{\theta}_{\mathcal{G}'_T} \in M_{\text{anti}}(\boldsymbol{\theta})$ and $\boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}'_T})$, the corresponding Pauli path takes the form illustrated in Fig. A.11. The configuration $\boldsymbol{\theta}_{\mathcal{G}'_T} \in M_{\text{anti}}(\boldsymbol{\theta})$ acts as a “bridge” that transports the Pauli operator Q_2 to the location of gate T , while simultaneously ensuring that $\{P_T, Q_2\} = 0$.

Figure A.11: Pauli path of the T -activating MPQC propagated from the observable P_β . The orange line marks the target single-qubit rotation gate T . The choice of parameters $\boldsymbol{\theta} \in M_t$ and $\boldsymbol{\theta}_{\mathcal{G}'_T} \in M_{\text{anti}}(\boldsymbol{\theta})$ ensures that a nontrivial Pauli operator is transported along the backward-propagated path to the location of T . The additional $\mathcal{G}(\boldsymbol{\theta})$ inserted before T then swaps the Pauli operator onto the corresponding ancilla qubit, thereby preserving a non-vanishing Pauli path.

Therefore $\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})} \left[\frac{\partial L_T^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})}{\partial \theta_T} \right]$ can be lower bounded as

$$\begin{aligned}
& \text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})} \left[\frac{\partial L_T^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})}{\partial \theta_T} \right] \\
& \geq \frac{1}{4^{m+3n+6}} \sum_{\substack{\boldsymbol{\theta} \in M_t \\ \boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}'_T}) \\ \boldsymbol{\theta}_{\mathcal{G}'_T} \in M_{\text{anti}}(\boldsymbol{\theta})}} c_{\beta}^2 f \left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \beta)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), I \otimes P_{\beta}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right)^2 \\
& \geq \frac{1}{4^{m+3n+6}} \sum_{\substack{\boldsymbol{\theta} \in M_t \\ \boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}'_T}) \\ \boldsymbol{\theta}_{\mathcal{G}'_T} \in M_{\text{anti}}(\boldsymbol{\theta})}} c_{\beta}^2 \tau^{K+1} \\
& \geq \frac{c_{\beta}^2 \tau^{K+1}}{4^{m+3n+6}} 4^m \left(\frac{1}{2} \right)^{f_{\mathcal{G}, O}^{\mathcal{C}}} 4^4 4^{3n} \left(\frac{1}{4} \right)^{K+3} \\
& = c_{\beta}^2 \left(\frac{1}{2} \right)^{f_{\mathcal{G}, O}^{\mathcal{C}}+8} \left(\frac{\tau}{4} \right)^{K+1} \\
& \geq \|O\|_{\min}^2 \left(\frac{1}{2} \right)^{\mathcal{O}(\log n)} \left(\frac{\tau}{4} \right)^{\mathcal{O}(\log n)} = \Omega \left(\frac{1}{\text{poly}(n)} \right).
\end{aligned} \tag{H7}$$

Here, the second inequality holds because the Pauli operator $\mathbf{s}_0^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \beta)}$ acts trivially (i.e., as the identity I) on all system qubits, while its support on the ancilla qubits has weight at most $K+1$.

□

Supplementary Information I: Strategy for activating multiple parameters

In this section, we present a strategy to activate multiple parameters in PQCs. Suppose we aim to activate a set of parameters contained in the gate set $\{T_1, T_2, \dots\}$. A straightforward approach is to directly extend the method in Appendix H: specifically, we modify multiple gadgets $\mathcal{G}(\boldsymbol{\theta})$ into $\mathcal{G}'_{T_i}(\boldsymbol{\theta})$ and insert an additional $\mathcal{G}(\boldsymbol{\theta})$ before each T_i . According to the proof technique in Theorem A.8, $\mathcal{O}(\log n)$ parameters can be activated simultaneously.

We next propose a nontrivial approach to activate parameters that are located in close proximity to each other. Specifically, we first identify the parameters placed nearest to the measurement layer and record the qubits they act on as $t_1, \dots, t_S$. We then consider a backward light cone of these S qubits in the original circuit, which defines a region that contains all parameters to be activated. We refer to this region as the *activation zone*, highlighted by the red dashed line in Fig. A.12. To activate the parameters within the activation zone, we modify $S \mathcal{G}(\boldsymbol{\theta})$ in the gadget layer into $\mathcal{G}'_{T_i}(\boldsymbol{\theta})$, each acting on qubits $t_1, \dots, t_S$, respectively. Finally, we insert a layer of $\mathcal{G}(\boldsymbol{\theta})$ gates within the support of the activation zone. The resulting circuit is referred to as the $\{T_1, T_2, \dots\}$ -*activating MPQC*, and the entire construction procedure is illustrated in Fig. A.12.

Next, we prove that, under certain conditions, the parameters within the activation zone are trainable. To establish this result, we introduce the following notations. Let the unitary blocks in the activation zone be denoted by $U_i(\theta_i)$ for $i \in \text{act}$ and denote the support size of the activation zone by K_{act} . We represent the corresponding quantum channel as $\Phi_{\{T_1, T_2, \dots\}}^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})$, and its unitary representation (including the ancilla qubits) as $\mathbf{U}_{\{T_1, T_2, \dots\}}^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})$, where, as before, $\boldsymbol{\theta}_{\mathcal{G}'_T}$ denotes the parameters in all enlarged gadgets $\mathcal{G}'_{T_i}(\boldsymbol{\theta})$, and $\boldsymbol{\theta}_{\mathcal{G}}$ collects the parameters in all gadgets $\mathcal{G}(\boldsymbol{\theta})$.

Figure A.12: Modified MPQC to activate multiple parameters. The region enclosed by the red dashed line is referred to as the activation zone, where the orange boxes indicate parameterized rotation gates. $\{t_1, \dots, t_S\}$ denotes the set of qubit indices on which the gates in the last layer of the activation zone act. K_{act} denotes the support size of this region. All parameters within this zone can be simultaneously activated by this circuit.

We are now ready to prove the following theorem, which guarantees that parameters in $\{\theta_i\}_{i \in act}$ are trainable:

Theorem A.9. Consider a $\{T_1, T_2, \dots\}$ -activating MPQC $\Phi_{\{T_1, T_2, \dots\}}^C(\theta, \theta_G, \theta_{G'_T})$ measured a k -local observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$ and a parameter θ_j in the activation zone. Suppose that the following conditions are satisfied:

- There exists a Pauli word P_{β} in the observable O and a configuration $\theta \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that the backward-propagated Pauli operator $s_L^{(\theta, \beta)}$ reaches the gadget layer and satisfies $s_L^{(\theta, \beta)}|_{\{t_1, \dots, t_S\}} \neq I$.
- For arbitrary Pauli word P whose support lies in $\{t_1, \dots, t_S\}$, we backward propagate the unitaries in the activation zone, i.e., $\{U_i(\theta_i)\}$, $i \in act$ from arbitrary Pauli word $\mathbf{P}$ whose support lies in $\{t_1, \dots, t_S\}$, achieve another $2n$ -qubit Pauli path $\bar{s}_{act}^{(\{\theta_i\}_{i \in act}, \mathbf{P})}$. Suppose there exist some $\mathbf{P}_{act}$ and $\{\theta_i\}_{i \in act}$ for all $\theta_i \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$ such that

$$\{\mathbf{P}_j, \mathbf{s}_{act|\mathbf{P}_j}^{(\{\theta_i\}_{i \in act}, \mathbf{P}_{act})}\} = 0, \quad (11)$$

where $\mathbf{s}_{act|\mathbf{P}_j}^{(\{\theta_i\}_{i \in act}, \mathbf{P}_{act})}$ denotes the Pauli operator associated with the segment following $U_j(\theta_j)$ in $\bar{s}_{act}^{(\{\theta_i\}_{i \in act}, \mathbf{P})}$.

- K , K_{act} , $f_{G,O}^C$, and f_{act}^C (defined as the number of parameters within the activation zone) are all of order $\mathcal{O}(\log n)$.

Then, we have that for the loss function of the $\{T_1, T_2, \dots\}$ -activating MPQC:

$$\begin{aligned} L_{\{T_1, T_2, \dots\}}^C(\theta, \theta_G, \theta_{G'_T}) &= \text{tr} \left\{ \Phi_{\{T_1, T_2, \dots\}}^C(\theta, \theta_G, \theta_{G'_T})(\rho) O \right\} \\ &= \text{tr} \left\{ \mathbf{U}_{\{T_1, T_2, \dots\}}^C(\theta, \theta_G, \theta_{G'_T}) \left(\text{op}(|0\rangle\langle 0|)^{\otimes(n+K_{act})} \otimes \rho \right) \mathbf{U}_{\{T_1, T_2, \dots\}}^C(\theta, \theta_G, \theta_{G'_T})^\dagger I \otimes O \right\}, \end{aligned} \quad (12)$$

the gradient variance with respect to a parameter θ_j for $j \in act$ can be lower bounded as

$$\text{Var}_{(\theta, \theta_G, \theta_{G'_T})} \left[\frac{\partial L_{\{T_1, T_2, \dots\}}^C(\theta, \theta_G, \theta_{G'_T})}{\partial \theta_j} \right] \geq \|O\|_{min}^2 \left(\frac{1}{2} \right)^{f_{G,O}^C + f_{act}^C + 8S} \left(\frac{\tau}{4} \right)^{K+K_{act}} = \Omega \left(\frac{1}{\text{poly}(n)} \right). \quad (13)$$

Proof. The proof technique is similar to that of Theorem A.8. The main difference lies in the need to handle the backward propagation of the Pauli path throughout the entire activation zone. We again express

$\text{Var}_{(\theta, \theta_G, \theta_{G'_T})} \left[\frac{\partial L_{\{T_1, T_2, \dots\}}^C(\theta, \theta_G, \theta_{G'_T})}{\partial \theta_j} \right]$ in the form of Pauli path integral combined with the quantum rotation 2-design,

and derive a lower bound by focusing on a specific P_β in O :

$$\begin{aligned}
& \text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T})} \left[\frac{\partial L_{\{T_1, T_2, \dots\}}^C}{\partial \theta_j} (\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T}) \right] \\
&= \frac{1}{4^{m+3(n-S+K_{act})+6S}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3(n-S+K_{act})} \\ \boldsymbol{\theta}_{G'_T} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{6S} \\ \{ \mathbf{P}_j, \mathbf{s}_j^{((\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T}), \beta)} \}_{j=0}}} \sum_{\alpha} c_{\alpha}^2 f \left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T}), \alpha)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T}), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes(n+K_{act})} \otimes \rho \right)^2 \\
&\geq \frac{1}{4^{m+3(n-S+K_{act})+6S}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_G \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3(n-S+K_{act})} \\ \boldsymbol{\theta}_{G'_T} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{6S} \\ \{ \mathbf{P}_j, \mathbf{s}_j^{((\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T}), \beta)} \}_{j=0}}} c_{\beta}^2 f \left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T}), \beta)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G, \boldsymbol{\theta}_{G'_T}), I \otimes P_{\beta}, \text{op}(|0\rangle\langle 0|)^{\otimes(n+K_{act})} \otimes \rho \right)^2.
\end{aligned} \tag{I4}$$

We again consider a specific set of angle configurations in the circuit, where all angles belong to $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}$. To formalize our construction, we partition the angles in $\boldsymbol{\theta}$ into three parts:

- $\boldsymbol{\theta}_{af} \in [0, 2\pi)^{\#af}$ denotes the set of angles after the gadget layer, where $\#af$ is the number of such parameterized gates;
- $\boldsymbol{\theta}_{act} \in [0, 2\pi)^{\#act}$ denotes the set of angles within the activation zone, where $\#act$ is the number of such parameterized gates;
- $\bar{\boldsymbol{\theta}} \in [0, 2\pi)^{m-\#af-\#act}$ denotes the remaining angles in $\boldsymbol{\theta}$, excluding $\boldsymbol{\theta}_{af}$ and $\boldsymbol{\theta}_{act}$.

In the following, we demonstrate how to choose $\boldsymbol{\theta}_{af}$, $\boldsymbol{\theta}_{G'_T}$, $\boldsymbol{\theta}_{act}$, $\boldsymbol{\theta}_G$ and $\bar{\boldsymbol{\theta}}$ in the discrete angle set to derive a lower bound of order $\Omega\left(\frac{1}{\text{poly}(n)}\right)$ for Eq. (I4).

We first select configurations of $\boldsymbol{\theta}_{af}$ such that the backward-propagated Pauli operator $s_L^{(\boldsymbol{\theta}, \beta)}$ (i.e., the operator reaching the gadget layer) satisfies $s_L^{(\boldsymbol{\theta}, \beta)}|_{\{t_1, \dots, t_S\}} \neq I$. Since the backward light cone of P_β before the gadget layer contains at most $f_{G,O}^C$ gates, we only need to fix at most $f_{G,O}^C$ angles in $\boldsymbol{\theta}_{af}$ to make this requirement hold. Let M_{af} denote the maximal set of such angle configurations of $\boldsymbol{\theta}_{af}$, we have

$$|M_{af}| \geq 4^{\#af - f_{G,O}^C} 2^{f_{G,O}^C} = 4^{\#af} \left(\frac{1}{2}\right)^{f_{G,O}^C}. \tag{I5}$$

We then illustrate the choice of $\boldsymbol{\theta}_{G'_T}$. Specifically, we select $\boldsymbol{\theta}_{G'_T}$ such that the Pauli operator propagated to the activation zone becomes $\mathbf{P}_{act}$, ensuring that $\{\mathbf{s}_{act|\mathbf{P}_j}^{(\{\theta_i\}_{i \in act}, \mathbf{P}_{act})}\}_{j=0} = 0$ for some $\boldsymbol{\theta}_{act}$. Here, we employ the same discrete angle construction of $\mathcal{G}'_T(\boldsymbol{\theta})$ as used in the proof of Theorem A.8, which first swaps the nontrivial Pauli operator to the ancilla and then uses another three angles to generate the desired Pauli operator $\mathbf{P}_{act}$. Again, we denote by $M_{anti}(\boldsymbol{\theta}_{af})$ the set of parameter configurations $\boldsymbol{\theta}_{G'_T} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{6S}$ that satisfy the required condition. Similar to the counting argument in Eq. (H5), we obtain

$$|M_{anti}(\boldsymbol{\theta}_{af})| \geq 4^{4S}, \tag{I6}$$

as the weight of $\mathbf{P}_{act}$ is at most S .

We now move on to the choice of $\boldsymbol{\theta}_{act}$. We choose $\boldsymbol{\theta}_{act}$ such that $\{\mathbf{s}_{act|\mathbf{P}_j}^{(\{\theta_i\}_{i \in act}, \mathbf{P}_{act})}, \mathbf{P}_j\} = 0$. Since the number of parameterized gates in the activation zone is at most f_{act}^C , we only need to fix f_{act}^C angles. Let M_{act} denote the maximal set of such angle configurations of $\boldsymbol{\theta}_{act}$. Then, we have

$$|M_{act}| \geq 4^{\#act - f_{act}^C} 2^{f_{act}^C} = 4^{\#act} \left(\frac{1}{2}\right)^{f_{act}^C}. \tag{I7}$$

For $\theta_{\mathcal{G}}$, we adopt the same configuration as in the proof of Theorem A.6, which transforms the operator IP into PI . Here, $\theta_{\mathcal{G}}$ consists of two parts: one located in the gadget layer and the other positioned before the activation zone (as shown on the leftmost side of Fig. A.12). For the $\theta_{\mathcal{G}}$ in the gadget layer, since the support size of the Pauli operator propagated from P_{β} is at most K , and we replace S of them with $\mathcal{G}'_T(\theta)$, we only need to fix the angle configurations of $K - S$ gadgets, while the remaining $n - K - S$ gadgets can take arbitrary angle configurations in $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^3$, as their inputs are $I \otimes I$. For the $\mathcal{G}(\theta)$ gates located at the left boundary of the activation zone, since there are at most K_{act} such gadgets, we need to fix at most K_{act} of them. We denote this set of configurations as $M_{\text{swap}}(\theta_{af}, \theta_{act})$. Following a similar argument to that in the proof of Theorem A.6, we obtain that for any θ_{af} and θ_{act} ,

$$|M_{\text{swap}}(\theta_{af}, \theta_{act})| \geq 4^{3(n-K-S)} 16^{K-S} 16^{K_{act}} = 4^{3(n-S+K_{act})} \left(\frac{1}{4}\right)^{K_{act}+K+2S}. \quad (\text{I8})$$

For $\bar{\theta}$, it can take arbitrary angle configurations within $\{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{m-\#af-\#act}$.

From a geometric perspective, when choosing $\theta_{af} \in M_{af}$, $\theta_{\mathcal{G}'_T} \in M_{\text{anti}}(\theta_{af})$, $\theta_{act} \in M_{act}$ and $\theta_{\mathcal{G}} \in M_{\text{swap}}(\theta_{af}, \theta_{act})$, the corresponding Pauli path takes the form illustrated in Fig. A.11, which extend the case in Fig. A.11 to multiple parameters.

Figure A.13: Pauli path propagated from the observable P_{β} of the $\{T_1, T_2, \dots\}$ -activating MPQC. The region enclosed by the red dashed line denotes the activation zone, while the ancilla qubits introduced by the insertion of $\mathcal{G}(\theta)$ gates before the activation zone are located below the black dashed line. The choices of $\theta_{af} \in M_{af}$ and $\theta_{\mathcal{G}'_T} \in M_{\text{anti}}(\theta_{af})$ ensure that $\mathbf{P}_{act}$ is backward propagated into the activation zone. Then, by choosing $\theta_{act} \in M_{act}$, we guarantee that $\{\mathbf{P}_j, \mathbf{s}_{act|\mathbf{P}_j}^{(\{\theta_i\}_{i \in act}, \mathbf{P}_{act})}\} = 0$. Finally, the configuration $\theta_{\mathcal{G}} \in M_{\text{swap}}(\theta_{af}, \theta_{act})$ swaps these operators onto the corresponding ancilla qubits, thereby ensuring nonvanishing Pauli paths and maintaining finite gradient variance for the parameters θ_j within the activation zone.

Then $\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})} \left[\frac{\partial L_{\{T_1, T_2, \dots\}}^c(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})}{\partial \theta_j} \right]$ can be lower bounded as

$$\begin{aligned}
& \text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})} \left[\frac{\partial L_{\{T_1, T_2, \dots\}}^c(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T})}{\partial \theta_j} \right] \\
& \geq \frac{1}{4^{m+3(n-S+K_{act})+6S}} \sum_{\substack{\boldsymbol{\theta}_{af} \in M_{af}, \boldsymbol{\theta}_{act} \in M_{act}, \bar{\boldsymbol{\theta}} \\ \boldsymbol{\theta}_{\mathcal{G}'_T} \in M_{anti}(\boldsymbol{\theta}_{af}) \\ \boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta}_{af}, \boldsymbol{\theta}_{act})}} c_{\beta}^2 f \left(\bar{\mathbf{s}}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \beta)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), I \otimes P_{\beta}, \text{op}(|0\rangle\langle 0|)^{\otimes(n+K_{act})} \otimes \rho \right)^2 \\
& \geq \frac{1}{4^{m+3(n-S+K_{act})+6S}} \sum_{\substack{\boldsymbol{\theta}_{af} \in M_{af}, \boldsymbol{\theta}_{act} \in M_{act}, \bar{\boldsymbol{\theta}} \\ \boldsymbol{\theta}_{\mathcal{G}'_T} \in M_{anti}(\boldsymbol{\theta}_{af}) \\ \boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta}_{af}, \boldsymbol{\theta}_{act})}} c_{\beta}^2 \tau^{K+K_{act}} \\
& \geq \frac{1}{4^{m+3(n-S+K_{act})+6S}} \sum_{\boldsymbol{\theta}_{af} \in M_{af}, \boldsymbol{\theta}_{act} \in M_{act}, \bar{\boldsymbol{\theta}}} |M_{anti}(\boldsymbol{\theta}_{af})| |M_{\text{swap}}(\boldsymbol{\theta}_{af}, \boldsymbol{\theta}_{act})| c_{\beta}^2 \tau^{K+K_{act}} \\
& \geq \frac{c_{\beta}^2 \tau^{K+K_{act}}}{4^{m+3(n-S+K_{act})+6S}} \underbrace{4^{\#af} \left(\frac{1}{2}\right)^{f_{\mathcal{G}, O}^c}}_{\leq |M_{af}|} \underbrace{4^{\#act} \left(\frac{1}{2}\right)^{f_{act}^c}}_{\leq |M_{act}|} \underbrace{4^{m-\#af-\#act}}_{\text{all possible } \bar{\boldsymbol{\theta}}} \underbrace{4^{4S}}_{\leq |M_{anti}(\boldsymbol{\theta}_{af})|} \underbrace{4^{3(n-S+K_{act})} \left(\frac{1}{4}\right)^{K_{act}+K+2S}}_{\leq |M_{\text{swap}}(\boldsymbol{\theta}_{af}, \boldsymbol{\theta}_{act})|} \\
& = c_{\beta}^2 \left(\frac{1}{2}\right)^{f_{\mathcal{G}, O}^c + f_{act}^c + 8S} \left(\frac{\tau}{4}\right)^{K_{act}+K} \\
& \geq \|O\|_{min}^2 \left(\frac{1}{2}\right)^{\mathcal{O}(\log n)} \left(\frac{\tau}{4}\right)^{\mathcal{O}(\log n)} = \Omega\left(\frac{1}{\text{poly}(n)}\right).
\end{aligned} \tag{19}$$

Similarly, the second inequality holds because the Pauli operator $\mathbf{s}_0^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}, \boldsymbol{\theta}_{\mathcal{G}'_T}), \beta)}$ acts trivially (i.e., as the identity I) on all system qubits, while its support on the ancilla qubits has weight at most $K + K_{act}$. $\square$

Remark. In Theorem A.9, we assumed the existence of a Pauli word P_{β} in the observable O and a configuration $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that the Pauli path $s_L^{(\boldsymbol{\theta}, \beta)}|_{\{t_1, \dots, t_S\}} \neq I$. In fact, this assumption can be weakened to only require the existence of a Pauli word P_{β} and a configuration $\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m$ such that at least one Pauli path $s_L^{(\boldsymbol{\theta}, \beta)}$ has weight at least S . This relaxed condition can be handled using a construction similar to that in Fig. A.9. If no such path exists, we note that $S \leq K_{act} = \mathcal{O}(\log n)$ according to Theorem A.9, and we can always shift the gadget layer earlier in the circuit to increase the weight of the Pauli operator reached the gadget layer, thereby ensuring that activation is still possible.

Supplementary Information J: Proof of Theorem 4

In this section, we prove that BP can also be eliminated in MPQCs even in the presence of noise. We begin by introducing the noise model and explaining how it affects the Pauli path. Finally, we present the noisy counterparts of Theorem A.7, Theorem A.7, and Theorem A.8, thereby completing the proof of Theorem 4.

1. Noise model and Pauli path integral with noise

We consider the case of Pauli type noises, which is a common type of noise in quantum circuits and can be described by the following quantum channel $\mathcal{N}$:

$$\mathcal{N}(\rho) = (1 - \sum_i p_i) \rho + \sum_i p_i \sigma_i \rho \sigma_i^{\dagger}, \tag{J1}$$

where σ_i denotes a non-identity Pauli operator, p_i is the corresponding probability, and the total probability $\sum_i p_i < 1$ characterizes the noise strength, which we denote by $\gamma_{\mathcal{N}}$. In our discussion, we assume that the Pauli noises appear in the quantum circuit. The gates are followed by Pauli noise channels, as shown in Fig A.14.

Figure A.14: The noisy channel $\tilde{U}$: ideal gate U followed by Pauli noise channel $\mathcal{N}$ acting on the output.

Because of the anti-commuting property of the Pauli operator, the Pauli noise channel $\mathcal{N}$ ($\mathcal{N}^\dagger$) acting on the normalized Pauli operator s can be expressed as:

$$\mathcal{N}(s) = \mathcal{N}^\dagger(s) = (1 - \sum_i p_i) s + \sum_i p_i \sigma_i s \sigma_i^\dagger = \left(1 - 2 \sum_i \mathbf{1}_{ac}(s, \sigma_i) p_i \right) s, \quad (\text{J2})$$

where $\mathbf{1}_{ac}(s, \sigma_i)$ is the indicator function that equals to 1 if s and σ_i anti-commute, otherwise it equals to 0. Thus there is $\mathcal{N}(s) = cs$ for some constant c , and because of $\sum_i p_i = \gamma_{\mathcal{N}}$, we have

$$c = \text{tr}\{s\mathcal{N}(s)\} = 1 - 2 \sum_i \mathbf{1}_{ac}(s, \sigma_i) p_i \geq 1 - 2\gamma_{\mathcal{N}}. \quad (\text{J3})$$

We assume that there is a Pauli noise channel $\mathcal{N}_i$ is following the i -block $\mathbf{U}_i(\theta_i)$ in the MPQC. Or in other words, the ideal gate $\mathbf{U}_i(\theta_i)$ is replaced by the noisy channel $\tilde{\mathbf{U}}_j(\theta_j)(\cdot) = \mathcal{N}_i \circ \mathbf{U}_i(\theta_i)(\cdot) \mathbf{U}_i(\theta_i)^\dagger$ in the noisy MPQC. Moreover, we assume that each $\mathcal{N}_i$ takes the form

$$\mathcal{N}_i = \mathcal{I} \otimes \mathcal{N}'_i, \quad (\text{J4})$$

where $\mathcal{N}'_i$ is a Pauli noise channel acting on the same qubits as $\mathbf{U}_i(\theta_i)$, which is a reasonable assumption for current quantum devices.

Similarly, for the two-qubit gates in the gadget layer, we assume that a Pauli noise channel is applied after each layer. Specifically, the ideal sequence of ideal gates

$$\prod_{i=1}^n (R_{Z_i Z_{i+n}}(\theta_{\mathcal{G}_{i,1}}) R_{Y_i Y_{i+n}}(\theta_{\mathcal{G}_{i,2}}) R_{X_i X_{i+n}}(\theta_{\mathcal{G}_{i,3}}))$$

is transformed into

$$\mathcal{N}_{\mathcal{G}_1} \circ \prod_{i=1}^n \mathcal{R}_{Z_i Z_{i+n}}(\theta_{\mathcal{G}_{i,1}}) \circ \mathcal{N}_{\mathcal{G}_2} \circ \prod_{i=1}^n \mathcal{R}_{Y_i Y_{i+n}}(\theta_{\mathcal{G}_{i,2}}) \circ \mathcal{N}_{\mathcal{G}_3} \circ \prod_{i=1}^n \mathcal{R}_{X_i X_{i+n}}(\theta_{\mathcal{G}_{i,3}}), \quad (\text{J5})$$

where we write $\mathcal{R}_P(\theta)$ as the channel representation for rotation gate $R_P(\theta)$. This assumption is reasonable since the gates $\prod_{i=1}^n R_{Z_i Z_{i+n}}(\theta_{\mathcal{G}_{i,1}})$ ($\prod_{i=1}^n R_{Y_i Y_{i+n}}(\theta_{\mathcal{G}_{i,2}})$ or $\prod_{i=1}^n R_{X_i X_{i+n}}(\theta_{\mathcal{G}_{i,3}})$) can be applied in parallel within a single layer. Finally, we define a Pauli noise channel $\mathcal{N}_{op}$ that follows the application of n copies of op , i.e., $\tilde{op}^{\otimes n}(\cdot) = \mathcal{N}_{op} \circ op^{\otimes n}(\cdot)$.

As a result, the noisy circuit $\tilde{\mathbf{U}}^{\mathcal{C}}(\theta, \theta_{\mathcal{G}})$ can be expressed as:

$$\begin{aligned} \tilde{\mathbf{U}}^{\mathcal{C}}(\theta, \theta_{\mathcal{G}}) = & \mathcal{N}_m \circ \mathbf{U}_m(\theta_m) \cdots \mathcal{N}_{L+1} \circ \mathbf{U}_{L+1}(\theta_{L+1}) \circ \mathcal{N}_{\mathcal{G}_1} \circ \prod_{i=1}^n \mathcal{R}_{Z_i Z_{i+n}}(\theta_{\mathcal{G}_{i,1}}) \circ \\ & \mathcal{N}_{\mathcal{G}_2} \circ \prod_{i=1}^n \mathcal{R}_{Y_i Y_{i+n}}(\theta_{\mathcal{G}_{i,2}}) \circ \mathcal{N}_{\mathcal{G}_3} \circ \prod_{i=1}^n \mathcal{R}_{X_i X_{i+n}}(\theta_{\mathcal{G}_{i,3}}) \circ \mathcal{N}_L \circ \mathbf{U}_L(\theta_L) \cdots \mathcal{N}_1 \circ \mathbf{U}_1(\theta_1). \end{aligned} \quad (\text{J6})$$

Under this condition, the noisy loss function $\tilde{L}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$, corresponding to Eq. (D3), can be expressed as:

$$\begin{aligned}
\tilde{L}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) &= \text{tr} \left\{ \tilde{\mathbf{U}}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) (\tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho) I \otimes O \right\} \\
&= \sum_{\alpha, \mathbf{s}_m} c_\alpha \text{tr} \{ I \otimes P_\alpha \mathbf{s}_m \} \text{tr} \left\{ \tilde{\mathbf{U}}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) (\tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho) \mathbf{s}_m \right\} \\
&= \sum_{\substack{\alpha, \mathbf{s}_m, \mathbf{s}_{m-1}, \dots, \mathbf{s}_0 \\ \mathbf{s}_{G_{1,1}}, \mathbf{s}_{G_{1,2}}, \dots, \mathbf{s}_{G_{n,3}}}} c_\alpha \text{tr} \{ I \otimes P_\alpha \mathbf{s}_m \} \text{tr} \left\{ \mathcal{N}_m^\dagger(\mathbf{s}_m) \mathbf{U}_m(\theta_m) \mathbf{s}_{m-1} \mathbf{U}_m(\theta_m)^\dagger \right\} \cdots \text{tr} \left\{ \mathcal{N}_{L+1}^\dagger(\mathbf{s}_{L+1}) \mathbf{U}_{L+1}(\theta_{L+1}) \mathbf{s}_{G_{1,1}} \mathbf{U}_{L+1}(\theta_{L+1})^\dagger \right\} \\
&\quad \cdot \text{tr} \left\{ \mathcal{N}_{G_1}^\dagger(\mathbf{s}_{G_{1,1}}) R_{11}(\boldsymbol{\theta}_{G_{11}}) \mathbf{s}_{G_{1,2}} R_{11}(-\boldsymbol{\theta}_{G_{11}}) \right\} \text{tr} \left\{ \mathbf{s}_{G_{1,2}} R_{12}(\boldsymbol{\theta}_{G_{12}}) \mathbf{s}_{G_{1,3}} R_{12}(-\boldsymbol{\theta}_{G_{12}}) \right\} \cdots \text{tr} \left\{ \mathbf{s}_{G_{n,3}} R_{n3}(\boldsymbol{\theta}_{G_{n3}}) \mathbf{s}_L R_{n3}(-\boldsymbol{\theta}_{G_{n3}}) \right\} \\
&\quad \cdot \text{tr} \left\{ \mathcal{N}_L^\dagger(\mathbf{s}_L) \mathbf{U}_L(\theta_L) \mathbf{s}_{L-1} \mathbf{U}_L(\theta_L)^\dagger \right\} \cdots \text{tr} \left\{ \mathcal{N}_1^\dagger(\mathbf{s}_1) \mathbf{U}_1(\theta_1) \mathbf{s}_0 \mathbf{U}_1(\theta_1)^\dagger \right\} \text{tr} \left\{ \mathcal{N}_{op}^\dagger(\mathbf{s}_0) \tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right\} \\
&= \sum_{\alpha, \vec{\mathbf{s}}} c_\alpha g(\vec{\mathbf{s}}) f(\vec{\mathbf{s}}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G), I \otimes P_\alpha, \tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho),
\end{aligned} \tag{J7}$$

where $g(\vec{\mathbf{s}})$ is the noise effect factor on the Pauli path $\vec{\mathbf{s}}$, defined as the product of the coefficients computed in Eq. (J2).

$$g(\vec{\mathbf{s}}) := \text{tr} \left\{ \mathbf{s}_0 \mathcal{N}_{op}^\dagger \otimes \mathcal{I}(\mathbf{s}_0) \right\} \prod_{i=1}^m \text{tr} \left\{ \mathbf{s}_i \mathcal{N}_i^\dagger(\mathbf{s}_i) \right\} \prod_{i=1}^3 \text{tr} \left\{ \mathbf{s}_{G_{i,1}} \mathcal{N}_{G_i}^\dagger(\mathbf{s}_{G_{i,1}}) \right\}. \tag{J8}$$

2. Lower bounds of variance and gradient variance of the loss function of noisy MPQCs

With the descriptions in the previous subsection, we can prove the following theorem

Theorem A.10. *For an MPQC measured with a k -local observable $O = \sum_\alpha c_\alpha P_\alpha$, suppose the conditions stated in Appendix F.2 hold, then under Pauli noise with strength at most $\gamma < 1/2$ applied after each block, the variance of the loss function is lower bounded by*

$$\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} \left[\tilde{L}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) \right] \geq (1 - 2\gamma)^{2(f_{G,o}^C + 4)} \left(\frac{\tau}{4} \right)^K \|O\|_{HS}^2 = \Omega \left(\frac{1}{\text{poly}(n)} \right).$$

Proof. We first express the variance of the loss function of noisy MPQC:

$$\begin{aligned}
&\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} \left[\tilde{L}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) \right] \\
&= \mathbb{E}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} \sum_{\alpha, \beta, \vec{\mathbf{s}}, \vec{\mathbf{s}}'} c_\alpha c_\beta g(\vec{\mathbf{s}}) g(\vec{\mathbf{s}}') f \left(\vec{\mathbf{s}}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G), I \otimes P_\alpha, \tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right) f \left(\vec{\mathbf{s}}', (\boldsymbol{\theta}, \boldsymbol{\theta}_G), I \otimes P_\beta, \tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right) \\
&\quad - \left(\mathbb{E}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} \sum_{\alpha, \vec{\mathbf{s}}} c_\alpha g(\vec{\mathbf{s}}) f \left(\vec{\mathbf{s}}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G), I \otimes P_\alpha, \tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right) \right)^2.
\end{aligned} \tag{J9}$$

Following the same proof of Eq. (D9), we can prove the orthogonality of different Pauli path and the second term in the above equation equals 0. More precisely, we have

$$\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} \left[\tilde{L}^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) \right] = \mathbb{E}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_G)} \sum_{\alpha, \vec{\mathbf{s}}} c_\alpha^2 g(\vec{\mathbf{s}})^2 f \left(\vec{\mathbf{s}}, (\boldsymbol{\theta}, \boldsymbol{\theta}_G), I \otimes P_\alpha, \tilde{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho \right)^2. \tag{J10}$$

Again similar with the proof of Theorem A.6, we lower bound Eq. (J9) by considering some specific angle configurations

of the gadget layer:

$$\begin{aligned}
\text{Var}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})} \left[\tilde{L}^{\mathcal{C}}(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) \right] &= \mathbb{E}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})} \sum_{\alpha} c_{\alpha}^2 g(\vec{s})^2 f\left(\vec{s}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2 \\
&= \frac{1}{4^{m+3n}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_{\mathcal{G}} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}}} \sum_{\alpha} c_{\alpha}^2 g(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})^2 f\left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2 \\
&\geq \frac{1}{4^{m+3n}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta})}} \sum_{\alpha} c_{\alpha}^2 g(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})^2 f\left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2 \quad (\text{J11}) \\
&\geq \frac{(1-2\gamma)^{2(f_{\mathcal{G}, O}^{\mathcal{C}}+4)}}{4^{m+3n}} \sum_{\substack{\boldsymbol{\theta} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^m \\ \boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta})}} \sum_{\alpha} c_{\alpha}^2 f\left(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}, (\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), I \otimes P_{\alpha}, \text{op}(|0\rangle\langle 0|)^{\otimes n} \otimes \rho\right)^2 \\
&\geq (1-2\gamma)^{2(f_{\mathcal{G}, O}^{\mathcal{C}}+4)} \left(\frac{\tau}{4}\right)^K \|O\|_{HS}^2 = \Omega\left(\frac{1}{\text{poly}(n)}\right).
\end{aligned}$$

Here, in the second-to-last inequality, we use the following result:

$$g(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}) \geq (1-2\gamma)^{2(f_{\mathcal{G}, O}^{\mathcal{C}}+4)}. \quad (\text{J12})$$

This inequality holds for the following reasons. First, when we choose $\boldsymbol{\theta}_{\mathcal{G}} \in M_{\text{swap}}(\boldsymbol{\theta})$, each gadget transforms the backward-propagated operator IP into PI . This implies that for all $i \leq L$ (recall that the gadget layer is located right after $U_L(\theta_L)$), we have $\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}|_{\geq n} = I$, i.e., the part of $\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}$ on the system qubits is the identity operator. Then we have that for all $i \leq L$,

$$\text{tr}\left\{\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_i^{\dagger}(\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} = 1. \quad (\text{J13})$$

Second, when $U_{i'}(\theta_{i'})$ does not belong to the backward light cone of P_{α} , the supports of $\mathbf{s}_{i'}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}$ and $\mathcal{N}_{i'}$ do not overlap, since $\mathcal{N}_{i'}$ acts on the same qubits as $U_{i'}(\theta_{i'})$. Hence, it follows that

$$\text{tr}\left\{\mathbf{s}_{i'}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_{i'}^{\dagger}(\mathbf{s}_{i'}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} = 1. \quad (\text{J14})$$

By combining the two observations above, we obtain

$$\begin{aligned}
g(\vec{s}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)}) &= \text{tr}\left\{\mathbf{s}_0^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_{\text{op}}^{\dagger}(\mathbf{s}_0^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} \prod_{i=1}^m \text{tr}\left\{\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_i^{\dagger}(\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} \prod_{i=1}^3 \text{tr}\left\{\mathbf{s}_{\mathcal{G}_{i,1}}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_{\mathcal{G}_i}^{\dagger}(\mathbf{s}_{\mathcal{G}_{i,1}}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} \\
&= \text{tr}\left\{\mathbf{s}_0^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_{\text{op}}^{\dagger}(\mathbf{s}_0^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} \prod_{\substack{i > L \\ U_i(\theta_i) \in \text{BLig}_{\alpha}^{\mathcal{C}}}} \text{tr}\left\{\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_i^{\dagger}(\mathbf{s}_i^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} \prod_{i=1}^3 \text{tr}\left\{\mathbf{s}_{\mathcal{G}_{i,1}}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)} \mathcal{N}_{\mathcal{G}_i}^{\dagger}(\mathbf{s}_{\mathcal{G}_{i,1}}^{((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), \alpha)})\right\} \\
&\geq (1-2\gamma)^{f_{\mathcal{G}, O}^{\mathcal{C}}+4}, \quad (\text{J15})
\end{aligned}$$

where we define $\text{BLig}_{\alpha}^{\mathcal{C}}$ as the backward lightcone of P_{α} in $\mathcal{C}(\boldsymbol{\theta})$, and the last inequality follows from the fact that at most $f_{\mathcal{G}, O}^{\mathcal{C}}$ parameters in $\text{BLig}_{\alpha}^{\mathcal{C}}$ lie after the gadget layer. $\square$

Following similar techniques, we can prove that BP can be guaranteed to be avoided for some particular parameters of the noisy MPQC corresponding to Theorem 2 and Theorem 3.

Theorem A.11. *For an MPQC with a k -local observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$, suppose that the conditions stated in Theorem A.10 hold, then under Pauli noise with strength at most $\gamma < 1/2$ applied after each block, the variance of the gradient of the parameters $\boldsymbol{\theta} \in [0, 2\pi)^m$ in the circuit follows the following rules:*

- For parameter θ_j located after the gadget layer, if $\text{Var}_{\theta} \left[\frac{\partial \langle O \rangle}{\partial \theta_j} \right] \neq 0$, then $\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial L^c(\theta, \theta_G)}{\partial \theta_j} \right]$ is lower bounded by

$$\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial \tilde{L}^c(\theta, \theta_G)}{\partial \theta_j} \right] \geq (1 - 2\gamma)^{f_{G,O}^c + 4} \left(\frac{1}{2} \right)^{f_{j,O}^c} \left(\frac{\tau}{4} \right)^K \|O\|_{\min}^2 = \Omega \left(\frac{1}{\text{poly}(n)} \right). \quad (\text{J16})$$

- For parameters located before the gadget layer, the gradient variance of the MPQC is at least of the same scaling as that of the original PQC without the gadget layer, i.e.

$$\text{Var}_{(\theta, \theta_G)} \left[\frac{\partial \tilde{L}^c(\theta, \theta_G)}{\partial \theta_j} \right] \geq \Omega \left(\frac{1}{\text{poly}(n)} \right) \text{Var}_{\theta} \left[\frac{\partial \tilde{L}(\theta)}{\partial \theta_j} \right], \quad (\text{J17})$$

where $\tilde{L}(\theta)$ is the loss function of the noisy original PQC.

- Also for the noisy T -activating MPQC, we have

$$\text{Var}_{(\theta, \theta_G, \theta_{G_T})} \left[\frac{\partial \tilde{L}_T^c(\theta, \theta_G, \theta_{G_T})}{\partial \theta_T} \right] \geq (1 - 2\gamma)^{f_{G,O}^c + 12} \left(\frac{1}{2} \right)^{f_{G,O}^c + 2} \left(\frac{\tau}{4} \right)^{K+1} \|O\|_{\min}^2 = \Omega \left(\frac{1}{\text{poly}(n)} \right) \quad (\text{J18})$$

where $\tilde{L}_T^c(\theta, \theta_G)$ is the loss function of the noisy T -activating MPQC.

Supplementary Information K: Analysis of trainable op

Previously, the proofs of our results relied on a deterministic construction of op . In this section, we show that the alternative construction illustrated in Fig. A.15 preserves all the desirable properties of the corresponding MPQC.

Figure A.15: Trainable construction of op . Q and P are Pauli operators.

It is easy to verify from Eq. (B14) that under Heisenberg evolution, for any Pauli operator $P \neq I$, among the $4 * 4 = 16$ possible combinations of $\theta_1, \theta_2 \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^2$, at least 4 lead to the resulting operator Q being equal to Z .

In all the proofs, the only parts involving op are as follows:

$$\text{tr} \left\{ s \cdot \left[op(|0\rangle\langle 0|)^{\otimes n} \right] \right\}^2, \quad (\text{K1})$$

for some n -qubit Pauli word s with weight at most K (or $K + \mathcal{O}(\log n)$, which we denote simply as K for clarity). As there are parameters in all op , we also need to take the average over these angles, namely,

$$\mathbb{E}_{\theta_{op}} \text{tr} \left\{ s \left(\bigotimes_{i=1}^n R_{Y_i}(\theta_{op,i,2}) R_{X_i}(\theta_{op,i,1}) |0\rangle\langle 0| R_{X_i}(-\theta_{op,i,1}) R_{Y_i}(-\theta_{op,i,2}) \right) \right\}^2, \quad (\text{K2})$$

where we define $\theta_{op} \in [0, 2\pi)^{2n}$ for the parameters in op . Without loss of generality, we assume that the first $K' \leq K$ qubits of the Pauli word s are nontrivial. By employing the property of the rotation 2-design stated in Corollary A.1, the expression in Eq. (K2) can be reformulated and lower bounded as

$$\begin{aligned} & \mathbb{E}_{\theta_{op}} \text{tr} \left\{ s \left(\bigotimes_{i=1}^n R_{Y_i}(\theta_{op,i,2}) R_{X_i}(\theta_{op,i,1}) |0\rangle\langle 0| R_{X_i}(-\theta_{op,i,1}) R_{Y_i}(-\theta_{op,i,2}) \right) \right\}^2 \\ &= \mathbb{E}_{\theta_{op} \in \{0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}\}^{3n}} \text{tr} \left\{ \left[\bigotimes_{i=1}^n R_{X_i}(-\theta_{op,i,1}) R_{Y_i}(-\theta_{op,i,2}) \right] s \left[\bigotimes_{i=1}^n R_{Y_i}(\theta_{op,i,2}) R_{X_i}(\theta_{op,i,1}) \right] |0\rangle\langle 0| \right\}^2 \\ &\geq \frac{4^{2(n-K')}}{4^{2n}} \text{tr} \left\{ Z^{\otimes K'} \otimes I |0^n\rangle\langle 0^n| \right\}^2 = \left(\frac{1}{4} \right)^{K'} \geq \left(\frac{1}{4} \right)^K. \end{aligned} \quad (\text{K3})$$

By substituting Eq. (K3) into all Theorems, we obtain the lower bounds on the variance and gradient variance of the MPQC loss function when employing a trainable op , simply by replacing τ with $1/4$.

Supplementary Information L: Hardness of classical simulation of MPQC

In this section, we demonstrate that the classical simulation hardness of MPQCs is not easier than that of the original PQCs. We evaluate two widely used metrics—the worst-case error (WCE) and the mean squared error (MSE)—and prove that, even in the average case, adding the gadget layer does not compromise the classical intractability of the circuit.

1. Worst case error

Here we prove that if we can design an efficient classical algorithm which can compute the loss function $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$ with low error for all $(\boldsymbol{\theta}, \boldsymbol{\theta}_G) \in [0, 2\pi)^{m+3n}$, then we can simulate the loss function of the original PQC efficiently.

Theorem A.12. *For an arbitrary MPQC $\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$ and an arbitrary observable O , suppose there exists a classical algorithm that outputs $\mathcal{D}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_G), O)$ in $\mathcal{O}(\text{poly}(n, \frac{1}{\epsilon}))$ time such that for any $(\boldsymbol{\theta}, \boldsymbol{\theta}_G) \in [0, 2\pi)^{m+3n}$*

$$|L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) - \mathcal{D}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_G), O)| \leq \epsilon. \quad (\text{L1})$$

Then, there exists a classical algorithm that outputs an estimate of $L(\boldsymbol{\theta}) = \text{tr}\{\mathcal{C}(\boldsymbol{\theta})\rho\mathcal{C}^\dagger(\boldsymbol{\theta})O\}$ for any $\boldsymbol{\theta} \in [0, 2\pi)^m$ with error at most ϵ in $\mathcal{O}(\text{poly}(n, \frac{1}{\epsilon}))$ time.

Proof. To approximate $L(\boldsymbol{\theta})$, we directly output $\mathcal{D}_{\Phi^C}((\boldsymbol{\theta}, \mathbf{0}), O)$. Since $\mathcal{C}(\boldsymbol{\theta})\rho\mathcal{C}^\dagger(\boldsymbol{\theta}) = \Phi^C(\boldsymbol{\theta}, \mathbf{0})(\rho)$, we have

$$|L(\boldsymbol{\theta}) - \mathcal{D}_{\Phi^C}((\boldsymbol{\theta}, \mathbf{0}), O)| = |L^C(\boldsymbol{\theta}, \mathbf{0}) - \mathcal{D}_{\Phi^C}((\boldsymbol{\theta}, \mathbf{0}), O)| \leq \epsilon. \quad (\text{L2})$$

The running time of the above algorithm is also $\mathcal{O}(\text{poly}(n, \frac{1}{\epsilon}))$. $\square$

2. Average case error

In this subsection, we demonstrate that simulating an MPQC in the average case is no easier than simulating the original PQC. The proof idea is as follows: starting from an efficient classical algorithm that approximates $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$ with small average error, we estimate the value of $L(\boldsymbol{\theta}) = L^C(\boldsymbol{\theta}, \mathbf{0})$ by randomly sampling $\boldsymbol{\theta}_G$ within a small hypercube centered at $\mathbf{0}$. Since $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$ is a continuous function of $\boldsymbol{\theta}_G$, the obtained value will be close to $L^C(\boldsymbol{\theta}, \mathbf{0})$, with high probability.

We first establish the continuity of $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$, as summarized in the following lemma.

Lemma A.9. *For an MPQC measured with a local Pauli word P , regard its loss function $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) = \text{tr}\{\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)(\rho)P\}$ as a function of $\boldsymbol{\theta}_G$. Then, for any fixed $\boldsymbol{\theta}$, the function $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$ is Lipschitz continuous with respect to $\boldsymbol{\theta}_G$, with Lipschitz constant l_θ upper bounded by $\sqrt{3K}$, where K is the support size of P 's backward light cone at the gadget layer.*

Proof. Without loss of generalization, we assume that the first K gadgets lie in the backward light cone of P , i.e., the remaining $n - K$ gadgets do not affect the value of $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)$. Therefore, we set their parameters to zero and denote $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G) = L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \theta_{G_{12}}, \dots, \theta_{G_{K3}}, \mathbf{0}))$.

For the function $L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \theta_{G_{12}}, \dots, \theta_{G_{K3}}, \mathbf{0}))$, it is Lipschitz continuous since it can be expressed as a finite linear combination of products of $\sin\theta_{G_{ij}}$ and $\cos\theta_{G_{ij}}$, each of which is a smooth function. Consequently, its Lipschitz constant l_θ can be upper bounded by the supremum of the ℓ_2 -norm of its gradient with respect to $\boldsymbol{\theta}_G$, namely,

$$\begin{aligned} l_\theta &= \sup_{\boldsymbol{\theta}_G} \|\nabla L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_G)\| = \sup_{\boldsymbol{\theta}_G} \|\nabla L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \theta_{G_{12}}, \dots, \theta_{G_{K3}}, \mathbf{0}))\|_2 \\ &= \sup_{\boldsymbol{\theta}_G} \left\| \left(\frac{\partial}{\partial \theta_{G_{11}}} L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \theta_{G_{12}}, \dots, \theta_{G_{K3}}, \mathbf{0})) \right), \dots, \left(\frac{\partial}{\partial \theta_{G_{K3}}} L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \theta_{G_{12}}, \dots, \theta_{G_{K3}}, \mathbf{0})) \right), 0, \dots \right\|_2. \end{aligned} \quad (\text{L3})$$

For each element, the parameter-shift rule gives

$$\begin{aligned} \frac{\partial}{\partial \theta_{G_{ij}}} L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \theta_{G_{12}}, \dots, \theta_{G_{K3}}, \mathbf{0})) &= \frac{L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \dots, \theta_{G_{ij}} + \pi/2, \dots, \mathbf{0})) - L^C(\boldsymbol{\theta}, (\theta_{G_{11}}, \dots, \theta_{G_{ij}} - \pi/2, \dots, \mathbf{0}))}{2} \\ &\leq 1. \end{aligned} \quad (\text{L4})$$

Consequently, $L^C(\boldsymbol{\theta}, (\theta_{\mathcal{G}_{11}}, \theta_{\mathcal{G}_{12}}, \dots, \theta_{\mathcal{G}_{K3}}, \mathbf{0}))$ is a Lipschitz continuous function of $\boldsymbol{\theta}_{\mathcal{G}}$ with Lipschitz constant

$$l_{\boldsymbol{\theta}} \leq \sqrt{3K}. \quad (\text{L5})$$

□

The above theorem implies that, for arbitrary $\boldsymbol{\theta}$, if $\|\boldsymbol{\theta}_{\mathcal{G}} - \boldsymbol{\theta}'_{\mathcal{G}}\|_2 \leq \epsilon$, then $|L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) - L^C(\boldsymbol{\theta}, \boldsymbol{\theta}'_{\mathcal{G}})| \leq \sqrt{3K}\epsilon$. With this result, we are able to prove the following theorem:

Lemma A.10. *For an arbitrary MPQC $\Phi^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ measured with a local Pauli word P , suppose there exists a classical algorithm that outputs $\mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), P)$ in $\mathcal{O}(\text{poly}(n, \frac{1}{\epsilon}))$ time such that*

$$\mathbb{E}_{(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}), P)]^2 \leq \epsilon. \quad (\text{L6})$$

Then, there exists a randomized classical algorithm $A_{\text{rand}}(\boldsymbol{\theta})$ that outputs $\mathcal{A}_C(\boldsymbol{\theta})$ such that

$$\Pr_{\boldsymbol{\theta} \in [0, 2\pi]^m} \{\Pr\{|L(\boldsymbol{\theta}) - \mathcal{A}_C(\boldsymbol{\theta})| \geq \epsilon_{\text{error}}\} \geq \delta\} \leq 1 - \epsilon_{\text{rate}}. \quad (\text{L7})$$

The runtime of $A_{\text{rand}}(\boldsymbol{\theta})$ scales as $K^{3K} \mathcal{O}(\text{poly}(n, \frac{1}{\delta}, \frac{1}{\epsilon_{\text{error}}}, \frac{1}{\epsilon_{\text{rate}}}))$, when the support size of P 's backward light cone at the gadget layer K satisfies $K = \mathcal{O}(\log n)$.

Proof. Similarly to the proof of Lemma A.9, without loss of generality, we assume that the first K gadgets lie within the backward light cone of P . For simplicity, we denote by $\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} = (\theta_{\mathcal{G}_{11}}, \dots, \theta_{\mathcal{G}_{K3}})$ the set of rotation angles that directly affect the computation of $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$, and by $\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} = (\theta_{\mathcal{G}_{(K+1)1}}, \dots, \theta_{\mathcal{G}_{n3}})$ the remaining gadget parameters that do not influence it.

We then expand Eq. (L6) over the entire parameter space and while fixing $\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} = \mathbf{0}$ and restricting $\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}$ to a hypercube $[0, \epsilon_1]^{3K}$ for some $\epsilon_1 > 0$, which will be determined later. Note that the output of the classical algorithm might depend on $\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}}$. However, without loss of generality, we assume that when $\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} = \mathbf{0}$, the error with respect to $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0})$ is minimized. This assumption implies that the MSE must be smaller when $\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} = \mathbf{0}$. As a consequence, we have

$$\begin{aligned} \epsilon &\geq \left(\frac{1}{2\pi}\right)^{m+3n} \int_{\boldsymbol{\theta} \in [0, 2\pi]^m} \int_{\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, 2\pi]^{3K}} \int_{\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} \in [0, 2\pi]^{3(n-K)}} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}}), P)]^2 d\boldsymbol{\theta} d\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} d\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} \\ &\geq \left(\frac{1}{2\pi}\right)^{m+3n} \int_{\boldsymbol{\theta} \in [0, 2\pi]^m} \int_{\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, 2\pi]^{3K}} \int_{\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} \in [0, 2\pi]^{3(n-K)}} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)]^2 d\boldsymbol{\theta} d\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} d\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} \\ &= \left(\frac{1}{2\pi}\right)^{m+3K} \int_{\boldsymbol{\theta} \in [0, 2\pi]^m} \int_{\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, 2\pi]^{3K}} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)]^2 d\boldsymbol{\theta} d\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \\ &\geq \left(\frac{1}{2\pi}\right)^{m+3K} \int_{\boldsymbol{\theta} \in [0, 2\pi]^m} \int_{\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, \epsilon_1]^{3K}} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)]^2 d\boldsymbol{\theta} d\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \\ &= \left(\frac{\epsilon_1}{2\pi}\right)^{3K} \left(\frac{1}{2\pi}\right)^m \left(\frac{1}{\epsilon_1}\right)^{3K} \int_{\boldsymbol{\theta} \in [0, 2\pi]^m} \int_{\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, \epsilon_1]^{3K}} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)]^2 d\boldsymbol{\theta} d\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \\ &= \left(\frac{\epsilon_1}{2\pi}\right)^{3K} \mathbb{E}_{\substack{\boldsymbol{\theta} \in [0, 2\pi]^m \\ \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, \epsilon_1]^{3K}}} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)]^2. \end{aligned} \quad (\text{L8})$$

It implies that

$$\mathbb{E}_{\substack{\boldsymbol{\theta} \in [0, 2\pi]^m \\ \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, \epsilon_1]^{3K}}} [L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)]^2 \leq \left(\frac{2\pi}{\epsilon_1}\right)^{3K} \epsilon. \quad (\text{L9})$$

Eq. (L9) provides an upper bound on the MSE of the given classical algorithm over the hypercube $\boldsymbol{\theta} \in [0, 2\pi]^m$, $\boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, \epsilon_1]^{3K}$ and $\bar{\boldsymbol{\theta}}_{\mathcal{G}_{\mathcal{P}}} = \mathbf{0}$. Then, by applying Markov's inequality, we obtain

$$\begin{aligned} \Pr_{\substack{\boldsymbol{\theta} \in [0, 2\pi]^m \\ \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, \epsilon_1]^{3K}}} \{|L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)| \geq \epsilon_2\} &\leq \mathbb{E}_{\substack{\boldsymbol{\theta} \in [0, 2\pi]^m \\ \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}} \in [0, \epsilon_1]^{3K}}} |L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_{\mathcal{P}}}, \mathbf{0}), P)| / \epsilon_2 \\ &\leq \left(\frac{2\pi}{\epsilon_1}\right)^{3K/2} \frac{\sqrt{\epsilon}}{\epsilon_2}, \end{aligned} \quad (\text{L10})$$

where $\epsilon_2 > 0$ is a constant to be determined later. The last inequality follows from the fact that for any random variable X , we have $(\mathbb{E}[X])^2 \leq \mathbb{E}[X^2]$.

Eq. (L10) implies that the output of the classical algorithm, when evaluated in the hypercube $\boldsymbol{\theta} \in [0, 2\pi)^m$, $\boldsymbol{\theta}_{\mathcal{G}_P} \in [0, \epsilon_1)^{3K}$ and $\bar{\boldsymbol{\theta}}_{\mathcal{G}_P} = \mathbf{0}$, will have very low error with high probability. Hence, by choosing ϵ_1 to be small and leveraging the fact that $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0})$ is a Lipschitz continuous function, the output will also be close to $L(\boldsymbol{\theta}) = L^C(\boldsymbol{\theta}, \mathbf{0})$ with high probability.

Based on this observation, we construct a randomized classical algorithm $A_{\text{rand}}(\boldsymbol{\theta})$ to compute the value of $L^C(\boldsymbol{\theta}, \mathbf{0})$. For an arbitrary $\boldsymbol{\theta}$, this algorithm randomly selects a $\boldsymbol{\theta}_{\mathcal{G}_P} \in [0, \epsilon_1)^{3K}$ and $\bar{\boldsymbol{\theta}}_{\mathcal{G}_P} = \mathbf{0}$, runs the classical algorithm under the assumptions of the theorem, and outputs $\mathcal{A}_C(\boldsymbol{\theta}) := \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P)$ with some given MSE ϵ . We now analyze this randomized algorithm $A_{\text{rand}}(\boldsymbol{\theta})$ and show that it can achieve the performance stated in the theorem for a suitably chosen ϵ .

We first calculate the probability of $\boldsymbol{\theta}$ for which our algorithm can achieve low error with high probability. To this end, we define a function $p(\boldsymbol{\theta})$, which represents the probability that $A_{\text{rand}}(\boldsymbol{\theta})$ incurs high error for a given $\boldsymbol{\theta}$.

$$p(\boldsymbol{\theta}) := \Pr_{\boldsymbol{\theta}_{\mathcal{G}_P} \in [0, \epsilon_1)^{3K}} \{ |L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P)| \geq \epsilon_2 \}. \quad (\text{L11})$$

It is easy to verify that

$$\mathbb{E}_{\boldsymbol{\theta} \in [0, 2\pi)^m} [p(\boldsymbol{\theta})] = \Pr_{\substack{\boldsymbol{\theta} \in [0, 2\pi)^m \\ \boldsymbol{\theta}_{\mathcal{G}_P} \in [0, \epsilon_1)^{3K}}} \{ |L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P)| \geq \epsilon_2 \} \leq \left(\frac{2\pi}{\epsilon_1} \right)^{3K/2} \frac{\sqrt{\epsilon}}{\epsilon_2}. \quad (\text{L12})$$

Again, applying Markov's inequality, we obtain

$$\Pr_{\boldsymbol{\theta} \in [0, 2\pi)^m} \{ p(\boldsymbol{\theta}) \geq \delta \} \leq \mathbb{E}_{\boldsymbol{\theta} \in [0, 2\pi)^m} [p(\boldsymbol{\theta})] / \delta \leq \left(\frac{2\pi}{\epsilon_1} \right)^{3K/2} \frac{\sqrt{\epsilon}}{\epsilon_2 \delta}. \quad (\text{L13})$$

Eq. (L13) implies that, with probability at least $1 - \left(\frac{2\pi}{\epsilon_1} \right)^{3K/2} \frac{\sqrt{\epsilon}}{\epsilon_2 \delta}$ over $\boldsymbol{\theta} \in [0, 2\pi)^m$, the output of $A_{\text{rand}}(\boldsymbol{\theta})$ has an error smaller than ϵ_2 with probability at least $1 - \delta$. Focusing on these values of $\boldsymbol{\theta}$ and on those $\boldsymbol{\theta}_{\mathcal{G}_P}$ that violates the condition in Eq. (L11), $A_{\text{rand}}(\boldsymbol{\theta})$ produces an output $\mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P)$ that satisfies

$$|L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}) - \mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P)| \leq \epsilon_2. \quad (\text{L14})$$

Then, by employing the triangle inequality and the Lipschitz continuity of $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ as a function of $\boldsymbol{\theta}_{\mathcal{G}}$, we have

$$\begin{aligned} |\mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P) - L(\boldsymbol{\theta})| &= |\mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P) - L^C(\boldsymbol{\theta}, \mathbf{0}, \mathbf{0})| \\ &\leq |\mathcal{A}_{\Phi^C}((\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}), P) - L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0})| + |L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}_P}, \mathbf{0}) - L^C(\boldsymbol{\theta}, \mathbf{0}, \mathbf{0})| \\ &\leq \epsilon_2 + \epsilon_1 \sqrt{3K} l_{\boldsymbol{\theta}} \leq \epsilon_2 + \epsilon_1 3K. \end{aligned} \quad (\text{L15})$$

In the end, we determine the unfixed parameters introduced earlier. To ensure that $A_{\text{rand}}(\boldsymbol{\theta})$ achieves an error of at most ϵ_{error} , we need to set $\epsilon_2 + 3K\epsilon_1 \leq \epsilon_{\text{error}}$. Hence, we choose $\epsilon_2 = \frac{\epsilon_{\text{error}}}{2}$ and $\epsilon_1 = \frac{\epsilon_{\text{error}}}{6K}$ to satisfy the error condition. Next, to ensure that $A_{\text{rand}}(\boldsymbol{\theta})$ works with probability at least $1 - \epsilon_{\text{rate}}$ over $\boldsymbol{\theta}$, we apply Eq. (L13) and set $\left(\frac{2\pi}{\epsilon_1} \right)^{3K/2} \frac{\sqrt{\epsilon}}{\epsilon_2 \delta} \leq \epsilon_{\text{rate}}$. Substituting the values of ϵ_1 and ϵ_2 into the inequality, we obtain

$$\epsilon \leq \frac{(12\pi K)^{-3K}}{4} \epsilon_{\text{rate}}^2 \epsilon_{\text{error}}^{3K+2} \delta^2 = K^{-3K} \frac{\epsilon_{\text{rate}}^2 \epsilon_{\text{error}}^{\mathcal{O}(\log n)} \delta^2}{\mathcal{O}(\text{poly}(n))}. \quad (\text{L16})$$

The above calculation implies that, to achieve a randomized classical algorithm that satisfies the conditions in the theorem, we first randomly pick each $\theta_{\mathcal{G}_{ij}} \in \boldsymbol{\theta}_{\mathcal{G}_P}$ from the interval $[0, \frac{\epsilon_{\text{error}}}{6K})$. We then run the classical algorithm to compute $L^C(\boldsymbol{\theta}, \boldsymbol{\theta}_{\mathcal{G}})$ with MSE at most $K^{-3K} \left(\frac{3}{\pi} \right)^{3K} \epsilon_{\text{rate}}^2 \epsilon_{\text{error}}^{3K} \delta^2$. The running time of $A_{\text{rand}}(\boldsymbol{\theta})$ is $\mathcal{O}\left(\text{poly}(n, K^{3K} \frac{1}{\epsilon_{\text{rate}} \epsilon_{\text{error}} \delta^2})\right) = K^{3K} \mathcal{O}\left(\text{poly}(n, \frac{1}{\delta}, \frac{1}{\epsilon_{\text{error}}}, \frac{1}{\epsilon_{\text{rate}}})\right)$, which satisfies the condition in the theorem. $\square$

Based on the above lemma, we can directly extend the observable from a single local Pauli word to an arbitrary k -local observable $\mathcal{O}$:

Theorem A.13. *Suppose there exists a classical algorithm running in $\mathcal{O}\left(\text{poly}\left(n, \frac{1}{\zeta}\right)\right)$ time that can estimate the expectation value of any local observable for arbitrary MPQCs with MSE no larger than ζ . Then, for any PQC $\mathcal{C}(\theta)$ and any local observable $O = \sum_{\alpha} c_{\alpha} P_{\alpha}$ consisting of a polynomial number of Pauli terms, there exists a randomized classical algorithm that, with probability at least $1 - 1/\text{poly}(n)$ over θ , outputs an estimate of $L(\theta) = \text{tr}\{\mathcal{C}(\theta)\rho\mathcal{C}^{\dagger}(\theta)O\}$ with error at most ϵ with success probability at least $1 - \delta$. The runtime of this algorithm scales as $\mathcal{O}\left(\text{poly}\left(n, \frac{1}{\delta}, \frac{1}{\epsilon}\right)\right)$.*

Proof. To compute $L(\theta) = \text{tr}\{\mathcal{C}(\theta)\rho\mathcal{C}^{\dagger}(\theta)O\} = \langle O \rangle$, we first construct an MPQC $\Phi^{\mathcal{C}}(\theta, \theta_G)$ from $\mathcal{C}(\theta)$ such that the backward-propagated support of all Pauli components P_{α} in O through the gadget layer is at most K .

Using the classical algorithm established in the theorem, which efficiently computes $\text{tr}\{\Phi^{\mathcal{C}}(\theta, \theta_G)(\rho)P_{\alpha}\}$, we estimate the expectation value $\langle P_{\alpha} \rangle$ for each Pauli term and then reconstruct $\langle O \rangle$ via the weighted sum $\sum_{\alpha} c_{\alpha} \langle P_{\alpha} \rangle$. Let $\#O = \mathcal{O}(\text{poly}(n))$ denote the number of Pauli terms in O . For each $\langle P_{\alpha} \rangle$, according to Lemma A.10, we can design a randomized classical algorithm $A_{\text{rand}}^{P_{\alpha}}(\theta)$ that estimates $\langle P_{\alpha} \rangle$ within error $\frac{\epsilon}{|c_{\alpha}|\#O}$ and with success probability at least $1 - \frac{\delta}{\#O}$, for probability at least $1 - \frac{1}{\#O\text{poly}(n)}$ over θ . The runtime of $A_{\text{rand}}^{P_{\alpha}}(\theta)$ is

$$K^{3K} \mathcal{O}\left(\text{poly}\left(n, \frac{\#O}{\delta}, \frac{|c_{\alpha}|\#O}{\epsilon}, \#O\text{poly}(n)\right)\right) = K^{3K} \#O \cdot \text{poly}(n) \mathcal{O}\left(\text{poly}\left(n, \frac{1}{\delta}, \frac{1}{\epsilon}\right)\right). \quad (\text{L17})$$

Summing the outputs of all $A_{\text{rand}}^{P_{\alpha}}(\theta)$ yields the final algorithm $A_{\text{rand}}^O(\theta)$ for $L(\theta)$, whose runtime is upper bounded by $K^{3K} (\#O)^2 \text{poly}(n) \mathcal{O}\left(\text{poly}\left(n, \frac{1}{\delta}, \frac{1}{\epsilon}\right)\right) = K^{3K} \mathcal{O}\left(\text{poly}\left(n, \frac{1}{\delta}, \frac{1}{\epsilon}\right)\right)$.

By the union bound, the probability (over θ) that any $A_{\text{rand}}^{P_{\alpha}}(\theta)$ fails to satisfy the required condition is at most $\#O \cdot \frac{1}{\#O\text{poly}(n)} = \frac{1}{\text{poly}(n)}$. Hence, focusing on those θ —which occur with probability at least $1 - \frac{1}{\text{poly}(n)}$ —for which each $A_{\text{rand}}^{P_{\alpha}}(\theta)$ outputs an estimate with error at most $\frac{\epsilon}{|c_{\alpha}|\#O}$ and success probability at least $1 - \frac{\delta}{\#O}$, we obtain that, again by the union bound, the probability that any single $A_{\text{rand}}^{P_{\alpha}}(\theta)$ exceeds its error threshold $\frac{\epsilon}{|c_{\alpha}|\#O}$ is at most $\#O \cdot \frac{\delta}{\#O} = \delta$. Conditioning on the successful instances, the total error is bounded by

$$\sum_{\alpha} |c_{\alpha}| \frac{\epsilon}{|c_{\alpha}|\#O} = \epsilon, \quad (\text{L18})$$

which satisfies the theorem's conditions. Because the assumption classical algorithm works for arbitrary MPQCs, and we can always construct an MPQC with $K = \mathcal{O}(1)$ for any PQC, the runtime of the final algorithm scales as $\mathcal{O}\left(\text{poly}\left(n, \frac{1}{\delta}, \frac{1}{\epsilon}\right)\right)$. $\square$

Remark. Theorem A.13 implies that if MPQCs are classically simulable on average, then arbitrary PQCs would also be efficiently simulable by a BPP Turing machine on average. In other words, the average-case classical simulation of PQCs would belong to the heuristic complexity class HeurBPP [61, 62]. Notably, existing works on classical simulation of quantum circuits typically rely on specific assumptions about the distribution of circuit gates [39], and whether general PQCs are classically simulable on average remains an open question.

Supplementary Information M: Numerical experiments

In this section, we provide details of numerical results in the manuscript. First, we construct a deliberately designed example in which the original PQC becomes untrainable even at small system sizes, while the corresponding MPQC remains trainable and is able to recover the optimal solution. Second, we consider the task of approximating the ground state of a complex Hamiltonian, where we also show that, by employing the activation strategy introduced in Appendix I, MPQC can further reduce the loss and achieve a better ground-state approximation.

1. Effectiveness of MPQC under a poorly designed PQC ansatz

Owing to the limitations of current classical simulation methods for variational quantum algorithms, the system sizes that can be explored numerically are relatively small. In particular, for MPQC, the additional ancilla qubits introduced by the gadget layers further constrain the maximum system size accessible to simulation, typically to at most a few tens of qubits. In this regime, although gradients may scale exponentially with system size in principle, their magnitudes are not necessarily extremely small, and PQCs can still be trainable.

Nevertheless, extremely small gradients can still occur even at these moderate system sizes, depending on the specific circuit architecture. To clearly illustrate the advantage brought by MPQC, we construct an artificial yet representative example in which a PQC becomes untrainable due to an unfavorable circuit design. Specifically, we construct the PQC as follows, which is obtained by replacing all rotation gates in the circuit in the manuscript into R_x in Section VI.

Figure A.16: An example of a poorly designed PQC obtained by restricting all rotation gates with R_x gates.

We consider the task of finding the ground state of the following two-local transverse-field Ising Hamiltonian:

$$H_{\text{TFI}} = - \sum_{j=1}^n X_j X_{j+1} - h \sum_{j=1}^n Z_j \quad (\text{M1})$$

defined on a periodic one-dimensional chain, where $h > 0$ is treated as a tunable parameter. With the above choice of rotation gates, the Pauli-operator evolution governed by Eq. (B14) shows that the circuit parameters fail to influence the XX terms in the Hamiltonian, since the rotation gate generators commute with the Pauli operators backward-propagated from the XX terms. Consequently, when h is chosen sufficiently small, the gradient variance with respect to all circuit parameters becomes uniformly small. This allows us to artificially construct barren-plateau-like behavior even for circuits of small depth and modest system size. In contrast, after inserting the gadget layer, the diversity of Pauli paths is significantly enhanced, thereby restoring nontrivial couplings between the circuit parameters and the XX terms in the Hamiltonian.

We then perform numerical experiments to demonstrate that MPQC remains capable of finding the ground state even when the original PQC suffers from such an unfavorable design. Concretely, we set $n = 6$ and consider $h = 0.01$ and $h = 0.5$ in Eq. (M1). The original PQC consists of six blocks, each corresponding to the structure shown in Fig. A.16. The associated MPQC is obtained by inserting a gadget layer after the fourth block, i.e., two blocks before the final measurement. In addition, we construct a “shallow” PQC containing only a single block, illustrating that even very shallow circuits with this unfavorable design remain untrainable.

For all three circuit architectures, parameters are initialized randomly from the uniform distribution $[0, 2\pi)$, and we perform ten independent training runs with different random seeds to mitigate the effect of unlucky initializations. Optimization is carried out using the Adam optimizer [63] with a learning rate of 0.01 for 1000 training epochs. All simulations are performed using *PennyLane* [64]. Detailed numerical results and further discussion are presented in the main text.

2. Application of parameter activation strategy

In this subsection, we demonstrate the employment of the activation strategy and present additional numerical evidence showing that MPQC achieves substantially better performance than the original PQC. We consider a random-sign 2-local XYZ Hamiltonian of the form

$$H_G = \sum_{\{i,j\} \in E} (J_{ij}^{(x)} X_i X_j + J_{ij}^{(y)} Y_i Y_j + J_{ij}^{(z)} Z_i Z_j), \quad (\text{M2})$$

where $G = (V, E)$ is an undirected graph with vertex set $V = \{1, 2, \dots, n\}$ and X_i, Y_i, Z_i denote Pauli operators acting on qubit i and identity on all other qubits. The couplings in H_G are i.i.d. random signs, e.g. $J_{ij}^{(\alpha)} \in \{-1, +1\}$ with equal probability for each $\alpha \in \{x, y, z\}$ and each edge $\{i, j\} \in E$. Here to ensure the hardness of the optimization problem, we choose G to be the complete graph on 12 vertices.

Random-sign spin Hamiltonians are canonical models of disorder and frustration, widely used to study spin-glass physics and as challenging benchmark instances for quantum optimization and variational ground-state preparation [65, 66]. From the computational-complexity viewpoint, the task of estimating (or deciding) the ground-state energy of generic 2-local quantum Hamiltonians is QMA-complete [50], and hardness persists under physically motivated restrictions such as geometrically local interactions [67].

To address this task, we extend the PQC architecture from a one-dimensional chain to a two-dimensional lattice, reflecting the structure of the target Hamiltonian H_G . The resulting ansatz is composed of repeated blocks, each of which is shown in Fig. A.17. Starting from a PQC consisting of eight such blocks, we construct the corresponding MPQC by inserting a gadget layer in the middle of the circuit, i.e., after the fourth block.

To further improve the optimization performance, we activate the parameters in the first block, as illustrated in Fig. A.18. Here, our goal is to activate the entire block. According to the strategy described in Appendix I, this would in principle require introducing an additional gadget layer before the first block. To reduce the complexity of the numerical simulations, we reuse the ancilla qubits introduced by the gadget layer in Fig. A.18(a).

Figure A.17: One block of the 2D lattice ansatz used to approximate the ground state of H_G . The complete circuit is constructed by repeating this block multiple times.

Figure A.18: (a) Construction of MPQC, where a gadget layer is inserted in the middle of the original PQC. (b) Strategy for activating the parameters in the first block. Gates denoted by “...” correspond to blocks 2, 3, and 4, while $B1$ represents the gates in the first block.

To demonstrate that MPQC outperforms the original PQC, we perform numerical simulations using the 2D ansatz with different circuit depths. Specifically, we train a family of PQCs with the number of blocks ranging from 1 to 8. As in the previous section, all circuit parameters are initialized independently from the uniform distribution $[0, 2\pi)$, and 10 independent training runs with different random seeds are performed for each setting. Optimization is carried out using the Adam optimizer with a learning rate of 0.01 for 3000 iterations for all PQCs.

For MPQC, we first optimize the circuit shown in Fig. A.18(a) for 2000 iterations. We then further minimize the loss by activating the parameters as in Fig. A.18(b) and continuing the optimization for an additional 1000 iterations. The newly introduced parameters are initialized to zero so that the second-stage optimization starts from the state obtained in the first stage. We emphasize that the activation strategy is not optimized in this example, and further performance improvements may still be possible.

Efficient explicit circuit for quantum state preparation of piecewise continuous functions

Abstract. Efficiently uploading data into quantum states is essential for many quantum algorithms to achieve advantage across various applications. In this paper, we address this challenge by developing a method to upload a polynomial function $f(x)$ on the interval $x \in [-1, 1]$ into a pure quantum state consisting of qubits, where a discretized $f(x)$ is the amplitude of this state. The preparation cost has $\mathcal{O}(n \log n)$ scaling in the number of qubits n and linear scaling with the degree of the polynomial Q . This efficiency allows the preparation of states whose amplitudes correspond to high-degree polynomials (up to 10^4), enabling accurate approximation of functions that admit efficient polynomial series representations and whose amplitude profiles are not extremely localized. We provide a fully explicit circuit realization, based on four real polynomials that meet specific parity and boundedness conditions. We extend this construction to cover piece-wise polynomial functions, a case not previously addressed explicitly in the literature, the algorithm scaling linearly with the number of piecewise parts. Our method achieves efficient quantum circuit implementation and we present detailed gate counting and resource analysis.

I. INTRODUCTION

Efficient quantum state preparation is a key prerequisite for many quantum algorithms [1, 2], yet it is often treated as an implicit primitive. Our goal is to provide an explicit, resource-transparent circuit that loads the values of a continuous (or piecewise continuous) complex function into the amplitudes of an n -qubit state. The construction exploits two standard ideas: (i) polynomial representations of functions [3, 4] and (ii) quantum singular-value transformation / qubitization to implement these polynomials coherently [5, 6]. We also extend the same pipeline to piecewise-polynomial functions with only linear overhead in the number of pieces. We present Table I which describe cost of creating well known functions.

Table I: Polynomial Degree and Gate Counts for Various Functions [3, 4]. The polynomial degree corresponds to truncating the series to achieve error ϵ over the stated domain, and gate counts follow from Theorem 1. Here $n = \log_2 N$.

Name	Notation	Poly. degree	Gate counts	Domain
Exponent	$e^{\alpha x}$	$\mathcal{O}\left(\frac{ \alpha + \log(1/\epsilon)}{\log(1 + \log(1/\epsilon)/ \alpha)}\right)$	$\mathcal{O}\left(n \log n \cdot \frac{ \alpha + \log(1/\epsilon)}{\log(1 + \log(1/\epsilon)/ \alpha)}\right)$	$x \in [-1, 1], \alpha \in \mathbb{C}$
Cosine	$\cos(tx)$	$\mathcal{O}\left(t + \frac{\log(1/\epsilon)}{\log(e + \log(1/\epsilon)/t)}\right)$	$\mathcal{O}\left(n \log n \left(t + \frac{\log(1/\epsilon)}{\log(e + \log(1/\epsilon)/t)}\right)\right)$	$x \in [-1, 1], t \in \mathbb{R}$
Sine	$\sin(tx)$	$\mathcal{O}\left(t + \frac{\log(1/\epsilon)}{\log(e + \log(1/\epsilon)/t)}\right)$	$\mathcal{O}\left(n \log n \left(t + \frac{\log(1/\epsilon)}{\log(e + \log(1/\epsilon)/t)}\right)\right)$	$x \in [-1, 1], t \in \mathbb{R}$
Sigmoid	$\frac{1}{1 + e^{-2x}}$	$\mathcal{O}(\log(1/\epsilon))$	$\mathcal{O}(n \log n \cdot \log(1/\epsilon))$	$x \in [-\pi/2, \pi/2]$
Gaussian	$\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{1}{2}(x/\sigma)^2}$	$\mathcal{O}\left(\frac{\log(1/\epsilon) + \log(1/\sigma)}{\log(1 + 2\sigma \log(1/\epsilon))}\right)$	$\mathcal{O}\left(n \log n \cdot \frac{\log(1/\epsilon) + \log(1/\sigma)}{\log(1 + 2\sigma \log(1/\epsilon))}\right)$	$x \in [-1, 1], \sigma > 0$
Bessel	$J_n(\alpha x)$	$\mathcal{O}\left(\frac{\log(1/\epsilon)}{\log(1 + \frac{2}{ \alpha } \log(1/\epsilon))}\right)$	$\mathcal{O}\left(n \log n \cdot \frac{\log(1/\epsilon)}{\log(1 + \frac{2}{ \alpha } \log(1/\epsilon))}\right)$	$x \in [-1, 1], \alpha \in \mathbb{R}$
Reciprocal	$\frac{1}{x}$	$\mathcal{O}\left(\delta \sqrt{L_\epsilon(L_\epsilon + L_\delta)}\right)$ $L_\epsilon = \log(1/\epsilon), L_\delta = \log(\delta)$	$\mathcal{O}\left(\delta n \log n \cdot \sqrt{L_\epsilon(L_\epsilon + L_\delta)}\right)$	$x \in [-1, -1/\delta] \cup [1/\delta, 1]$
ReLU	$\text{ReLU}(x)$	$\mathcal{O}(1)$	$\mathcal{O}(n \log n)$	$x \in \mathbb{R}$
Leaky ReLU	$\text{LeakyReLU}(x)$	$\mathcal{O}(1)$	$\mathcal{O}(n \log n)$	$x \in \mathbb{R}$

II. RESULTS

Problem setting and summary of achievements. We consider a complex-valued function $f(x)$ defined on a finite interval, which we take as $[-1, 1]$ without loss of generality. Our goal is to prepare an n -qubit state whose amplitudes

encode a *uniform-grid discretization* of f :

$$x_k = -1 + \frac{2k}{2^n - 1}, \quad k = 0, 1, \dots, 2^n - 1, \quad (1)$$

and

$$|\psi_f\rangle^n = \frac{1}{N_f} \sum_{k=0}^{2^n-1} f(x_k) |k\rangle^n, \quad N_f = \sqrt{\sum_{k=0}^{2^n-1} |f(x_k)|^2}. \quad (2)$$

The main technical contribution of this paper is an *explicit, gate-transparent* construction of a unitary U_f that prepares $|\psi_f\rangle^n$ from $|0\rangle^n$ using only one- and two-qubit gates, with resource scaling $\mathcal{O}(Q n \log n)$ when f is a degree- Q polynomial on $[-1, 1]$, and a linear overhead in the number of pieces for piecewise polynomial functions. Our construction is based on block-encoding and polynomial transformation techniques [5, 6], and is presented with explicit circuit structure and gate counts.

What U_f guarantees (informal). Throughout the paper, U_f denotes a unitary acting on the system register of n qubits together with a fixed number of ancillas initialized in $|0\rangle$, such that measuring a designated set of workspace ancillas in the all-zero outcome projects the system register onto $|\psi_f\rangle^n$:

$$U_f |0\rangle^a |0\rangle^n = \sqrt{P} |0\rangle^a |\psi_f\rangle^n + \sqrt{1-P} |\Phi_\perp\rangle, \quad (3)$$

where a is the number of workspace ancillas, $|\Phi_\perp\rangle$ is a state orthogonal to $|0\rangle^a \otimes \mathbb{C}^{2^n}$, and P is the success probability. Thus a single postselection on the workspace ancillas prepares $|\psi_f\rangle^n$ with probability P .

Main result: piecewise polynomial functions. We now state the central performance guarantee in the general setting relevant for applications, where f is specified by different polynomial expressions on different subintervals.

Theorem 1 (Piecewise polynomial state preparation) *Let $f : [a, b] \rightarrow \mathbb{C}$ be a piecewise continuous function with breakpoints*

$$a = K_0 < K_1 < \dots < K_{G-1} < K_G = b,$$

such that on each interval it agrees with a complex polynomial. In particular,

$$f(x) = \begin{cases} f_1(x) = \sum_{i=0}^{Q_1} \sigma_i^{(1)} x^i, & \text{if } K_1 \geq x \geq a, \\ f_2(x) = \sum_{i=0}^{Q_2} \sigma_i^{(2)} x^i, & \text{if } K_2 \geq x > K_1, \\ \vdots \\ f_G(x) = \sum_{i=0}^{Q_G} \sigma_i^{(G)} x^i, & \text{if } b \geq x > K_{G-1}, \end{cases} \quad \sigma_i^{(g)} \in \mathbb{C}.$$

Let $Q_{\max} = \max_g Q_g$. Then there exists an explicit quantum circuit implementing a unitary U_f of the form (3) that prepares the discretized state (2) with success probability P and uses no more than:

1. $\mathcal{O}(Q_{\max} n \log n + Gn + Q_{\max} G)$ one- and two-qubit gates;
2. $n + \lceil \log_2 G \rceil - 1$ pure ancillas, in addition to a fixed $\mathcal{O}(\log n)$ workspace register.

Success probability and the filling ratio. The postselection probability P depends on how “spread out” the squared magnitude $|f(x)|^2$ is over the domain. Following [7], we quantify this by the *filling ratio*, see Fig. 1.

Definition 1 (Filling ratio [7]) *For a bounded Riemann-integrable function f on $[-1, 1]$, define*

$$\mathcal{F} := \frac{\|f\|_2^2}{2\|f\|_{\max}^2}, \quad \|f\|_2^2 = \int_{-1}^1 |f(x)|^2 dx, \quad \|f\|_{\max} = \max_{x \in [-1, 1]} |f(x)|.$$

Geometrically, $\mathcal{F}$ is the area under $|f(x)|^2$ relative to the area of the rectangle of height $2\|f\|_{\max}^2$ over $[-1, 1]$; see Fig. 1. In our construction, the success probability scales as $P \sim \mathcal{F}$: for typical non-pathological functions, $\mathcal{F}$ is not exponentially small in n , so a constant number of repetitions suffices to obtain $|\psi_f\rangle^n$ with high probability.

Fig. 1: The geometrical interpretation of the filling ratio. The filling ratio is the area under the function $|f(x)|^2$ (blue area) relative to its doubled absolute maximum value $2|f_{\max}|^2$ (area in the dashed rectangle).

Sensitivity Bounds of Multiparameter Metrology at Thermal Equilibrium

Zhu Cao^{1, 2, *}

Quantum metrology aims to enhance measurement precision beyond the classical limit by leveraging quantum resources. Unlike multi-parameter dynamic quantum metrology, many questions regarding multiparameter quantum metrology at thermal equilibrium remain elusive. In particular, the ultimate precision limits achievable in this equilibrium setting are not yet well understood. In this work, we examine the fundamental limits of estimating multiple parameters with a quantum probe at thermal equilibrium. We first show that the Heisenberg limit with respect to the number of probes can be achieved, and our bound coincides with the known single-parameter bound when only one parameter is estimated. We then consider the low temperature limit, revealing a qualitatively different behavior compared to the finite temperature case. We give an example to illustrate the usage of our main results. Finally, we show the conditions under which the sensitivity bound can be attained and the optimal measurements to achieve it. (<https://arxiv.org/abs/2605.19669>)

Introduction—Quantum metrology [1–12] is a rapidly developing field at the intersection of quantum physics and precision measurement science, dedicated to exploiting uniquely quantum phenomena to enhance the sensitivity of measurements beyond the limits imposed by classical physics. Applications of quantum metrology span a wide range of domains: improving the accuracy of gravitational wave detectors [13, 14], advancing magnetic resonance imaging at the nanoscale [15, 16], refining frequency standards in next-generation atomic clocks [17, 18], and even enabling possible extensions of the Standard Model of particle physics [19]. Furthermore, quantum metrology provides a bridge between fundamental and applied science, linking abstract concepts such as entanglement entropy [20] and Fisher information [21] to tangible experimental outcomes. In doing so, it also drives innovation in quantum technologies more broadly, including quantum communication [22] and computation [23]. As experimental control over quantum systems continues to advance, quantum metrology stands as one of the most promising avenues for translating the counterintuitive principles of quantum mechanics into transformative real-world capabilities [24].

Currently, the most studied quantum metrology is dynamic metrology [1]. In single-parameter dynamic metrology, an initial N -partite quantum state ρ_0 undergoes a quantum channel with parameter θ for a period of time t , after which a measurement is performed. The parameter is then inferred from the measured statistics. For single-parameter dynamic metrology, its fundamental sensitivity limit has been established in Ref. [2] as $F \leq O(N^2 t^2)$, where F is the quantum Fisher information (QFI). This quadratic dependence on t characterizes the ideal noiseless case; under Lindblad-type noise, the QFI typically grows at most linearly in t for short times [25]. For multi-parameter dynamic metrology, its fundamental limit is also understood [26]. Specifically, for an arbitrary real vector $\mathbf{n}$ that satisfies $\|\mathbf{n}\|_2 = 1$ (i.e., its

2-norm is 1), we have $\mathbf{n}^T \mathbf{F} \mathbf{n} \leq O(N^2 t^2)$, where $\mathbf{F}$ is the quantum Fisher information matrix.

Another important type of quantum metrology is equilibrium metrology. In this setting, an N -partite Gibbs state is prepared with respect to a system Hamiltonian H at inverse temperature β , thus encoding the Hamiltonian parameters. For gapped Hamiltonians, such a Gibbs state can be obtained via passive thermalization, whereas for gapless Hamiltonians, its preparation generally requires active control (see for example the method in Ref. [27]). The Gibbs state is subsequently measured, the outcome of which is then utilized to estimate the parameters of interest [28]. We note a crucial difference between dynamic metrology and equilibrium metrology. In dynamic metrology, the parameter is imprinted through unitary evolution, so the distinguishability of states grows quadratically with the interrogation time t . In equilibrium metrology, by contrast, the probe is assumed to have fully thermalized to the Gibbs state $\rho = e^{-\beta H} / \text{Tr}(e^{-\beta H})$. The parameter dependence is encoded in the static structure of the Hamiltonian within this equilibrium state rather than accumulated dynamically over a controllable evolution time. Consequently, t does not constitute a metrological resource; instead, the relevant energy scale is set by the inverse temperature β , which plays a role analogous to t in dynamic scenarios.

Recently, the fundamental precision limit of single-parameter equilibrium metrology has been established as $F \leq O(\beta^2 N^2)$ [29]. In contrast, the multi-parameter case has received comparatively little attention [30, 31]. In Ref. [30], multi-parameter estimation at finite temperature is performed through the two-impurity Kondo model. Ref. [31] establishes a link between metrological symmetries and the number of effective parameters that can be estimated in quantum equilibrium metrology. Despite these progresses, the fundamental precision limit for multi-parameter equilibrium metrology is poorly understood. In particular, its scaling with the number of probes N and the inverse temperature β remains elusive.

In this work, we fill this gap by establishing the fundamental precision limits of multi-parameter equilibrium metrology. Let the parameter vector be $\Theta = (\theta_1, \dots, \theta_M)$. The (j, k) -th entry of the parameter covariance matrix Σ is defined by $\Sigma_{jk} = \text{Cov}(\theta_j, \theta_k)$. A modified quantum Cramér-Rao bound (QCRB) dictates $\mathbf{n}^T \Sigma \mathbf{n} \geq 1/\mathbf{n}^T \mathbf{F} \mathbf{n}$ [26], for any real M -dimensional vector $\mathbf{n}$ that satisfies $\|\mathbf{n}\|_2 = 1$ and that the scalar $\mathbf{n}^T \mathbf{F} \mathbf{n}$ is positive. Note that this bound remains valid even when $\mathbf{F}$ is degenerate, a regime in which the standard quantum Cramér-Rao bound ceases to apply. We show that

$$\mathbf{n}^T \mathbf{F} \mathbf{n} \leq O(\beta^2 N^2), \quad (1)$$

for finite inverse temperature β , and

$$\mathbf{n}^T \mathbf{F} \mathbf{n} \leq O(N^2/\Delta^2), \quad (2)$$

in the zero-temperature limit $\beta \rightarrow \infty$, where Δ is the energy gap of the Hamiltonian H . To showcase the power of these bounds, we provide a concrete example that compares the exact quantum Fisher information with the derived sensitivity bound. We also examine the attainability of the bounds and give concrete examples in which they are saturated. Finally, we identify the optimal measurements that can achieve the maximal Fisher information for a given thermal state. A summary of the results of our work and related work is shown in Table I.

TABLE I. A collection of sensitivity bounds for both dynamic metrology and equilibrium metrology, for both the case of single-parameter estimation and that of multiple-parameter estimation. Our work fills the last missing piece of the table.

	Dynamic metrology	Equilibrium metrology
Single parameter	$F \leq O(N^2 t^2)$ [2]	$F \leq O(\beta^2 N^2)$ [29]
Multiple parameters	$\mathbf{n}^T \mathbf{F} \mathbf{n} \leq O(N^2 t^2)$ [26]	$\mathbf{n}^T \mathbf{F} \mathbf{n} \leq O(\beta^2 N^2)$ (This work)

Multiparameter Estimation via Equilibrium States—In this section, we present the quantum Fisher information matrix for multiparameter estimation using equilibrium states. This provides the basis for later analysis of the sensitivity bounds.

For multi-parameter estimation [32], the (μ, ν) -th entry of the quantum Fisher information matrix $\mathbf{F} = (F_{\mu, \nu})_{\mu, \nu \in [M]}$ has the form

$$F_{\mu, \nu} = \text{Tr} \left[\dot{\rho}_\mu J_{B, \rho}^{-1} [\dot{\rho}_\nu] \right], \quad (3)$$

where $\dot{\rho}_\mu \equiv \partial \rho / \partial \mu$ and likewise for $\dot{\rho}_\nu$. The superoperator $J_{B, \rho}^{-1}$ is defined as $J_{B, \rho}^{-1}[A] = 2 \int_0^\infty ds e^{-\rho s} A e^{-\rho s}$ and is the inverse operator of $J_{B, \rho}$, which acts as $J_{B, \rho}[A] = (\rho A + A \rho)/2$ [33].

Substituting the Gibbs state $\rho = e^{-\beta H} / \text{Tr}[e^{-\beta H}]$, we obtain

$$\beta^{-2} F_{\mu, \nu} = \text{Tr}[\dot{H}_\mu \mathcal{J}_\rho[\dot{H}_\nu]] - \text{Tr}[\rho \dot{H}_\mu] \text{Tr}[\rho \dot{H}_\nu]. \quad (4)$$

Here, $\dot{H}_\mu \equiv \partial H / \partial \mu$, and likewise for $\dot{H}_\nu$. The operator $\mathcal{J}_\rho$ is defined as $\mathcal{J}_\rho = J_{L, \rho} \circ J_{B, \rho}^{-1} \circ J_{L, \rho}$, where $J_{L, \rho}[A] = \int_0^1 ds \rho^s A \rho^{1-s}$.

Bounds for Multiparameter Fisher Information Matrix at Thermal Equilibrium—In this section, we present upper bounds of quantum Fisher information (QFI) matrix for multi-parameter estimation at thermal equilibrium.

In the rest of the paper, we consider a Hamiltonian that encodes the parameters locally,

$$H = \sum_{m=1}^M \left(\sum_{k=1}^{N_m} h_m^{(k)} \right) \theta_m, \quad (5)$$

where $h_m^{(k)}$ acts on different qubits in the system and θ_m are the parameters. For simplicity, we assume that all operators $h_m^{(k)}$ share the same spectrum, with eigenvalues $\pm 1/2$, and are identical up to their action on different subsystems. It is important to note that this assumption can be relaxed to that each operator $h_m^{(k)}$ are spectrally bounded by a constant without affecting the main results.

To give the bound for the QFI matrix, we first introduce the covariance matrix $\Gamma(\rho, H)$ associated with the state ρ and the Hamiltonian H . Its (μ, ν) -th entry is defined as $\Gamma(\rho, H)_{\mu, \nu} = \text{Tr}[\rho(\dot{H}_\mu \dot{H}_\nu + \dot{H}_\nu \dot{H}_\mu)/2] - \text{Tr}[\rho \dot{H}_\mu] \text{Tr}[\rho \dot{H}_\nu]$. We have that, for any real column vector $\mathbf{n} = (n_1, \dots, n_M)$ that satisfies $\|\mathbf{n}\|_2 = 1$, the following inequality holds

$$\mathbf{n}^T \mathbf{F}(\rho, H) \mathbf{n} \leq \beta^2 \mathbf{n}^T \Gamma(\rho, H) \mathbf{n}, \quad (6)$$

which provides an upper bound on the QFI matrix.

To give a more accessible bound, we next examine the quadratic form $\mathbf{n}^T \Gamma(\rho, H) \mathbf{n}$. By maximizing over all quantum states ρ , we find

$$\beta^2 \mathbf{n}^T \Gamma(\rho, H) \mathbf{n} \leq \beta^2 \mathbf{n}^T \Gamma_{HL} \mathbf{n}, \quad (7)$$

where $\Gamma_{HL} = \mathbf{v} \cdot \mathbf{v}^T / 4$, with $\mathbf{v} = (\epsilon_1 N_1, \dots, \epsilon_M N_M)$ and $\epsilon_k = \text{sgn}(n_k)$. The upper bound is saturated by the quantum state $\rho = |\psi\rangle\langle\psi|$, where

$$|\psi\rangle = \frac{1}{2} (|N_1, \epsilon_1\rangle \otimes |N_2, \epsilon_2\rangle \otimes \dots \otimes |N_M, \epsilon_M\rangle + |N_1, -\epsilon_1\rangle \otimes |N_2, -\epsilon_2\rangle \otimes \dots \otimes |N_M, -\epsilon_M\rangle). \quad (8)$$

Here, $|N_m, 1\rangle$ ($|N_m, -1\rangle$) denotes a tensor product of N_m eigenstates of h_m , each with eigenvalue value $1/2$ ($-1/2$). This is a GHZ state of M large collective spins, aligned along a direction ϵ in parameter space, simultaneously extremal for all generators. When $M = 1$, this state reduces to the normal cat state.

For the single-parameter case ($M = 1$), the bound reduces to $F \leq \beta^2 N^2 / 4$, which is consistent with the known single-parameter QFI bound presented in Ref. [29], taking $\|h\| = \max_m \|h_m\| = 1$. For $M > 1$ and $N_1 = \dots = N_M = N$, the bound implies

$$\mathbf{n}^T \Sigma \mathbf{n} \geq O(1/\beta^2 N^2), \quad (9)$$

which is the second main result of this work.

Low temperature limit—It can be observed that the bound Eq. (9) becomes trivial in the zero-temperature limit, i.e., when the inverse temperature satisfies $\beta = \infty$. Therefore we present in this section an alternative non-trivial sensitivity bound applicable at zero temperature.

Let $|i\rangle$ be an eigenstate of the Hamiltonian H , satisfying $H|i\rangle = E_i|i\rangle$, where E_i is the corresponding eigenvalue. The Gibbs state associated with H is given by $\rho = \sum p_i |i\rangle\langle i|$, with $p_i = e^{-\beta E_i} / (\sum_j e^{-\beta E_j})$. Introducing the notation $a := p_i$ and $\Pi_a := |i\rangle\langle i|$, the density operator can be written compactly as $\rho = \sum_a a \Pi_a$.

Using this notion, one finds

$$\begin{aligned} \text{Tr}[B\mathcal{J}_\rho[A]] &= \sum_a a \text{Tr}[B\Pi_a A\Pi_a] \\ &+ \sum_{a \neq b} \frac{2(a-b)^2}{(\ln a - \ln b)^2(a+b)} \text{Tr}[B\Pi_b A\Pi_a]. \end{aligned} \quad (10)$$

Substituting Eq. (10) into the expression of $\beta^{-2} F_{\mu,\nu}$, we obtain

$$\begin{aligned} \beta^{-2} F_{\mu,\nu} &= \text{Tr}[\sum_a a (\Pi_a \dot{H}_\mu \Pi_a) (\Pi_a \dot{H}_\nu \Pi_a)] \\ &- \text{Tr}[\sum_a a \Pi_a \dot{H}_\mu \Pi_a] \text{Tr}[\sum_a a \Pi_a \dot{H}_\nu \Pi_a] \\ &+ \sum_{a \neq b} \frac{2(a-b)^2}{(\ln a - \ln b)^2(a+b)} \text{Tr}[\dot{H}_\mu \Pi_b \dot{H}_\nu \Pi_a]. \end{aligned} \quad (11)$$

Let $H^e = \sum_{i=1}^M n_i \dot{H}_i$. Then, the quadratic form of the QFI matrix can be written as

$$\beta^{-2} \mathbf{n}^T \mathbf{F} \mathbf{n} = \text{Var}(H^e) + \sum_{i \neq j} \frac{2(p_i - p_j)^2 |H_{ij}^e|^2}{(\ln p_i - \ln p_j)^2 (p_i + p_j)}, \quad (12)$$

where H_{ij}^e is the (i, j) -th entry of H^e . Writing $\beta^2 \text{Var}(H^e)$ as F^{diag} , we have

$$\mathbf{n}^T \mathbf{F} \mathbf{n} = F^{diag} + \sum_{i < j} \frac{4(p_i - p_j)^2 |H_{ij}^e|^2}{(E_i - E_j)^2 (p_i + p_j)}. \quad (13)$$

Here, $p_i = \exp(-\beta E_i)$, with E_i the eigenvalue of H^e . Let $\Delta = E_1 - E_0$ denote the energy gap. In the limit of large β , we find

$$\begin{aligned} F^{diag} &= O(e^{-\beta \Delta}), \\ \sum_{0 < i < j} \frac{4(p_i - p_j)^2 |H_{ij}^e|^2}{(E_i - E_j)^2 (p_i + p_j)} &= O(e^{-\beta \Delta}). \end{aligned} \quad (14)$$

Consequently,

$$\mathbf{n}^T \mathbf{F} \mathbf{n} = \sum_{i>0} \frac{4|H_{0i}^e|^2}{(E_i - E_0)^2} + O(e^{-\beta \Delta}). \quad (15)$$

By suitable manipulation of the inequalities, we have

$$\mathbf{n}^T \mathbf{F} \mathbf{n} \leq \frac{\|H^e\|^2}{\Delta^2} + O(e^{-\beta \Delta}). \quad (16)$$

To make the N -scaling apparent, we now analyze the norm of $\|H^e\|$. Each operator $\dot{H}_i$ is a sum of $O(N)$ local terms,

$$\dot{H}_i = \sum_{k=1}^N h_i^{(k)}, \quad (17)$$

where each $h_i^{(k)}$ acts nontrivially only on a constant number of sites and satisfies $\|h_i^{(k)}\| = O(1)$. By subadditivity of the operator norm,

$$\|\dot{H}_i\| \leq \sum_{k=1}^N \|h_i^{(k)}\| = O(N). \quad (18)$$

Since $H^e = \sum_i n_i \dot{H}_i$ contains only a finite number M of such operators (independent of N), we further obtain

$$\|H^e\| \leq \sum_{i=1}^M |n_i| \|\dot{H}_i\| = O(N). \quad (19)$$

Substituting the norm of H^e , we have

$$\mathbf{n}^T \mathbf{F} \mathbf{n} \leq O\left(\frac{N^2}{\Delta^2}\right). \quad (20)$$

If the many-body energy gap Δ remains finite as the system size N increases (i.e., away from criticality), the bound implies Heisenberg scaling with respect to N . By contrast, near a quantum phase transition the gap typically closes as $\Delta \sim N^{-z}$ in a finite system at criticality. In this case,

$$\mathbf{n}^T \mathbf{F} \mathbf{n} \lesssim O(N^{2+2z}), \quad (21)$$

leading to apparent super-Heisenberg scaling with respect to N .

Conclusion—In summary, we have shown that multi-parameter quantum sensing with thermal states can achieve the Heisenberg limit with respect to the number of probes for closed systems. We considered two cases: the finite temperature case and the zero temperature case. The quantum Fisher information scales quadratically with the inverse temperature in the former case, and quadratically with the inverse of the energy gap in the latter case. The quantum Fisher information in both cases scales quadratically with the resources, i.e., the number of probes.

Extended Abstract of Thermal-Drift Sampling: Generating Thermal Ensembles for Learning Many-Body Systems

Jiyu Jiang¹ Mingrui Jing¹ Jizhe Lai¹ Xin Wang¹ Lei Zhang¹

¹ *The Hong Kong University of Science and Technology (Guangzhou), Guangzhou, China.*

Abstract. Thermal equilibrium states of many-body Hamiltonians are central to studying quantum chaos, phases of matter, and quantum machine learning. Yet generating large ensembles of thermal states across different Hamiltonians remains prohibitively costly with existing methods. Here, we introduce the quantum thermal-drift channel, a new primitive that enables a measurement-controlled sampling algorithm to autonomously generate thermal states together with their Hamiltonian labels for general physical models. We prove that the algorithm is efficient: its total gate count scales polynomially with system size and quadratically with inverse temperature, establishing a polynomial resource bound for random thermal-state generation. For a two-dimensional transverse-field Ising model, we find that the sampled thermal states exhibit a crossover to Wigner–Dyson level statistics, demonstrating nontrivial chaotic correlations. As an application, we show that a variational quantum classifier trained on the generated dataset achieves near-optimal accuracy in predicting Hamiltonian properties of unseen states. These results establish a scalable, quantum-native route to thermodynamic simulation and quantum generative learning in many-body systems.

Keywords: Thermal state, quantum many-body system, quantum supervised learning

Introduction: Random quantum states are a fundamental resource in quantum information science [1] which can be useful for benchmarking quantum devices [2, 3] and probing the limits of classical simulability [4, 5]. Recently, the rise of quantum machine learning has created a new demand for these states [6]. Large collections of quantum states are treated as “quantum data” to learn the underlying patterns of many-body systems [7, 8].

Beyond preparing a single thermal state, data-driven applications such as Hamiltonian learning demand a large, labeled collection: many thermal states, each paired with the Hamiltonian from which it was generated. Producing such paired data $(G_{\beta,H}, H)$ at scale is an important task for supervised learning with quantum data.

Practical generation of random thermal states, however, remains costly with existing algorithms. Current quantum methods rely on quantum phase estimation combined with imaginary-time evolution [9–13] or quantum Metropolis and Lindbladian thermalization algorithms [14–26] that couple the system to an effective bath. These methods do not directly address the task of sampling thermal states from a family of Hamiltonians, as shown in Figure 2(a-b). Extending them to random thermal ensembles requires reconfiguring the circuit for each Hamiltonian instance, incurring substantial classical overhead that limits scalability.

Overview of the results: In this work, we solve this critical problem by introducing a quantum algorithm for the scalable generation of random thermal states. In particular, we establish the following:

- (i) *Quantum thermal-drift channel:* We find a channel that applies random non-unitary dynamics to the input state. The whole channel can be implemented within $\tilde{O}(n)$ quantum elementary gates and $2n$ ancilla qubits.
- (ii) *Measurement-controlled sampling algorithm:* We propose an efficient algorithm for sampling thermal states from a family of Hamiltonians. The complexity of elementary gates scales polynomially with precision ε , inverse temperature β , and system size n .
- (iii) *Supervised learning based on thermal states:* We perform a numerical experiment to show that our sampling algorithm can reliably provide labeled quantum datasets for supervised learning tasks in many-body systems.

Quantum thermal-drift channel: One of our main contributions is the thermal-drift channel, the core component of our measurement-controlled sampling algorithm. This channel is implemented using system-ancilla coupling in a dilated Hilbert space, followed by measuring and tracing out the flag register, with only elementary gates. Given a Pauli op-

(b) Pseudo code for our thermal state sampler

Input : Inverse temperature β , Pauli set $\Sigma = \{\sigma_j\}_{j=1}^L$ with bounds $h \in \mathbb{R}_+^L$, steps N .

Output: Thermal state $\rho \approx G_{\beta,H}$ with Hamiltonian label H

erator σ and input state ρ , the channel is written as $\mathcal{N}_\sigma(\rho) = 1/2 \cosh(\tau) \cdot (|\uparrow\rangle\langle\uparrow| \otimes \mathcal{E}_\sigma^\uparrow(\rho) + |\downarrow\rangle\langle\downarrow| \otimes \mathcal{E}_\sigma^\downarrow(\rho))$. Here, for any state ρ , the maps $\mathcal{E}_\sigma^\uparrow$ and $\mathcal{E}_\sigma^\downarrow$ are two completely positive and non-trace-preserving operations defined as $e^{+\tau\sigma/2}\rho e^{+\tau\sigma/2}$ and $e^{-\tau\sigma/2}\rho e^{-\tau\sigma/2}$, respectively, with a thermal strength $\tau > 0$. The first register of $\mathcal{N}_\sigma(\rho)$ naturally generates a random branch. Measuring this flag register indicates which direction the state is thermalized toward, with probabilities proportional to the corresponding unnormalized traces. The resource complexity of this channel is summarized in the following theorem.

Theorem S7 (Channel implementation) *For any n -qubit Pauli operator σ , Figure 1(a) implements $\mathcal{N}_\sigma$ using $2n$ ancilla qubits and $\mathcal{O}(n \log(1/\delta))$ elementary gates with success probability $\geq 1 - \delta$.*

Measurement-controlled sampling algorithm:

Leveraging the thermal-drift channel, we implement our measurement-controlled sampling algorithm by applying N blocks to an initial state ρ_0 . In block k , a thermal-drift channel $\mathcal{N}_{\sigma_{j_k}}$ is applied, where σ_{j_k} is selected independently from the set Σ of L Pauli operators. The probability of choosing $\mathcal{N}_{\sigma_j}$ is weighted by the bound h_j , so that the distribution is h_j/λ . The thermal strength is fixed across all blocks to $\tau = \beta\lambda/N$. After the thermal-drift channel, a measure-and-trace operation $\mathcal{M}_{m_k}$ is applied to the flag register, generating a measurement outcome m_k . This outcome is recorded as $m_k \in \{+1, -1\}$ corresponding to $\uparrow$ and $\downarrow$. The overall algorithm is shown in Figure 1(b).

The full circuit is labeled by an ordered list of values $\mathbf{j} = \{j_1, \dots, j_N\}$ and an ordered list of directions $\mathbf{m} = \{m_1, \dots, m_N\}$, that corresponds to the

channel $\mathcal{E}_{\mathbf{j},\mathbf{m}} = \mathcal{M}_{m_N} \circ \mathcal{N}_{\sigma_{j_N}} \circ \dots \circ \mathcal{M}_{m_1} \circ \mathcal{N}_{\sigma_{j_1}}$. Accumulating the drift terms, the overall Hamiltonian label is given by $H_{\mathbf{j},\mathbf{m}} = \frac{\lambda}{N} \sum_{j=1}^N \sum_{k:j_k=j} m_k \sigma_j$. The following theorem characterizes the sampling error and gate complexity.

Theorem 1 (Sampling precision) *For any system size n , inverse temperature β , and sufficiently large N , our algorithm uses $\mathcal{O}(nN \log(1/\delta))$ gates to sample a thermal state and its label, with precision $\tilde{\mathcal{O}}(n^{3/2}\lambda^3\beta^3N^{-3/2})$ and failure probability at most δ .*

This result guarantees that the gate resources required by the sampler scale polynomially in all problem parameters. As the number of thermal-drift steps N increases, the trace-distance error between the sampled state and the target thermal state decreases as $N^{-3/2}$, providing a route to higher-fidelity sampling. Beyond precision guarantees, we also characterize the distribution of sampled labels.

Theorem 2 (Label distribution) *For any system size n and inverse temperature β , a label H can be sampled with probability density proportional to an L -dimensional multivariate normal distribution reweighted by the partition function $\text{Tr}[e^{-\beta H}]$.*

The sampling probability is governed by two factors, the partition-function weight $\text{Tr}[e^{-\beta H}]$ and the normal density $D(\mathbf{x})$ arising from the central-limit behavior of the underlying lattice random walk. Together, they define a physically motivated measure over the Hamiltonian family.

We also apply our algorithm to study the level statistics of the generated thermal state ensemble. We compare an initial reference state whose spectrum exhibits near-Poisson statistics with the output states produced by the algorithm for a

Figure 2: **(a-b)** Difference between classical sampling and measurement-controlled sampling. The task is to sample a thermal state together with its Hamiltonian label. Panel (a) shows the classical workflow: sample label first, then prepare thermal state. Panel (b) shows our approach: sample state and label jointly via mid-circuit measurements. **(c)** Classification accuracy of a quantum classifier trained on sampled thermal states of a two-qubit Ising model. Gray traces show individual trial runs, the blue curve shows the mean success probability across independent test sets over 10 trials, the shaded region marks the 25–75 percentile band, and the orange band indicates the range of theoretical upper bound on success probability.

transverse-field Ising model on a 3×3 2D grid. The output distribution shifts toward the Wigner–Dyson prediction, indicating that the sampler accesses a substantially more chaotic sector of Hilbert space than the structured input.

Supervised learning based on thermal states:

Our thermal state sampler provides a scalable data source for quantum supervised learning algorithms [27–29] that learn properties of quantum systems from their thermal states. Consider classifying a black-box quantum system with an unknown Hamiltonian $H \in \mathfrak{H}$ by a label function $f(H) \in \{0, 1\}$, given access to only a single copy of its thermal state. A natural approach is to deploy a variational quantum classifier [7, 8, 30] (VQC) on a large labeled dataset of thermal states.

We train a VQC to classify two-qubit Ising models $\{aX \otimes X + bZ \otimes I + cI \otimes Z : |a|, |b|, |c| \leq 1\}$ by the sign of the coefficient a , where the optimal success probability is upper bounded by the Helstrom limit [31]. As shown in Figure 2(c), the prediction accuracy approaches the Helstrom limit in most trials, with noticeable trial-to-trial variability. In particular, the classifier trains on approximate states sampled from the thermal-weighted normal distribution (Theorem 2) yet generalizes to test states drawn from a uniform distribution. This distribution-shift robustness is enabled by the polynomial sampling cost (Theorem 1), which allows generating sufficiently large and diverse training sets without individual state preparation. Combined with the built-in Hamiltonian labeling, the sampler serves as

an end-to-end data source for quantum supervised learning in this setting. See the Supplemental Material for training details.

Conclusion: We have introduced the quantum thermal-drift channel and used it to develop an algorithm that generates random thermal states for Hamiltonians drawn from general Pauli models, with sampling cost polynomial in both the system size and the inverse temperature. Our protocol relies on elementary gates and mid-circuit measurements, and can be viewed as a stochastic subroutine for generating labeled quantum data on early fault-tolerant devices. A classification experiment further demonstrates that the sampled dataset can serve as a practical data source for quantum learning tasks.

Several avenues for future research remain open. Improving the system-size scaling by exploiting structure of quantum systems remains an important direction. We note that the polynomial efficiency achieved here contrasts with the known limitations of leading classical approaches [32, 33] for generic models. Formalizing this contrast into a rigorous quantum advantage proof remains an interesting open question. On the machine learning side, extending the classification framework to more settings and scalable optimization strategies would further establish the practical utility of quantum-generated thermal state datasets.

Thermal equilibrium states of many-body Hamiltonians are central to studying quantum chaos, phases of matter, and quantum machine learning. Yet generating large ensembles of thermal states across different Hamiltonians remains prohibitively costly with existing methods. Here, we introduce the quantum thermal-drift channel, a new primitive that enables a measurement-controlled sampling algorithm to autonomously generate thermal states together with their Hamiltonian labels for general physical models. We prove that the algorithm is efficient: its total gate count scales polynomially with system size and quadratically with inverse temperature, establishing a polynomial resource bound for random thermal-state generation. For a two-dimensional transverse-field Ising model, we find that the sampled thermal states exhibit a crossover to Wigner–Dyson level statistics, demonstrating nontrivial chaotic correlations. As an application, we show that a variational quantum classifier trained on the generated dataset achieves near-optimal accuracy in predicting Hamiltonian properties of unseen states. These results establish a scalable, quantum-native route to thermodynamic simulation and quantum generative learning in many-body systems.

Introduction.— Random quantum states are a fundamental resource in quantum information science [1] which exhibit universal entanglement and spectral properties predicted by random matrix theory, making them indispensable for benchmarking quantum devices [2, 3] and probing the limits of classical simulability [4, 5]. They are essential for understanding quantum chaos [6] and black-hole physics [7], and serve as testbeds for quantum supremacy [8, 9] and device characterization [10]. Recently, the rise of quantum machine learning has created a new demand for these states [11]. Large collections of quantum states are treated as “quantum data” to learn the underlying patterns of many-body systems [12, 13].

The random-state families studied so far, such as Haar-random states [14], unitary t -designs [15], and random stabilizer states [16], consist of pure states whose statistical properties are determined without reference to quantum many-body systems. By contrast, thermal states describe realistic many-body systems at finite temperature. They allow us to probe the eigenstate thermalization hypothesis [17] and spectral statistics governed by random matrix theory [1]. Random thermal states therefore constitute a physically grounded family for probing universal many-body phenomena, motivating the development of efficient generation methods. Beyond preparing a single thermal state, data-driven applications such as Hamiltonian learning and quantum device benchmarking demand a large, labeled collection: many thermal states, each paired with the Hamiltonian from which it was generated. Producing such paired data ($G_{\beta,H}, H$) at scale is an important task for supervised learning with quantum data.

With quantum processors advancing toward the early fault-tolerant regime, efficient algorithms for thermal state preparation on quantum hardware are increasingly sought after. Practical generation of random thermal states, however, remains costly with existing both classical and quantum algorithms. Current quantum methods rely on quantum phase

Fig 1. Difference between classical sampling and measurement-controlled sampling. The task is to sample a thermal state together with its Hamiltonian label. (a) Sampling the label via classical computers. The thermal state is prepared using existing thermal-state preparation circuits. (b) Sampling the thermal state and label via one structured random circuit. The label is generated by a lattice walk based on outcomes of mid-circuit measurements.

estimation combined with imaginary-time evolution [18–22] or quantum Metropolis and Lindbladian thermalization algorithms [23–35] that couple the system to an effective bath. These instance-oriented methods can be effective for preparing one thermal state, but do not directly address the task of sampling thermal states from a family of Hamiltonians. Extending them to random thermal ensembles requires reconfiguring the circuit for each Hamiltonian instance, incurring substantial classical overhead that limits scalability.

In this letter, we solve this critical problem by introducing a scalable quantum algorithm for the generation of random thermal states, as illustrated in Figure 1. The device is programmed solely with a target set of L Pauli operators $\Sigma = \{\sigma_1, \dots, \sigma_L\}$ representing the interaction topology. Our algorithm autonomously generates the thermal state $G_{\beta,H} = e^{-\beta H} / \text{Tr}[e^{-\beta H}]$ together with its label $H = \sum c_j \sigma_j$, with coefficients c_j drawn from a thermal-weighted normal distribution, effectively functioning as a stochastic subroutine.

TABLE I. Resource complexity for generating a thermal state together with its Hamiltonian label H . Here n , β , λ , ϵ , and δ denote the number of qubits, inverse temperature, sum of coefficient bounds, target precision, and failure probability; $\tilde{\mathcal{O}}(\cdot)$ omits the effect of ϵ and δ ; t_{mix} denotes the mixing time of a β -dependent Markov chain determined by the sampled H . Note that the prior methods were designed for preparing the thermal state of a single given Hamiltonian; the listed complexities reflect the cost of combining them with a classical label-sampling step.

Workflow	Query model	Complexity
Sample label + prepare state	Block encoding of normalized H [20]	$\tilde{\mathcal{O}}\left(2^{n/2}\lambda\beta/\text{Tr}[e^{-\beta H}]\right)$
	Block encodings of jump operators [30]	$\tilde{\mathcal{O}}(\beta t_{\text{mix}})$
Sample state with label	Elementary gates (this work)	$\mathcal{O}\left(n^2\lambda^2\beta^2\epsilon^{-2/3}\log(1/\delta)\right)$

Conceptually, the circuit performs a measurement-driven random walk in Hamiltonian space while approximately thermalizing the system state; the same measurement record that steers the evolution also specifies the Hamiltonian label.

Our algorithm applies a sequence of thermal-drift channels to generate the target thermal state. Unlike previous instance-oriented approaches [20, 30], it provides the first explicit polynomial scaling of resource complexity with respect to all problem parameters in an elementary-gate model, as summarized in Table I. The thermal-drift channel introduced here converts mid-circuit measurement randomness directly into physically meaningful Hamiltonian parameters, unifying state preparation and Hamiltonian sampling in a single quantum protocol. Systematic benchmarking validates the predicted β -dependence and sampling efficiency. We analyze the level-spacing statistics of the sampled states to validate that they carry physically meaningful correlations. Then we show that this sampling algorithm can provide labeled quantum datasets for learning tasks in many-body systems.

Generation of random thermal states.— The task is to sample a thermal ensemble which is composed of a thermal state $G_{\beta,H}$ as “data” together with its Hamiltonian H as “label”, and H is from a structured family of Pauli Hamiltonians. Given a set of L distinct n -qubit Pauli operators Σ and the inverse temperature $\beta > 0$, such family is described by a set of all linear combinations of operators in Σ with bounded coefficients as

$$\mathfrak{H} = \left\{ \sum_j c_j \sigma_j : |c_j| \leq h_j, c_j \in \mathbb{R}, \sigma_j \in \Sigma \right\}. \quad (1)$$

where h_j ’s are the boundary values of the coefficients. Unlike the pure-state families discussed in the introduction, our setting asks for generating a structured thermal state that is linked to an explicit physical Hamiltonian. This provides a controllable generating set essential for later applications.

This setting imposes no restrictions on the locality or commutativity of the interactions. Our verification experiments consider two physical models on a 3×3 two-dimensional grid, where two-local Pauli operators act on nearest-neighbor pairs. The first is a Heisenberg model with Σ containing operators of

the form XX , YY , and ZZ ; the second is a transverse-field Ising model with Σ containing operators of the form ZZ and X (or XX and Z). For both models, the coefficient bounds h_j are uniform, and we denote $\lambda = \sum_j h_j$, which upper bounds the largest eigenvalue of any $H \in \mathfrak{H}$. Experimental details in this work are deferred to the Supplemental Material.

Quantum thermal-drift channel.— Ground state preparation is known to be QMA-hard in the worst case [36, 37], and low-temperature thermal state preparation faces comparable complexity barriers [38]. A standard ‘sample-then-prepare’ pipeline, which first selects a Hamiltonian H and subsequently attempts to prepare its thermal state, is therefore often costly. To circumvent this, we implement quantum operations involving randomness on the quantum hardware.

We define the thermal-drift channel $\mathcal{N}_\sigma$ for any Pauli operator σ , which is the core component of our algorithm. For any input state ρ , the channel is defined as

$$\mathcal{N}_\sigma(\rho) = \frac{1}{2 \cosh(\tau)} (|\uparrow\rangle\langle\uparrow| \otimes \mathcal{E}_\sigma^\uparrow(\rho) + |\downarrow\rangle\langle\downarrow| \otimes \mathcal{E}_\sigma^\downarrow(\rho)). \quad (2)$$

Here, for any state ρ , the maps $\mathcal{E}_\sigma^\uparrow$ and $\mathcal{E}_\sigma^\downarrow$ are two completely positive operations defined as $e^{-\tau\sigma/2}\rho e^{-\tau\sigma/2}$ and $e^{+\tau\sigma/2}\rho e^{+\tau\sigma/2}$, respectively, with a thermal strength $\tau > 0$. The first register of $\mathcal{N}_\sigma(\rho)$ induces a random branch. Measuring this flag register indicates which direction the state is thermalized toward, with probabilities proportional to the corresponding unnormalized state traces.

The thermal-drift channel can be implemented using system-ancilla coupling in a dilated Hilbert space, followed by measuring and tracing out the flag register, such that the whole channel can be implemented within $\tilde{\mathcal{O}}(n)$ quantum elementary gates and $2n$ ancilla qubits. The resource cost is notably independent of the thermal strength τ . We refer to the Supplemental Material for a detailed implementation.

Thermal state generation algorithm.— Our algorithm is implemented as a circuit of N blocks applied to an initial state ρ_0 . In block k , a thermal-drift channel $\mathcal{N}_{\sigma_{j_k}}$ is applied, where σ_{j_k} is selected independently from the set Σ . The probability of choosing $\mathcal{N}_{\sigma_j}$ is weighted by the bound h_j , so that the distribution is h_j/λ . The thermal strength is fixed across all blocks to $\tau = \beta\lambda/N$. After this thermal-drift channel, a measure-and-trace operation $\mathcal{M}_{m_k}$ is applied to the flag register, generating a measurement outcome m_k . This outcome is recorded as $m_k \in \{+1, -1\}$ corresponding to $\uparrow$ and $\downarrow$.

The full circuit implementation is labeled by an ordered list of values $\mathbf{j} = \{j_1, \dots, j_N\}$ and an ordered list of directions $\mathbf{m} = \{m_1, \dots, m_N\}$, that corresponds to a channel $\mathcal{E}_{\mathbf{j},\mathbf{m}}$. In particular, one can collect the accumulated drift along each Pauli axis σ_j , which defines the overall Hamiltonian label $H_{\mathbf{j},\mathbf{m}} = \lambda/N \cdot \sum_{j=1}^N \sum_{k:j_k=j} m_k \sigma_j$. When ρ_0 is the maximally mixed state, the output state $\mathcal{E}_{\mathbf{j},\mathbf{m}}(\rho_0)$ is an approximate copy of the thermal state $G_{\beta,H_{\mathbf{j},\mathbf{m}}}$, thereby completing the task of random thermal state generation.

Theoretical guarantees of sampling process.— Unlike randomized algorithms such as QDRIFT [39], where the randomness is Markovian and can be analyzed directly in channel form, each measurement outcome in our algorithm de-

Fig 2. Numerical verification of the theoretical predictions for the thermal-drift sampling algorithm applied to a 3×3 two-dimensional Heisenberg model. (a) Precision ϵ between the output state and the ideal thermal state as a function of the inverse temperature β , for different step scalings. (b) Empirical marginal distribution of a nearest-neighbor YY interaction coefficient, compared with the theoretical prediction from Theorem 2. Here $Y_{i,j}$ denotes the Pauli- Y on the site at row i and column j . (c) Trade-off between inverse precision and effective sample range at fixed β , as the number of steps N increases from $C\beta$ to $C\beta^3$, where C is a fixed constant.

depends on the evolving state, and hence the process is generally non-Markovian. We apply matrix-martingale concentration inequalities to bound the sampling error, and lattice random-walk theory to characterize the induced distribution over Hamiltonian labels.

We start with the sampling error ϵ , quantified by the trace distance between the sampled state and the ideal thermal state. Given the sampled outcomes j and m , we consider the effective Hamiltonian $H_{\approx}$ such that $\mathcal{E}_{j,m}(\rho_0) = e^{-\beta H_{\approx}} / \text{Tr}[e^{-\beta H_{\approx}}]$. Then the sampling error is bounded by $\epsilon \leq \beta \|H_{j,m} - H_{\approx}\|_\infty$. When the number of steps N is not large enough, the sampling error behaves like the discretization error of a second-order Trotter product formula [40], scaling as $\mathcal{O}(\beta^3)$. However, when N is sufficiently large so that Pauli operators are likely repetitive, we treat m as random variables conditional on a fixed j . In this regime, the Freedman inequality for matrix martingales [41] implies an $\mathcal{O}(\beta^2)$ scaling almost surely. This is numerically verified in Figure 2(a). For increasing inverse temperature starting at $\beta = 1$, we test our algorithm with number of steps $N = \mathcal{O}(\beta^k)$ for $k = 1.5, 2$ and 2.5 , and observe that the average sampling error scales as $\mathcal{O}(\beta^{2-k})$, which is consistent with the following result. Here $\tilde{\mathcal{O}}(\cdot)$ omits the logarithm terms.

Theorem 1 (Sampling precision) *For any system size n , inverse temperature β , and sufficiently large N , our algorithm uses $\mathcal{O}(nN \log(1/\delta))$ gates to sample a thermal state and its label, with precision $\tilde{\mathcal{O}}(n^{3/2} \lambda^3 \beta^3 N^{-3/2})$ and failure probability at most δ .*

This result guarantees that the gate resources required by the sampler scale polynomially in all problem parameters. The cubic dependence on β reflects the accumulation of discretization error in the second-order Trotter product formula. Then as the number of thermal-drift steps N increases, the trace-distance error between the sampled state and the target thermal state decreases as $N^{-3/2}$, providing a route to higher-fidelity sampling.

To obtain a theoretical analysis of the sample distribution, we consider an asymptotic regime where the number of sam-

pling steps N tends to infinity, so that every possible label $H \in \mathfrak{H}$ can be sampled. Then our algorithm can be modeled as a random walk $(\mathbf{x}^{(k)})_k$ on an L -dimensional integer lattice $\mathbb{Z}^L$, such that $\mathbf{x}^{(0)}$ and $\mathbf{x}^{(N)}$ correspond to the identity matrix and the sampled label H , respectively. Such a walk sequence satisfies for all $k \geq 1$,

$$\Pr(\mathbf{x}^{(k)} - \mathbf{x}^{(k-1)} = \pm e_j) = \Pr(m_k = \pm 1) \cdot h_j / \lambda, \quad (3)$$

where e_j denotes the j -th unit vector. Applying lattice-based random walk theory [42] yields a Gaussian approximation to the endpoint distribution under appropriate scaling. Combined with the thermal reweighting from $\Pr(m_k = \pm 1)$, the sampling rule takes a product form involving the partition function and a normal density.

Theorem 2 (Label distribution) *For any inverse temperature β , a label $H \in \mathfrak{H}$ can be asymptotically sampled by our algorithm with probability proportional to $\text{Tr}[e^{-\beta H}] D(\mathbf{x})$, where D is an L -dimensional multivariate normal distribution and $\mathbf{x}$ satisfies $\mathbf{x}_j = \text{Tr}[H \sigma_j] / \lambda \cdot N$.*

The sampling probability is governed by two factors. The partition-function weight $\text{Tr}[e^{-\beta H}]$ biases the sampler toward Hamiltonians with more thermally accessible states, i.e., those with lower free energy at the given temperature. The normal density $D(\mathbf{x})$ arises from the central-limit behavior of the underlying lattice random walk and concentrates the sampled coefficients near the origin. Together, they define a physically motivated measure over the Hamiltonian family.

We numerically show that a similar result holds in non-asymptotic cases. Taking $\beta = 2$, we sample from our algorithm and visualize one-dimensional slices of the marginal distribution of a chosen Pauli coefficient. As shown in Figure 2(b), the empirical distribution closely matches the ideal one. Note that the difference mainly occurs in both ends of the distribution, which will get smaller as the number of sampling step further increases.

We apply Theorems 1 and 2 to identify a trade-off between the sampling accuracy and the effective range of sampled

Fig 3. Validation and application of the thermal state sampler. Task details are deferred to the *Validation via signatures of quantum chaos* section and the *Application to state classification* section. **(a)** Level-spacing ratio statistics used to verify the physical fidelity of sampled thermal states for a 3×3 two-dimensional transverse-field Ising model. The orange histogram in the background corresponds to the initial state, while the blue histogram in the foreground corresponds to the output state generated by the sampling algorithm. The dashed curve indicates the GOE prediction, and the dash-dotted curve indicates the Poisson prediction. **(b)** Classification accuracy of a quantum classifier trained on sampled thermal states of a two-qubit Ising model. Gray traces show individual trial runs, the blue curve shows the mean success probability across independent test sets over 10 trials, the shaded region marks the 25–75 percentile band, and the orange band indicates the range of theoretical upper bound on success probability.

Hamiltonians. Due to the nature of random walks, higher accuracy comes with a more concentrated label distribution, and vice versa. As shown in Figure 2(c), for $\beta = 2$, as the number of steps N increases from $\mathcal{O}(\beta)$ to $\mathcal{O}(\beta^3)$, the inverse precision $1/\epsilon$ increases while the effective sample range $\|H\|_\infty$ decreases at a similar rate. Therefore, despite the efficiency of a single execution, it is not recommended to use our algorithm for preparing thermal states of one fixed Hamiltonian. However, this characteristic makes our algorithm particularly well-suited for ensemble-level applications.

Validation via signatures of quantum chaos.— Level statistics is a well-established diagnostic for thermodynamic phases in quantum many-body systems, probing spectral correlations that distinguish ergodic from localized regimes [43, 44]. We employ this diagnostic to verify that the thermal states produced by our sampler exhibit the spectral signatures expected of physically faithful thermal ensembles. Given any random density operator with an ordered many-body eigenvalue spectrum $\{\lambda_j\}_j$, one defines the adjacent logarithmic level spacings $\delta_j = \log(\lambda_j/\lambda_{j+1})$ and the dimensionless spacing (gap) ratio [45, 46] $r_j = \min\{\delta_j, \delta_{j+1}\} / \max\{\delta_j, \delta_{j+1}\}$, whose distribution is insensitive to spectral unfolding and thus widely used in finite-size studies [5, 47, 48]. In ergodic systems satisfying the eigenstate thermalization hypothesis, strong level repulsion leads to Wigner–Dyson statistics [48, 49], whereas in the many-body localization phase, emergent local integrals of motion suppress correlations and produce Poisson level statistics [1, 50]. The Wigner–Dyson distribution describes the probability of the spacing ratio in the Gaussian orthogonal ensemble (GOE), serving as the universal signature of chaos for quantum systems that preserve time-reversal symmetry [47, 51].

To verify that the generated states possess the spectral correlations expected of thermal equilibrium, we compute the level-spacing statistics from the output ensemble of our algorithm. An initial reference state whose spectrum exhibits near-Poisson statistics is compared with the output states pro-

duced by the sampler. As shown in Figure 3(a), aggregating $\{r_j\}_j$ over samples yields a robust, unfolding-free diagnostic. The level statistics shift from a Poissonian distribution in the reference state to a Wigner–Dyson distribution in the output thermal ensemble, confirming that the sampler captures the spectral correlations of the ergodic regime. The thermal-drift mechanism thus drives the system into a substantially more chaotic sector of Hilbert space than the structured input, producing states whose spectral correlations are consistent with physical thermalization.

Application to state classification.— Our thermal state sampler provides a scalable data source for quantum supervised learning algorithms [52–54] that learn properties of quantum systems from their thermal states. Consider classifying a black-box quantum system with an unknown Hamiltonian $H \in \mathfrak{H}$ by a label function $f(H) \in \{0, 1\}$, given access to only a single copy of its thermal state. A natural approach is to deploy a variational quantum classifier [12, 13, 55] (VQC) on a large labeled dataset of thermal states. Theorem 1 implies that our sampler can generate such a dataset with cost polynomial in system size and inverse temperature, bypassing the need for individual state preparation. In the expectation-value-based formulation, training typically requires repeatedly measuring the same input state to estimate observables; here, we instead use single-shot measurements on freshly regenerated batches from the sampler, which is naturally compatible with a stochastic data source.

As a proof of concept, a VQC is trained to classify two-qubit Ising models described by $\Sigma = \{XX, ZI, IZ\}$ and $h = (1, 1, 1)$ according to the sign of the XX coefficient, where the optimal success probability is upper bounded by the Helstrom limit [56]. The classifier is optimized via a stochastic variant of the parameter-shift rule [57, 58]. In our implementation, each gradient evaluation uses single-shot measurements on a freshly regenerated batch of 10^3 approximate thermal states from our sampler. The classifier is evaluated, in each trial, on an independently generated test set of

3×10^3 exact thermal states. As shown in Figure 3(b), the prediction accuracy approaches the Helstrom limit in most trials, with noticeable trial-to-trial variability. In particular, the classifier trains on approximate states sampled from the thermal-weighted normal distribution (Theorem 2) yet generalizes to test states drawn from a uniform distribution. This distribution-shift robustness is enabled by the polynomial sampling cost (Theorem 1), which allows generating sufficiently large and diverse training sets without individual state preparation. Combined with the built-in Hamiltonian labeling, the sampler serves as an end-to-end data source for quantum supervised learning in this setting. See the Supplemental Material for training details.

Conclusion and outlook.— We have introduced the quantum thermal-drift channel and used it to develop an algorithm that generates random thermal states for Hamiltonians drawn from general Pauli models, with sampling cost polynomial in both the system size and the inverse temperature. Our protocol relies on elementary gates and mid-circuit measurements, and can be viewed as a stochastic subroutine for generating labeled quantum data on early fault-tolerant devices. Level-statistics analysis of the sampled ensemble validates that the generated states faithfully reproduce the spectral correlations of the ergodic regime. A proof-of-concept classification experiment further demonstrates that the sampled dataset can serve as a practical data source for quantum learning tasks.

Several avenues for future research remain open. Improv-

ing the system-size scaling by exploiting structure of quantum systems remains an important direction. We note that the polynomial efficiency achieved here contrasts with the known limitations of leading classical approaches [59, 60] for generic models. Formalizing this contrast into a rigorous quantum advantage proof remains an interesting open question. On the machine learning side, extending the classification framework to more settings and scalable optimization strategies would further establish the practical utility of quantum-generated thermal state datasets.

Supplemental Material for Thermal-Drift Sampling: Generating Thermal Ensembles for Learning Many-Body Systems

In this supplementary material, we offer detailed proofs of the theorems and propositions in the manuscript ‘Thermal-Drift Sampling: Generating Thermal Ensembles for Learning Many-Body Systems.’ In section A, we will introduce the notations and the basic lemmas that we used in the proofs and the analysis. We then, introduce the details of our thermal-drift channel in section B which serves as the core of our algorithm. After that, the fundamental setups of the random thermal state generation task and the algorithm statements are clarified in section C. We also provide performance and error analysis of our algorithm in the subsections of the same section. The applications towards the level statistics and the state classification are discussed in section D. The corresponding experimental details are provided in the followed section E for board interests.

Appendix A: Notations and Preliminaries

Asymptotic notations. Let $[N] = \{1, 2, \dots, N\}$ for any positive integer N . We use asymptotic notations to describe the scaling of complexity and error bounds. For two non-negative functions $f(x)$ and $g(x)$, we write $f(x) = \mathcal{O}(g(x))$ if there exist constants $C > 0$ and x_0 such that $f(x) \leq Cg(x)$ for all $x \geq x_0$. Conversely, $f(x) = \Omega(g(x))$ indicates that $f(x) \geq cg(x)$ for some constant $c > 0$ and sufficiently large x . The notation $f(x) = o(g(x))$ implies that $\lim_{x \rightarrow \infty} f(x)/g(x) = 0$. We also use the soft-O notation $\tilde{\mathcal{O}}(g(x))$ to suppress polylogarithmic factors, i.e., $\tilde{\mathcal{O}}(g(x)) \equiv \mathcal{O}(g(x) \text{poly}(\log g(x)))$.

Operators. We denote the single-qubit Pauli operators by the set $\{I, X, Y, Z\}$, defined as $I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, $X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, $Y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}$ and $Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$. The set of n -qubit Pauli operators is denoted as $\{I, X, Y, Z\}^{\otimes n}$. We denote the Hadamard gate and the single-qubit rotation around the y -axis by: $H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ and $R_y(\theta) = e^{-i\theta Y/2} = \begin{pmatrix} \cos(\theta/2) & -\sin(\theta/2) \\ \sin(\theta/2) & \cos(\theta/2) \end{pmatrix}$. The commutator of operators A and B is $[A, B] = AB - BA$. The adjoint action (Lie bracket) is defined recursively as $\text{ad}_A(B) = [A, B]$ and $\text{ad}_A^k(B) = [A, \text{ad}_A^{k-1}(B)]$ for $k \geq 2$.

Quantum systems. Let $\mathcal{H}$ denote a finite-dimensional complex Hilbert space. A density operator ρ is a linear operator acting on $\mathcal{H}$ that is positive semi-definite matrix with unit trace, and we write $\mathcal{D}(\mathcal{H}_A)$ for the set of density operators on a system A with Hilbert space $\mathcal{H}_A$. For a composite system with Hilbert space $\mathcal{H}_{AB} = \mathcal{H}_A \otimes \mathcal{H}_B$, we write $X_A = X \otimes I_B$ to denote an operator X acting locally on subsystem A , where I_B is the identity on $\mathcal{H}_B$.

Norms. For a vector $\mathbf{x} = (x_1, \dots, x_L) \in \mathbb{C}^L$, we define the Euclidean norm as $\|\mathbf{x}\| = \sqrt{\sum_{i=1}^L |x_i|^2}$. For a matrix $A \in \mathbb{C}^{d \times d}$, we define the spectral norm $\|A\|_\infty$ as the largest singular value of A , and the trace norm $\|A\|_1$ as the sum of the singular values of A .

Parity functions. For $N \in \mathbb{N}$ and $\mathbf{x} = (x_1, \dots, x_L) \in \mathbb{Z}^L$, define the *reachability parity function* $a_N : \mathbb{Z}^L \rightarrow \{0, 2\}$ by

$$a_N(\mathbf{x}) = \begin{cases} 2, & \text{if } \sum_{j=1}^L |x_j| \leq N \text{ and } N - \sum_{j=1}^L |x_j| \text{ is even;} \\ 0, & \text{otherwise.} \end{cases} \quad (\text{S1})$$

Thus $a_N(\mathbf{x}) = 0$ whenever $\mathbf{x}$ is not reachable from the origin in N steps of the walk, and $a_N(\mathbf{x}) = 2$ otherwise. Define the *bitwise parity function* for $x \in \mathbb{N}$ as

$$p(x) = \begin{cases} 0, & \text{if } \sum_i x_i \text{ is even;} \\ 1, & \text{otherwise,} \end{cases} \quad (\text{S2})$$

where $x_{N-1} \dots x_0$ is the binary representation of $x = \sum_i 2^i x_i$. Denote the first $l-1$ bits of x as $x_{1:l} := x_1 \dots x_{l-1}$.

Martingales. A *filtration* is a sequence of σ -algebras $\{\mathcal{F}_0, \mathcal{F}_1, \dots\}$ satisfying $\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \dots$. A sequence of random variables $\{X_k\}_{k \geq 0}$ is a *martingale* with respect to $\{\mathcal{F}_k\}$ if X_k is $\mathcal{F}_k$ -measurable, $\mathbb{E}[|X_k|] < \infty$, and $\mathbb{E}[X_{k+1} | \mathcal{F}_k] = X_k$. A sequence $\{Y_k\}_{k \geq 1}$ is a *martingale difference sequence* (MDS) if it is adapted to the filtration and satisfies $\mathbb{E}[Y_{k+1} | \mathcal{F}_k] = 0$. An MDS is typically constructed from a martingale $\{X_k\}_k$ by setting $Y_k = X_k - X_{k-1}$.

1. Useful lemmas

This section collects auxiliary lemmas used in later proofs.

Lemma S1 (Fréchet derivative of matrix exponential, [62]) *Let A, E be two matrices. Then*

$$\frac{d}{dt} e^{A+tE} = \int_0^1 e^{s(A+tE)} E e^{(1-s)(A+tE)} ds. \quad (\text{S3})$$

Lemma S2 *For any Hermitian matrix X and positive semidefinite matrix R ,*

$$\left\| \int_0^1 R^s X R^{1-s} ds \right\|_1 \leq \|X\|_\infty \|R\|_1 \quad (\text{S4})$$

Proof Suppose R has the spectral decomposition $R = UDU^\dagger = \sum_j p_j |j\rangle\langle j|$ for some orthonormal basis $\{|j\rangle\}_j$. Denote $\mathcal{L}(X) = \int_0^1 D^s X D^{1-s} ds$. Consider the (i, j) th element of $\mathcal{L}(X)$:

$$\langle i | \mathcal{L}(X) | j \rangle = \langle i | \int_0^1 \sum_k p_k^s |k\rangle\langle k| X \sum_{k'} p_{k'}^{1-s} |k'\rangle\langle k'| ds | j \rangle \quad (\text{S5})$$

$$= \langle i | X | j \rangle \int_0^1 p_i^s p_j^{1-s} ds \quad (\text{S6})$$

$$= X_{i,j} L(p_i, p_j), \quad (\text{S7})$$

where

$$L(a, b) = \begin{cases} a, & \text{if } a = b; \\ \frac{a-b}{\log a - \log b}, & \text{if } a \neq b. \end{cases} \quad (\text{S8})$$

Denote the (i, j) th element of matrix $\mathcal{L}$ as $L(p_i, p_j)$. The matrix $\mathcal{L}$ is the Loewner matrix of the Schlicht function $\log z$ mapping the upper half-plane into itself [63], so $\mathcal{L}$ is positive semidefinite (PSD). Since $\mathcal{L}(X) = X \odot \mathcal{L}$, where $\odot$ is the Hadamard product, the Schur product theorem [64, Section 7.5] implies that $\mathcal{L}(X)$ is PSD whenever X is PSD. Therefore,

$$\mathcal{L}(\|X\|_\infty I) = \|X\|_\infty D \succeq \mathcal{L}(X) \succeq -\|X\|_\infty D = \mathcal{L}(-\|X\|_\infty I). \quad (\text{S9})$$

Denote $\lambda_1(X), \lambda_2(X), \dots$ as the eigenvalues of X in ascending order. $\mathcal{L}(X) \succeq -\|X\|_\infty D$ means $-\lambda_j(\mathcal{L}(X)) \leq \|X\|_\infty \lambda_j(D)$ for all j satisfying $\lambda_j(\mathcal{L}(X)) < 0$, while $\|X\|_\infty D \succeq \mathcal{L}(X)$ means $\lambda_j(\mathcal{L}(X)) \leq \|X\|_\infty \lambda_j(D)$ for all j satisfying $\lambda_j(\mathcal{L}(X)) \geq 0$. Combining, we have

$$\|\mathcal{L}(X)\|_1 = \sum_j |\lambda_j(\mathcal{L}(X))| \leq \|X\|_\infty \sum_j \lambda_j(D) = \|X\|_\infty \|D\|_1 = \|X\|_\infty \|R\|_1. \quad (\text{S10})$$

■

Lemma S3 (Baker–Campbell–Hausdorff formula for $e^X e^Y e^X$, [65]) *For matrices X and Y ,*

$$\log(e^X e^Y e^X) = 2X + Y - \frac{1}{6} [X + Y, [X, Y]] + \mathcal{O}((\|X\|_\infty + \|Y\|_\infty)^5). \quad (\text{S11})$$

Lemma S4 (Freedman Inequality for Hermitian matrices, [41]) *Let $(\mathcal{F}_k)_k$ be a filtration, and let $(X_k)_k$ be a martingale difference sequence of d -dimensional Hermitian matrices such that $\|X_k\|_\infty \leq R$ for some $R > 0$. Then the partial sum $Y_k = \sum_{i=1}^k X_i$ and the predictable quadratic variation process $W_k = \sum_{i=1}^k \mathbb{E}[X_i^2 | \mathcal{F}_{i-1}]$ satisfies for all $t \geq 0$ and $\sigma^2 > 0$,*

$$\Pr(\exists k > 0 : \|Y_k\|_\infty > t \text{ and } \|W_k\|_\infty \leq \sigma^2) \leq 2d \exp\left(-\frac{t^2/2}{\sigma^2 + Rt/3}\right). \quad (\text{S12})$$

Lemma S5 (Lattice-based random walk, [42]) *Consider a random walk $(\mathbf{x}^{(k)})_k$ on a lattice $\{-N, \dots, N\}^{\times L}$ with $\mathbf{x}^{(0)} = 0$, and there exists $p_1, \dots, p_L$ such that for all j and k , $\Pr(\mathbf{x}^{(k)} - \mathbf{x}^{(k-1)} = \pm e_j) = p_j/2$. Then for any endpoint $\mathbf{x} \in \mathbb{Z}^L$ such that $\sum_j \mathbf{x}_j^2 = N$,*

$$\Pr_Q(\mathbf{x}^{(N)} = \mathbf{x}) = \frac{a_N(\mathbf{x})}{(2\pi N)^{L/2} \sqrt{\prod_{j=1}^L p_j}} \exp\left(-\frac{1}{2N} \sum_j \frac{\mathbf{x}_j^2}{p_j}\right) + o(N^{-L/2}), \quad (\text{S13})$$

where a_N is the reachable parity function in Equation (S1).

Appendix B: Thermal-drift channel

Let σ be an n -qubit Pauli operator and let $\tau \in \mathbb{R}_+$. We define the unnormalized imaginary-time evolution (ITE) maps at time τ in the two opposite directions by

$$\mathcal{E}_\sigma^\uparrow(\rho) = e^{-\tau\sigma/2} \rho e^{-\tau\sigma/2} \quad \text{and} \quad \mathcal{E}_\sigma^\downarrow(\rho) = e^{+\tau\sigma/2} \rho e^{+\tau\sigma/2}. \quad (\text{S1})$$

Throughout this section, we use “ $\uparrow\downarrow$ ” to discuss both directions simultaneously. The goal is to construct a circuit that applies one of these two maps at random to an input state ρ on the main system and records the applied direction in an ancilla register.

To formalize this task, we introduce a $2n$ -qubit ancilla system AB and the n -qubit main system S . Based on the identity that

$$\text{Tr}[\mathcal{E}_\sigma^\uparrow(\rho) + \mathcal{E}_\sigma^\downarrow(\rho)] = \text{Tr}[(e^{-\tau\sigma} + e^{\tau\sigma})\rho] = (e^\tau + e^{-\tau}) \text{Tr}[\rho] = 2 \cosh(\tau), \quad (\text{S2})$$

we define the thermal-drift channel $\mathcal{N}_\sigma(\rho) : \mathcal{D}(\mathcal{H}_S) \rightarrow \mathcal{D}(\mathcal{H}_{ABS})$ satisfying

$$\text{Tr}_{AB}[\Pi_{AB}^{\uparrow\downarrow} \mathcal{N}_\sigma(\rho)] = \frac{1}{2 \cosh(\tau)} \mathcal{E}_\sigma^{\uparrow\downarrow}(\rho), \quad (\text{S3})$$

where $\Pi^{\uparrow\downarrow}$ are mutually orthogonal projectors on AB such that $\Pi^\uparrow + \Pi^\downarrow \prec I_{AB}$. Measuring the ancilla system AB in the projection-valued measure extending $\{\Pi^\uparrow, \Pi^\downarrow\}$ reveals which branch of Equation (S3) occurred; the corresponding post-measurement state on S is obtained by tracing out AB and normalizing in the usual way.

The map satisfying Equation (S3) is completely positive and trace-preserving under the chosen normalization, and thus admits a unitary dilation. The next theorem provides an explicit implementation with $\mathcal{O}(n)$ elementary gates, up to a heralded failure outcome Π° .

Theorem S6 Suppose $\tau > 0$ and σ is an n -qubit Pauli operator that has no local identity term. Then there exists a projection-valued measure $\{\Pi^\uparrow, \Pi^\downarrow, \Pi^\circ\}$ on system AB , a τ -dependent ansatz U_τ and two fixed ansatzes T, V , such that the map $\mathcal{N}_\sigma : \mathcal{D}(\mathcal{H}_S) \rightarrow \mathcal{D}(\mathcal{H}_{ABS})$ constructed in Figure S1 (dashed area) satisfies for all $\rho \in \mathcal{D}(\mathcal{H}_S)$,

$$\text{Tr}_{AB}[\Pi_{AB}^\circ \mathcal{N}_\sigma(\rho)] = p\rho \quad \text{and} \quad \text{Tr}_{AB}[\Pi_{AB}^{\uparrow\downarrow} \mathcal{N}_\sigma(\rho)] = (1-p) \text{Tr}_{AB}[\Pi_{AB}^{\uparrow\downarrow} \mathcal{N}_\sigma(\rho)], \quad (\text{S4})$$

where $p^{-1} = 2 \cosh^2(\tau/2)$, $\text{Tr}[\Pi^\uparrow] = \text{Tr}[\Pi^\downarrow]$ and $\mathcal{N}_\sigma$ is given as in Equation (S3). Moreover, implementation of $\mathcal{N}_\sigma$ takes $\mathcal{O}(n)$ single-qubit gates and CNOT gates; the projection-valued measure can be done in the computational basis.

Fig S1. A circuit implementing the channel $\mathcal{N}_\sigma$. Repeating $\mathcal{N}_\sigma$ and measuring AB in the computational basis until the outcome is not in Π° implements $\mathcal{N}_\sigma$.

Theorem S6 assumes that the Pauli operator has no local identity term; the next theorem removes this restriction and provides the resource bound for implementing a random-direction Pauli ITE step.

Theorem S7 Suppose $\tau > 0$ and σ is an n -qubit Pauli operator. Then there exists a quantum channel $\mathcal{N}_\sigma : \mathcal{D}(\mathcal{H}_S) \rightarrow \mathcal{D}(\mathcal{H}_{ABS})$ and a measure-and-trace operation $\mathcal{M} : \mathcal{D}(\mathcal{H}_{ABS}) \rightarrow \{1, -1\} \times \mathcal{D}(\mathcal{H}_S)$ such that for all $\rho \in \mathcal{D}(\mathcal{H}_S)$,

$$\mathcal{M} \circ \mathcal{N}_\sigma(\rho) = \begin{cases} (1, \mathcal{E}_\sigma^\uparrow(\rho) / \text{Tr}[e^{-\tau\sigma}\rho]), & \text{with probability } \text{Tr}[e^{-\tau\sigma}\rho] / (2 \cosh \tau); \\ (-1, \mathcal{E}_\sigma^\downarrow(\rho) / \text{Tr}[e^{\tau\sigma}\rho]), & \text{with probability } \text{Tr}[e^{\tau\sigma}\rho] / (2 \cosh \tau). \end{cases} \quad (\text{S5})$$

Moreover, one can use $2n$ ancilla qubits and at most $\mathcal{O}(n \log(1/\delta))$ single-qubit gates and CNOT gates to implement $\mathcal{N}_\sigma$ with probability at least $1 - \delta$; $\mathcal{M}$ requires only computational-basis measurements and classical post-processing of the outcomes.

Proof We first consider the case where σ has no local identity term. Theorem S6 provides a projection-valued measure $\{\Pi^\uparrow, \Pi^\downarrow, \Pi^\circ\}$ and a channel $\mathcal{N}_\approx$ such that

$$\text{Tr}_{AB}[\Pi_{AB}^\circ \mathcal{N}_\approx(\rho)] = \frac{1}{2 \cosh^2(\tau/2)} \rho \quad \text{and} \quad \text{Tr}_{AB}[\Pi_{AB}^{\uparrow\downarrow} \mathcal{N}_\approx(\rho)] = \left(1 - \frac{1}{2 \cosh^2(\tau/2)}\right) \text{Tr}_{AB}[\Pi_{AB}^{\uparrow\downarrow} \mathcal{N}_\sigma(\rho)] \quad (\text{S6})$$

Measuring $\mathcal{N}_\approx(\rho)$ on system AB with respect to $\{\Pi^\circ, I_{AB} - \Pi^\circ\}$ partitions the output into a fallback branch to ρ and a success branch to $\mathcal{N}_\sigma(\rho)$. Define $\mathcal{M}_\circ$ to be the operation that measures AB and, upon obtaining Π° , traces out AB and outputs the remaining state on S ; define $\mathcal{M}_{\uparrow\downarrow}$ analogously for the complementary event $I_{AB} - \Pi^\circ$. For an integer $k \geq 1$, consider the repeat-until-success map

$$\mathcal{M}_{\uparrow\downarrow} \circ \mathcal{N}_\approx + \mathcal{M}_{\uparrow\downarrow} \circ \mathcal{N}_\approx \circ \mathcal{M}_\circ \circ \mathcal{N}_\approx + \dots + \mathcal{M}_{\uparrow\downarrow} \circ \mathcal{N}_\approx \circ (\mathcal{M}_\circ \circ \mathcal{N}_\approx)^{\circ k}. \quad (\text{S7})$$

Since the fallback probability in each invocation is at most $1/2$, the probability of fallback in all $k+1$ attempts is at most $2^{-(k+1)}$. Choosing $k = \mathcal{O}(\log(1/\delta))$ ensures failure probability at most δ . Each invocation of $\mathcal{N}_\approx$ uses $\mathcal{O}(n)$ elementary gates by Theorem S6, so the total gate count is $\mathcal{O}(n \log(1/\delta))$.

Conditioned on the success event $I_{AB} - \Pi^\circ$, the output is proportional to $\mathcal{N}_\sigma(\rho)$ as defined in Equation (S3). We now define $\mathcal{M}$ to measure AB with respect to $\{\Pi^\uparrow, \Pi^\downarrow\}$, trace out AB , and normalize the post-measurement state on S . Using $\text{Tr}[\Pi^\uparrow] = \text{Tr}[\Pi^\downarrow] = 2^{2n-2}$ and the fact that $\mathcal{E}_\sigma^\uparrow(\rho)$ and $\mathcal{E}_\sigma^\downarrow(\rho)$ have traces $\text{Tr}[e^{-\tau\sigma}\rho]$ and $\text{Tr}[e^{\tau\sigma}\rho]$, respectively, we obtain

$$\text{Pr}(m=1) = \left(1 - \frac{1}{2 \cosh^2(\tau/2)}\right) \text{Tr}[\Pi_{AB}^\uparrow \mathcal{N}_\sigma(\rho)] = \frac{\text{Tr}[e^{-\tau\sigma}\rho]}{2 \cosh \tau}, \quad (\text{S8})$$

$$\text{Pr}(m=-1) = \left(1 - \frac{1}{2 \cosh^2(\tau/2)}\right) \text{Tr}[\Pi_{AB}^\downarrow \mathcal{N}_\sigma(\rho)] = \frac{\text{Tr}[e^{\tau\sigma}\rho]}{2 \cosh \tau}. \quad (\text{S9})$$

Conditioning on each event yields the normalized post-measurement states $\mathcal{E}_\sigma^\uparrow(\rho)/\text{Tr}[e^{-\tau\sigma}\rho]$ and $\mathcal{E}_\sigma^\downarrow(\rho)/\text{Tr}[e^{\tau\sigma}\rho]$, as stated.

We now extend the construction to a general σ that may contain local identity terms. Let σ' be the tensor product of the non-identity local Pauli terms of σ , and let P be an n -qubit permutation gate such that $\sigma = P^\dagger(\sigma' \otimes I)P$. For any $\rho \in \mathcal{D}(\mathcal{H}_S)$,

$$P^\dagger(\mathcal{E}_{\sigma'}^{\uparrow\downarrow} \otimes \mathbb{1})(P\rho P^\dagger)P = P^\dagger(e^{\mp\tau\sigma'/2} \otimes I)P \cdot \rho \cdot P^\dagger(e^{\mp\tau\sigma'/2} \otimes I)P \quad (\text{S10})$$

$$= e^{\mp\tau\sigma/2} \rho e^{\mp\tau\sigma/2} = \mathcal{E}_\sigma^{\uparrow\downarrow}(\rho). \quad (\text{S11})$$

Applying the above implementation to σ' (on the nontrivial subsystem) and conjugating by P therefore realizes the required instrument for σ . The permutation P can be implemented with at most $\mathcal{O}(n)$ CNOT gates, so the overall gate complexity remains $\mathcal{O}(n \log(1/\delta))$. $\blacksquare$

The remainder of this section proves Theorem S6 by explicitly constructing U_τ , T , and V . We start from a SWAP-based construction that realizes a family of Kraus operators from a unitary on a larger space.

Lemma S8 Suppose U is a unitary acting on a bipartite system AB . Then for $G_{jk} = \text{Tr}_A[U|00\rangle\langle jk|U^\dagger]$ and an additional system B' such that $|B'| = |B|$, the following circuit of systems ABB' holds

Proof Let $U = \sum_{x,y,z,t} C_{xyzt} |xy\rangle\langle zt|$ and $\text{SWAP} = \sum_{l,m} |lm\rangle\langle ml|$. For the operator acting on B' conditioned on outcomes (j,k) on AB , we compute

$$(\langle j_A j_B | U^\dagger)_{AB} \text{SWAP}_{BB'} (U | k_A k_B \rangle)_{AB} \quad (\text{S12})$$

$$= \sum_{x,y,z,t,m,l} C_{j_A j_B z t}^* C_{x y k_A k_B} (\langle z |_A \otimes \langle t |_B) (|l\rangle\langle m|_B \otimes |m\rangle\langle l|_{B'}) (|x\rangle_A \otimes |y\rangle_B) \quad (\text{S13})$$

$$= \sum_{x,y,z,t,m,l} C_{j_A j_B z t}^* C_{x y k_A k_B} \delta_{z,x} \delta_{t,l} \delta_{m,y} |m\rangle\langle l|_{B'} \quad (\text{S14})$$

$$= \sum_{x,y,z,t} C_{j_A j_B z t}^* C_{x y k_A k_B} \delta_{z,x} |y\rangle\langle t| \quad (\text{S15})$$

$$= \text{Tr}_A \left[\sum_{x,y,z,t} C_{j_A j_B z t}^* C_{x y k_A k_B} |x y\rangle\langle z t|_{AB} \right] = \text{Tr}_A [U |k_A k_B\rangle\langle j_A j_B| U^\dagger]. \quad (\text{S16})$$

For any pure state $|\psi\rangle$ on B' , substituting this identity into the circuit shows that

$$U_{AB}^\dagger \text{SWAP}_{BB'} U_{AB} (|00\rangle \otimes |\psi\rangle) = \sum_{j,k} |jk\rangle\langle jk|_{AB} U_{AB}^\dagger \text{SWAP}_{BB'} U_{AB} (|00\rangle \otimes |\psi\rangle) \quad (\text{S17})$$

$$= \sum_{j,k} |jk\rangle_{AB} (\langle jk| U^\dagger)_{AB} \text{SWAP}_{BB'} (U|00\rangle)_{AB} |\psi\rangle_{B'} \quad (\text{S18})$$

$$= \sum_{j,k} |jk\rangle_{AB} G_{jk} |\psi\rangle_{B'} = \sum_{j,k} |jk\rangle \otimes G_{jk} |\psi\rangle. \quad (\text{S19})$$

When the system AB is measured to be jk , the unnormalized post-measurement state on B' is $G_{jk}|\psi\rangle$, and hence the normalized post-measurement state is $G_{jk}|\psi\rangle / \|G_{jk}|\psi\rangle\|$. By linearity, the same conclusion holds for a mixed input ρ , yielding the claimed output state $G_{jk}\rho G_{jk}^\dagger / \text{Tr}[G_{jk}\rho G_{jk}^\dagger]$. ■

We now prove Theorem S6. All three systems A, B, S are n -qubit. In the following analysis, A_i denotes the i -th qubit in system A (counting from top to bottom), and similarly for B and S .

Theorem S6 (Complete version) Suppose $\tau > 0$ and σ is an n -qubit Pauli operator that has no local identity term. Consider the following construction of a projection-valued measure on the system AB ,

$$\Pi^\circ = |1\rangle\langle 1|_{A_n}, \quad \Pi^\uparrow = |0\rangle\langle 0|_{A_n} \otimes |0\rangle\langle 0|_{B_n}, \quad \Pi^\downarrow = |0\rangle\langle 0|_{A_n} \otimes |1\rangle\langle 1|_{B_n}, \quad (\text{S20})$$

and of circuit ansatzes on system ABS ,

$$U_\tau = \left(\prod_{i=1}^n \text{CNOT}_{A_i B_i} \right) \left(\prod_{i=1}^{n-1} \text{CNOT}_{A_i A_n} \right) \left(H^{\otimes(n-1)} \otimes R_y(2\theta) \right)_A, \quad (\text{S21})$$

$$V = \left(\prod_{i=1}^n \text{CNOT}_{B_i B_n} \right) \left(\prod_{i=1}^n \text{CNOT}_{B_i S_i} \text{CZ}_{A_i S_i} \right) \left(\prod_{i=1}^{n-1} \text{CNOT}_{A_n A_i} \right), \quad (\text{S22})$$

$$T \text{ satisfies } T Z^{\otimes n} T^\dagger = \sigma, \quad (\text{S23})$$

where $\theta = \arccos \sqrt{e^{-\tau/2} / (2 \cosh(\tau/2))}$. Then the map $\mathcal{N}_\approx$ constructed in Figure S1 (dashed area) satisfies

$$\text{Tr}_{AB} [\Pi_{AB}^\circ \mathcal{N}_\approx(\rho)] = \frac{1}{2 \cosh^2(\tau/2)} \rho \quad \text{and} \quad \text{Tr}_{AB} [\Pi_{AB}^{\uparrow\downarrow} \mathcal{N}_\approx(\rho)] = \frac{1}{4 \cosh^2(\tau/2)} \mathcal{E}_\sigma^{\uparrow\downarrow}(\rho). \quad (\text{S24})$$

Proof The proof is decomposed into two parts: we first (1) analyze what G_{jk} is by taking U_τ into Lemma S8, and show that (2) V can decode, map and group these G_{jk} to be either $e^{-\tau\sigma/2}$, $e^{\tau\sigma/2}$ or the identity matrix. Taking the whole picture gives the statement.

(1) For the first part, one can derive that for all $|j\rangle = |j_1 \cdots j_n\rangle$ in system A ,

$$\left(\prod_{i=1}^{n-1} \text{CNOT}_{A_i A_n} \right) \left(H^{\otimes(n-1)} \otimes R_y(2\theta) \right) |j\rangle \quad (\text{S25})$$

$$= \left(\prod_{i=1}^{n-1} \text{CNOT}_{A_i A_n} \right) \left(H^{\otimes(n-1)} |j_{1:n}\rangle \otimes R_y(2\theta) |j_n\rangle \right) \quad (\text{S26})$$

$$= \frac{1}{\sqrt{2^{n-1}}} \left(\prod_{i=1}^{n-1} \text{CNOT}_{A_i A_n} \right) \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle \otimes (\cos(\theta) |j_n\rangle + (-1)^{j_n} \sin(\theta) X |j_n\rangle) \quad (\text{S27})$$

$$= \frac{1}{\sqrt{2^{n-1}}} \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle \otimes \left(\cos(\theta) |j_n \oplus p(x)\rangle + (-1)^{j_n} \sin(\theta) |j_n \oplus p(x) \oplus 1\rangle \right), \quad (\text{S28})$$

where $j_{1:n} = j_1 \cdots j_{n-1}$, $\oplus$ is the bitwise addition and $p(x)$ is the bitwise parity function defined in Equation (S2). Taking the last piece of U_τ gives

$$U_\tau |jk\rangle = \left(\prod_{i=1}^n \text{CNOT}_{A_i B_i} \right) \left(\prod_{i=1}^{n-1} \text{CNOT}_{A_i A_n} \right) \left(H^{\otimes(n-1)} \otimes R_y(2\theta) \right) (|j\rangle_A \otimes |k\rangle_B) \quad (\text{S29})$$

$$= \left(\prod_{i=1}^n \text{CNOT}_{A_i B_i} \right) \frac{1}{\sqrt{2^{n-1}}} \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle_{A_{1:n}} \otimes \left(\cos(\theta) |j'_n\rangle_{A_n} + (-1)^{j_n} \sin(\theta) |j'_n \oplus 1\rangle_{A_n} \right) \otimes |k\rangle_B \quad (\text{S30})$$

$$= \sum_{x \in \{0,1\}^{n-1}} \frac{(-1)^{x \cdot j_{1:n}}}{\sqrt{2^{n-1}}} |x\rangle_{A_{1:n}} |k_{1:n} \oplus x\rangle_{B_{1:n}} \left(\cos(\theta) |j'_n\rangle_{A_n} |k'_n\rangle_{B_n} + (-1)^{j_n} \sin(\theta) |j'_n \oplus 1\rangle_{A_n} |k'_n \oplus 1\rangle_{B_n} \right) \quad (\text{S31})$$

for $j'_n = j_n \oplus p(x)$ and $k'_n = k_n \oplus j'_n$. When j and k are both zero, we have

$$U_\tau |00\rangle = \frac{1}{\sqrt{2^{n-1}}} \sum_{x \in \{0,1\}^{n-1}} |x\rangle_{A_{1:n}} |x\rangle_{B_{1:n}} \left(\cos(\theta) |p(x)\rangle_{A_n} |p(x)\rangle_{B_n} + \sin(\theta) |p(x) \oplus 1\rangle_{A_n} |p(x) \oplus 1\rangle_{B_n} \right). \quad (\text{S32})$$

Then we have

$$U_\tau |00\rangle \langle jk| U_\tau^\dagger = \frac{1}{2^{n-1}} \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle \langle x|_{A_{1:n}} |x\rangle \langle k_{1:n} \oplus x|_{B_{1:n}}. \quad (\text{S33})$$

$$\left(\cos(\theta) |p(x)\rangle_{A_n} |p(x)\rangle_{B_n} + \sin(\theta) |p(x) \oplus 1\rangle_{A_n} |p(x) \oplus 1\rangle_{B_n} \right). \quad (\text{S34})$$

$$\left(\cos(\theta) |j'_n\rangle_{A_n} \langle k'_n|_{B_n} + (-1)^{j_n} \sin(\theta) |j'_n \oplus 1\rangle_{A_n} \langle k'_n \oplus 1|_{B_n} \right). \quad (\text{S35})$$

G_{jk} in Lemma S8 is given as

$$G_{jk} = \text{Tr}_A [U_\tau |00\rangle \langle jk| U_\tau^\dagger] = \frac{1}{2^{n-1}} \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle \langle k_{1:n} \oplus x| \otimes Q_{j_n k_n}, \quad (\text{S36})$$

where $Q_{j_n k_n}$ is constructed as

$$Q_{j_n k_n} = \delta_{p(x), j'_n} (\cos^2(\theta) |p(x)\rangle \langle k'_n| + (-1)^{j_n} \sin^2(\theta) X |p(x)\rangle \langle k'_n| X) + \quad (\text{S37})$$

$$\frac{1}{2} \delta_{p(x), (j'_n \oplus 1)} \sin(2\theta) (X |p(x)\rangle \langle k'_n| + (-1)^{j_n} |p(x)\rangle \langle k'_n| X). \quad (\text{S38})$$

(2) For the second part, without loss of generality, suppose $\rho = |\psi\rangle \langle \psi|$ is a pure state. At this point, by Lemma S8, the output state $|\psi'\rangle$ of the following circuit

can be expressed as $|\psi'\rangle = \sum_{j,k} |jk\rangle \otimes G_{jk} |\psi\rangle$. Then

$$V |\psi'\rangle = \left(\prod_{i=1}^n \text{CNOT}_{B_i B_n} \right) \left(\prod_{i=1}^n \text{CNOT}_{B_i S_i} \text{CZ}_{A_i S_i} \right) \left(\prod_{i=1}^{n-1} \text{CNOT}_{A_n A_i} \right) \sum_{j,k} |j\rangle \otimes |k\rangle \otimes G_{jk} |\psi\rangle \quad (\text{S39})$$

$$= \left(\prod_{i=1}^n \text{CNOT}_{B_i B_n} \right) \left(\prod_{i=1}^n \text{CNOT}_{B_i S_i} \text{CZ}_{A_i S_i} \right) \sum_{j,k} \left(\bigotimes_{i=1}^{n-1} |j_i \oplus j_n\rangle \right) \otimes |j_n\rangle \otimes |k\rangle \otimes G_{jk} |\psi\rangle \quad (\text{S40})$$

$$= \left(\prod_{i=1}^n \text{CNOT}_{B_i B_n} \right) \left(\prod_{i=1}^n \text{CNOT}_{B_i S_i} \right) \left(\prod_{i=1}^n \text{CZ}_{A_i S_i} \right) \sum_{j,k} \left(\bigotimes_{i=1}^{n-1} |j_i \oplus j_n\rangle \right) \otimes |j_n\rangle \otimes |k\rangle \otimes G_{jk} |\psi\rangle \quad (\text{S41})$$

$$= \left(\prod_{i=1}^n \text{CNOT}_{B_i B_n} \right) \sum_{j,k} \left(\bigotimes_{i=1}^{n-1} |j_i \oplus j_n\rangle \right) \otimes |j_n\rangle \otimes |k\rangle \otimes E_{jk} |\psi\rangle \quad (\text{S42})$$

$$= \sum_{j,k} \left(\bigotimes_{i=1}^{n-1} |j_i \oplus j_n\rangle \right) \otimes |j_n\rangle \otimes |k_{1:n}\rangle \otimes |p(k)\rangle \otimes E_{jk} |\psi\rangle \quad (\text{S43})$$

for E_{jk} constructed as

$$E_{jk} = X^{(k)} \left(\prod_{i=1}^{n-1} Z_{S_i}^{j_i + j_n} \right) Z_{S_n}^{j_n} G_{jk}, \quad (\text{S44})$$

where $X^{(k)}$ is short for $\bigotimes_{i=1}^n X^{k_i}$. Now we analyze what E_{jk} will be for three cases: $j_n = 1$, $(j_n, p(k)) = (0, 0)$ and $(j_n, p(k)) = (0, 1)$.

If $j_n = 1$, then $j'_n = j_n \oplus p(x) = p(x) \oplus 1$, $k'_n = k_n \oplus j'_n = k_n \oplus p(x) \oplus 1$ and $Q_{j_n k_n}$ in Equation (S37) satisfies

$$Q_{j_n k_n} = \frac{1}{2} \sin(2\theta) (X|p(x)\rangle\langle k_n \oplus p(x)|X - |p(x)\rangle\langle k_n \oplus p(x)|) \quad (\text{S45})$$

and hence

$$G_{jk} = \frac{1}{2^n} \sin(2\theta) \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle\langle k_{1:n} \oplus x| \otimes (X|p(x)\rangle\langle k_n \oplus p(x)|X - |p(x)\rangle\langle k_n \oplus p(x)|) \quad (\text{S46})$$

and hence

$$E_{jk} = \frac{\sin(2\theta)}{2^n} X^{(k)} \left(\prod_{i=1}^{n-1} Z_{S_i}^{j_i + 1} \right) Z_{S_n} \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle\langle k_{1:n} \oplus x| \otimes (X|p(x)\rangle\langle k_n \oplus p(x)|X - |p(x)\rangle\langle k_n \oplus p(x)|) \quad (\text{S47})$$

$$= \frac{\sin(2\theta)}{2^n} X^{(k)} \sum_{x \in \{0,1\}^{n-1}} (-1)^x |x\rangle\langle k_{1:n} \oplus x| \otimes \left((-1)^{p(x)+1} |p(x) \oplus 1\rangle\langle k_n \oplus p(x) \oplus 1| - (-1)^{p(x)} |p(x)\rangle\langle k_n \oplus p(x)| \right) \quad (\text{S48})$$

$$= \frac{\sin(2\theta)}{2^n} \sum_{x \in \{0,1\}^{n-1}} (-1)^x |x \oplus k_{1:n}\rangle\langle k_{1:n} \oplus x| \otimes (-1)^{p(x)+1} (|p(x) \oplus k_n \oplus 1\rangle\langle k_n \oplus p(x) \oplus 1| + |p(x) \oplus k_n\rangle\langle k_n \oplus p(x)|) \quad (\text{S49})$$

$$= -\frac{\sin(2\theta)}{2^n} \sum_{x \in \{0,1\}^{n-1}} |x \oplus k_{1:n}\rangle\langle k_{1:n} \oplus x| \otimes I = -\frac{1}{2^n} \sin(2\theta) I_S. \quad (\text{S50})$$

If $j_n = 0$, then $j'_n = j_n \oplus p(x) = p(x)$, $k'_n = k_n \oplus j'_n = k_n \oplus p(x)$ and hence

$$Q_{j_n k_n} = \cos^2(\theta) |p(x)\rangle\langle k_n \oplus p(x)| + \sin^2(\theta) X |p(x)\rangle\langle k_n \oplus p(x)|X \quad (\text{S51})$$

$$\Rightarrow G_{jk} = \frac{1}{2^{n-1}} \sum_{x \in \{0,1\}^{n-1}} (-1)^{x \cdot j_{1:n}} |x\rangle\langle k_{1:n} \oplus x| \otimes (\cos^2(\theta) |p(x)\rangle\langle k_n \oplus p(x)| + \sin^2(\theta) X |p(x)\rangle\langle k_n \oplus p(x)|X), \quad (\text{S52})$$

which gives

$$E_{jk} = X^{(k)} Z_{S_{1:n}}^{(j_{1:n})} G_{jk} \quad (\text{S53})$$

$$= \frac{1}{2^{n-1}} X^{(k)} \sum_{x \in \{0,1\}^{n-1}} |x\rangle\langle k_{1:n} \oplus x| \otimes (\cos^2(\theta) |p(x)\rangle\langle k_n \oplus p(x)| + \sin^2(\theta) X |p(x)\rangle\langle k_n \oplus p(x)|X) \quad (\text{S54})$$

$$= \frac{1}{2^{n-1}} X^{(k)} \left[\sum_{x \in \{0,1\}^{n-1}} |x\rangle\langle x| \otimes (\cos^2(\theta)|p(x)\rangle\langle p(x)| + \sin^2(\theta)X|p(x)\rangle\langle p(x)|X) \right] X^{(k)}. \quad (\text{S55})$$

Denote $C = 2 \cosh(\tau/2) = e^{-\tau/2} + e^{\tau/2}$. Since $\cos^2(\theta) = e^{-\tau/2}/C$ and $\sin^2(\theta) = e^{\tau/2}/C$, the expression surrounded by the square bracket is simplified as

$$\sum_{x \in \{0,1\}^{n-1}} |x\rangle\langle x| \otimes (\cos^2(\theta)|p(x)\rangle\langle p(x)| + \sin^2(\theta)X|p(x)\rangle\langle p(x)|X) \quad (\text{S56})$$

$$= \frac{1}{C} \sum_{x \in \{0,1\}^{n-1}} |x\rangle\langle x| \otimes (e^{-\tau/2}|p(x)\rangle\langle p(x)| + e^{\tau/2}|p(x) \oplus 1\rangle\langle p(x) \oplus 1|) \quad (\text{S57})$$

$$= \frac{1}{C} \sum_{x \in \{0,1\}^{n-1}} |x\rangle\langle x| \otimes \exp(-\frac{\tau}{2}(-1)^{p(x)}Z) = \frac{1}{C} e^{-\tau Z^{\otimes n}/2}, \quad (\text{S58})$$

where the last equality comes from the fact that $Z^{\otimes(n-1)}|x\rangle = (-1)^{p(x)}|x\rangle$. Then

$$E_{jk} = \frac{1}{2^{n-1}C} X^{(k)} e^{-\tau Z^{\otimes n}/2} X^{(k)} \quad (\text{S59})$$

$$= \frac{1}{2^{n-1}C} \begin{cases} e^{-\tau Z^{\otimes n}/2}, & \text{if } p(k) = 0, \\ e^{\tau Z^{\otimes n}/2}, & \text{if } p(k) = 1. \end{cases} \quad (\text{S60})$$

As a result, omitting subsystems $A_{1:n}$ and $B_{1:n}$, since $TZ^{\otimes n}T^\dagger = \sigma$, we have

$$T_S V T_S^\dagger |\psi'\rangle = \sum_{j,k} \dots \otimes |j_n\rangle_{A_n} \otimes |p(k)\rangle_{B_n} \otimes T E_{jk} T^\dagger |\psi\rangle \quad (\text{S61})$$

$$= - \sum_{j_n=1} \dots \otimes |1\rangle_{A_n} \otimes |p(k)\rangle_{B_n} \otimes \frac{1}{2^n} \sin(2\theta) |\psi\rangle + \quad (\text{S62})$$

$$\sum_{(j_n, p(k))=(0,0)} \dots \otimes |0\rangle_{A_n} \otimes |0\rangle_{B_n} \otimes \frac{1}{2^{n-1}C} e^{-\tau\sigma/2} |\psi\rangle + \quad (\text{S63})$$

$$\sum_{(j_n, p(k))=(0,1)} \dots \otimes |0\rangle_{A_n} \otimes |1\rangle_{B_n} \otimes \frac{1}{2^{n-1}C} e^{\tau\sigma/2} |\psi\rangle. \quad (\text{S64})$$

There are 2^{2n-1} , 2^{2n-2} , 2^{2n-2} pairs of (j, k) for satisfying $j_n = 1$, $(j_n, p(k)) = (0, 0)$ and $(j_n, p(k)) = (0, 1)$, respectively. Finally, taking $\Pi^\odot$, $\Pi^\uparrow$, $\Pi^\downarrow$ in Equation (S20) gives

$$\text{Tr}_{AB} [\Pi_{AB}^\odot \mathcal{N}_\approx(|\psi\rangle\langle\psi|)] = 2^{2n-1} \cdot \frac{1}{2^{2n}} \sin^2(2\theta) |\psi\rangle\langle\psi| = \frac{1}{2 \cosh^2(\tau/2)} |\psi\rangle\langle\psi|, \quad (\text{S65})$$

$$\text{Tr}_{AB} [\Pi_{AB}^\uparrow \mathcal{N}_\approx(|\psi\rangle\langle\psi|)] = 2^{2n-2} \cdot \frac{1}{2^{2n-2}C^2} e^{-\tau\sigma/2} |\psi\rangle\langle\psi| e^{-\tau\sigma/2} = \frac{1}{4 \cosh^2(\tau/2)} \mathcal{E}_\sigma^\uparrow(|\psi\rangle\langle\psi|), \quad (\text{S66})$$

$$\text{Tr}_{AB} [\Pi_{AB}^\downarrow \mathcal{N}_\approx(|\psi\rangle\langle\psi|)] = 2^{2n-2} \cdot \frac{1}{2^{2n-2}C^2} e^{\tau\sigma/2} |\psi\rangle\langle\psi| e^{\tau\sigma/2} = \frac{1}{4 \cosh^2(\tau/2)} \mathcal{E}_\sigma^\downarrow(|\psi\rangle\langle\psi|). \quad (\text{S67})$$

The statement holds by generalizing $|\psi\rangle\langle\psi|$ to ρ by linearity. ■

Appendix C: Sampling thermal states and their labels

Let $\beta > 0$ and let $\Sigma = \{\sigma_j\}_{j=1}^L$ be a set of L n -qubit Pauli operators with a boundary vector $h \in \mathbb{R}_+^L$. The goal of random thermal state generation is to sample a datum $(G_{\beta,H}, H)$ from the dataset

$$S(\beta, \Sigma, h) = \left\{ (G_{\beta,H}, H) : H = \sum_{j=1}^L c_j \sigma_j, |c_j| \leq h_j, c_j \in \mathbb{R}, \sigma_j \in \Sigma \right\} \quad (\text{S1})$$

where $G_{\beta,H} = e^{-\beta H} / \text{Tr}[e^{-\beta H}]$ is the thermal state of the Hamiltonian H at temperature β^{-1} . To avoid sampling continuous coefficients directly, we sample from a quantized surrogate. For $N \geq 1$ define

$$S_N(\beta, \Sigma, h) = \left\{ (G_{\beta,H}, H) : H = \sum_{j=1}^L c_j \sigma_j, |c_j| \leq h_j, c_j/h_j \in (1/N)\mathbb{Z}, \sigma_j \in \Sigma \right\} \quad (\text{S2})$$

so that $\bigcup_{N \geq 1} S_N(\beta, \Sigma, h)$ is dense in $S(\beta, \Sigma, h)$ with respect to the sup-norm on the coefficient vector. The following algorithm describes how to sample a data from $S_N(\beta, \Sigma, h)$.

Algorithm 1: Pseudo code for our thermal state sampler

Input : Inverse temperature β , a set Σ of n -qubit Pauli operators with a boundary vector h , a number of steps N
Output: A datum $(G_{\beta,H}, H) \in S_N(\beta, \Sigma, h)$
1 $\tau \leftarrow \lambda\beta/N, \rho \leftarrow I^{\otimes n}/2^n$;
2 **SAMPLE** $\leftarrow$ a classical function that returns a value j with weight $p_j = h_j/\lambda$;
3 **for** $k = 1, \dots, N$ **do**
4 $j_k \leftarrow \text{SAMPLE}()$;
5 $\mathcal{M}_{j_k}, \mathcal{N}_{\sigma_{j_k}} \leftarrow$ Theorem S7 wrt. σ_{j_k} .
6 $(m_k, \rho) \leftarrow (\mathcal{M}_{j_k} \circ \mathcal{N}_{\sigma_{j_k}})(\rho)$;
7 $c_j \leftarrow \lambda \sum_{k: j_k=j} m_k/N, H \leftarrow \sum_{j=1}^L c_j \sigma_j$;
8 **return** (H, ρ)

This section develops two technical components used to analyze Algorithm 1. First, we prove the trace-norm error bound between the algorithmic output state and the target thermal state (Theorem 1). Second, we set up the random-walk viewpoint for the induced Hamiltonian coefficients, which underlies the sampling-probability analysis in Theorem 2.

1. Error analysis

Fix the step number N and a sequence of indices $(j_k)_{k=1}^N \subset [L]$ selecting Pauli operators from $\Sigma = \{\sigma_j\}_{j=1}^L$, as in Algorithm 1. Let ρ_k denote the (normalized) system state after k steps, and define the step size $\tau = \lambda\beta/N$. Then $(\rho_k)_{k=0}^N$ evolves according to the Markovian update rule

$$\rho_0 = I/2^n, \quad \rho_k = \mathcal{M}_{j_k} \circ \mathcal{N}_{j_k}(\rho_{k-1}) = \frac{e^{B_k} \rho_{k-1} e^{B_k}}{\text{Tr}[e^{B_k} \rho_{k-1} e^{B_k}]}, \quad (\text{S3})$$

where $\mathcal{M}_{j_k}, \mathcal{N}_{j_k}$ are specified by Theorem S7 for σ_{j_k} . The corresponding random variable B_k takes the form

$$B_k = \begin{cases} \tau \sigma_{j_k}/2, & \text{with probability } \text{Tr}[e^{\tau \sigma_{j_k}} \rho_{k-1}]/2 \cosh \tau, \\ -\tau \sigma_{j_k}/2, & \text{with probability } \text{Tr}[e^{-\tau \sigma_{j_k}} \rho_{k-1}]/2 \cosh \tau. \end{cases} \quad (\text{S4})$$

Iterating Equation (S3) shows that the final output state can be written as

$$\rho_N = \frac{(\prod_{k=N}^1 e^{B_k}) \rho_0 (\prod_{k=1}^N e^{B_k})}{\text{Tr}[\text{same above}]} = \frac{(\prod_{k=N}^2 e^{B_k}) e^{2B_1} (\prod_{k=2}^N e^{B_k})}{\text{Tr}[\text{same above}]}, \quad (\text{S5})$$

where $\prod_{k=N}^2$ denotes the ordered product from N down to 2. The corresponding target thermal state is

$$G_{\beta,H} = \frac{e^{-\beta H}}{\text{Tr}[e^{-\beta H}]} \quad \text{for} \quad H = -\frac{2}{\beta} \sum_{k=1}^N B_k. \quad (\text{S6})$$

In this subsection, we prove Theorem 1, which shows that, with probability at least $1 - \delta$ and for sufficiently large N ,

$$\|\rho_N - G_{\beta,H}\|_1 \leq \mathcal{O}\left((n + \log(N/\delta))^{3/2} \lambda^3 \beta^3 N^{-3/2}\right). \quad (\text{S7})$$

Two lemmas simplify the proof. The first lemma compares the palindromic product in ρ_N with the exponential of the accumulated generator.

Lemma S10 Let $(B_k)_{k=1}^N$ be a sequence of matrices. Denote $S_k = \sum_{j=1}^k B_j$. Suppose $\max_{1 \leq j \leq N} \|B_j\|_\infty = \tau \ll 1$. Then

$$\log \left(\left(\prod_{j=N}^2 e^{B_j} \right) e^{2B_1} \left(\prod_{j=2}^N e^{B_j} \right) \right) = 2S_N + \Delta_N + \mathcal{R}_N, \quad (\text{S8})$$

where $\Delta_k = -\frac{1}{6} \sum_{j=2}^k [B_j + 2S_{j-1}, [B_j, 2S_{j-1}]]$ denotes the terms of order 3 and $\mathcal{R}_N$ denotes the remainder terms. We have

$$\|\mathcal{R}_N\|_\infty = \mathcal{O} \left(\sum_{r=5, r \text{ is odd}}^{\infty} \frac{1}{r!} \sum_{k=2}^N \|\text{ad}_{2S_{k-1}}^{r-1}(B_k)\|_\infty \right). \quad (\text{S9})$$

Proof For Hermitian X and Y , since $(e^X e^Y e^X)^{-1} = e^{-X} e^{-Y} e^{-X}$, we have

$$\log(e^X e^Y e^X) + \log(e^{-X} e^{-Y} e^{-X}) = 0, \quad (\text{S10})$$

which implies $f(X, Y) = \log(e^X e^Y e^X) = -f(-X, -Y)$. Hence, the BCH expansion of $\log(e^X e^Y e^X)$ contains no even-order terms.

We proceed by induction using the palindromic products

$$M_k := \left(\prod_{j=k}^2 e^{B_j} \right) e^{2B_1} \left(\prod_{j=2}^k e^{B_j} \right), \quad Z_k := \log(M_k). \quad (\text{S11})$$

We have $M_1 = e^{2B_1}$, and for $k \geq 2$, $M_k = e^{B_k} M_{k-1} e^{B_k} = e^{B_k} e^{Z_{k-1}} e^{B_k}$.

For $k = 1$, we have $Z_1 = \log(e^{2B_1}) = 2B_1 = 2S_1$, so the claim holds.

Now fix $k \geq 2$ and assume inductively that $Z_{k-1} = 2S_{k-1} + \Delta_{k-1} + \mathcal{R}_{k-1}$, where Δ_{k-1} collects the cubic terms and $\mathcal{R}_{k-1}$ collects the remaining odd-order terms of degree at least 5. Applying Lemma S3 to $e^{B_k} e^{Z_{k-1}} e^{B_k}$ gives

$$Z_k = \log(e^{B_k} e^{Z_{k-1}} e^{B_k}) \quad (\text{S12})$$

$$= \log(e^{B_k} e^{2S_{k-1} + \Delta_{k-1} + \mathcal{R}_{k-1}} e^{B_k}) \quad (\text{S13})$$

$$= 2S_k + \Delta_{k-1} + \mathcal{R}_{k-1} - \frac{1}{6} [B_k + 2S_{k-1} + \Delta_{k-1} + \mathcal{R}_{k-1}, [B_k, 2S_{k-1} + \Delta_{k-1} + \mathcal{R}_{k-1}]]. \quad (\text{S14})$$

Separating the cubic contribution from higher-order terms yields

$$\Delta_k = \Delta_{k-1} - \frac{1}{6} [B_k + 2S_{k-1}, [B_k, 2S_{k-1}]], \quad (\text{S15})$$

$$\mathcal{R}_k = \mathcal{R}_{k-1} - \frac{1}{6} [B_k + 2S_{k-1}, [B_k, \Delta_{k-1} + \mathcal{R}_{k-1}]] - \frac{1}{6} [\Delta_{k-1} + \mathcal{R}_{k-1}, [B_k, 2S_{k-1} + \Delta_{k-1} + \mathcal{R}_{k-1}]]. \quad (\text{S16})$$

Iterating the recursion for Δ_k gives

$$\Delta_N = \Delta_{N-1} - \frac{1}{6} [B_N + 2S_{N-1}, [B_N, 2S_{N-1}]] \quad (\text{S17})$$

$$= -\frac{1}{6} \sum_{k=2}^N [B_k + 2S_{k-1}, [B_k, 2S_{k-1}]]. \quad (\text{S18})$$

It remains to bound the remainder terms in $\mathcal{R}_N$. Write $\mathcal{R}_k = \sum_{r \geq 5, r \text{ odd}} \mathcal{R}_{k,r}$, where $\mathcal{R}_{k,r}$ denotes the homogeneous terms of total order r , and assume $\|B_k\|_\infty = \mathcal{O}(\|S_{k-1}\|_\infty)$ for $k \geq 2$. From the recursive definition of $\mathcal{R}_k$, the order- r component obeys

$$\mathcal{R}_{k,r} = \mathcal{R}_{k-1,r} + \frac{1}{6} [B_k + 2S_{k-1}, [\mathcal{R}_{k-1,r-2}, B_k]] + \frac{1}{6} \sum_{j=3}^{r-4} [\mathcal{R}_{k-1,j}, [\mathcal{R}_{k-1,r-1-j}, B_k]]. \quad (\text{S19})$$

We claim that, for each odd $r \geq 5$, the increment $\mathcal{R}_{k,r} - \mathcal{R}_{k-1,r}$ is dominated (up to constants depending only on r) by terms of the form $\text{ad}_{2S_{k-1}}^{r-1}(B_k)$. The claim is immediate for $r = 5$, and the recursion preserves the dominance for higher odd orders.

Finally, since the coefficient of $\text{ad}_X^{r-1}(Y)$ in the BCH expansion of $\log(e^X e^Y e^X)$ has magnitude $2/r!$, there exists a constant C_r (depending only on r) such that, for all odd $r \geq 5$,

$$\|\mathcal{R}_{N,r}\|_\infty \leq \frac{C_r}{r!} \sum_{k=2}^N \|\text{ad}_{2S_{k-1}}^{r-1}(B_k)\|_\infty. \quad (\text{S20})$$

Summing over odd $r \geq 5$ gives the stated bound on $\|\mathcal{R}_N\|_\infty$. ■

The second lemma controls the effect of normalizing matrix exponentials.

Lemma S11 *Let A, E be two Hermitian matrices. Then*

$$\left\| \frac{e^{A+E}}{\text{Tr}[e^{A+E}]} - \frac{e^A}{\text{Tr}[e^A]} \right\|_1 \leq 2\|E\|_\infty. \quad (\text{S21})$$

Proof Consider $t \in [0, 1]$, $A(t) = A + tE$ and $\rho(t) = e^{A(t)}/\mathcal{Z}(t)$ with $\mathcal{Z}(t) = \text{Tr}[e^{A(t)}]$. By Lemma S1, we have

$$\frac{d}{dt} e^{A(t)} = \int_0^1 e^{sA(t)} E e^{(1-s)A(t)} ds. \quad (\text{S22})$$

Differentiating $\rho(t) = e^{A(t)}/\mathcal{Z}(t)$ gives

$$\frac{d}{dt} \rho(t) = \frac{d}{dt} \left(e^{A(t)} \cdot \frac{1}{\mathcal{Z}(t)} \right) = F(t) - \rho(t) \text{Tr}[F(t)], \quad (\text{S23})$$

where

$$F(t) = \frac{1}{\mathcal{Z}(t)} \frac{d}{dt} e^{A(t)} = \int_0^1 \rho(t)^s E \rho(t)^{1-s} ds. \quad (\text{S24})$$

By Lemma S2, $\|F(t)\|_1 \leq \|E\|_\infty$. In addition,

$$\text{Tr}[F(t)] = \int_0^1 \text{Tr}[\rho(t)^s E \rho(t)^{1-s}] ds = \int_0^1 \text{Tr}[\rho(t) E] ds = \text{Tr}[\rho(t) E] \leq \|E\|_\infty. \quad (\text{S25})$$

Therefore $\|\frac{d}{dt} \rho(t)\|_1 \leq 2\|E\|_\infty$ for all $t \in [0, 1]$, and integrating over t yields

$$\|\rho(1) - \rho(0)\|_1 \leq 2\|E\|_\infty, \quad (\text{S26})$$

as claimed. ■

The main error bound is stated and proved below. The argument is most informative when indices repeat frequently (i.e., $N \gg \max(L, n)$), where the palindromic product can be compared sharply with an exponential via higher-order BCH control, yielding a tighter bound than a second-order Trotter decomposition [40].

Theorem 1 (Complete version) *Let $N = \Omega(n\lambda^2\beta^2)$ and $\delta > 0$. Then ρ_N in Equation (S3) and $G_{\beta,H}$ in Equation (S6) satisfy*

$$\Pr\left(\|\rho_N - G_{\beta,H}\|_1 > \mathcal{O}\left(K_0^{3/2} N^{3/2} \tau^3\right)\right) \leq \delta \quad (\text{S27})$$

for $K_0 = (n+2)\log 2 + \log(N/\delta)$.

Proof Denote $S_k = \sum_{i=1}^k B_i$. By Lemma S10,

$$E := 2S_N - \log\left(\left(\prod_{k=N}^2 e^{B_k}\right) e^{2B_1} \left(\prod_{k=2}^N e^{B_k}\right)\right) = \frac{1}{3}(E_1 - 2E_2) - R_N \quad (\text{S28})$$

for $E_1 = \sum_{k=2}^N [B_k, [B_k, S_{k-1}]]$, $E_2 = \sum_{k=2}^N [S_{k-1}, [B_k, S_{k-1}]]$ and some remainder term R_N . Lemma S11 reduces the trace-norm comparison to a spectral-norm bound on E :

$$\|\rho_N - G_{\beta,H}\|_1 = \left\| \frac{e^{\log\left(\prod_{k=N}^2 e^{B_k}\right) e^{2B_1} \left(\prod_{k=2}^N e^{B_k}\right)}}{\text{Tr}[\text{same above}]} - \frac{e^{E+\log\left(\prod_{k=N}^2 e^{B_k}\right) e^{2B_1} \left(\prod_{k=2}^N e^{B_k}\right)}}{\text{Tr}[\text{same above}]} \right\|_1 \leq 2\|E\|_\infty. \quad (\text{S29})$$

It therefore suffices to upper bound $\|E_1\|_\infty$, $\|E_2\|_\infty$, and $\|R_N\|_\infty$ with high probability, and then combine these bounds.

We begin by controlling $\|S_k\|_\infty$. Let $\mathcal{F}_k = (B_i)_{i=1}^k$ be the natural filtration, define the drift $D_k = \mathbb{E}[B_k | \mathcal{F}_{k-1}]$, and let $M_k = B_k - D_k$. Then $S_k = \sum_{i=1}^k D_i + \sum_{i=1}^k M_i$. For the drift term, we have

$$\|D_k\|_\infty = \|\mathbb{E}[B_k | \mathcal{F}_{k-1}]\|_\infty = \left\| \left[\frac{\text{Tr}[e^{\tau\sigma_{j_k}\rho_{k-1}}]}{2 \cosh \tau} - \frac{\text{Tr}[e^{-\tau\sigma_{j_k}\rho_{k-1}}]}{2 \cosh \tau} \right] \cdot \frac{\tau\sigma_{j_k}}{2} \right\|_\infty \quad (\text{S30})$$

$$\leq |\text{Tr}[e^{\tau\sigma_{j_k}\rho_{k-1}}] - \text{Tr}[e^{-\tau\sigma_{j_k}\rho_{k-1}}]| \cdot \frac{\tau}{4 \cosh \tau} \quad (\text{S31})$$

$$= |(e^\tau - e^{-\tau}) \text{Tr}[\sigma_{j_k}\rho_{k-1}]| \cdot \frac{\tau}{2(e^\tau + e^{-\tau})} \quad (\text{S32})$$

$$\leq \frac{1}{2} \tau \tanh \tau = \tau^2 + \mathcal{O}(\tau^4) < 0.1\tau, \quad (\text{S33})$$

for $\tau \ll 1$. The sequence $(M_k)_k$ is a martingale difference sequence of Hermitian matrices with respect to $(\mathcal{F}_k)_k$, since $\mathbb{E}[M_k | \mathcal{F}_{k-1}] = 0$. In particular, $\|M_k\|_\infty \leq \|B_k\|_\infty + \|D_k\|_\infty \leq \tau + 0.1\tau = 1.1\tau$. Applying Lemma S4, for any k and $t_k > 0$,

$$\Pr\left(\left\|\sum_{i=1}^k M_i\right\|_\infty > t_k \text{ and } \left\|\sum_{i=1}^k \mathbb{E}[M_i^2 | \mathcal{F}_{i-1}]\right\|_\infty \leq \frac{k\tau^2}{4}\right) \leq 2^{n+1} \exp\left(-\frac{t_k^2/2}{k\tau^2/4 + 1.1\tau t_k/3}\right). \quad (\text{S34})$$

We also have

$$\sum_{i=1}^k \mathbb{E}[M_i^2 | \mathcal{F}_{i-1}] = \sum_{i=1}^k \mathbb{E}[B_i^2 | \mathcal{F}_{i-1}] - D_i^2 = \sum_{i=1}^k \frac{\tau^2}{4} I - D_i^2 \quad (\text{S35})$$

$$\implies \left\|\sum_{i=1}^k \mathbb{E}[M_i^2 | \mathcal{F}_{i-1}]\right\|_\infty \leq \sum_{i=1}^k \left\|\frac{\tau^2}{4} I - D_i^2\right\|_\infty \leq \sum_{i=1}^k \left\|\frac{\tau^2}{4} I\right\|_\infty = \frac{k}{4} \tau^2, \quad (\text{S36})$$

so choosing $K = (n+1) \log 2 + \log \delta^{-1}$ and $t_k = \tau \sqrt{kK/2} + 2.2\tau K/3$ implies $(t_k/\tau)^2/(k/2 + \frac{2.2}{3}t_k/\tau) \geq K$, and therefore

$$\Pr\left(\left\|\sum_{i=1}^k M_i\right\|_\infty > t_k\right) \leq 2^{n+1} \exp\left(-\frac{t_k^2}{k\tau^2/2 + 2.2\tau t_k/3}\right) = 2^{n+1} \exp\left(-\frac{(t_k/\tau)^2}{k/2 + 2.2/3 \cdot (t_k/\tau)}\right) \quad (\text{S37})$$

$$\leq 2^{n+1} e^{-K} = \delta. \quad (\text{S38})$$

Combining the drift and martingale parts yields

$$\|S_k\|_\infty \leq \left\|\sum_{i=1}^k M_i\right\|_\infty + \sum_{i=1}^k \|D_i\|_\infty \implies \Pr(\|S_k\|_\infty > t_k + k\tau^2) \leq \delta. \quad (\text{S39})$$

We next bound $\|E_1\|_\infty$. Since $B_k \sim \{\tau\sigma_{j_k}/2, -\tau\sigma_{j_k}/2\}$,

$$\|E_1\|_\infty = \left\|\sum_{k=2}^N [B_k, [B_k, S_{k-1}]]\right\|_\infty \quad (\text{S40})$$

$$\leq \sum_{k=2}^N \|[B_k, [B_k, S_{k-1}]]\|_\infty = \sum_{k=2}^N \|B_k^2 S_{k-1} + S_{k-1} B_k^2 - 2B_k S_{k-1} B_k\|_\infty \quad (\text{S41})$$

$$= \frac{\tau^2}{2} \sum_{k=2}^N \|S_{k-1} - \sigma_{j_k} S_{k-1} \sigma_{j_k}\|_\infty \leq \tau^2 \sum_{k=2}^N \|S_{k-1}\|_\infty \quad (\text{S42})$$

$$\implies \Pr\left(\|E_1\|_\infty > \tau^2 \sum_{k=2}^N (t_k + k\tau^2)\right) \leq \delta. \quad (\text{S43})$$

The term E_2 is handled in a similar way. Assume $\|S_k\|_\infty \leq t_k + k\tau^2$ (we account for this event in the final probability bound). Define $Q_k = [S_k, [M_{k+1}, S_k]]$, so that

$$[S_{k-1}, [B_k, S_{k-1}]] = Q_{k-1} + [S_{k-1}, [D_k, S_{k-1}]] \quad (\text{S44})$$

with $\| [S_{k-1}, [D_k, S_{k-1}]] \|_\infty \leq 4 \|S_k\|_\infty^2 \|D_{k+1}\|_\infty = 4(t_k + k\tau^2)^2 \tau^2$. One can verify that $\mathbb{E}[Q_k | \mathcal{F}_k] = 0$ and

$$\|Q_k\|_\infty \leq 4 \|S_k\|_\infty^2 \|M_{k+1}\|_\infty = 4.4(t_k + k\tau^2)^2 \tau, \quad (\text{S45})$$

$$\|\mathbb{E}[Q_k^2 | \mathcal{F}_{k-1}]\|_\infty \leq 4 \|S_k\|_\infty^4 \|M_{k+1}\|_\infty^2 \leq 20(t_k + k\tau^2)^4 \tau^2, \quad (\text{S46})$$

$$\left\| \sum_{k=1}^N \mathbb{E}[Q_k^2 | \mathcal{F}_{k-1}] \right\|_\infty \leq 20N(t_N + N\tau^2)^4 \tau^2. \quad (\text{S47})$$

Lemma S4 therefore implies that, for any k and $s_k > 0$,

$$\Pr\left(\left\| \sum_{i=1}^k Q_i \right\|_\infty > s_k\right) \leq 2^{n+1} \exp\left(-\frac{s_k^2/2}{20N(t_N + N\tau^2)^4 \tau^2 + 4.4(t_k + k\tau^2)^2 \tau s_k/3}\right). \quad (\text{S48})$$

Taking $s_k = \sqrt{40KN}(t_N + N\tau^2)^2 \tau + 8.8(t_k + k\tau^2)^2 K\tau/3$ simplifies the bound to

$$\Pr\left(\left\| \sum_{i=1}^k Q_i \right\|_\infty > s_k\right) \leq 2^{n+1} e^{-K} \leq \delta. \quad (\text{S49})$$

Consequently,

$$\|E_2\|_\infty = \left\| \sum_{k=2}^N [S_{k-1}, [B_k, S_{k-1}]] \right\|_\infty \leq \left\| \sum_{k=2}^N Q_{k-1} \right\|_\infty + \sum_{k=2}^N \| [S_{k-1}, [D_k, S_{k-1}]] \|_\infty \quad (\text{S50})$$

$$\implies \Pr\left(\|E_2\|_\infty > s_N + 4 \sum_{k=2}^N (t_k + k\tau^2)^2 \tau^2\right) \leq \delta. \quad (\text{S51})$$

We now combine the bounds. Since $N \gg n$, for all $k \leq N$ we have $t_k + k\tau^2 \leq t_N + N\tau^2 = \mathcal{O}(\tau\sqrt{NK}) + N\tau^2 = \mathcal{O}(\tau\sqrt{NK})$. Therefore, $\|E_1\|_\infty \leq \tau^2 \sum_{k=2}^N (t_k + k\tau^2) = \mathcal{O}(N\tau^3\sqrt{NK})$ and $\|E_2\|_\infty \leq s_N + 4 \sum_{k=2}^N (t_k + k\tau^2)^2 \tau^2 = \mathcal{O}(\tau^3 K^{3/2} N^{3/2})$, which implies $\|E_1 - 2E_2\|_\infty = \mathcal{O}(\tau^3 K^{3/2} N^{3/2})$.

It remains to bound the remainder term. By Lemma S10,

$$\|\mathcal{R}_N\|_\infty = \mathcal{O}\left(\sum_{r=5, r \text{ is odd}}^{\infty} \frac{1}{r!} \sum_{k=2}^N \|\text{ad}_{2S_{k-1}}^{r-1}(B_k)\|_\infty\right). \quad (\text{S52})$$

For an odd order $r \geq 5$, applying Lemma S4 yields

$$\frac{1}{r!} \sum_{k=2}^N \|\text{ad}_{2S_{k-1}}^{r-1}(B_k)\|_\infty = \frac{2^r}{r!} \mathcal{O}\left((\sqrt{NK}\tau)^r\right) = o(\tau^3 K^{3/2} N^{3/2}). \quad (\text{S53})$$

Alternatively, the triangle inequality gives

$$\frac{1}{r!} \sum_{k=2}^N \|\text{ad}_{2S_{k-1}}^{r-1}(B_k)\|_\infty = \frac{2^{2r}}{r!} \mathcal{O}\left(N\tau(\sqrt{NK}\tau)^{r-1}\right). \quad (\text{S54})$$

For $r^* = \left\lceil \frac{\log(K\tau^2\sqrt{NK})}{\log(\tau\sqrt{NK})} \right\rceil$, this implies $\|\mathcal{R}_N\|_\infty = \mathcal{O}(\tau^3 K^{3/2} N^{3/2})$. We therefore apply Lemma S4 for $r < r^*$ and use the triangle inequality for $r \geq r^*$; the remaining tail ($r > r^*$) decays exponentially and can be neglected at the stated precision.

Substituting these bounds into $\|\rho_N - G_{\beta,H}\|_1 \leq 2\|E\|_\infty$ yields

$$\Pr\left(\|\rho_N - G_{\beta,H}\|_1 \leq \mathcal{O}\left(K^{3/2} N^{3/2} \tau^3\right)\right) \geq 1 - \delta. \quad (\text{S55})$$

It remains to account for the overall failure probability. The proof applies Lemma S4 $(r^* - 1)/2 + N$ times. Setting $\delta' = \delta/((r^* - 1)/2 + N)$ and taking a union bound ensures that the total failure probability is at most δ . Under this rescaling, $K = (n + 1) \log 2 + \log(((r^* - 1)/2 + N)/\delta)$. Given $N \gg n$ and $\tau\sqrt{NK} \ll 1$, we may assume $N \gg K$ and obtain

$$r^* \leq 2 + \frac{\log(K\tau)}{\log(\tau\sqrt{NK})} \ll N, \quad (\text{S56})$$

which implies $K \leq (n + 2) \log 2 + \log(N/\delta) \ll N$. Taking $K_0 = (n + 2) \log 2 + \log(N/\delta)$ therefore yields the stated bound. ■

2. Sample distribution

Recall that Algorithm 1 generates a path $\mathcal{P} = ((j_1, m_1), \dots, (j_N, m_N)) \in [L] \times \{1, -1\}$. In Section C 1, we assumed $\mathcal{P}$ is fixed so that the evolution sequence can be analyzed without randomness. This section uses a random walk to incorporate the randomness of j_k and m_k .

Consider how the sampled Hamiltonian evolves as the path develops. Stopping the algorithm at step $k \in [N]$ yields the intermediate Hamiltonian $H^{(k)} = \sum_{t=1}^k m_t \sigma_{j_t}$. The sampling process can thus be described as a sequence $(H^{(k)})_k$, with $H^{(N)}$ being the final output. Equivalently, this sequence is a random walk on a lattice:

$$\mathbf{x}^{(k)} = \sum_{t=1}^k m_t e_{j_t} \in \{-N, \dots, N\}^{\times L}, \quad \mathbf{x}^{(0)} = 0, \quad (\text{S57})$$

where e_{j_t} is the standard vector in the lattice corresponding to σ_{j_t} , and every forward step satisfies

$$\Pr(\mathbf{x}^{(k)} - \mathbf{x}^{(k-1)} = \pm e_j) = \Pr(m_k = \pm 1) \cdot h_j / \lambda. \quad (\text{S58})$$

The sign of m_k is determined by the quantum measurement in Theorem S7, which is difficult to analyze directly. We therefore introduce a reference probability measure Q with $\Pr_Q(m_k = \pm 1) = 1/2$, giving

$$\Pr_Q(\mathbf{x}^{(k)} - \mathbf{x}^{(k-1)} = \pm e_j) = h_j / 2\lambda \quad (\text{S59})$$

corresponding to $N \rightarrow \infty$. The relation between the reference probability measure and the true probability measure is stated by the likelihood ratio $L_N(\mathcal{P}) = \Pr(\mathcal{P}) / \Pr_Q(\mathcal{P})$ in the following statement.

Lemma S13 *If $N = \Omega(n\lambda^2\beta^2)$, then for $H = H^{(N)}$,*

$$\log L_N(\mathcal{P}) = \log\left(\frac{1}{2^n} \text{Tr}[e^{-\beta H}]\right) + \mathcal{O}\left(\frac{\lambda^2\beta^2}{N}\right). \quad (\text{S60})$$

Proof For convenience, denote $\rho_{\mathbf{x}}$ as the thermal state of Hamiltonian with respect to $\mathbf{x}$ and $M_j(\mathbf{x}) = \text{Tr}[\sigma_j \rho_{\mathbf{x}}]$. By Theorem S7, the outcome distribution at step t given the Pauli operator σ_{j_t} can be written as

$$\Pr(m_t = \pm 1 \mid j_t) = \frac{1}{2} \left(1 \mp \tanh \tau \text{Tr}[\sigma_{j_t} M_j(\mathbf{x}^{(t-1)})]\right) \quad (\text{S61})$$

Since $\Pr_Q(m_t = \pm 1 \mid j_t) = 1/2$ and the probabilities for sampling j_t for both measures are the same, the likelihood ratio takes the product form

$$L_N(\mathcal{P}) = 2^N \prod_{t=1}^N \Pr(m_t = \pm 1 \mid j_t) = \prod_{t=1}^N \left(1 - m_t \tanh(\tau) M_{j_t}(\mathbf{x}^{(t-1)})\right). \quad (\text{S62})$$

Using $\log(1 + y) = y + \mathcal{O}(y^2)$ and $\tanh \tau = \tau + \mathcal{O}(\tau^3)$ gives

$$\log L_N(j, m) = -\tau \sum_{t=1}^N m_t M_{j_t}(\mathbf{x}^{(t-1)}) + \mathcal{O}(N\tau^2). \quad (\text{S63})$$

Denote the partition function of $H^{(t)}$ at the t -th step as

$$\mathcal{Z}(\mathbf{x}^{(t)}) = \text{Tr}[\exp(-\beta H^{(t)})] = \text{Tr}\left[\exp\left(-\tau \sum_{j=1}^L \mathbf{x}_j^{(t)} \sigma_j\right)\right]. \quad (\text{S64})$$

Observe that differentiating $\log \mathcal{Z}(\mathbf{x})$ with respect to $\mathbf{x}_j$ gives

$$\partial_{\mathbf{x}_j} \log \mathcal{Z}(\mathbf{x}) = \frac{1}{\mathcal{Z}(\mathbf{x})} \text{Tr}\left[(-\tau \sigma_j) \exp\left(-\tau \sum_{j=1}^L \mathbf{x}_j \sigma_j\right)\right] = -\tau M_j(\mathbf{x}). \quad (\text{S65})$$

Therefore, since $\mathbf{x}^{(t)} - \mathbf{x}^{(t-1)} = m_t e_{j_t}$,

$$-\tau m_t M_{j_t}(\mathbf{x}^{(t-1)}) = m_t \partial_{\mathbf{x}^{(t-1)}} \log \mathcal{Z}(\mathbf{x}^{(t-1)}) = \nabla_{\mathbf{x}} \log \mathcal{Z}(\mathbf{x}^{(t-1)}) \cdot (\mathbf{x}^{(t)} - \mathbf{x}^{(t-1)}). \quad (\text{S66})$$

Because $\mathcal{Z}(\mathbf{x})$ depends on $\mathbf{x}$ through $\tau \mathbf{x}$ and $\tau \ll 1$, a Taylor expansion of $\log \mathcal{Z}$ along one lattice step gives

$$\log \mathcal{Z}(\mathbf{x}^{(t)}) - \log \mathcal{Z}(\mathbf{x}^{(t-1)}) = \nabla_{\mathbf{x}} \log \mathcal{Z}(\mathbf{x}^{(t-1)}) \cdot (\mathbf{x}^{(t)} - \mathbf{x}^{(t-1)}) + \mathcal{O}(\tau^2). \quad (\text{S67})$$

Summing over $t = 1, \dots, N$ and substituting into Equation (S63) yields

$$\log L_N(j, m) = \log \mathcal{Z}(\mathbf{x}^{(N)}) - \log \mathcal{Z}(0) + \mathcal{O}(N\tau^2). \quad (\text{S68})$$

Finally, $\mathcal{Z}(0) = \text{Tr}[I] = 2^n$ and $\mathcal{Z}(\mathbf{x}^{(N)}) = \text{Tr}[\exp(-\tau \sum_j \mathbf{x}_j \sigma_j)] = \text{Tr}[e^{-\beta H^{(N)}}]$, so the statement follows from $N\tau^2 = \lambda^2 \beta^2 / N$. $\blacksquare$

We now state the theoretical result for the sample distribution.

Theorem 2 (Complete version) Suppose $n \gg 1$ and $N = \Omega(n\lambda^2\beta^2)$. Let $H = \sum_{j=1}^L c_j \sigma_j$ and $p_j = c_j/\lambda$. When $\sum_j c_j^2 \leq N\lambda^2$, the datum $(G_{\beta, H}, H)$ can be sampled by Algorithm 1 with probability proportional to $\frac{1}{2^n} \text{Tr}[e^{-\beta H}] \cdot D(\mathbf{x})$, where D is given as

$$D(\mathbf{x}) = \frac{a_N(\mathbf{x})}{(2\pi N)^{L/2} \sqrt{\prod_{j=1}^L p_j}} \exp\left(-\frac{1}{2N} \sum_j p_j \mathbf{x}_j^2\right) + o(N^{-L/2}). \quad (\text{S69})$$

Proof Fix $H = \sum_{j=1}^L c_j \sigma_j$ on the output grid, and let $\mathbf{x} \in \mathbb{Z}^L$ be the corresponding endpoint vector $\mathbf{x}_j = c_j N/\lambda$. Denote $\mathcal{P}_{\mathbf{x}}$ the set of paths whose endpoint equals $\mathbf{x}$. Then the event that Algorithm 1 returns H is exactly the endpoint event $\mathbf{x}^{(N)} = \mathbf{x}$.

By definition of the likelihood ratio and Lemma S13,

$$\Pr(\mathcal{P}) = \Pr_Q(\mathcal{P}) \cdot \exp\left(\log\left(\frac{1}{2^n} \text{Tr}[e^{-\beta H}]\right) + \mathcal{O}\left(\frac{\lambda^2 \beta^2}{N}\right)\right). \quad (\text{S70})$$

When $\|\mathbf{x}\| = \mathcal{O}(\sqrt{N})$. Therefore, absorbing the $\mathbf{x}$ -independent normalization into the proportionality constant, summing over all $\mathcal{P}$ with same endpoint, we obtain

$$\begin{aligned} \Pr(\mathbf{x}^{(N)} = \mathbf{x}) &= \exp\left(\log\left(\frac{1}{2^n} \text{Tr}[e^{-\beta H}]\right) + \mathcal{O}\left(\frac{\lambda^2 \beta^2}{N}\right)\right) \cdot \sum_{\mathcal{P} \in \mathcal{P}_{\mathbf{x}}} \Pr_Q(\mathcal{P}) \\ &\propto \frac{1}{2^n} \text{Tr}[e^{-\beta H}] \cdot \Pr_Q(\mathbf{x}^{(N)} = \mathbf{x}). \end{aligned} \quad (\text{S71})$$

Denote $D(\mathbf{x}) = \Pr_Q(\mathbf{x}^{(N)} = \mathbf{x})$. Substituting Lemma S5 yields the Gaussian approximation claimed in the theorem. $\blacksquare$

Appendix D: Application details

1. Level statistics of quantum density operators

This section outlines the framework for analyzing the spectral properties of the generated quantum thermal states, which we use as a benchmark for whether the sampler captures nontrivial chaotic correlations. Level statistics, commonly applied to Hamiltonian energy spectra to diagnose quantum chaos and ergodicity [45, 49], extend naturally to density operators ρ via the modular Hamiltonian.

For a strictly positive density operator ρ , its spectral properties are closely related to those of the fictitious Hamiltonian governing the thermal distribution. We define the modular Hamiltonian H by $\rho = \frac{e^{-H}}{\text{Tr}(e^{-H})}$. The eigenvalues of ρ , denoted by $\{p_i\}$, are directly related to the spectrum of H , denoted by $\{\xi_i\}$, via the transformation $\xi_i = -\ln(p_i) - \ln Z$. The level statistics of ρ are thus analyzed through the unfolding of the "entanglement energies" or modular levels $\{\xi_i\}$.

To avoid the ambiguities associated with spectral unfolding in finite-size systems, we utilize the adjacent gap ratio statistics introduced by Oganessian and Huse [45]. Let the sorted spectrum of the modular Hamiltonian be ordered such that $\xi_1 \leq \xi_2 \leq \dots \leq \xi_D$, where D is the dimension of the Hilbert space. We define the nearest-neighbor level spacing as:

$$\delta_n = \xi_{n+1} - \xi_n \geq 0. \quad (\text{S1})$$

The dimensionless level spacing ratio r_n is defined as:

$$r_n = \frac{\min(\delta_n, \delta_{n+1})}{\max(\delta_n, \delta_{n+1})} = \min\left(\tilde{r}_n, \frac{1}{\tilde{r}_n}\right) \in [0, 1] \quad (\text{S2})$$

where $\tilde{r}_n = \delta_{n+1}/\delta_n$. The distribution of r_n , denoted as $P(r)$, and its mean value $\langle r \rangle$, serve as robust indicators of the nature of the correlations in the quantum state. The following summarizes the known results of the average spacing ratios with respect to the specific RMT ensembles [66]:

- *Integrable (Poissonian) limit:* Systems with uncorrelated levels, typical of integrable models or localized phases, exhibit level spacings following a Poisson distribution with $P(r) = \frac{2}{(1+r)^2}$ and $\langle r \rangle_{\text{Poisson}} \approx 0.386$.
- *Chaotic (Wigner–Dyson) limit:* Ergodic quantum systems exhibit level repulsion characteristic of Random Matrix Theory (RMT), with statistics depending on the symmetry class: $\langle r \rangle_{\text{GOE}} \approx 0.536$ for systems with time-reversal symmetry, and $\langle r \rangle_{\text{GUE}} \approx 0.603$ for systems without.

In our algorithm, $\langle r \rangle$ values approaching the GUE/GOE limits in the sampled thermal states indicate that the generated state captures the complexity and correlations of a thermalizing many-body system. Conversely, $\langle r \rangle \approx 0.39$ would suggest a failure to capture thermal correlations or an underlying integrability in the generator set.

2. State classification by Hamiltonian properties

Let us specify the background first. Let Σ and h be as defined in Section C that describe a set of Hamiltonians $\mathfrak{H}$. For a label function $f : \mathfrak{H} \rightarrow \{0, 1\}$ that divide this set to group 0 and group 1, given access to an unknown thermal state $G_{\beta, H}$ (with known temperature β), the goal of state classification is to predict whether $f(H)$ is 0 or 1. Denote the labelled set $D_y = \{\rho : (\rho, H) \in S(\beta, \Sigma, h), f(H) = y\}$ for $y = 0, 1$, and without loss of generality, suppose $|D_0| = |D_1|$. Then, equivalently, we are looking for an n -to-1 channel $\mathcal{E}$ that maximizes the average success probability of prediction

$$P(\mathcal{E}) = \frac{1}{2} \sum_{y=0}^1 \Pr(\text{predict } y \mid \rho \in D_y) = \frac{1}{2} \sum_{y=0}^1 \int_{D_y} \text{Tr}[\mathcal{E}(\rho) \cdot |0\rangle\langle 0|] \, d\rho = \frac{1}{2} \sum_{y=0}^1 \text{Tr}[\mathcal{E}(\rho_y) \cdot |y\rangle\langle y|] \quad (\text{S3})$$

for $\rho_y = \int_{D_y} \rho \, d\rho$ is the average mixture of the state set D_y , and $\rho_y = \frac{1}{|D_y|} \sum_{\rho \in D_y} \rho$ when D_y is finite. Theoretically, this average success probability of prediction is upper bounded by the Helstrom limit [56],

$$P(\mathcal{E}) \leq \frac{1}{2}(1 + \|\rho_0 - \rho_1\|_1). \quad (\text{S4})$$

In later experiment, the Helstrom limit is used to evaluate the convergence performance.

The rest of this section outlines an example training algorithm on how to use our sampler as data source to find a protocol to tackle this task. In the standard expectation-value-based formulation, each loss evaluation typically requires many circuit repetitions on the same input state; here we instead use single-shot outcomes on freshly sampled batches from the stochastic data source. We model the n -to-1 channel $\mathcal{E}$ by an $(n+1)$ -qubit parameterized quantum circuit [55] $U(\theta)$ with one ancilla qubit. The circuit takes an n -qubit state ρ as input and traces out the main system; we denote the resulting parameterized channel as $\mathcal{E}_\theta$. Then for a finite set of input state $\rho_1, \dots, \rho_d$ that approximates thermal states $G_{\beta, H_1}, \dots, G_{\beta, H_d}$ generated by our sampler, respectively, and their 0/1 label vector $\hat{y} = (f(H_1), \dots, f(H_d)) \in \{0, 1\}^d$, the average prediction loss is defined as the stochastic function

$$\mathcal{L}(\theta) = \left(1 - \frac{1}{d} y(\theta) \cdot \hat{y}\right)/2, \quad \text{where } \Pr(y_i(\theta) = \hat{y}_i) = \text{Tr}[\mathcal{E}_\theta(G_{\beta, H_i}) \cdot |f(H_i)\rangle\langle f(H_i)|] \quad (\text{S5})$$

such that the expectation is the average failure probability of prediction,

$$\mathbb{E}[\mathcal{L}(\theta)] = 1 - \frac{1}{d} \sum_{i=1}^d \text{Tr}[\mathcal{E}_\theta(G_{\beta, H_i}) \cdot |f(H_i)\rangle\langle f(H_i)|]. \quad (\text{S6})$$

Then our objective is to find the optimal parameters $\theta^* = \arg \min_{\theta} \mathbb{E}[\mathcal{L}(\theta)]$. Since $\mathcal{L}(\theta)$ is stochastic, we estimate the gradient using a stochastic variant of the parameter-shift rule [57, 58]. Unlike the standard formulation based on expectation-value estimation, each loss evaluation here is obtained from single-shot measurements on a freshly sampled batch. For each parameter θ_j associated with a Pauli-rotation gate $U(\theta_j) = \exp(-i\theta_j P/2)$, the gradient component can be estimated by

$$\nabla_j \mathcal{L}(\theta) = \frac{\mathcal{L}(\theta + \frac{\pi}{2} e_j) - \mathcal{L}(\theta - \frac{\pi}{2} e_j)}{2}, \quad (\text{S7})$$

where e_j is the unit vector in the j th coordinate. This estimator is unbiased in the presence of a stochastic data source, i.e., $\mathbb{E}[\nabla \mathcal{L}(\theta)] = \nabla_{\theta} \mathbb{E}[\mathcal{L}(\theta)]$. The complete training procedure is summarized in Algorithm 2. Here ϵ controls the sampling precision of our sampler, and w is a weight function that controls the importance of each Hamiltonian.

Algorithm 2: Training a parameterized quantum circuit for state classification

Input : A label function f , inverse temperature β , a set Σ of n -qubit Pauli operators with boundary vector h , precision ϵ , training steps T , batch size d , learning rate γ , weight function $w(H) \in \mathbb{R}_+$

Output: A channel $\mathcal{E}$ that approximately maximizes $P(\mathcal{E})$ in Equation (S3)

```

1  $N \leftarrow \lambda^2 \beta^2 \epsilon^{-2/3}$ ;
2  $\text{SAMPLE} \leftarrow$  Algorithm 1 with inputs  $\beta, \Sigma, h, N$ ;
3 Choose a circuit ansatz  $U(\theta)$  with random parameters  $\theta$ , and define  $\mathcal{E}_{\theta} \leftarrow \text{Tr}_{\text{sys}}[U(\theta) (|0\rangle\langle 0|_{\text{anc}} \otimes (\cdot)_{\text{sys}}) U(\theta)^{\dagger}]$ ;
4 for  $t = 1, \dots, T$  do
5    $g \leftarrow 0^{|\theta|}$ ;
6   for  $j = 1, \dots, |\theta|$  do
7     for  $s \in \{+1, -1\}$  do
8       for  $i = 1, \dots, d$  do
9          $(\rho_i, H_i) \leftarrow \text{SAMPLE}()$ ;
10         $y_i \leftarrow \text{measure } \mathcal{E}_{\theta+s \cdot \frac{\pi}{2} e_j}(\rho_i), \hat{y}_i \leftarrow f(H_i)$ ;
11         $\mathcal{L}_s \leftarrow (1 - \sum_i w(H_i) y_i \hat{y}_i / \sum_i w(H_i)) / 2$ ;
12       $g_j \leftarrow (\mathcal{L}_{+1} - \mathcal{L}_{-1}) / 2$ ;
13    $\theta \leftarrow \theta - \gamma \cdot g$  (or use Adam optimizer);
14 return  $\mathcal{E} = \mathcal{E}_{\theta}$ 
```

The convergence of Algorithm 2 depends on the variance of the parameter-shift gradient estimate. Since each iteration requires $2|\theta|$ stochastic loss evaluations, both the evaluation budget and the batch size d affect the gradient noise in the presence of data and measurement sampling. If d is not large enough, the variance may be too high for the classifier to converge. The weight function w adjusts the loss in Equation (S5) to emphasize Hamiltonians whose importance is not too small, thereby improving the effective signal-to-noise ratio.

Appendix E: Experimental setting

Figure 2-3a

All experiments for Figure 2 and Figure 3a are performed on a 3×3 two-dimensional grid of $n = 9$ qubits, with sites labeled $1, \dots, 9$ in row-major order. The nearest-neighbor pairs $\langle i, j \rangle$ consist of 12 edges connecting horizontally and vertically adjacent sites. For the Heisenberg model, the sampled Hamiltonians take the form

$$H_{\text{Heis}} = \sum_{\langle i, j \rangle} \left(c_{ij}^{(X)} X_i X_j + c_{ij}^{(Y)} Y_i Y_j + c_{ij}^{(Z)} Z_i Z_j \right), \quad (\text{S1})$$

where the coefficients $c_{ij}^{(\alpha)}$ are generated by the sampling algorithm and satisfy $|c_{ij}^{(\alpha)}| \leq h$ for a uniform bound $h > 0$. For the transverse-field Ising model, the sampled Hamiltonians take the form

$$H_{\text{Ising}} = \sum_{\langle i, j \rangle} c_{ij} Z_i Z_j + \sum_{i=1}^n g_i X_i, \quad (\text{S2})$$

where the coefficients c_{ij} and g_i are similarly bounded. In both cases, $\lambda = \sum_j h_j$ denotes the sum of all coefficient bounds. Throughout, we set the step-number constant $C = \lambda^2 / \epsilon_0^{2/3}$ with target precision $\epsilon_0 = 10^{-6}$.

For Figure 2, all three panels use the Heisenberg model with the maximally mixed state I/d as the initial state. In panel (a), we scan the inverse temperature from $\beta = 1$ to $\beta = 10$ and test three scaling exponents $k \in \{1.5, 2.0, 2.5\}$, which define the step number as $N = C\beta^k$. For each parameter pair (β, N) , we perform 100 independent sampling runs and record the maximal trace-distance error ϵ among the samples. Panels (b) and (c) both fix $\beta = 2$. In panel (b), we set $N = C\beta^2$ and generate 10 000 independent samples to obtain the empirical coefficient distribution; the theoretical curve is computed from the normal distribution predicted by Theorem 2, reweighted by the thermal partition function and estimated via Monte Carlo with 10 000 samples. In panel (c), we scan the scaling exponent k from 1 to 3 and perform 100 independent runs for each $N = C\beta^k$. The inverse precision is defined as $1/\epsilon$, where ϵ is the maximal trace-distance error among the samples. The effective sample range is quantified by the operator norm $\|H\|_\infty$ of each sampled Hamiltonian; we report the sample mean and standard error over the thermal ensemble.

For Figure 3(a), we use the transverse-field Ising model to generate the output states. The initial state is a thermal state of a Heisenberg Hamiltonian, whose modular spectrum exhibits near-Poisson statistics in this finite-size setting. We fix $\beta = 2$ and $N = C\beta^2$, and perform 20 independent sampling runs. For each output state ρ , we define the modular Hamiltonian $K = -\log \rho$ and compute the adjacent gap-ratio statistic r from the spectrum of K . To handle near-degeneracies, eigenvalues within a relative tolerance of 10^{-6} are merged into a single representative level before evaluating the spacing ratios. The resulting r values are aggregated over all samples to form the final histogram.

Figure 3b

Fig S2. Training details for the state classification task, showing both accuracy and loss as functions of the training iteration.

The complete figure of Figure 3b, including loss values, is shown in Figure S2. In this experiment, we follow the procedure described in Section D 2 to classify two-qubit Hamiltonians by the sign of their $X \otimes X$ coefficient, using their thermal states at inverse temperature $\beta = 2$. The Hamiltonians take the form $H = h_1 X \otimes X + h_2 I \otimes Z + h_3 Z \otimes I$ with $|h_1|, |h_2|, |h_3| \leq 1$. We further restrict to Hamiltonians whose $X \otimes X$ coefficient satisfies $|h_1| \geq 0.03$. We run Algorithm 2 over 10 independent trials with the following setting:

- $f : H \mapsto h_1/|h_1|$,
- $\Sigma = \{X \otimes X, I \otimes Z, Z \otimes I\}$ with $h = (1, 1, 1)$,
- number of training step $T = 100$, number of training size $d = 1000$,
- parameter-shift value $\pi/2$, learning rate $\gamma = 0.1$,
- the weight function $w(H) = 0.05 + 0.95 \text{Sigmoid}((|h_1| - 0.01\lambda)/0.0025\lambda)$.

We choose the implementation of the variational quantum classifier to consist of a universal 2-qubit layer (built from parameterized single-qubit universal gates U and Pauli-rotation gates R_z, R_y) on the input state, together with two additional single-qubit universal gates on the ancilla before and after coupling it to the system, shown as follows.

For each independent trial, we also prepare a separate test set of size 3000 to evaluate the model at each training iteration. For each test set, we compute the Helstrom limit in Equation (S4), which yields an upper bound of approximately 0.72–0.74. To assess generalization, the test set consists of exact thermal states with Hamiltonian coefficients h_1, h_2, h_3 sampled from a uniform distribution, in contrast to the training set whose approximate thermal states are sampled from the thermal-weighted normal distribution (Theorem 2). The performance metric is the average success probability of prediction defined in Equation (S3).

Restoring Heisenberg-Limited Precision in Non-Markovian Open Quantum Systems via Dynamical Decoupling

Abstract. Non-classical resources enable measurements to achieve a precision that exceeds the limits predicted by the central limit theorem. However, environmental noise arising from system-environment interactions severely limits the performance of such resources through decoherence. While significant progress has been made in mitigating Markovian noise, the extent to which non-Markovian noise can be mitigated remains poorly understood. We demonstrate that Heisenberg Scaling, the ultimate quantum limit on measurement precision, can be recovered in quantum metrology under non-Markovian noise by leveraging carefully designed Dynamical Decoupling Techniques. Importantly, our approach does not rely on assumptions of Markovian dynamics. By imposing appropriate conditions on the control Hamiltonian, we show that Heisenberg Scaling can be achieved irrespective of whether the noise is Markovian or non-Markovian. We also prove necessary and sufficient conditions for the existence of such control Hamiltonians. As an illustrative example, we apply our framework to the damped Jaynes-Cummings model, successfully mitigating memory effects and maintaining measurement precision in complex, non-Markovian environments. These findings highlight the power of quantum control to overcome decoherence challenges and enhance metrological performance in realistic, noisy quantum systems

Keywords: Non-classical resources, Markovian noise, non-Markovian noise, Quantum metrology, Heisenberg Scaling, Dynamical Decoupling Techniques

1 Introduction

A typical quantum metrological protocol involves three steps: (i) preparation of a probe state, (ii) parameter encoding through an evolution governed by the parameter of interest, and (iii) measurement for parameter estimation. The estimation precision depends on the probe's quantum nature. Classically correlated probes are limited by the *shot-noise limit* (SNL), scaling as $1/N$ with the number of probes and $1/t$ with time, while quantum resources such as entanglement or coherence enable the *Heisenberg scaling* (HS) of $1/N^2$ and $1/t^2$. Achieving HS, however, requires coherent evolution, which is hindered in realistic systems by decoherence. Existing strategies such as *quantum error correction* (QEC) [1, 2, 3] mainly address *Markovian noise*, where the environment has no memory. In contrast, many practical systems—such as solid-state platforms—experience *non-Markovian noise* due to strong system-environment coupling.

In this work, we show that *Heisenberg scaling can be recovered* in open quantum systems affected by non-Markovian noise through *time-dependent control Hamiltonians* based on *dynamical decoupling techniques* (DDT). We (i) derive necessary and sufficient conditions for control Hamiltonians that suppress both Markovian and non-Markovian noise while preserving nontrivial parameter encoding, (ii) demonstrate that the *quantum Fisher information* (QFI) retains its quadratic time scaling ($\mathcal{F} \propto t^2$), and (iii) validate our results using the *damped Jaynes-Cummings model* with detuning, confirming the restoration of HS under DDT. These results establish DDT as a robust framework for achieving noise-resilient quantum metrology.

2 Restoring HS in Open Quantum Systems via DDT

The central idea is to construct a time-dependent control Hamiltonian $H_C(t)$ acting solely on the system to counteract system-environment interactions. The total Hamiltonian is given by

$$H_{\text{tot}}(t) = H_S(\omega) \otimes \mathbb{1}_E + H_C(t) \otimes \mathbb{1}_E + \mathbb{1}_S \otimes H_E + H_{SE}, \quad (1)$$

where $H_C(t)$ generates the control propagator $U_C(t) = \mathcal{T} \exp \left[-i \int_0^t ds H_C(s) \right]$. In the control frame, the total evolution operator becomes $\tilde{U}_{\text{tot}}(\omega, t) = \mathcal{T} \exp \left[-i \int_0^t ds \tilde{H}_{\text{tot}}(s) \right]$, with $\tilde{H}_{\text{tot}}(t) = (U_C^\dagger(t) \otimes \mathbb{1}_E) H_{\text{tot}}(U_C(t) \otimes \mathbb{1}_E)$.

For sufficiently short control intervals of duration T , the dynamics can be approximated as a sequence of time-independent evolutions:

$$\tilde{U}_{\text{tot}}(\omega, 0 \rightarrow nT) \approx \prod_{k=0}^{n-1} e^{-iT \tilde{H}_{\text{tot}}(kT)} \approx e^{-iT \sum_{k=0}^{n-1} \tilde{H}_{\text{tot}}(kT)}, \quad (2)$$

which becomes exact in the limit $T \rightarrow 0$. Substituting the effective Hamiltonian components yields

$$\tilde{U}_{\text{tot}}(\omega, 0 \rightarrow nT) \approx e^{-inT(H_S^{\text{eff}} \otimes \mathbb{1}_E + \mathbb{1}_S \otimes H_E + H_{SE}^{\text{eff}})}, \quad (3)$$

where

$$H_S^{\text{eff}} = \frac{1}{n} \sum_{k=0}^{n-1} U_C^\dagger(kT) H_S U_C(kT),$$

$$H_{SE}^{\text{eff}} = \frac{1}{n} \sum_{k=0}^{n-1} (U_C^\dagger(kT) \otimes \mathbb{1}_E) H_{SE} (U_C(kT) \otimes \mathbb{1}_E).$$

*baqmou@gmail.com

†bbtankc@gmail.com

To achieve decoupling, the control unitaries $U_C(kT)$ at each time interval k are designed to satisfy the dynamical decoupling (DD) condition:

$$\frac{1}{n} \sum_{k=0}^{n-1} \left(U_C^\dagger(kT) \otimes \mathbb{1}_E \right) H_{SE} (U_C(kT) \otimes \mathbb{1}_E) = c \mathbb{1}_S \otimes J_E, \quad (4)$$

where c is a constant and J_E is a Hermitian operator acting on the environment Hilbert space. For parameter estimation, we additionally require that the effective system Hamiltonian $H_S^{\text{eff}}(\omega)$ generates a nontrivial parameter-dependent evolution:

$$\frac{1}{n} \sum_{k=0}^{n-1} U_C^\dagger(kT) H_S(\omega) U_C(kT) \not\propto \mathbb{1}_S. \quad (5)$$

Eqs. (4) and (5) together ensure that the system is effectively decoupled from its environment—suppressing noise while preserving the ability to encode the parameter ω . The goal is thus to identify a set of quantum control operations $\{U_C(kT)\}_{k=0}^{n-1}$ that simultaneously satisfy both conditions. The following theorem establishes the necessary and sufficient conditions for the existence of such a control.

Theorem 1 (Necessary and sufficient conditions for dynamically decoupled quantum sensing). *For any system–environment interaction $H_S \otimes \mathbb{1}_E + \mathbb{1}_S \otimes H_E + H_{SE}$, there exists a collection of unitary operators $\{U_C(kT)\}_{k=0}^{n-1}$ satisfying*

$$H_S^{\text{eff}} = \frac{1}{n} \sum_{k=0}^{n-1} U_C^\dagger(kT) H_S U_C(kT) \not\propto \mathbb{1}_S$$

and

$$\begin{aligned} H_{SE}^{\text{eff}} &= \frac{1}{n} \sum_{k=0}^{n-1} \left(U_C^\dagger(kT) \otimes \mathbb{1}_E \right) H_{SE} (U_C(kT) \otimes \mathbb{1}_E) \\ &= c \mathbb{1}_S \otimes J_E, \end{aligned}$$

for some constant c and Hermitian operator J_E , if and only if there exists a mixed-unitary channel Φ such that $\Phi(H_S)$ is nontrivial and

$$\text{Tr} \left\{ \left[\Phi(H_S) - \text{Tr}(H_S) \frac{\mathbb{1}_S}{d} \right] \Phi \left[{}_E \langle \psi | H_{SE} | \psi \rangle_E \right] \right\} = 0,$$

and

$$\langle i | \Phi \left[{}_E \langle \psi | H_{SE} | \psi \rangle_E \right] | i \rangle = \text{constant},$$

for every eigenvector $|i\rangle$ of $\Phi(H_S)$ and state vector $|\psi\rangle_E$.

A detailed proof of this theorem is provided in the original paper [4]. Satisfying the above conditions ensures that the interaction term H_{SE} is effectively averaged out, fully decoupling the system’s dynamics from the environment. Consequently, the system evolves independently under its effective Hamiltonian $H_S^{\text{eff}}(\omega)$, thereby restoring Heisenberg scaling (HS) in the presence of noise.

Geometry-Controlled Suppression of Nuclear Spin Relaxation in SERF Vapor Cells for Quantum Sensing

Xihui Dou^{1 *}

Abstract. SERF vapor cell quantum sensors rely on long-lived nuclear spin coherence, yet fabrication-induced stem structures can enhance gradient-induced relaxation through restricted diffusion. We investigate this relaxation channel using a Monte Carlo random walk model with polarization gradient fields, and examine it experimentally in vapor cells with controlled filling port areas and laser-trimmed stem lengths. In 3 mm cubic cells, reducing the filling port area increases the transverse nuclear spin relaxation rate by about 5-6 times, while stem shortening improves relaxation suppression efficiency from 35% to 49% over 185-195 °C. These results provide structural design rules for compact SERF quantum metrology platforms.

Keywords: SERF quantum sensors, nuclear spin relaxation, restricted diffusion, vapor cell

1 Motivation: nuclear spin coherence in SERF quantum sensors

Spin-exchange relaxation-free (SERF) co-magnetometers constitute a compact class of atomic spin sensors for precision measurement, inertial sensing, and quantum metrology [1, 2]. In these systems, the vapor cell serves as the central sensing element, where optically pumped alkali electron spins are coupled to noble gas nuclear spins through spin-exchange interactions [3]. The transverse nuclear spin relaxation time, T_2 , characterizes the coherence time of nuclear spin precession and is closely linked to the stability and low-frequency noise suppression of SERF-based measurements. Preserving nuclear spin coherence is therefore a fundamental requirement for high-performance SERF vapor cell quantum sensors.

For miniaturized SERF implementations, nuclear spin relaxation is governed not solely by intrinsic spin interactions, external magnetic shielding, or residual field compensation. The actual geometry of the vapor cell can also reshape the diffusion dynamics of noble gas atoms within the sensing volume. In particular, magnetic field gradients produced by nonuniform electron spin polarization constitute an important source of transverse nuclear spin relaxation in atomic co-magnetometers [4, 5]. When residual stem and filling port structures are introduced during vapor cell fabrication, the effective diffusion space departs from the ideal spherical or cubic geometries commonly assumed in conventional gradient-relaxation models.

This work focuses on this geometry-dependent relaxation mechanism in stemmed SERF vapor cells. Instead of regarding the stem as a passive fabrication remnant, we treat the stem length and filling port area as structural parameters that govern restricted diffusion in polarization gradient fields. This perspective links vapor cell geometry directly to nuclear spin coherence preservation and motivates a geometry-level route for suppressing

transverse relaxation in compact SERF quantum sensors.

2 Stem geometry as a relaxation channel

The residual stem of a vapor cell is introduced by the filling and sealing process and is often treated as a secondary fabrication feature. In miniaturized SERF vapor cells, however, this simplification becomes inadequate. As illustrated in Fig. 1, the stem and filling port form an additional diffusion volume connected to the main chamber. Noble gas atoms can repeatedly enter this narrow region, so that restricted gas diffusion modifies the spatial sampling of the nuclear spin ensemble and increases its exposure to nonuniform magnetic environments.

Figure 1: Vapor cell geometry incorporating a fine stem structure (a) Actual image of the vapor cell, (b) Definition of the key geometrical parameters: vapor cell size L , wall thickness H_1 , stem length H_2 , filling port cross-sectional area S_1 , and stem cross-sectional area S_2 .

This effect is especially relevant when nonuniform alkali electron spin polarization produces internal magnetic field gradients through the Fermi contact interaction. In this case, the stem does not merely add inactive volume; it changes the correlation between atomic diffusion trajectories and local polarization gradient fields, thereby providing a geometry-controlled pathway for transverse

*douxihui@buaa.edu.cn

†liufeng1991@buaa.edu.cn

‡quanwei@buaa.edu.cn

nuclear spin relaxation. Related studies have shown that stem geometry can influence gradient-induced spin relaxation [6, 7]. However, these studies did not establish a systematic treatment of fine stem geometry for SERF vapor cells, where miniaturized cell dimensions, polarization gradient fields, and stem-induced restricted diffusion are coupled.

From this perspective, the stem length H_2 and the filling port cross-sectional area S_1 , as defined in Fig. 1(b), should be treated as physically meaningful design parameters rather than secondary fabrication details. This interpretation identifies H_2 and S_1 as the two stem-related parameters that must be explicitly retained when evaluating nuclear spin relaxation in practical SERF vapor cells.

3 Physical picture and supporting evidence

The physical picture is diffusion-mediated phase dispersion under a realistic stemmed geometry and a polarization-gradient field. Instead of treating the vapor cell as an ideal cube, the simulation explicitly incorporates the effective diffusion space formed by the main chamber, filling port, and fine stem. The key structural parameters are the vapor cell size L , stem length H_2 , and filling port cross-sectional area S_1 . In parallel, the magnetic environment is obtained from the spatially nonuniform alkali electron spin polarization under SERF operation, which generates an internal field gradient through the Fermi contact interaction.

Figure 2: Simulated dependence of transverse nuclear spin relaxation time on fine stem parameters.

A Monte Carlo random walk model is then used to describe ^{21}Ne diffusion in this combined geometrical and magnetic-field environment. At each diffusion step, the atom samples a local magnetic field, accumulates a Larmor phase, and contributes to the ensemble transverse magnetization. The decay envelope of the simulated macroscopic free induction signal is fitted to obtain the effective transverse relaxation time T_2 . Before being applied to stemmed cells, the model was checked in a stan-

dard cubic geometry, where its scaling agrees with the analytical gradient-relaxation expression [8].

Fig. 2 summarizes the representative simulation trend for the 3 mm cubic vapor cell used in the detailed analysis. Under a fixed polarization gradient field, shorter H_2 and larger S_1 consistently yield longer transverse relaxation times. Because the model isolates the restricted-diffusion contribution associated with the fine stem structure, the simulated values are used mainly to establish relative geometrical trends, which are then tested experimentally.

4 Results and significance for quantum metrology

The experimental results confirm that the fine stem geometry provides a practical structural degree of freedom for suppressing transverse nuclear spin relaxation. Instead of retaining the full parameter table, the key cell parameters are summarized here. Two 3 mm cubic vapor cells were used, both filled with 1 atm ^{21}Ne and 50 Torr N_2 . Vapor cell A has a relatively large filling port cross-sectional area, $S_1 = 1.762 \pm 0.022 \text{ mm}^2$, with H_2 reduced from $4.10 \pm 0.09 \text{ mm}$ to $1.29 \pm 0.08 \text{ mm}$. Vapor cell B has a much smaller filling port area, $S_1 = 0.095 \pm 0.005 \text{ mm}^2$, with H_2 reduced from $4.05 \pm 0.11 \text{ mm}$ to $1.24 \pm 0.09 \text{ mm}$. The stem shortening operation is illustrated in Fig. 3, where the red marks indicate the stem length H_2 and the blue marks indicate the filling port cross-sectional area S_1 .

Figure 3: Stem shortening operation for vapor cell B. The red marks indicate the stem length H_2 , and the blue marks indicate the filling port cross-sectional area S_1 .

The influence of S_1 is reflected by comparing the relaxation behavior of vapor cells A and B in Fig. 4(a) and Fig. 4(b). Over the 185–195 °C operating range, the cell with the smaller filling port area exhibits a transverse nuclear spin relaxation rate approximately 5–6 times higher than that of the cell with the larger filling port area. This observation is consistent with the picture of restricted diffusion: a narrow filling port enhances confinement in the stem region, prolongs the field-correlation time experienced by diffusing nuclear spins, and thereby increases gradient-induced relaxation.

The effect of H_2 is obtained from the before-and-after comparison within each vapor cell. As shown in Fig. 4, stem shortening reduces $R_2 = 1/T_2$ in both vapor cells over the practical operating range of 185-195 °C. This reduction is especially pronounced for vapor cell B, where shortening H_2 from approximately 4.05 mm to 1.24 mm increases the relaxation suppression efficiency from 35% to 49%. The stronger suppression at elevated temperatures indicates that the geometrical contribution becomes more significant when polarization-gradient relaxation is enhanced by increased alkali density.

Figure 4: Transverse nuclear spin relaxation rate before and after stem trimming. (a) Vapor cell A. (b) Vapor cell B.

These results indicate that vapor cell geometry is an active part of the coherence budget in SERF quantum sensors, rather than a passive fabrication constraint. By tuning S_1 and H_2 , the diffusion pathways of noble gas atoms can be engineered to weaken their correlation with polarization gradient fields, thereby suppressing a structural source of transverse nuclear spin relaxation. This mechanism complements optical homogenization and magnetic field compensation by acting directly on how nuclear spins sample the gradient field through

restricted diffusion [9]. The resulting relaxation suppression provides a geometry-level design principle for compact SERF quantum metrology platforms where long-lived nuclear spin coherence is essential.

A full technical version of this work, including the relaxation model, Monte Carlo simulation, vapor-cell preparation, uncertainty analysis, and experimental validation, has been published in Measurement [10].

Abstract. In this work, we show that a two-qubit entangled state admitting at least one *pure* steered state is Einstein-Podolsky-Rosen (EPR) steerable from Alice to Bob. Pure steered states signifies that the quantum steering ellipsoid of Bob is tangent to his Bloch sphere at least at a single point. Furthermore, we prove that for a two-qubit entangled state, Bob's quantum steering ellipsoid is tangent to his Bloch sphere at exactly N points, for $N \in \{0, 1, 2, \infty\}$, so is the ellipsoid of Bob. For any two-qubit entangled state, therefore, if one party can steer the other to at least one pure state, the state is two-way EPR steerable.

Keywords: EPR steering, LHS model, Quantum steering ellipsoid, Pure steered state, Tangency point

1 Introduction

Einstein-Podolsky-Rosen (EPR) steering can be formulated in a two-party scenario, for instance, involving Alice and Bob, where Alice, by performing local measurements, can remotely prepare an assemblage of conditional states for Bob in a way that cannot be reproduced by any local hidden-state (LHS) model [1, 2, 3]. In contrast to entanglement [1, 2] and Bell nonlocality [4], EPR steering contains intrinsic asymmetry since it corresponds to a one-sided device-independent scenario. Consequently, one party's steerability does not necessarily imply steerability by other parties [3]. For practical applications, EPR steering is essential for realizing one-sided device-independent quantum protocols [5].

Detection of EPR steering, being of both fundamental and practical interest, is a challenging problem in quantum information theory [6]. Despite extensive efforts, the problem is still far from being fully understood, even for two-qubit states. The main difficulty arises because arbitrary projective measurements are allowed. Bell-diagonal states [7] are so far the only case for which a necessary and sufficient condition has been derived analytically [8, 9]. Otherwise, there exist entangled states for which even known numerical methods, e.g., Ref. [10], fail to determine the steering bounds [11]. Interestingly, these states admit a pure steered state, which also makes the construction of an LHS model exceptionally difficult. All these naturally raise the converse question of whether the existence of a pure steered state implies EPR steering, or not. Quantum steering ellipsoid (QSE) is a useful tool to tackle the question [8, 12, 13]. Notice that a physically realizable QSE may be tangent to the Bloch sphere at zero, one, two, or infinitely many points, where each point corresponds to a pure steered state [14]. Although the usefulness of a pure steered state has been evidenced [15, 16, 17], it remains valid only in limited cases.

In this work, we establish a general sufficient condition for two-qubit EPR steering in terms of a pure steered

Figure 1: One-to-one correspondence between the pair $\{\mathcal{E}_B, \mathbf{b}\}$ and the assemblage $\{p_{\pm|s}\rho_{\pm|s}\}_s$ obtained from all projective measurements. The point $\mathbf{b}$ inside QSE $\mathcal{E}_B$ and the points $\mathbf{s}_\pm$ on its surface represent the Bloch vectors of Bob's reduced state ρ_B and the steered states $\rho_{\pm|s}$, respectively. $\{\mathcal{E}_B, \mathbf{b}\}$ and $\{p_{\pm|s}\rho_{\pm|s}\}_s$ determine each other and hence determine EPR steerability from Alice to Bob.

state. We show that a two-qubit state is two-way EPR steerable whenever the assemblage generated by all possible projective measurements contains at least one pure steered state. Equivalently, the condition for two-way steering can be rephrased as a QSE being tangent to the Bloch sphere at least at a single point. We prove this result by exploiting the one-to-one correspondence between the assemblage and Bob's QSE, together with his Bloch vector. We show that no LHS model can reproduce the assemblage in this scenario.

Preliminaries. EPR steering, an assemblage, and quantum steering ellipsoid (QSE) are related as follows. For any two-qubit state ρ_{AB} , if Alice performs all possible projective measurements, the set of Bob's possible conditional states, together with their probabilities, can be denoted by an assemblage $\Sigma_B := \{p_{\pm|s}\rho_{\pm|s}\}_{s \in \mathcal{S}}$ [18]. In the context of an LHS model, EPR steerability is fully characterized by the assemblage Σ_B [3, 18]. The surface of QSE of Bob is the set of all Bloch vectors of Bob's normalized conditional states that Alice can remotely prepare by performing all possible projective measurements on her subsystem [12]. Moreover, Σ_B determines both Bob's QSE $\mathcal{E}_B$ and the Bloch vector $\mathbf{b}$ of his reduced state

*songqiucheng@kaist.ac.kr

†joonwoo.bae@kaist.ac.kr

Figure 2: Illustration of Alice's response function in a hypothetical LHS model. If an LHS model exists, it must include the pure state ρ_p at the tangency point p with sufficient probability, together with other LHSs distributed over the Bloch ball $\mathcal{B}$ with probability density μ . Any steered state σ_e at point e on the QSE $\mathcal{E}$ can be simulated by ρ_p with some probability, together with LHSs within a region $\mathcal{B}^+$ specified by the response function $p(+|\hat{n}_e, \lambda)$. We find that no LHS model exists in this scenario.

ρ_B of ρ_{AB} ; we denote this pair by $\{\mathcal{E}_B, \mathbf{b}\}$. Conversely, $\{\mathcal{E}_B, \mathbf{b}\}$ determines Σ_B , and hence also determines EPR steerability from Alice to Bob. Hence, there exists a one-to-one correspondence between $\{\mathcal{E}_B, \mathbf{b}\}$ and Σ_B obtained from all possible projective measurements as shown in Fig. 1.

We now specify the scenario considered in this work.

Definition 1 (Scenario) Let Alice and Bob share a two-qubit entangled state. Alice is allowed to perform arbitrary projective measurements on her subsystem, thereby generating an assemblage, denoted by Σ_B , for Bob. The assemblage contains at least one pure state with nonzero probability. Equivalently, Bob's quantum steering ellipsoid, denoted by $\mathcal{E}_B$, is tangent to his Bloch sphere $\mathcal{S}_B$ at least at a single point.

We first show that no LHS model with finitely many local hidden states can reproduce this scenario.

Lemma 2 A finite number of local hidden states cannot construct a model for a scenario in which a quantum steering ellipsoid with nonzero volume has at least one tangency point with a Bloch sphere.

The proof, as well as the proofs of all subsequent theorems, is provided in the extended version posted as arXiv:2605.18243. We now state one of our main results.

Theorem 3 For a quantum steering ellipsoid of Bob with nonzero volume, exactly one tangency point between the ellipsoid and a Bloch sphere implies EPR steering from Alice to Bob.

Alice's response function is illustrated in Fig. 2. We find that no LHS model exists in this scenario. If $\mathcal{E}$ is tangent to $\mathcal{S}$ at two points in Scenario 1, then the following result holds.

Figure 3: The one-to-one correspondence between Alice's pure steered state $|\alpha\rangle$ and Bob's pure steered state $|\beta\rangle$.

Theorem 4 For a quantum steering ellipsoid of Bob with nonzero volume, exactly two tangency points between the ellipsoid and his Bloch sphere imply EPR steering from Alice to Bob.

Theorems 3 and 4 establish criteria for EPR steering from Alice to Bob when a QSE has one or two tangency points. EPR steering from Bob to Alice can be found as follows.

Theorem 5 For a two-qubit entangled state, a quantum steering ellipsoid of Alice is tangent to her Bloch sphere at exactly N points for $(N \in \{0, 1, 2, \infty\})$, so is the ellipsoid of Bob.

The proofs we presented are also constructive. For instance, we have constructed five classes of two-qubit entangled states in arXiv:2605.18243. We emphasize the following key property identified in the proofs of Theorem 5, as illustrated in Fig. 3.

Proposition 6 There exists a one-to-one correspondence between Alice's pure steered state $|\alpha\rangle_A$ and Bob's pure steered state $|\beta\rangle_B$. Specifically, Alice can steer Bob's system to $|\beta\rangle_B$ via the measurement effect $|\alpha^\perp\rangle\langle\alpha^\perp|_A$, while Bob can steer Alice's system to $|\alpha\rangle_A$ via $|\beta^\perp\rangle\langle\beta^\perp|_B$, where $\langle\alpha|\alpha^\perp\rangle = 0$ and $\langle\beta|\beta^\perp\rangle = 0$.

The case $N = \infty$ corresponds to a two-qubit pure state. By Gisin's theorem, all two-qubit pure entangled states are Bell nonlocal [21]. Since Bell nonlocality implies EPR steering, such states are necessarily steerable [3]. Combining Theorems 3, 4, and 5, we obtain the following main result.

Theorem 7 Suppose that Alice and Bob share a two-qubit entangled state such that one of them can steer a pure state to the other with nonzero probability. Then, the shared state is two-way EPR steerable.

This theorem is equivalent to the following statement: For any QSE with nonzero volume, the existence of at least one point of tangency between the QSE and the Bloch sphere implies two-way EPR steering.

Example 1 We consider a class of entangled two-qubit states that admit a unique pure steered state, given by

$$\rho_{AB} = q|\psi_-\rangle\langle\psi_-| + (1-q)|0\rangle\langle 0| \otimes \frac{I}{2}, \quad (1)$$

Figure 4: QSEs for the state ρ_{AB} (1) with $q = 1/2$. The two QSEs are both tangent to the Bloch sphere $\mathcal{S}$ at the same point $|0\rangle$. Alice's QSE $\mathcal{E}_A$ is a sphere with radius $1/2$, while Bob's QSE $\mathcal{E}_B$ has semiaxes $1/\sqrt{3}$, $1/\sqrt{3}$, and $2/3$.

where $|\psi_{-}\rangle = (|01\rangle - |10\rangle)/\sqrt{2}$ and $0 < q \leq 1$. The state is entangled for all $q > 0$ and admits a local hidden-variable (LHV) model for projective measurements when $q \leq 1/2$ [22]. For $0 < q < 1$, either party, by performing the Pauli measurement σ_z , can steer the other party's state to a unique pure state, namely $|0\rangle$, with nonzero probability. According to Theorem 7, the state ρ_{AB} (1) is therefore two-way steerable, despite its asymmetry between Alice and Bob.

Figure 5: QSEs for the state ρ_{AB} (2) with $x = 3/4$. Alice's QSE $\mathcal{E}_A$ is a sphere with radius $2/3$ and is tangent to her Bloch sphere $\mathcal{S}_A$ at $|0\rangle$. Bob's QSE $\mathcal{E}_B$, with semiaxes $1/\sqrt{3}$, $1/\sqrt{3}$, and $1/2$, is tangent to his Bloch sphere $\mathcal{S}_B$ at the state $(\sqrt{3}|0\rangle + |1\rangle)/2$.

Example 2 The second example is given by

$$\rho_{AB} = \begin{pmatrix} \frac{1}{4} & 0 & \frac{X}{2\sqrt{3}} & \frac{1-x}{2\sqrt{3}} \\ 0 & \frac{1}{4} & -\frac{x}{2\sqrt{3}} & -\frac{X}{2\sqrt{3}} \\ \frac{X}{2\sqrt{3}} & -\frac{x}{2\sqrt{3}} & \frac{x}{2} & \frac{1}{2}X \\ \frac{1-x}{2\sqrt{3}} & -\frac{X}{2\sqrt{3}} & \frac{1}{2}X & \frac{1-x}{2} \end{pmatrix} \quad (2)$$

where $0 < x < 1$ and $X := \sqrt{x(1-x)}$. Alice can steer Bob's system to the unique pure state $|\beta\rangle_B = \sqrt{x}|0\rangle + \sqrt{1-x}|1\rangle$ by the measurement effect $|1\rangle\langle 1|$. Similarly, Bob can steer Alice's system to the unique pure state $|\alpha\rangle_A = |0\rangle$ by the measurement effect $|\bar{b}\rangle\langle \bar{b}|$, where $|\bar{b}\rangle = \sqrt{1-x}|0\rangle - \sqrt{x}|1\rangle$. We show an illustrative example for the state ρ_{AB} (2) with $x = 3/4$ as shown in Fig. 5.

Figure 6: QSEs for the state ρ_{AB} (3) with $x = 1/2$, $y = 1/2$, and $z = 1/3$. Alice's QSE $\mathcal{E}_A$ is tangent to her Bloch sphere $\mathcal{S}_A$ at $|0\rangle$, while Bob's QSE $\mathcal{E}_B$ is tangent to his Bloch sphere $\mathcal{S}_B$ at $|1\rangle$.

Example 3 The third example is defined as

$$\rho_{AB} = \begin{pmatrix} xy & -XyZ_+ & 0 & \sqrt{x}YZ_- \\ -XyZ_+ & y - xy & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \sqrt{x}YZ_- & 0 & 0 & 1 - y \end{pmatrix} \quad (3)$$

where $0 < x, y, z < 1$, $X := \sqrt{x(1-x)}$, $Y := \sqrt{y(1-y)}$ and $Z_{\pm} := \frac{1}{2}(\sqrt{z} \pm \sqrt{2-2z})$. Alice can steer Bob's system to the unique pure state $|\beta\rangle_B = |1\rangle$ by the measurement effect $|1\rangle\langle 1|$. Similarly, Bob can steer Alice's system to the unique pure state $|\alpha\rangle_A = |0\rangle$ by the measurement effect $|0\rangle\langle 0|$. We show an illustrative example for the state ρ_{AB} (3) with $x = 1/2$, $y = 1/2$, and $z = 1/3$ as shown in Fig. 6.

Remark 1 Our results solve a critical problem in steering detection that remains inaccessible even to known numerical methods [10, 11]. We provide a simple sufficient condition for detecting two-qubit steering based on quantum steering ellipsoids: if the ellipsoid is tangent to the Bloch sphere at least a single point, equivalently, if the corresponding assemblage contains one pure steered state, then the two-qubit entangled state is two-way EPR steerable. This result identifies steerable states beyond the reach of existing numerical approaches. Our results are also practical, leading to a substantial simplification in the verification of EPR steering.

Remark 2 We remark that our results establish the Gisin theorem [21] for EPR-steering. Our results ask about the significance of pure states in quantum steering, as in Bell nonlocality, where pure entangled states imply nonlocality. Namely, we have established the framework for EPR steering in terms of pure steered states. As the Gisin theorem generalizes to arbitrary pure states [23, 24], it would also be interesting to determine whether our results with a pure steered state hold in high-dimensional and multipartite quantum systems.

Bridging Quantum Mechanics and ETH: Irreversible Correlations as the Arrow of Time

Qing-yu Cai,¹ *

² *School of Physics and Optoelectronic Engineering, Hainan University, Haikou 570228, China*

Abstract. The reconciliation between the unitarity of quantum mechanics and the irreversibility of thermodynamics remains a foundational challenge in quantum information physics. While the Second Law dictates an arrow of time via monotonic entropy growth, closed quantum systems undergo unitary evolution that strictly conserves global von Neumann entropy. This tension is particularly manifest in the Eigenstate Thermalization Hypothesis (ETH), which describes how isolated quantum many-body systems come to thermalize locally. In this work, we provide a rigorous quantum-mechanical foundation for the arrow of time and local thermalization by shifting the focus to correlation dynamics. We establish a foundational no-go theorem proving that total correlations (quantified by quantum mutual information) in unknown states of closed quantum systems cannot be universally removed or reduced by any completely positive and trace-preserving (CPTP) physical operation. This structural constraint elevates correlation generation to an inherently irreversible process under information-conserving unitary dynamics. When applied to multi-particle quantum systems undergoing ETH, this fundamental irreversibility guarantees that chaotic scrambling and operator spreading accelerate correlation build-up. As a result, subsystems inevitably evolve from pure to mixed states by diffusing localized information into global complex correlations. This mechanism increases the effective microstate space accessible to subsystems, driving the monotonic growth of thermodynamic entropy and irreversible relaxation toward equilibrium without requiring any coarse-graining assumptions. Furthermore, we show that this non-decreasing behavior of correlations underpins the consistency of quantum entropy production, establishing it as a reliable metric for a local arrow of time. Our findings bridge information theory and statistical mechanics, providing a unified framework for quantum irreversibility spanning from multi-body ETH systems to black hole evaporation dynamics.

Abstract. Quantum walks are versatile algorithms for solving many problems. We develop efficient classical simulation methods for Szegedy quantum walks without explicitly constructing the full unitary operator. Our framework, based on update and reflection operators, supports broader Szegedy walk formulations than previous approaches. We also extend these methods to simulate QPE-based algorithms, including implementations for large sparse graphs. The algorithms achieve optimal $O(N^2)$ scaling for dense graphs and linear scaling with the number of edges for sparse graphs. We implement these techniques in the Python package SQWLib and demonstrate applications to quantum simulated annealing and quantum search on graphs.

Keywords: Quantum Machine Learning, Quantum Walks, Classical Simulation.

1 Introduction

Quantum walks are a central framework in quantum computing, often providing quadratic speedups over classical random walks for a wide range of computational problems. Among them, the Szegedy quantum walk [1] offers a general quantization of arbitrary Markov chains and has found applications in problems of optimization [2, 3], classification [4], quantum search [5], and blockchain technologies [6]. In particular, when combined with quantum phase estimation (QPE), Szegedy walks enable algorithms such as quantum simulated annealing and search protocols with potential quantum advantages and high impact on quantum machine learning.

Despite their theoretical importance, the numerical study of Szegedy quantum walks remains limited. Existing simulation methods typically require constructing the full unitary evolution operator, leading to computational costs scaling as $\mathcal{O}(N^3)$ for graphs with N nodes. Recently, more efficient methods avoiding explicit unitary construction reduced this complexity to $\mathcal{O}(N^2)$ for dense graphs [7]. However, those approaches are restricted to the original walk formulation and cannot simulate QPE-based algorithms.

In this work, we develop a generalized classical simulation framework for Szegedy quantum walks and QPE-based protocols without explicitly constructing the full unitary operator. Our approach is based on the direct simulation of more fundamental operators, enabling efficient implementation of multiple Szegedy walk formulations. Furthermore, we extend these techniques to sparse graphs, where the computational complexity scales linearly with the number of edges.

We implement these methods in a Python package called SQWLib, extending the capabilities of the previous framework. Using this library, we demonstrate simulations of representative algorithms, including quantum simulated annealing [8] and quantum search on graphs [9].

2 Szegedy Quantum Walk

Consider a classical Markov chain represented by a transition matrix G on a graph with N nodes. The Szegedy quantum walk is defined on the Hilbert space

$$\mathcal{H} = \mathbb{C}^N \otimes \mathbb{C}^N, \quad (1)$$

where the first register represents the walker position and the second register encodes possible transitions.

For each node i , we define the state

$$|\psi_i\rangle = |i\rangle \otimes \sum_{k=0}^{N-1} \sqrt{G_{ki}} |k\rangle. \quad (2)$$

The walk evolution is generated using two operators: a reflection R around the states $|\psi_i\rangle$:

$$R = 2 \sum_i |\psi_i\rangle \langle \psi_i| - \mathbb{I}, \quad (3)$$

and a swap operator S :

$$S|i, j\rangle = |j, i\rangle. \quad (4)$$

The quantum walk evolution is obtained by first applying the reflection operator, which is equivalent to tossing a coin for deciding the next transition, followed by the swap operator that produces the movement [10]. Thus, the unitary evolution operator is defined as

$$U = SR. \quad (5)$$

The reflection operator R can be decomposed in more fundamental operators. Let us define an update operator V such that

$$V|i, 0\rangle = |\psi_i\rangle. \quad (6)$$

This allows decomposing the reflection R as

$$R = VR_0V^\dagger, \quad (7)$$

where R_0 is a reflection around the states $|i, 0\rangle$. Rearranging these fundamental operators leads to alternative walk constructions useful for wider algorithms. For example, an interesting formulation used for annealing schemes is the following

$$\tilde{U} = V^\dagger SVR_0. \quad (8)$$

Figure 1: Expansion-recomposition example for a graph with $N = 3$ nodes. For the expansion in the set of states $|x_i\rangle$, the coefficients are calculated by the element-wise multiplication of the matrix X and the matrix state Φ , and then adding over the rows. For the recomposition on a set of states $|y_i\rangle$, the coefficients vector C is multiplied element-wise with each row of the matrix Y .

3 Efficient Classical Simulation

Direct simulation of the walk would require constructing an $N^2 \times N^2$ unitary matrix, resulting in prohibitive memory and computational costs. To avoid this, we first represent arbitrary quantum states as $N \times N$ matrices rather than vectors. Let us consider the following arbitrary state:

$$|\phi\rangle = \sum_{i,j} a_{ij} |i, j\rangle. \quad (9)$$

The amplitudes a_{ij} are stored in a matrix Φ whose entries correspond to basis-state amplitudes.

With this representation, the swap operator can be simulated simply by transposing the matrix state, and the reflection R_0 inverting the sign of the first row. The difficult part lies in the update operator V . In this work we show how it can be simulated using element-wise operations between $N \times N$ matrix objects, so that the computational complexity of the simulation algorithm achieve optimal $\mathcal{O}(N^2)$ scaling in both time and memory for dense graphs. Concretely, its simulation lies in a primitive operation we denote as expansion-recomposition, whose generic operator is

$$\Pi_{XY} = \sum_{i=0}^{N-1} |y_i\rangle \langle x_i|, \quad (10)$$

where the states $|x_i\rangle$ (and also $|y_i\rangle$) are defined as

$$|x_i\rangle := |i\rangle_1 \otimes \sum_{k=0}^{N-1} X_{ki} |k\rangle_2. \quad (11)$$

with X (or Y) an $N \times N$ matrix. The simulation process for this primitive is shown in Figure 1.

For sparse graphs, we exploit the reduced Hilbert subspace associated with the graph backbone, reducing the computational cost to scale linearly with the number of edges.

4 Quantum Phase Estimation Simulation

Many important Szegedy-based algorithms rely on quantum phase estimation. Standard simulation approaches would require explicit controlled-unitary matrices, which become infeasible for large systems. Instead, we simulate QPE directly using the efficient methods for the walk operators described previously.

An arbitrary QPE state can be expressed as

$$|\xi\rangle = \sum_{x=0}^{2^p-1} a_x |x\rangle \otimes |\phi_x\rangle, \quad (12)$$

where the first register stores the phase information and the second corresponds to walk states. Thus, it can be

Figure 2: How to apply the controlled- U operations of the QPE circuit on an arbitrary state $|\xi\rangle$, for an example with $p = 3$ phase qubits, i.e., $2^p = 8$ columns. At each time step of a *for* loop, the walk evolution is applied in a vectorized manner to a batch of column states. This batch decreases its size at each time step from the left, so that in the end, the x -th column has evolved x times. The initial batch (red) comprises the states from $x = 1$, decreasing its size until $x = 2^p - 1 = 7$ (brown).

represented as a matrix state where each column corresponds to a walk state. Controlled unitaries of the walk in the QPE circuit correspond to different powers of the unitary on each walk state. These are implemented by evolving batches of walk states in a vectorized manner (see Figure 2). Regarding the Hadamard gates and the inverse quantum Fourier transforms acting on the phase register, they are simulated using efficient classical FFT and Walsh-Hadamard transforms along the column axis.

5 Applications and Results

The developed algorithms were implemented in the Python package SQWLib. We tested the framework on several representative quantum-walk algorithms. For example, the quantum simulated annealing, which samples the stationary distribution of reversible Markov chains associated with Boltzmann distributions. Another example is the quantum search on graphs, which allows to sample the reduced stationary distribution of a Markov chain in a set of marked nodes, with a quantum speedup. These examples demonstrate that the proposed framework enables practical simulations of complex quantum-walk-based algorithms that were previously inaccessible without explicit unitary construction.

Abstract. We investigate one- and two-qubit reduced-state stabilizer Rényi entropy (SRE), associated with non-stabilizer resources (quantum magic), as a probe of quantum phase transitions in the transverse axial next-nearest-neighbor Ising (TANNNI) model and the one-dimensional quantum compass model (QCM). In the TANNNI model, the purity-corrected SRE detects the antiphase–floating phase transition in the high-frustration regime, while the raw SRE better captures the ferromagnetic–paramagnetic transition in the low-frustration regime. For the QCM, the reduced-state SRE clearly signals the first-order transition at $J_x/J_z = 1$. Our results demonstrate that reduced-state SRE provides an efficient and complementary indicator of quantum criticality in these spin systems.

Keywords: Quantum magic, Stabilizer Rényi entropy, Quantum phase transition, Transverse ANNNI model, Quantum compass model

1 Introduction

Quantum phase transitions (QPTs) are driven by quantum fluctuations and are accompanied by significant restructuring of quantum correlations in the ground state [2]. Quantum-information-theoretic quantities such as entanglement entropy, concurrence, quantum discord, and coherence have been widely used to characterize critical behavior in many-body systems [3–6]. Recently, quantum magic has emerged as an important nonclassical resource associated with the computational advantage of universal quantum computation beyond the stabilizer formalism [7–10].

The stabilizer Rényi entropy (SRE) provides a computationally accessible measure associated with non-stabilizer resources. For an n -qubit density matrix ρ , the second-order SRE is defined as

$$M_2(\rho) = -\log_2 \left(\frac{1}{2^n} \sum_{P \in \mathcal{P}_n} [\text{Tr}(\rho P)]^4 \right), \quad (1)$$

where $\mathcal{P}_n$ denotes the n -qubit Pauli group. For mixed reduced states, we use the purity-corrected form

$$\widetilde{M}_2(\rho) = M_2(\rho) - S_2(\rho), \quad (2)$$

where $S_2(\rho) = -\log_2 \text{Tr}(\rho^2)$ is the second-order Rényi entropy.

Direct evaluation of SRE for full many-body states becomes exponentially expensive with increasing system size because the number of Pauli operators scales as 4^n . This difficulty is avoided in our study by considering one- and two-qubit reduced density matrices, where the relevant Pauli operator set remains small. This reduced-density-matrix approach enables efficient numerical analysis while preserving signatures of the underlying many-body criticality.

2 TANNNI Model

The Hamiltonian of the transverse axial next-nearest-neighbor Ising (TANNNI) model is given by

$$H = -J_1 \sum_i \sigma_i^z \sigma_{i+1}^z + J_2 \sum_i \sigma_i^z \sigma_{i+2}^z - \gamma \sum_i \sigma_i^x, \quad (3)$$

where J_1 and J_2 denote nearest-neighbor and next-nearest-neighbor couplings, respectively, and γ is the transverse field. Competition between J_1 and J_2 introduces frustration and leads to a rich phase diagram containing ferromagnetic, paramagnetic, floating, and antiphase regions.

We compute the ground state of the TANNNI model using exact diagonalization and evaluate both the purity-corrected stabilizer Rényi entropy $\widetilde{M}_2$ and the raw (purity-uncorrected) stabilizer Rényi entropy M_2 of reduced density matrices. For the high-frustration regime ($J_2/J_1 > 0.5$), the purity-corrected SRE exhibits a pronounced change in curvature near the antiphase–floating phase transition. Correspondingly, the first derivative of $\widetilde{M}_2$ develops a sharp peak whose position converges toward the known critical point with increasing system size.

In contrast, in the low-frustration regime ($J_2/J_1 < 0.5$), the raw SRE M_2 detects the known ferromagnetic–paramagnetic phase boundaries more accurately than the purity-corrected quantity. The minima of $d(M_2)/d(\gamma/J_1)$ systematically approach the known quantum critical points through finite-size scaling analysis. These observations indicate that the mixedness contribution associated with entanglement in the reduced density matrix plays an important role in the low-frustration regime.

To compare the transitions extracted from the reduced-state SREs with the established phase structure of the TANNNI model, we summarize the transition lines obtained from both $\widetilde{M}_2$ and M_2 in the phase diagram shown in Fig. 1, together with the known phase boundaries from Ref. [11]. The black circular markers denote the transition points obtained from the purity-corrected SRE $\widetilde{M}_2$, while the blue triangular markers correspond to the transition points extracted from the raw

*georgebsws@gmail.com

†anindya@nitsikkim.ac.in

Figure 1: Phase diagram of the TANNNI model from [11], together with the transition lines extracted from the reduced-state purity corrected stabilizer Rényi entropy, raw stabilizer Rényi entropy, and Rényi entropy. The thin black curve with circular markers represents the transition points obtained from the purity-corrected SRE $\tilde{M}_2$, the blue triangle markers denote the transition points extracted from the raw (purity-uncorrected) SRE M_2 , and the red square marks denoted the transition points extracted from the Rényi entropy. The $\tilde{M}_2$ -based transition shows a mismatch with the established phase boundaries for $J_2/J_1 < 0.5$, whereas for $J_2/J_1 \geq 0.5$ it aligns well with the antiphase–floating phase boundary. In contrast, the transition points obtained from the raw M_2 are found to agree with the known quantum phase boundaries in both the low- and high-frustration regimes. The S_2 transition lines mismatch in the low frustration regime.

SRE M_2 . We observe that the $\tilde{M}_2$ -based transition line agrees well with the known antiphase–floating phase boundary in the high-frustration regime, whereas the raw M_2 -based transition points align with the established phase boundaries more accurately in the low-frustration regime. For completeness, we also investigate the behavior of S_2 itself as a probe of quantum criticality. We observe that, in the low-frustration regime, the transition points extracted from S_2 exhibit noticeable deviations from the known quantum phase boundaries. The transition points obtained from S_2 are also summarized in Fig. 1, where they are represented by red square markers.

We also compare the behavior of one-qubit and two-qubit reduced-state SREs and observe that both capture the same underlying critical behavior, despite quantitative differences in the numerical values of the SRE.

As representative examples, in Fig. 2 and Fig. 3, we present the behavior of the purity-corrected SRE $\tilde{M}_2(\rho_1)$ and the raw SRE $M_2(\rho_1)$, respectively, for the one-qubit reduced density matrix at $J_2/J_1 = 0.2$. The figures show the corresponding first derivatives with respect to γ/J_1 together with finite-size scaling analyses of the extracted critical points. For completeness, Fig. 4 shows a representative example of the behavior of S_2 near the phase transition points. These representative cases clearly illustrate the distinct critical signatures obtained from

Figure 2: Purity corrected stabilizer Rényi entropy (in left inset) of one qubit reduced density matrix ($\tilde{M}_2(\rho_1)$) and its first derivative with respect to the ratio of the transverse field strength to the nearest neighbor interaction strength, $\frac{d(\tilde{M}_2(\rho_1))}{d(\gamma/J_1)}$, plotted as functions of γ/J_1 for $J_2/J_1 = 0.2$. The figure shows results for two system sizes, $N = 16$ (blue curves) and $N = 24$ (black curves). The right inset panels display the finite-size scaling behavior of the maxima in $\frac{d(\tilde{M}_2(\rho_1))}{d(\gamma/J_1)}$. The critical points in the thermodynamic-limit are estimated from the finite-size scaling behavior. The estimated thermodynamic-limit critical points (C) corresponding to each frustration parameter are indicated in the respective right inset panels.

Figure 3: Purity uncorrected stabilizer Rényi entropy (in left inset) of one qubit reduced density matrix ($M_2(\rho_1)$) and its first derivative with respect to the ratio of the transverse field strength to the nearest neighbor interaction strength, $\frac{d(M_2(\rho_1))}{d(\gamma/J_1)}$, plotted as functions of γ/J_1 for $J_2/J_1 = 0.2$. The figure shows results for two system sizes, $N = 16$ (blue curves) and $N = 24$ (black curves). The right inset panels display the finite-size scaling behavior of the minima in $\frac{d(M_2(\rho_1))}{d(\gamma/J_1)}$, demonstrating the convergence of the finite-size critical points $C(N)$ toward the known thermodynamic-limit values with increasing system size. The known quantum critical points (C) corresponding to each frustration parameter are indicated in the respective right inset panels.

Figure 4: Rényi entropy (in left inset) of one qubit reduced density matrix ($S_2(\rho_1)$) and its first derivative with respect to the ratio of the transverse field strength to the nearest neighbor interaction strength, $\frac{d(S_2(\rho_1))}{d(\gamma/J_1)}$, plotted as functions of γ/J_1 for $J_2/J_1 = 0.3$. The figure shows results for two system sizes, $N = 16$ (blue curves) and $N = 24$ (black curves). The right inset panels display the finite-size scaling behavior of the maxima in $\frac{d(S_2(\rho_1))}{d(\gamma/J_1)}$. The critical points in the thermodynamic-limit are estimated from the finite-size scaling behavior. The estimated thermodynamic-limit critical points (C) corresponding to each frustration parameter are indicated in the respective right inset panels.

the purity-corrected and uncorrected forms of the reduced-state SRE in the low-frustration regime.

3 Quantum Compass Model

The Hamiltonian of the one-dimensional quantum compass model (QCM) is

$$H = - \sum_{i=1}^{N/2} (J_x \sigma_{2i-1}^x \sigma_{2i}^x + J_z \sigma_{2i}^z \sigma_{2i+1}^z). \quad (4)$$

The system undergoes a first-order quantum phase transition at the isotropic point $J_x/J_z = 1$.

To analyze the model, we employ the Jordan–Wigner (JW) transformation and map the spin Hamiltonian to a quadratic fermionic Hamiltonian. The resulting Bogoliubov–de Gennes Hamiltonian is diagonalized independently for each momentum mode. From the fermionic correlation matrix, we construct the reduced density matrices [12–13] and compute the corresponding SRE.

Our numerical results show that the purity-corrected SRE exhibits a clear change in curvature near the isotropic point. The derivative of $\widetilde{M}_2$ develops a pronounced dip at the same location, providing a direct signature of the first-order phase transition. Both one-qubit and two-qubit reduced-state SREs consistently capture the transition. The two-qubit case is shown in Figure 5.

4 Conclusion

We investigated reduced-state stabilizer Rényi entropy as a probe of quantum criticality in the TANNNI model and the one-dimensional quantum compass model. The reduced-density-matrix approach significantly simplifies the numerical

Figure 5: Purity corrected stabilizer Rényi entropy of two qubit reduced density matrix $\widetilde{M}_2(\rho_2)$ (in the inset) and its first derivative with respect to the coupling ratio $\frac{d(\widetilde{M}_2(\rho_2))}{d(J_x/J_z)}$ as a function of the coupling ratio J_x/J_z for the one-dimensional quantum compass model. The plot shows that a pronounced dip in $\frac{d(\widetilde{M}_2(\rho_2))}{d(J_x/J_z)}$ appears at the quantum phase transition point $J_x/J_z = 1$.

complexity while retaining signatures of many-body criticality.

For the TANNNI model, the purity-corrected SRE successfully captures the antiphase–floating phase transition in the high-frustration regime, while the raw SRE reproduces the known phase boundaries more accurately in the low-frustration regime. The transition points extracted from S_2 show noticeable deviations from the known phase boundaries in the low-frustration regime of the TANNNI model. This observation indicates that both the non-magic contribution S_2 and the magic contribution $\widetilde{M}_2$ need to be considered at the same time in the raw stabilizer Rényi Entropy M_2 to capture the underlying critical behavior.

For the QCM, the purity-corrected SRE clearly signals the first-order transition at the isotropic point. Our results demonstrate that reduced-state SRE provides a complementary indicator of quantum phase transitions and offers insight into the restructuring of non-stabilizer resources in many-body quantum systems.

Abstract. Quantum signal processing (QSP) implements polynomial functions on quantum computers and is widely employed as a subroutine in a wide range of algorithms. However, computing problem-specific angle sequences often suffers from numerical instability, resulting in circuit-design bottlenecks. We investigate instability arising from combining carving-based gate decomposition with the Berntson–Sünderhauf complementary polynomial, where attenuation of higher-order coefficients induces numerical ill-conditioning, and propose an alternative direction in the carving step: using the reciprocal polynomial of the complementary polynomial—a simple yet effective way to address this ill-conditioning. We demonstrate improved numerical stability and accuracy through numerical experiments on matrix inversion, Hamiltonian simulation, phase estimation, and eigenvalue filtering.

Keywords: quantum computing, quantum algorithms, QSP, QSVT

1 Introduction

Quantum Signal Processing (QSP) provides a framework for implementing polynomial transformations of block-encoded matrices [1, 2] and serves as a subroutine in many quantum algorithms [3]. In these applications, one must synthesize a problem-specific angle (phase) sequence that realizes the target transformation.

Angle synthesis methods are broadly classified into factorization-based and optimization-based approaches [4, 5]. The former is typically faster and more accurate, proceeding in two steps: (i) completion—given a target polynomial $F(\omega)$, construct a complementary $G(\omega)$ so that the associated 2×2 matrix is unitary on the unit circle—and (ii) decomposition—recover the angle sequence from (F, G) . Among completion methods [2, 6, 7, 8, 9, 10, 11], the Berntson–Sünderhauf (BS) method [11] is fast; among decompositions, carving [2] and halving [8] are common.

We observe that combining BS completion with carving decomposition can introduce ill-conditioning: the BS completion often yields complementary polynomials G with attenuated high-order coefficients, making the terminal angle ϕ_d numerically sensitive when the leading coefficients f_d and g_d are both small. This sensitivity can lead to significant errors in the recovered angle sequence. To retain computational advantages of the BS completion while addressing this issue, we propose a simple, readily integrable remedy: reverse-carving—carve on the reciprocal polynomial of G and then reverse the angles—thereby swapping the scaling of high- and low-order terms and improving numerical stability.

Our contributions.

- We formulate carving in the (W_Z, S_X) basis and identify why BS completion with carving decomposition can become ill-conditioned: the highest-degree coefficients of F and G are often strongly attenuated.

- We propose *reverse-carving*: carve on the reciprocal polynomial $G^\dagger$ (which reverses coefficient order) and then reverse the angle sequence, improving conditioning without increasing circuit depth or asymptotic cost.
- Numerical experiments on Hamiltonian simulation, matrix inversion, phase estimation, and eigenvalue filtering show consistently improved stability and accuracy.

2 Reverse-carving for (W_Z, S_X) -QSP

2.1 Preliminaries on (W_Z, S_X) -QSP [2, 8, 3]

We recall the (W_Z, S_X) -QSP framework. Let $\mathbb{T} = \{\omega \in \mathbb{C} : |\omega| = 1\}$ be the unit circle with $\omega = e^{it}$, $t \in \mathbb{R}$.

Definition 1 ((W_Z, S_X) -QSP operator sequence)

For an angle sequence $\Phi = (\phi_0, \dots, \phi_d) \in \mathbb{R}^{d+1}$,

$$U_Z(\omega, \Phi) := S_X(\phi_0) \prod_{k=1}^d (W_Z(\omega) S_X(\phi_k)), \quad (1)$$

where the signal operator $W_Z(\omega)$ and the signal-processing operator $S_X(\phi)$ are described as

$$W_Z(\omega) := e^{itZ} = \begin{pmatrix} \omega & 0 \\ 0 & \omega^{-1} \end{pmatrix}, \quad (2)$$

$$S_X(\phi) := e^{i\phi X} = \begin{pmatrix} \cos \phi & i \sin \phi \\ i \sin \phi & \cos \phi \end{pmatrix}. \quad (3)$$

Definition 2 (Unitary matrix for (W_Z, S_X) -QSP)

With real-coefficient Laurent polynomials $F, G \in \mathbb{R}[\omega, \omega^{-1}]$, let us define a unitary matrix U_{FG} as

$$U_{FG}(\omega) := \begin{pmatrix} F(\omega) & iG(\omega) \\ iG(\omega^{-1}) & F(\omega^{-1}) \end{pmatrix}. \quad (4)$$

Theorem 3 ((W_Z, S_X) -QSP [2, 8, 3])

For $d \in \mathbb{N}$, an angle sequence $\Phi \in \mathbb{R}^{d+1}$ exists such that $U_Z(\omega, \Phi) = U_{FG}(\omega)$ for all $\omega \in \mathbb{T}$, iff the following hold:

- $\deg(F) \leq d$, $\deg(G) \leq d$.
- $\text{Parity}(F) = \text{Parity}(G) = d \pmod{2}$.
- $\forall \omega \in \mathbb{T}$, $|F(\omega)|^2 + |G(\omega)|^2 = 1$.

*makino.kenzo@dw.mitsubishielectric.co.jp

2.2 Complementary Completion

Given $F(\omega)$, we seek $G(\omega)$ satisfying conditions (i)–(iii) of Theorem 3. Since the polynomial $1 - F(\omega)F(\omega^{-1})$ has roots occurring in reciprocal pairs on the real axis $\{r_i, 1/r_i\}_i$ and, off the real axis, in quadruples together with their complex conjugates $\{\xi_j, 1/\xi_j, \xi_j^*, 1/\xi_j^*\}_j$, we may factor it as

$$1 - F(\omega)F(\omega^{-1}) = c m(\omega) m(\omega^{-1}), \quad (5)$$

where $c > 0$ is a constant number and

$$m(\omega) := \prod_i (\omega - r_i) \prod_j (\omega - \xi_j) (\omega - \xi_j^*). \quad (6)$$

Imposing real coefficients on $G(\omega)$ then yields

$$G(\omega) = \sqrt{c} \omega^{-d} m(\omega). \quad (7)$$

There is arbitrariness in the root selection, so the complementary $G(\omega)$ for a given $F(\omega)$ is generally not unique [8]. In particular, the BS completion selects roots outside the unit circle in the contour integral [11]; consequently, $G(\omega)$ tends to exhibit attenuation in higher-order coefficients relative to lower-order ones, irrespective of $F(\omega)$.

2.3 Decomposition by Carving

Given $F(\omega), G(\omega)$ that satisfy Theorem 3, we consider the problem of recovering Φ such that $U_Z(\omega, \Phi) = U_{FG}(\omega)$. Based on the conventional carving method in the (W_X, S_Z) -QSP basis [2], we right-multiply the QSP operator sequence by the adjoints of the signal and signal-processing operators to reduce the degree while extracting the angles in the present (W_Z, S_X) -QSP basis.

For a degree- d sequence, right-multiplying by $S_X(\phi_d)^\dagger W_Z(\omega)^\dagger$ yields a degree- $(d-1)$ sequence, denoted by $U_{\tilde{F}\tilde{G}}$. Focusing on the first row, we have

$$\begin{pmatrix} \tilde{F}(\omega) & i\tilde{G}(\omega) \\ * & * \end{pmatrix} = \begin{pmatrix} F(\omega) & iG(\omega) \\ * & * \end{pmatrix} S_X(\phi_d)^\dagger W_Z(\omega)^\dagger,$$

and comparing the coefficients of ω^k on both sides gives

$$\tilde{f}_k = f_{k+1} \cos \phi_d + g_{k+1} \sin \phi_d, \quad (8)$$

$$\tilde{g}_k = -f_{k-1} \sin \phi_d + g_{k-1} \cos \phi_d. \quad (9)$$

For $k = d + 1$, since $\deg(\tilde{G}) \leq d - 1$, we obtain

$$0 = -f_d \sin \phi_d + g_d \cos \phi_d, \quad (10)$$

so the angle ϕ_d can be determined from the leading coefficients (f_d, g_d) . We refer to this as right-action carving. Repeating this step computes the entire QSP angle sequence as shown in Algorithm 1.

However, this procedure becomes numerically unstable at the step $\phi_k \leftarrow \text{atan2}(g_k, f_k)$ when the highest-degree coefficients of both F and G are attenuated. To mitigate this, we replace G with the reciprocal polynomial.

Definition 4 (Reciprocal polynomial)

For $G(\omega) = \sum_{k=-d}^d g_k \omega^k \in \mathbb{R}[\omega, \omega^{-1}]$, we define the reciprocal polynomial as $G^\dagger(\omega) = \sum_{k=-d}^d g_{-k} \omega^k$.

Algorithm 1 Calculate Φ in (W_Z, S_X) -QSP

```

1:  $T \leftarrow \begin{pmatrix} f_{-d} & f_{-d+1} & \cdots & f_d \\ g_{-d} & g_{-d+1} & \cdots & g_d \end{pmatrix}$ 
2:  $k \leftarrow d$ 
3: while do
4:    $f_k \leftarrow T[0, 2k + 1]$ 
5:    $g_k \leftarrow T[1, 2k + 1]$ 
6:    $\phi_k \leftarrow \text{atan2}(g_k, f_k)$ 
7:   if  $k = 0$  then
8:     break
9:   end if
10:   $\tilde{T} \leftarrow \begin{pmatrix} \cos \phi_k & \sin \phi_k \\ -\sin \phi_k & \cos \phi_k \end{pmatrix} T$ 
11:   $T[0, :] \leftarrow \tilde{T}[0, 2 : 2k + 1]$ 
12:   $T[1, :] \leftarrow \tilde{T}[1, 0 : 2k - 1]$ 
13:   $k \leftarrow k - 1$ 
14: end while
15: return  $(\phi_0, \phi_1, \dots, \phi_d)$ 
```

Theorem 5 (Transpose property of $U_Z(\omega, \Phi)$)

Let F, G satisfy the conditions (i)–(iii) of Theorem 3. Then F and $G^\dagger$ also satisfy them, and $U_Z(\omega, \Phi') = U_{FG^\dagger}(\omega)$, where $\Phi' = (\phi_d, \dots, \phi_0)$ is the reversal of Φ .

Proof. From Definition 4, $\forall \omega \in \mathbb{T}$, $G^\dagger(\omega) = G(\omega^{-1}) = \overline{(G(\omega))^*}$ and $|G^\dagger(\omega)|^2 = |G(\omega)|^2$, hence F together with $G^\dagger$ satisfies Theorem 3. Moreover,

$$U_Z(\omega, \Phi') = U_Z(\omega, \Phi)^\top = U_{FG}(\omega)^\top = U_{FG^\dagger}(\omega). \quad \square$$

We now present the algorithm for the proposed reverse-carving method in Algorithm 2. This is equivalent to left-multiplying $U_Z(\omega, \Phi)$ by $W_Z(\omega)^\dagger S_X(\phi_k)^\dagger$ to reduce the degree, and can be regarded as left-action carving.

Algorithm 2 reverse-carving: calculate Φ in (W_Z, S_X) -QSP

```

1:  $T \leftarrow \begin{pmatrix} f_{-d} & f_{-d+1} & \cdots & f_d \\ g_d & g_{d-1} & \cdots & g_{-d} \end{pmatrix}$ 
: (same updates as lines 2–14 of Algorithm 1)
15: return  $(\phi_d, \phi_{d-1}, \dots, \phi_0)$ 
```

3 Applications and Case Studies

As a demonstration, we compute QSP angle sequences for Hamiltonian simulation, matrix inversion, phase estimation, and eigenvalue filtering. We follow a unified pipeline: (i) approximate the target function $f(x)$ with a degree- d polynomial $p_d(x)$ and set $F(\omega) = p_d(\frac{\omega + \omega^{-1}}{2})/\alpha$, where α is a scaling factor; (ii) complete to a pair (F, G) via the Berntson–Sünderhauf (BS) method; and (iii) extract Φ by reverse-carving (Algorithm 2). The resulting Φ can be converted into a quantum singular value transformation (QSVT) phase sequence [3].

3.1 Hamiltonian Simulation

The target function is $f(x) = e^{-i\tau x}$ with $\tau \in \mathbb{R}$ [1, 2]. We take $p_d(x)$ to be the degree- d truncation of the

Figure 1: QSP outputs (top) and error vs. degree (bottom). (a, e) Hamiltonian simulation, (b, f) matrix inversion, (c, g) phase estimation, (d, h) eigenvalue filtering. Blue lines and cross marks show the results of right-action carving (Algorithm 1) for comparison, while red lines and dots show the results of left-action carving (Algorithm 2).

Jacobi–Anger expansion:

$$e^{-i\tau x} = J_0(\tau) + 2 \sum_{k=1}^{\infty} (-i)^k J_k(\tau) T_k(x), \quad (11)$$

where T_k and J_k denote the Chebyshev and Bessel functions, respectively. For the experiments, we set $\tau = 10$ and split $p_d(x)$ into its even and odd parts.

3.2 Matrix Inversion

The target function is $f(x) = 1/x$ on $|x| \in [a, 1]$ with $a \in (0, 1)$ [12]. According to [13, 14, 15], the minimax odd polynomial of degree $d = 2n - 1$ is described as

$$p_d(x) = \begin{cases} \frac{1}{x} - \frac{L_n\left(\frac{2x^2 - (1+a^2)}{1-a^2}\right)}{x L_n\left(-\frac{1+a^2}{1-a^2}\right)} & x \neq 0, \\ 0 & x = 0, \end{cases} \quad (12)$$

where

$$L_n(u) = \frac{1}{2^{n-1}} \left(T_n(u) + \frac{1-a}{1+a} T_{n-1}(u) \right). \quad (13)$$

We set $a = 0.1$ for the experiments.

3.3 Phase Estimation

The target function is $f(x) = \text{sgn}(\frac{1}{\sqrt{2}} - |x|)$ on $x \in [0, 1] \setminus [\frac{1}{\sqrt{2}} - \frac{\delta}{2}, \frac{1}{\sqrt{2}} + \frac{\delta}{2}]$ with $\delta \in (0, 2(\cos(3\pi/16) - 1/\sqrt{2})) \approx (0, 0.248)$ [3]. Since $f(x)$ is an even function, we approximate it with an even polynomial $p_d(x)$ of degree $d = 2n$:

$$p_d(x) = \sum_{k=0}^n c_k T_{2k}(x), \quad (14)$$

with the Remez algorithm. We set $\delta = 0.2$ for the experiments.

3.4 Eigenvalue Filtering

We design an even, two-sided filter with passband $|x| \leq a$ and stopbands $|x| \in [a, 1]$, with $a \in (0, 1)$. According to [16, 3], the uniform-deviation polynomial of degree $d = 2n$ is described as

$$p_d(x) = T_n\left(-1 + 2 \frac{x^2 - a^2}{1 - a^2}\right) / T_n\left(-1 + 2 \frac{-a^2}{1 - a^2}\right). \quad (15)$$

We set $a = 0.1$ for the experiments.

3.5 Results

Figure 1 shows (top) QSP output $\langle 0 | U_Z(\omega, \Phi) | 0 \rangle$ vs. $x(\omega)$ and (bottom) the QSP error versus degree, with gray curves denoting truncation error. We also included right-action carving (Algorithm 1). For small degrees, both methods are accurate; at higher degrees, where high-degree coefficients are attenuated, right-action carving degrades, whereas reverse-carving (left-action) remains stable down to 10^{-13} . All numerical experiments were conducted in double-precision arithmetic.

4 Summary

We investigated a source of numerical instability that arose when the carving decomposition was combined with the BS completion: attenuation of the leading coefficients in F and G made the terminal-angle step sensitive in finite-precision arithmetic. We addressed this with reverse-carving, which applied carving to the reciprocal polynomial $G^\dagger$. Across Hamiltonian simulation, matrix inversion, phase estimation, and eigenvalue filtering, the reverse-carving maintains high-degree accuracy, demonstrating the effectiveness of the proposed method.

Abstract. We consider communication over discrete memoryless interference channels or multiple access channels without feedback, where transmitters exploit classical, quantum, or no-signaling cooperation. Previous works have shown that, for channels associated with pseudo-telepathy games, quantum or no-signaling cooperation can increase the sum capacity. However, a full characterization of channels admitting such an improvement remains open. Motivated by common features of previously studied examples, we propose a broader class of game-induced channels. The proposed class recovers several previously studied channels and includes new examples.

Keywords: Network channel, sum capacity, quantum advantage, nonlocal game

1 Background and motivation

Quantum information processing has attracted significant attention due to its potential to outperform classical information processing in certain tasks, thus exhibiting quantum advantage. Quantum advantage is not only of theoretical interest but also provides justification for the practical implementation of quantum information processing. Examples of quantum advantage arise in the contexts of algorithmic complexity [24, 14, 11], security [3, 12, 2], privacy [17], nonlocal games [4, 9, 5], distributed computing [8, 1, 7], and communication over networks [16, 15, 19, 23, 26, 25].

In communication over networks, previous works [16, 15, 19, 26, 23, 25] considered scenarios in which multiple transmitters use pre-shared resources to cooperate while sending classical messages over classical interference channels (ICs) or multiple access channels (MACs). For a given IC or MAC, the fundamental limit of communication is described by the capacity region, the set of all achievable rate tuples, and the sum capacity, the maximum sum of achievable rates over this region. In this setting, quantum advantage is demonstrated when quantum cooperation enables a larger capacity region or sum capacity than classical cooperation.

Intuitively, quantum advantage arises from non-classical correlations induced by shared quantum resources. In both ICs and MACs, transmitted signals from multiple transmitters interfere with each other, thereby making it more difficult for a receiver to decode the desired message encoded in the transmitted signal, as depicted in Figure 1. Within this scenario, transmitters may cooperate with each other to generate correlated

Figure 1: A conceptual diagram for an interference channel $P_{Y_{[K]}|X_{[K]}}$ between $K = 3$ transmitter-receiver pairs. Channel output Y_i at receiver i can be affected by unintended channel input $X_{i'}$ from transmitter i' , $i' \neq i$ (dashed lines). Correlations between channel inputs can mitigate cross-link dependencies.

signals that would mitigate interference and increase the sum capacity. At this point, transmitters sharing a quantum resource can generate more general correlations than sharing a classical resource, and can thereby mitigate more general types of interference. Note that general quantum correlation cannot be simulated in classical systems, and is constrained by physical principles such as relativistic causality [20]. This constraint is captured by no-signaling correlations, and no-signaling cooperation has also been considered as a means to increase the sum capacity [21, 26, 25, 23]. Thus, it is natural to ask *for which class of channels the sum capacity can be strictly enlarged by quantum or no-signaling cooperation, compared with classical cooperation.*

Specifically, the works [26, 16, 15, 19, 23, 21, 25] defined discrete memoryless MACs and ICs where channel inputs are specified as tuples of questions and answers from a pseudo-telepathy game. Here, a question can be interpreted as the message-bearing component of the transmitted signal, while an answer can be viewed as a finite-alphabet coordination variable, analogous to a precoding or beamforming choice. Additionally, the channels

studied in [16, 15, 19, 23, 21] relay the questions from transmitters to one or more receivers noiselessly when the channel inputs satisfy the winning condition of the game. More general channels have also been considered, where the transmitted questions are subject to random erasure [21, 26], or to uniform random noise [25], even when the channel inputs satisfy the winning condition. However, it has not yet been fully determined for which channels the sum capacity can be increased by quantum or no-signaling cooperation. For example, we may consider more general types of noise other than erasure or uniform random noise.

2 Summary of results

In this work, we propose a broader class of ICs and MACs whose sum capacity can be enhanced by quantum or no-signaling cooperation. The technical details are provided in the extended version [18]. This class of channels includes the channels studied in prior works [16, 23, 15, 19] as well as new ones not considered in [26, 16, 15, 19, 23, 21, 25]. Since all results for ICs can be directly adapted to those for MACs by treating multiple receivers as a single receiver, we primarily focus on ICs throughout this letter.

Intuitively, the previously studied channels [26, 16, 15, 19, 23, 21, 25] share a common characteristic: *the interference is weaker when the channel inputs satisfy the winning condition of a pseudo-telepathy game than when they do not*. Based on this observation, we propose a class of channels involving pseudo-telepathy games by interpreting *weaker interference* in the following manner: When the channel inputs satisfy the winning condition of the game, a channel has lower conditional output uncertainty in terms of the conditional entropy of the channel output given channel inputs, and decomposes into parallel weakly symmetric subchannels with unique capacity-achieving input distribution.

Specifically, let G be a K -party non-local game and $P_{Y_1, \dots, Y_K | X_1, \dots, X_K} = P_{Y_{[K]} | X_{[K]}}$ be an IC between K transmitter-receiver pairs. We say that $P_{Y_{[K]} | X_{[K]}}$ is a G -game channel if

1. For all $i = 1, \dots, K$, channel input X_i is a pair of question Q_i and answer A_i for the i -th party of G , i.e., $X_i = (Q_i, A_i)$.
2. When channel inputs $x_{[K]}$ satisfy the winning condition of G , the channel splits into parallel subchannels that relay only questions from transmitters to receivers, i.e.,

$$P_{Y_{[K]} | X_{[K]}}(y_{[K]} | x_{[K]}) = \prod_{i=1}^K P_{Y_i | Q_i}(y_i | q_i).$$

3. For any channel inputs $x_{[K]} = (x_1, \dots, x_K)$ that satisfy the winning condition of G and any $x'_{[K]} = (x'_1, \dots, x'_K)$ that do not satisfy it, the conditional entropy of the channel outputs $Y_{[K]} = (Y_1, \dots, Y_K)$ given $x_{[K]}$ is strictly less than that given $x'_{[K]}$, i.e.,

$$H(Y_{[K]} | X_{[K]} = x_{[K]}) < H(Y_{[K]} | X_{[K]} = x'_{[K]}).$$

Figure 2: An example of G -game channels. If $X_{[3]}$ satisfies the winning condition, then $\tau_i(X_{[3]}) = Q_i$, and the channel between $\tau_i(X_{[3]})$ and Y_i has less conditional output entropy.

4. For all $i = 1, \dots, K$, the i -th sub-channel $P_{Y_i | Q_i}$ is weakly symmetric [10, Sec. 7.2], and it has a unique capacity-achieving distribution.

The weak-symmetry condition yields a closed-form capacity expression for each winning-state subchannel, while uniqueness of the capacity-achieving input distribution is used in the converse proof to show that the sum-capacity upper bound cannot be attained under classical cooperation. Moreover, this assumption holds for simple and physically motivated examples, including uniform random noise channels.

Condition 1 is common to previous works [26, 16, 15, 19, 23, 21, 25], and conditions 2 and 3 specify the notion of weaker interference in two different ways. Condition 2 means that, in the winning state, the signal observed by each receiver depends only on the corresponding transmitter's question and not on the other transmitters' questions. Thus, the winning condition acts as an interference-alignment condition: successful coordination removes cross-link interference, leaving only local point-to-point noise. Condition 3 means that the conditional output uncertainty in the winning mode is strictly less than that in every non-winning mode. The last condition is used in the proof to show the enhancement of the sum capacity, based on the fact that the output of a weakly symmetric channel is uniformly distributed when the channel input follows a capacity-achieving distribution.

We show that if G is a quantum (resp. no-signaling) pseudo-telepathy game, then quantum (resp. no-signaling) cooperation enhances the sum capacity of a G -game channel compared to classical cooperation. To prove this result, we first derive an upper bound on the sum capacity that cannot be achieved by classical cooperation. Then, we provide an achievability scheme that exploits a winning strategy of G achieves the sum rate equal to the derived upper bound.

There exist many G -game channels for a fixed game G . For example, fix a K -party game G . As depicted in Figure 2, consider a channel that first maps $X_{[K]} = (Q_{[K]}, A_{[K]})$ to an effective question tuple

$$\tilde{Q}_{[K]} = (\tau_1(X_{[K]}), \dots, \tau_K(X_{[K]})),$$

where each τ_i satisfies $\tau_i(X_{[K]}) = Q_i$, for every $i \in [K]$ and $X_{[K]}$ satisfying the winning condition. Thus, in the

winning mode, the effective input observed by the i -th local subchannel coincides with the intended question Q_i , whereas in the non-winning mode $\tau_i(X_{[K]})$ may include residual cross-link interference. Then, we define a channel from $\tilde{Q}_i$ to Y_i , which induces strictly less conditional output entropy in the winning mode.

As a constructive example, we can model each channel from $\tilde{Q}_i$ to Y_i as a uniform random noise channel. With probability η , the channel transmits the input symbol; with probability $1 - \eta$, it outputs an independent uniformly random symbol. By choosing η^w in the winning mode and η^l in the non-winning mode with $0 \leq \eta^l < \eta^w \leq 1$, the output conditional entropy is strictly less in the winning mode. Hence, the overall channel becomes a G -game channel as defined above.

The special case $\eta^w = 1$ and $\eta^l = 0$ for all $i \in [K]$ recovers the noiseless-winning/uniform-losing constructions used in several previous works [16, 23, 19, 15]. Allowing $0 \leq \eta^l < \eta^w \leq 1$ also permits noisy winning modes and non-winning modes with residual interference through the maps τ_i . Hence, this example extends the previously considered constructions based on uniform random noise. We note that many channels other than the uniform random noise channel can also be considered.

3 Impact and future work

Our result establishes a strict separation of sum capacity for the proposed G -game channels, which recover several previously studied channels as well as encompass many new ones. By establishing a sufficient condition for such separation derived from structural properties, rather than investigating specific channels case-by-case, our framework can be generalized to a broad class of interference channels. However, two questions remain open: whether the exact magnitude of the classical-to-quantum gap can be efficiently computed, and whether analogous separations can be proved for more physically standard channel models.

For the first point, it is necessary to quantify the sum capacity with classical cooperation. As one approach, the generalized Blahut-Arimoto algorithm [22], proposed for computing the classical sum capacity of MACs (which serves as an upper bound on the sum capacities of ICs), could be employed. However, although this algorithm can evaluate the sum capacities of certain MACs, it generally provides only lower bounds on the sum capacities [6]. Subsequently, [23] proposed an algorithm that computes the sum capacities of two-transmitter MACs within a given additive precision in quasi-polynomial time. As a future direction, it would also be interesting to investigate efficient algorithms for computing the sum capacity in scenarios with more than two transmitters.

For the second point, it would be desirable to determine whether quantum cooperation can enhance the sum capacity of practical channels, such as Gaussian or fading ICs/MACs. Our result does not directly apply to Gaussian or fading ICs/MACs, since it is formulated for discrete channels. Nevertheless, the mechanism identified here suggests a possible direction: state-dependent

or structured interference channels in which coordinated inputs can suppress cross-interference and induce lower effective noise. Establishing such an analogue for Gaussian or fading models remains an important open problem.

Another research direction would be to derive a single-letter characterization of the capacity region of general ICs or MACs with cooperation between transmitters. In this context, [19] derived a multi-letter characterization of the capacity region of a MAC, and [15] proposed multi-letter inner and outer bounds for the capacity region of an IC. Compared to single-letter characterizations, multi-letter characterizations have the limitation that it is not clear how to compute them [13]. A single-letter characterization would help characterize the set of all channels in which cooperation enlarges the capacity region.

Extended abstract: Two measurement bases are asymptotically informationally complete for any pure state tomography

T Feng, T Xiao, Y Wang, S Pang, F Hanif, X Zhou, Q Zhao, M. S. Kim, and J Sun

Quantum state tomography typically requires at least four measurement bases for pure states. We prove that just two bases are sufficient to uniquely determine any algebraic pure state, including those generated by finite-depth Clifford+T circuits. Since algebraic states can approximate any pure state to arbitrary precision, our scheme is asymptotically informationally complete for arbitrary pure states. Furthermore, we demonstrate that two local measurement bases suffice for sparse states (e.g., GHZ- and W-like states). Supported by numerical simulations up to 20 qubits, our results establishes a fundamental informational limit for state tomography in fault-tolerant quantum computing.

A fundamental question in quantum information theory is what is the minimum number of measurement bases required to determine an unknown pure quantum state. This is known as the Pauli problem which Pauli posed in 1933 [1, 2]: can an arbitrary wave function be uniquely determined (up to a global phase) by the probability distributions obtained from its position and momentum measurements? A generalisation of the Pauli problem is whether an unknown quantum state with dimension d can be uniquely determined using two measurement bases ($d = 2^n$ for an n -qubit system). The answer to the generalised Pauli problem is negative. The number of measurement bases is shown to be larger than 3 for $d \geq 9$ [3]. Subsequently, research progress has been made in understanding the requirements for achieving information completeness in high-dimensional pure states [4–9, 41]. Flammia *et al.* showed that a measurement with $2d - 1$ outcomes cannot be informationally complete and proved the failure of two complementary measurement bases for a unique determination of pure states [5]. From an information completeness perspective, a minimum of four measurement bases is necessary for pure-state tomography [4, 8].

Although two measurement bases are not informationally complete for determining any pure-state, we prove that they are sufficient to determine any states generated by Clifford + T circuits with finite depth which can approximate any state up to arbitrary finite precision. More generally, an unknown quantum state can be expressed as $|\psi\rangle = \sum_{k=0}^{d-1} \gamma_k |k\rangle$, and we refer to the states with the coefficient γ_k being an algebraic number for all k as pure *algebraic states*. We can readily find that any states generated from finite-depth Clifford + T circuits, and any constructed states with finite precision (e.g. states stored in classical memory in the task of pure state tomography), belong to the class of pure algebraic states. In this work, we prove that two measurement bases are informationally complete for determining any pure algebraic state. As the class of algebraic states is proven to be asymptotically equivalent to the whole pure state class, two measurement bases are asymptotically informationally complete for pure-state tomography.

Following the minimal number of measurement bases from an information completeness perspective, the next question is about the hardness in constructing and imple-

menting the measurement bases. For local measurement bases, so far a minimum of $mn + 1$ ($m \geq 2$) separable bases are required for n -qubit pure-state tomography and it fails for sparse states [14]. In addition, Verdeli *et al.* introduced a four-local-measurement scenario [15]. However, there is only numerical evidence without a theoretical validation of the solution [14, 15]. The second contribution of this work is that, along the line of general qudit state, we can readily find that for sparse algebraic states, two measurement bases that involve polynomial elementary gates (CNOT and single-qubit gates) are sufficient. Furthermore, we provide an explicit construction of the two measurement bases involving single-qubit local operations only, which we refer to as a two-local-measurement-bases scheme. Specifically, the first basis is the computational basis, and the second basis is designed to be a rotated computational basis, which can be realised by applying a single-qubit Pauli rotation gate before measurements. We prove that two local measurement bases are informationally complete for certain states such as GHZ- and W-like states. Moreover, we show that for pure states whose phases when expanded in computational basis are zero, two local measurements are sufficient for strict information completeness, i.e., there does not exist any state (which could be non-algebraic) that can reproduce the same probability distribution under the two measurement bases.

Thus far, we have given an affirmative answer to the Pauli problem when concerning physically relevant limitations, showing that two measurement bases are asymptotically informationally complete for determining any pure states. We confront a few plausible questions and discuss clearly under which scenario our two measurement schemes apply unambiguously in the section of Discussion. Moreover, we extend the discussion to mixed states with noise and prove that our two-measurement-bases scheme remains valid for mixed states with known types of noise, as, for instance, where the magnitudes of the noise coefficients and the noise type are known, the amplitude of the quantum state can be uniquely determined. Finally, we validate our scheme for both pure-state and mixed-state cases through numerical simulations. Numerical results manifest that the reconstructed quantum state generated from the measurement probability distributions is unique, as characterised by the high

average fidelity over a large number of randomly generated states. We test the effectiveness of the two-local-measurement-bases scheme for W-like states with up to 20 qubits. Moreover, we incorporate measurement and device noise into the state and find that our scheme can be robust against noise.

I. THE PAULI PROBLEM

Motivation.— We revisit and formulate the Pauli problem. An arbitrary d -dimensional quantum pure state can be represented in the computational basis as $|\psi\rangle = \sum_{k=0}^{d-1} \gamma_k |k\rangle$, where the coefficient can be represented as $\gamma_k := r_k e^{i\varphi_k}$ with non-negative modulus $r_k \geq 0$, and the sign of the modulus is incorporated into the unknown phase $\varphi_k \in [0, 2\pi)$. Since the global phase factor has no physical observation effects, without loss of generality, we set $\varphi_0 = 0$ hereafter. It is shown that quantum interference introduces nonlinear terms into the equations derived from the two measured probability distributions, potentially resulting in multiple solutions and thereby hindering the unique determination of the pure state [5]. The question is, what is the largest set of state spaces within which two measurements are sufficient to determine the state?

The quantum state generated from a finite-depth quantum circuit, indeed, is a subset of pure quantum states. For example, the quantum state generated by a finite number of Clifford and T gates can be expressed as: $|\phi\rangle = \sum_{k=0}^{d-1} r_k e^{i\pi\varphi_k} |k\rangle$, where $\varphi_k \in [0, 2\pi)$ and r_k are all algebraic numbers. This structure ensures that all parameters of $|\phi\rangle$ are algebraic numbers. This motivates us to consider this subset of pure states. To facilitate the discussion, let us put it formally by introducing a subset that is asymptotically equivalent to the full set.

Asymptotic information completeness.— We define the algebraic states as follows. Suppose that the pure state can be represented in the computational basis. A state is termed a pure *algebraic state* if all coefficients γ_k of the state are algebraic numbers. The set of all pure states, denoted as $\mathbb{P}$, consists of two subsets: $\mathbb{P}_A$ and $\mathbb{P}_{\bar{A}}$, satisfying $\mathbb{P} = \mathbb{P}_A \cup \mathbb{P}_{\bar{A}}$. Let $\mathbb{P}_A$ represent the set of algebraic states. The complement set of $\mathbb{P}_A$, $\mathbb{P}_{\bar{A}}$, represents the set of pure states of which there exists at least one coefficient that is a transcendental number. Correspondingly, pure states in $\mathbb{P}_{\bar{A}}$ are called *transcendental states*.

We prove that $\mathbb{P}_A$ can represent any states in $\mathbb{P}_{\bar{A}}$ with arbitrary precision. In other words, the subset of pure states $\mathbb{P}_A$ is asymptotically equivalent to $\mathbb{P}$. Our target problem is the following.

Problem 1. *What is the minimum number of orthogonal bases that are sufficient to uniquely determine a pure state $|\psi\rangle \in \mathbb{P}_A$ among all the other pure states in $\mathbb{P}_A$.*

II. MAIN RESULTS

Scheme.— We demonstrate that two measurement bases are sufficient to determine any pure algebraic states concerning the physical limitations. First, we measure the algebraic states with two different measurement bases, and obtain two probability distributions $\mathbf{P}$ and $\mathbf{Q}$. Then the target pure quantum state can be reconstructed by post-processing the acquired distributions. The first measurement basis is the computational basis,

$$\mathcal{B}_1 := \{|i\rangle\}, i = 0, 1, \dots, d-1. \quad (1)$$

The second measurement basis is realised by applying a quantum Fourier transform F for a qudit and diagonal operation P before projective measurements on a computational basis. For an n -qubit state, this Fourier transform corresponds to local Hadamard gates $H^{\otimes n}$. This can be expressed as,

$$\mathcal{B}_2 := \{S'|i\rangle\}, i = 0, 1, \dots, d-1, \quad (2)$$

where $S' = DF$ and F is the standard quantum Fourier transform, $F = \sum_{k,j=0}^{d-1} \frac{1}{\sqrt{d}} \omega^{jk} |j\rangle \langle k|$ with $\omega = e^{\frac{2\pi i}{d}}$ and the diagonal operation is $D = \text{Diag}\{e^{i\theta_0}, \dots, e^{i\theta_{d-1}}\}$ with angle θ_i . For the qubit case, the operator is $S' = DH^{\otimes n}$ and could be simplified for sparse states which we will discuss later.

In order to satisfy the uniqueness property, we impose the following constraints on the angles

$$\forall i \neq j, i' \neq j', |\theta_i - \theta_j| \neq |\theta_{i'} - \theta_{j'}|, \quad (3)$$

where all θ_i ($i \leq d-1$) are algebraic numbers. The choice of P is not unique. A simple example satisfying the above relationship is $\theta_k = 2^{k-1} z_0$ where z_0 is an arbitrary algebraic number for all $k \leq d-1$.

Asymptotic information completeness. We establish the uniqueness of the probability distributions of an algebraic quantum state under our two measurement bases using the method of contradiction. Briefly, any algebraic state generates unique probability distributions $\mathbf{P}$ and $\mathbf{Q}$.

Theorem 1 (Two measurement bases are asymptotically informationally complete for any pure states). *The two measurement bases in Eq. (1) and Eq. (2) that satisfy Eq. (3) are informationally complete with respect to all pure d -dimensional states $\in \mathbb{P}_A$.*

An equivalent expression is that the measurement outcomes on the two bases have a one-to-one correspondence with an algebraic state. Our result does not violate the established information-theoretic conclusions as it focuses on information completeness with respect to a subset of the whole pure state class.

Corollary 1 (Two measurement bases are informationally complete for any finite, yet arbitrary depth circuit

with Clifford and T gates.). *The two measurement bases in Eq. (1) and Eq. (2) that satisfy Eq. (3) are informationally complete with respect to all pure states generated by finite-depth quantum circuits composing of Clifford and T gates.*

Sketch of the proof.— Suppose that there exists such a $|\psi'\rangle \in \mathbb{P}_A$ can simulate the unknown algebraic state $|\psi\rangle$ under the computational basis, that is, $|\langle j|\psi'\rangle|^2 = |\langle j|\psi\rangle|^2$ for any j . Therefore, without losing generality, we represent the states as $|\psi\rangle = \sum_{j=0}^{d-1} r_j e^{i\varphi_j} |j\rangle$ and $|\psi'\rangle = \sum_{j=0}^{d-1} r'_j e^{i\varphi'_j} |j\rangle$, with non-negative modulus r_j . By assumption, $|\psi'\rangle$ can also simulate the unknown algebraic state $|\psi\rangle$ under the second basis and have the same measurement probability distributions $\mathbf{Q}$ as $|\psi\rangle$. That is, the difference of the probability distributions for the second basis between $|\psi\rangle$ and $|\psi'\rangle$ is $\Delta Q_j = Q_j - Q'_j = 0$ for any outcome. Since $\mathbf{Q}$ corresponds to the probability distribution of the measurements under the basis $\{S'|j\rangle\}$, $Q_j = |\langle j|S'^\dagger|\psi\rangle|^2$ and $Q'_j = |\langle j|S'^\dagger|\psi'\rangle|^2$. By grouping the terms, the identical distributions indicate that

$$\Delta Q_j = \sum_{s < l \in V} C_{sl}^{(j)} \cos(\theta_s - \theta_l) + S_{sl}^{(j)} \sin(\theta_s - \theta_l) = 0, \quad (4)$$

where $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are the sum of the two trigonometric functions, which is a linear combination of cosine and sine functions of the phase differences $\varphi_s - \varphi_l$ and $\varphi'_s - \varphi'_l$ (see technical version).

The proof of [Theorem 1](#) relies on the linear independence of sine and cosine functions: For a set of algebraic numbers $\mathcal{S} = \{\theta_k | |\theta_i| \neq |\theta_j|, \forall i, j\}$, $\{\cos \theta_i\}$ and $\{\sin \theta_j\}$ are linearly independent over the set $\mathcal{S}$ (see Lindemann–Weierstrass (LW) theorem, in Methods). A key point is that we put constraints on the angles $\{\theta_j\}$ in the measurement bases by [Eq. \(3\)](#), where $|\theta_s - \theta_l| \neq |\theta_m - \theta_n|$ for $s, l \neq m, n$ and all $\theta_s - \theta_l$ are algebraic numbers. As a result, there must be $\Delta Q_j \neq 0$ for all j (by using the LW theorem), which contradicts the assumption that $|\psi'\rangle \in \mathbb{P}_A$ can simulate $|\psi\rangle$. This completes the proof that two measurement bases are informationally complete for pure state tomography in $\mathbb{P}_A$. As $\mathbb{P}_A$ is asymptotically equal to $\mathbb{P}$, our scheme is asymptotically informationally complete for pure-state tomography.

Theoretical guarantee for multi-qubit pure sparse states.— For an n -qubit system with $d = 2^n$, the implementation of a global phase gate may become exponentially complex in the general case [22, 23]. Nonetheless, the implementation of the second basis can be significantly simplified for pure sparse states. If the number

of nonzero components of the quantum state in the computational basis scales polynomially with n , the operation $D^\dagger$ for the second basis can be simplified as follows: $D^\dagger = \sum_{m=0}^{d-1} e^{-i\theta_m(1-\delta_{r_m,0})} |m\rangle\langle m|$, where $\delta_{r_m,0}$ is the delta function. Note that a single phase-shifting gate $\sum_{m \neq k} (|m\rangle\langle m| + e^{-i\theta_k} |k\rangle\langle k|)$ can be implemented using a multi-qubit control phase gate (which can be realised by $\mathcal{O}(n)$ CNOT + single-qubit gates [22]) and single-qubit NOT gates [23].

Discussions on strict information completeness.— The above section shows that two measurement bases are informationally complete with respect to $\mathbb{P}_A$. Note that this result does not violate the minimum number of bases for pure-state tomography based on information-theoretic analysis. In the methods of technical version, we show that there exist multi-solutions belonging to $\mathbb{P}_A$ that can simulate the measurement outcomes $\mathbf{P}$ and $\mathbf{Q}$. Finally, we conclude by proving a certain class of pure states including GHZ states, W states, and Dicke states, two local measurements are strictly informationally complete with respect to the whole set of pure states $\mathbb{P}$.

Theorem 2 (For a certain class of pure states, two local measurements are strictly informationally complete). *For a state $|\psi\rangle \in \Lambda$ defined in [Sec. I](#) whose relative phase is 0 and amplitude r_k is non-negative in computational basis and Λ being the set of such states, there exists no pure state $|\psi'\rangle \in \mathbb{P}$, satisfying $|\psi'\rangle \neq |\psi\rangle$, which can simulate the measurement outcomes of $|\psi\rangle$ in the two local bases $\{|i\rangle\}$ and $\{H^{\otimes n}|i\rangle\}$.*

Why AQIS. We believe this work aligns with the scope of AQIS, as it addresses a fundamental question in quantum information processing: how many measurement bases are required to determine a state generated by a finite, yet arbitrary-depth, quantum circuit. Using an information-theoretic approach, this work demonstrates—impressively—that just two measurement bases are sufficient. This work also answers, what is the largest set of state spaces for which two measurement bases are sufficient. We find that the largest possible set is the algebraic state space, which includes, for example, states generated from the discretised fault-tolerant gate set (e.g. Clifford + T gate set) and any constructed states with finite precision which are concerned in the task of state tomography. We rigorously demonstrate that two measurement bases are sufficient to determine any pure algebraic state (both qudit and qubit states). Further, the two-local-measurement-bases scheme is numerically investigated for any pure algebraic qubit states (see technical version).

One of the fundamental questions in quantum information theory is to find how many measurement bases are required to obtain the full information of a quantum state. While a minimum of four measurement bases is typically required to determine an arbitrary pure state, we prove that for any states generated by finite-depth Clifford + T circuits, just two measurement bases are sufficient. More generally, we prove that two measurement bases are informationally complete for determining any algebraic pure states whose state-vector elements represented in the computational basis are algebraic numbers. Since any pure state can be asymptotically approximated by a sequence of algebraic states with arbitrarily high precision, our scheme is asymptotically informationally complete for pure state tomography. Furthermore, existing works mostly construct the measurements using entangled bases. So far, the best result requires $\mathcal{O}(n)$ local measurement bases for n -qubit pure-state tomography. Here, we first show that two measurement bases that involve a polynomial number of elementary gates are sufficient for uniquely determining sparse algebraic states. Moreover, we prove that two local measurement bases, involving single-qubit local operations only, are informationally complete for certain algebraic states, such as GHZ-like and W-like states. Besides, our two-measurement-bases scheme remains valid for mixed states with certain types of noises. We numerically test the uniqueness of the reconstructed states under two (local) measurement bases with and without measurement and depolarising types of noise. Our scheme provides a theoretical guarantee for pure state tomography in the fault-tolerant quantum computing regime.

A fundamental question in quantum information theory is what is the minimum number of measurement bases required to determine an unknown pure quantum state. This is known as the Pauli problem which Pauli posed in 1933 [1, 2]: can an arbitrary wave function be uniquely determined (up to a global phase) by the probability distributions obtained from its position and momentum measurements? A generalisation of the Pauli problem is whether an unknown quantum state with dimension d can be uniquely determined using two measurement bases ($d = 2^n$ for an n -qubit system). The answer to the generalised Pauli problem is negative. The number of measurement bases is shown to be larger than 3 for $d \geq 9$ [3]. Subsequently, research progress has been made in understanding the requirements for achieving information completeness in high-dimensional pure states [4–10]. Flammia *et al.* showed that a measurement with $2d - 1$ outcomes cannot be informationally complete and proved the failure of two complementary measurement bases for a unique determination of pure

states [5]. From an information completeness perspective, a minimum of four measurement bases is necessary for pure-state tomography [4, 8].

Although two measurement bases are not informationally complete for determining any pure state, we prove that they are sufficient to determine any states generated by Clifford + T circuits of arbitrary, but finite, depth, which can approximate any state up to arbitrary finite precision. More generally, an unknown quantum state can be expressed as $|\psi\rangle = \sum_{k=0}^{d-1} \gamma_k |k\rangle$. We refer to the states with the coefficient γ_k being an algebraic number for all k as pure *algebraic states*. We can readily find that any states generated from finite-depth Clifford + T circuits, most of practical quantum simulation circuits [11–14], and any constructed states with finite precision (e.g. states stored in classical memory in the task of pure state tomography), belong to the class of pure algebraic states. The first main result of this work is that two measurement bases are proven to be informationally complete for determining any pure algebraic state. Our scheme can be regarded as a kind of quantum state tomography (QST) that involves the measurement of copies of an unknown quantum state using a set of designed measurements, which leverage the prior knowledge of the unknown quantum state, like matrix product state [15, 16], or permutation invariant state [17, 18]. As the

class of algebraic states is proven to be asymptotically equivalent to the entire pure-state class, two measurement bases are asymptotically informationally complete for pure-state tomography.

An emerging issue, following the question of the minimal basis number, concerns the difficulty of constructing and implementing the measurement bases. Existing works mostly construct the measurements using entangled bases. For example, the construction of four measurement bases in Ref. [8] relies on Hermite functions and is challenging to realise. A comparison of representative construction methods [6, 7, 19–21] is shown in Table I (find methods for state verification and tomography in [21?–33]). The second result of this work is that two measurement bases, each implementable with a polynomial number of elementary gates (CNOT and single-qubit gates), are sufficient for determining sparse multi-qubit algebraic states. Furthermore, as a technically involved contribution, we provide an explicit construction of two *local* measurement bases that rely solely on single-qubit operations, along with criteria for their informational completeness. As an example, we prove the information completeness of these bases for specific classes of states, such as GHZ-like and W-like states. The third theoretical result is that for pure states whose phases when expanded in computational basis are zero, two local measurement bases are strict informationally complete for any pure state tomography. In other words, there does not exist any state (which could be non-algebraic) that can reproduce the same probability distribution under the two local measurement bases.

Finally, we extend the discussion to mixed states and demonstrate that our two-measurement-bases scheme remains valid for mixed states with known types of noise; For instance, where the magnitudes of the noise coefficients and the noise type are known, the amplitude of the quantum state can be uniquely determined. We also validate our scheme for both pure-state and mixed-state cases through numerical simulations. Numerical results manifest that the reconstructed quantum state generated from the measurement probability distributions is unique, as characterised by the high average fidelity over a large number of randomly generated states. The two-local-bases scheme for W-like states is shown to be effective with up to 20 qubits. Moreover, numerical results suggest that our scheme is robust in the presence of measurement and device noise.

Introduction to the Pauli Problem

Now we revisit and formulate the Pauli problem. An arbitrary d -dimensional quantum pure state can be represented in the computational basis as

$$|\psi\rangle = \sum_{k=0}^{d-1} \gamma_k |k\rangle, \quad (1)$$

where the coefficient can be represented as $\gamma_k := r_k e^{i\varphi_k}$ with non-negative modulus $r_k \geq 0$, and the sign of

the modulus is incorporated into the unknown phase $\varphi_k \in [0, 2\pi)$. Since the global phase factor has no physical observation effects, without loss of generality, we set $\varphi_0 = 0$ hereafter. It is straightforward to see that a pure quantum state has $2d - 2$ free parameters. By performing measurements on the canonical basis, we can obtain d measurement outcomes. Thus, 2 different measurements intuitively can provide $2(d - 1)$ equations (after removing the normalisation conditions), which aligns with the total number of unknown parameters of the pure quantum state. However, quantum interference introduces nonlinear terms into the equations derived from the two measured probability distributions, potentially resulting in multiple solutions and thereby hindering the unique determination of the pure state [5]. **The question is, what is the largest set of state spaces within which two bases are sufficient to determine the state?** Note that "measurement bases" is abbreviated as "bases" when there is no ambiguity.

Asymptotic information completeness

The quantum state generated from a finite-depth quantum circuit, indeed, is a subset of pure quantum states. For example, the quantum state generated by a finite number of Clifford and T gates can be expressed as: $|\psi\rangle = \sum_{k=0}^{d-1} \gamma_k |k\rangle$ where γ_k are all algebraic numbers (see Methods). This motivates us to consider this subset of pure states. To facilitate the discussion, let us put it formally by introducing a subset that is asymptotically equivalent to the full set.

We define the algebraic states as follows. Suppose that the pure state can be represented in the computational basis in Eq. (1). A state is termed a pure *algebraic state* if all coefficients γ_k of the state are algebraic numbers. The set of all pure states, denoted as $\mathbb{P}$, consists of two subsets: $\mathbb{P}_A$ and $\mathbb{P}_{\bar{A}}$, satisfying $\mathbb{P} = \mathbb{P}_A \cup \mathbb{P}_{\bar{A}}$. Let $\mathbb{P}_A$ represent the set of algebraic states. The complement set of $\mathbb{P}_A$, $\mathbb{P}_{\bar{A}}$, represents the set of pure states of which there exists at least one coefficient being a transcendental number. Correspondingly, pure states in $\mathbb{P}_{\bar{A}}$ are called *transcendental states*.

The subset of pure states $\mathbb{P}_A$ is proven to be asymptotically equivalent to $\mathbb{P}$ (see Methods). In other words, states in $\mathbb{P}_A$ can represent any states in $\mathbb{P}_{\bar{A}}$ with arbitrary precision. As such, our target problem is cast into the following problem.

Problem 1 (Minimal number of informationally complete bases). *What is the minimum number of orthogonal bases that are sufficient to uniquely determine a pure state $|\psi\rangle \in \mathbb{P}_A$ among all the other pure states in $\mathbb{P}_A$.*

This is essentially an information-completeness problem. A set of bases is informationally complete if any two distinct quantum states can be distinguished with confidence based on the outcomes of these measurements. To answer the question posed above, we frame it in the language of quantum information. For all $|\psi_1\rangle, |\psi_2\rangle \in \Lambda_A$,

if the following condition is satisfied,

$$\forall j, k, \quad |\langle \psi_1 | \phi_j^k \rangle|^2 = |\langle \psi_2 | \phi_j^k \rangle|^2 \Rightarrow |\psi_1\rangle = |\psi_2\rangle,$$

the projections $\{|\phi_j^k\rangle\langle\phi_j^k|\}$ are called informationally complete with respect to a subset Λ_A of all pure states $\mathbb{P}$. The above condition can be understood as follows. If any two states have the same probability distribution under any measurements, they must be the same.

We can see the connection with QST, which involves the measurement of copies of an unknown quantum state using a set of designed measurements, followed by the reconstruction of the original state using the chosen algorithm [5, 34]. In order to accurately reconstruct the original quantum state, the measurements used in the tomography should ideally be informationally complete with respect to a given set. This means that they should provide enough information to uniquely determine the state. As we shall prove below, two bases are asymptotically informationally complete for pure-state tomography. Nonetheless, we would like to emphasize that this asymptotic informational completeness does not imply that increasing measurement precision to infinity would make two bases sufficient for any pure state. Instead, it means that two bases are sufficient for any state within the algebraic state space which is asymptotically equivalent to the full pure-state space.

Two measurement bases scheme

Now, we demonstrate that two measurement bases are sufficient to determine any pure algebraic states concerning the physical limitations. The setting of bases is illustrated in Fig. 1. First, we measure the algebraic states with two different bases, and obtain two probability distributions **P** and **Q**. Then the target pure quantum state can be reconstructed by post-processing the acquired distributions. The first measurement basis is the computational basis,

$$\mathcal{B}_1 := \{|i\rangle\}, i = 0, 1, \dots, d-1. \quad (2)$$

For the qubit case, that is the z -direction projective measurement $\mathcal{B}_1 := \{|i\rangle\}^{\otimes n}, i = 0, 1$. The second measurement basis is realised by applying a quantum Fourier transform F for a qudit and diagonal operation P before projective measurements on a computational basis. For an n -qubit state, this Fourier transform corresponds to local Hadamard gates $H^{\otimes n}$. This can be expressed as,

$$\mathcal{B}_2 := \{S'|i\rangle\}, i = 0, 1, \dots, d-1, \quad (3)$$

where $S' = DF$ and F is the standard quantum Fourier transform, $F = \sum_{k,j=0}^{d-1} \frac{1}{\sqrt{d}} \omega^{jk} |j\rangle\langle k|$ with $\omega = e^{\frac{2\pi i}{d}}$ and the diagonal operation is $D = \text{Diag}\{e^{i\theta_0}, \dots, e^{i\theta_{d-1}}\}$ with angle θ_i as illustrated in Fig. 1(a). These two operations are experimentally feasible in quantum photonic systems, particularly on photonic chips [35, 36]. For the qubit case, the operator, $S' = DH^{\otimes n}$, is illustrated in Fig. 1(b) and could be simplified for sparse states which will be

FIG. 1. **Two-measurement-base scheme.** **a.** Scheme for a qudit state: F is the standard quantum Fourier transform, $F = \sum_{i,j=0}^{d-1} \frac{1}{\sqrt{d}} \omega^{ij} |i\rangle\langle j|$, where $\omega = e^{\frac{2\pi i}{d}}$, and the diagonal operation is $D = \text{Diag}\{e^{i\theta_0}, \dots, e^{i\theta_{d-1}}\}$ with angle θ_i . **b.** Two measurement bases for multi-qubit systems. If ρ is a sparse state, i.e. the number of non-zero components of r_k is $\mathcal{O}(\text{poly}(n))$, D can be reduced to be a diagonal operation with $\mathcal{O}(\text{poly}(n))$ phase shifts. **c.** Illustration of the concept of uniqueness: The pure quantum state $\in \mathbb{P}_A$ has a one-to-one correspondence to the measurement outcomes **P** and **Q**.

discussed later. Since the global phase has no physical observation effects, $\theta_0 = 0$ is set for convenience.

In order to satisfy the uniqueness property, we impose the following constraints on the angles

$$|\theta_i - \theta_j| \neq |\theta_{i'} - \theta_{j'}|, \quad (4)$$

for $\forall i \neq j$ and $i' \neq j'$, where all θ_i ($i \leq d-1$) are algebraic numbers. The choice of P is not unique. Here we give a few examples that satisfy the above relationship. A simple example satisfying the above relationship is $\theta_k = 2^{k-1} z_0$ where z_0 is an arbitrary algebraic number for all $k \leq d-1$. Another example is $\theta_k = \sqrt{q_k}$ where q_k is the k th prime number sorted from smallest to largest. In this section, we simply give a measurement scheme for qudit. The uniqueness of the states under such a measurement scheme is presented in Theorem 1, illustrated in Fig. 1(c).

Asymptotic information completeness of two bases and sketch of proof

The theorem below establishes the uniqueness of the probability distributions of an algebraic quantum state under the two bases using the method of contradiction.

Theorem 1 (Two measurements are asymptotically informationally complete for any pure states). *The two measurement bases in Eq. (2) and Eq. (3) that satisfy Eq. (4) are informationally complete with respect to all pure d -dimensional states $\in \mathbb{P}_A$.*

An equivalent expression is that the measurement outcomes on the two bases, **P** and **Q**, have a one-to-one

correspondence with an algebraic state, illustrated in Fig. 1(c). This result does not violate the established information-theoretic conclusions as it focuses on information completeness with respect to a subset of the whole pure state class. Below, we briefly illustrate the proof idea of Theorem 1 by contradiction, and refer to Supplementary Information for the technical details.

Assume there exists another different algebraic quantum state that can give the same probability distributions of the target state under the two bases (thus we call it a simulated state in this paper). As such, one can obtain a set of equations about the target state and the simulated state. We then apply the proved linear independence theorem (in Methods) to show that such a simulated state does not exist.

Specifically, suppose that there exists such a $|\psi'\rangle \in \mathbb{P}_A$ can simulate the unknown algebraic state $|\psi\rangle$ under the computational basis, that is, $|\langle j|\psi'\rangle|^2 = |\langle j|\psi\rangle|^2$ for any j . Therefore, without losing generality, we represent the states as $|\psi\rangle = \sum_{j=0}^{d-1} r_j e^{i\varphi_j} |j\rangle$ and $|\psi'\rangle = \sum_{j=0}^{d-1} r_j e^{i\varphi'_j} |j\rangle$, with non-negative modulus r_j in Eq. (1). By assumption, $|\psi'\rangle$ can also simulate the unknown algebraic state $|\psi\rangle$ under the second basis and have the same measurement probability distributions $\mathbf{Q}$ as $|\psi\rangle$. That is, the difference of the probability distributions for the second basis between $|\psi\rangle$ and $|\psi'\rangle$ is $\Delta Q_j = Q_j - Q'_j = 0$ for any outcome. Since $\mathbf{Q}$ corresponds to the probability distribution of the measurements under the basis $\{S'|j\rangle\}$, $Q_j = |\langle j|S'^\dagger|\psi\rangle|^2$ and $Q'_j = |\langle j|S'^\dagger|\psi'\rangle|^2$. By grouping the terms, the identical distributions indicate that

$$\Delta Q_j = \sum_{s,l \in V} C_{sl}^{(j)} \cos(\theta_s - \theta_l) + S_{sl}^{(j)} \sin(\theta_s - \theta_l) = 0, \quad (5)$$

where $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are the sum of the two trigonometric functions, which is a linear combination of cosine and sine functions of the phase differences $\varphi_s - \varphi_l$ and $\varphi'_s - \varphi'_l$ (see Supplementary Information).

The proof of Theorem 1 relies on the linear independence of sine and cosine functions: For a set of algebraic numbers $\mathcal{S} = \{\theta_k | |\theta_i| \neq |\theta_j|, \forall i, j\}$, $\{\cos \theta_i\}$ and $\{\sin \theta_j\}$ are linearly independent over the set $\mathcal{S}$ (see Lemma 1, Lindemann–Weierstrass theorem, in Methods). A key innovation is that we put constraints on the angles $\{\theta_j\}$ in the bases by Eq. (4), where $|\theta_s - \theta_l| \neq |\theta_m - \theta_n|$ for $s, l \neq m, n$ and all $\theta_s - \theta_l$ are algebraic numbers. As a result, there must be $\Delta Q_j \neq 0$ for all j (by using Lemma 2 in Methods), which contradicts the assumption that $|\psi'\rangle \in \mathbb{P}_A$ can simulate $|\psi\rangle$. This completes the proof of the information completeness of two bases with respect to $\mathbb{P}_A$. As $\mathbb{P}_A$ is asymptotically equal to $\mathbb{P}$, our scheme is asymptotically informationally complete for pure-state tomography.

Theoretical guarantee for multi-qubit sparse states

Our above proof shows for any pure algebraic state, two

bases are informationally complete from an information-theoretic perspective. Regarding the implementation, the complexity of implementing the second measurement basis, when restricted to local operations, may grow as the state dimension increases. For an n -qubit system with $d = 2^n$, the implementation of a global phase gate may become exponentially complex in the general case [37, 38]. Nonetheless, the implementation of the second basis can be significantly simplified for pure sparse states. If the number of nonzero components of the quantum state in the computational basis scales polynomially with n , the operation $D^\dagger$ for the second basis can be simplified as follows:

$$D^\dagger = \sum_{m=0}^{d-1} e^{-i\theta_m(1-\delta_{r_m,0})} |m\rangle\langle m|,$$

where $\delta_{r_m,0}$ is the delta function. Note that a single phase-shifting gate $\sum_{m \neq k} (|m\rangle\langle m| + e^{-i\theta_k} |k\rangle\langle k|)$ can be implemented using a multi-qubit control phase gate (which can be realised by $\mathcal{O}(n)$ CNOT + single-qubit gates [37]) and single-qubit NOT gates [38]. The gate complexity for a sparse $D^\dagger$ gate is $\mathcal{O}(\text{poly}(n))$. From an operation point of view, the $D^\dagger$ can be easily constructed given the measurement distribution on the first basis. The uniqueness of the sparse state $\in \mathbb{P}_A$ with simplified implementation also holds since the proof is the same as the general one.

Two-local-measurement-bases scheme

The above section mainly discussed the measurement scheme with entangled bases and the best result is $\mathcal{O}(n)$ though it does not have a theoretical guarantee for reconstructing the state. It is an open question whether a constant number of local bases is sufficient for information completeness with respect to $\mathbb{P}_A$. Here, we demonstrate that two local measurement bases are sufficient to determine a class of pure algebraic states, including GHZ-like states and W-like states.

We start by giving the local measurement and reconstruction strategy for multi-qubit cases. First, we measure the algebraic states with two different local bases, and obtain two probability distributions $\mathbf{P}$, $\mathbf{Q}$. The first measurement basis is chosen as $\mathcal{B}_1$ in Eq. (2) with $d = 2^n$, which is the tensor product of projective measurements $\{|0\rangle\langle 0|, |1\rangle\langle 1|\}$ on each qubit. The second basis is constructed by

$$\mathcal{B}_2 := S'_q \mathcal{B}_1,$$

where S'_q is a product of local rotations $S'_q = (R_n H) \otimes \cdots \otimes (R_1 H)$, H is the Hadamard operation, R_j is the phase operation

$$R_j = \begin{bmatrix} 1 & 0 \\ 0 & e^{i\alpha_j} \end{bmatrix}.$$

The task is similar to the qudit case, which is to find the appropriate α_j such that they can uniquely determine a pure algebraic state. However, the condition is

not easily to be satisfied. This is because when restricting the locality of the bases, the number of parameters is n , but the total number of linear equations is 2^n . Therefore, it is very likely that the parameters will become correlated, resulting in the failure of linear independence among all the equations. Therefore, there are multiple potential states that can have the same probability distribution and thus we cannot determine a unique state. The key is to ensure that their interference phase will not result in linear independence. A technical contribution of this work is that we carefully design the conditions in order to ensure linear independence for the interference term in ΔQ_j , and hence information completeness. The condition is shown in Eq. (15) in Methods.

Compared to the qudit case, the measurement bases are local, making it easy to realise in experiments. We find that two local bases are sufficient to characterise special classes of sparse algebraic states: W-like algebraic states and GHZ-like algebraic states. Specifically, a general W-like state and GHZ-like state are defined as follows respectively,

$$\begin{aligned} |\text{W-like}\rangle &= \sum_{j=1}^n r_j e^{i\varphi_j} |0\rangle^{\otimes(j-1)} \otimes |1\rangle \otimes |0\rangle^{\otimes(n-j)}, \\ |\text{GHZ-like}\rangle &= r_0 |0\rangle^{\otimes n} + r_1 e^{i\varphi} |1\rangle^{\otimes n}. \end{aligned}$$

Note that the prior information of the state is not needed. The criteria for identifying other sparse algebraic states is technically involved and is thus detailed in Appendix C in Supplementary Information.

Discussions on strict information completeness

The above section shows that two bases are informationally complete with respect to $\mathbb{P}_A$. Note that this result does not violate the minimum number of bases for pure-state tomography based on information-theoretic analysis. In Theorem 3 we show that there exist multi-solutions belong to $\mathbb{P}_A$ that can simulate the measurement outcomes $\mathbf{P}$ and $\mathbf{Q}$. Finally, we conclude by proving a certain class of pure states can be uniquely determined by two local measurements. Specifically, for a state $|\psi\rangle \in \Lambda$ defined in Eq. (1) whose relative phase is 0 and amplitude r_k is non-negative in computational basis and Λ being the set of such states, there exists no pure state $|\psi'\rangle \in \mathbb{P}$, satisfying $|\psi'\rangle \neq |\psi\rangle$, which can simulate the measurement outcomes of $|\psi\rangle$ in the bases $\{|i\rangle\}$ and $\{H^{\otimes n}|i\rangle\}$ (see Methods). Therefore, for a certain class of pure states, including GHZ states, W states, and Dicke states, two local measurements are strictly informationally complete with respect to the whole set of pure states $\mathbb{P}$.

Theorem 2 (For a certain class of pure states, two local measurements are strictly informationally complete). *For a state $|\psi\rangle \in \Lambda$ defined in Eq. (1) whose relative phase is 0 and amplitude r_k is non-negative in computational basis and Λ being the set of such states, there does not exist any pure state $|\psi'\rangle \in \mathbb{P}$ ($|\psi'\rangle \neq |\psi\rangle$) that*

can simulate the measurement outcomes of $|\psi\rangle$ in the two local bases $\{|i\rangle\}$ and $\{H^{\otimes n}|i\rangle\}$.

If we only consider a set that is comprised of pure states in Eq. (1) with all zero phases, a single computational basis is sufficient to determine any state within this set. However, it is important to note that one basis is insufficient if the set of the simulated states encompasses the entire pure state set. Theorem 2 indicates that two local bases are sufficient to differentiate states with all zero phases within an entire set of pure states. For example, if Alice aims to verify the target state of a W state, but this quantum pure state is prepared for her by Bob, it would require measurements in two bases to determine whether the target state is indeed a W state. One basis involves a computational basis to confirm the absolute values of the state amplitudes, while the other basis is used to assess the phases and determine if they are all zero. It is worth noting that although the relative phase of $|\psi\rangle$ is zero, we do not assume this is prior knowledge in the state tomography. The introduction of the second basis can verify if the relative phase is zero.

Understanding other works within our framework

The previous results can be understood within our framework, where the state space is restricted to a specific set. These results demonstrate that at least four eigenbases, although challenging to construct physically, are informationally complete with respect to $\mathbb{P}$. The original Pauli problem is whether a wavefunction is uniquely determined by its position and momentum probability distribution. Peres considered the discrete analogue problem of whether two eigenbases can uniquely determine all pure qudits except for a null set. The two eigenbases are $\{|k\rangle\}_{k=0}^{d-1}$ and its Fourier basis $\{F|k\rangle\}_{k=0}^{d-1}$ [40]. That is to say, for some set $C = \mathbb{P} - E$, two eigenbases are informationally complete with respect to C , where E is the null set. Efforts have been made along this line reducing the number of bases [6, 7] and making it easy to construct by using local basis [19]. However, methods in [5–7, 20] are not effective for pure states in a null set. In this work, we consider the space with the algebraic states $\Lambda = \mathbb{P}$ and $\Lambda_A = \mathbb{P}_A$. Two measurements are constructed, which are informationally complete with respect to all d -dimensional pure algebraic states. This aligns with the strategies for QST, in which prior knowledge of the target state is used to design the set of measurements that need to be informationally complete.

In existing works, the entangling bases in these works are non-orthonormal and may need to be adaptively changed according to the measurement outcomes, and they are not effective for determining certain states (in a set with measure zero). The comparison with other works is displayed in Table I.

Recently, Huang *et al.* considered a relatively simpler task, i.e., state certification [29], and showed that almost all pure states could be efficiently certified through local measurements [?]. Other learning-based pure-state tomography protocols can be found in [31, 32]. It would

Methods	Orthonormal Bases	Requirements and Limitations
Flammia <i>et al.</i> [5]	*	Requires at least $2d$ POVM elements or $3d - 2$ rank-1 projectors (two orthonormal bases are insufficient). Ineffective for some states in a measure zero set.
Finkelstein <i>et al.</i> [39]	*	Requires $2d$ rank-1 projectors, excluding a measure zero set. $3d - 2$ rank-1 projectors are insufficient for all pure states.
Jaming [8]	4	Uses 4 eigenbases constructed mathematically for all pure states. Physically challenging to implement.
Carmeli <i>et al.</i> [27]	5	Combines 4 eigenbases from [8] with the computational basis. No other mixed state matches the results, but physical implementation remains difficult.
Goyeneche <i>et al.</i> [6]	5	Uses two entangled bases for multi-qubit systems. Ineffective for some states in a measure zero set.
Zambrano <i>et al.</i> [7]	3	Guarantees at most $2^d - 1$ candidate states, filtered by a likelihood function. Excludes a measure zero set.
Pereira [20]	$mn + 1$ ($m \geq 2$)	Uses separable bases for multi-qubit systems, highly effective on NISQ computers. Average estimation fidelity increases with m , but lacks theoretical guarantees.
Verdeil <i>et al.</i> [19]	$2n + 1$	Utilizes Pauli measurements, suitable for NISQ computers. Not applicable to qudit systems and lacks theoretical guarantees.
This work	2	Measurement setup is shown in Fig. 1. Asymptotic information completeness for pure-state tomography.

TABLE I. **Comparison of pure-state tomography methods.** This table summarizes various approaches for pure-state tomography, evaluating their applicability to pure states, implementation feasibility, and effectiveness in multi-qubit systems. The requirements and limitations are displayed in the first and second row, respectively. All methods assume no prior knowledge of the target state. Note that all methods fail for some states in a measure zero set, except those addressed in [8, 27].

be interesting to discuss the information completeness in these tasks.

Numerical tests

In the above section, we have established rigorous proof of the asymptotic information completeness of two-measurement bases. Moreover, we have shown that two *local* measurement bases are sufficient for determining kinds of sparse states. In this section, we focus on testing the effectiveness of reconstructing multi-qubit states obtained from purely local measurements. We numerically test the two-local-measurement-bases scheme from different aspects.

Firstly, we consider the regimes where the target state is a pure state, and the ideal measurement probability distribution is obtained perfectly. The goal is to find quantum states that are as close as possible to the two sets of probability distributions $\mathbf{P}$ and $\mathbf{Q}$. We use the Monte Carlo algorithm and simulated annealing algorithm [41, 42] to post-process the measured data obtained by our two-bases scheme as a way to obtain the amplitudes and phases of the reconstructed state. We first generate a simulated state (a state whose matrix elements are randomly drawn from a certain distribution, and then the state is normalised) and compute its probability distributions $\mathbf{P}', \mathbf{Q}'$ under the two bases. We define the distance between $\mathbf{P}', \mathbf{Q}'$ and the actual measured probability distributions $\mathbf{P}$ and $\mathbf{Q}$:

$$\varepsilon_{\text{Prob}} = \|\mathbf{P}' - \mathbf{P}\|_2 + \|\mathbf{Q}' - \mathbf{Q}\|_2, \quad (6)$$

which is the error of probability distributions between the target and the reconstructed state. Small $\varepsilon_{\text{Prob}}$ indicates that the two states have similar performance when we observe from the measurement outcome, but it may not be sufficient to verify the uniqueness of the state. In contrast, fidelity is a more faithful indicator of the uniqueness of the state. This faithfulness can be verified

by the fidelity of the reconstructed state $|\langle\psi|\phi\rangle|^2$. We investigate the faithfulness of the reconstruction process by testing the relationship between $\varepsilon_{\text{Prob}}$ and the average fidelity on an ensemble of states. Our results indicate that when the $\varepsilon_{\text{Prob}}$ is lower than a certain value, the fidelity will be close to 1, which demonstrates the effectiveness of our algorithm.

We start with the W-like states, which are typical sparse states that can be easily prepared in short depth, $|\psi\rangle = \sum_{j=1}^n \gamma_j X_j |0\rangle^{\otimes n}$ with algebraic numbers γ_j and X_j being the Pauli X operator on the j th qubit. It is worth noting that the local bases are proven to be informationally complete for W-like states. The fidelity increase of the reconstructed states during the iteration process for the 20-qubit W-like state can reach more than 99.99%, and we leave the tomographic results in Supplementary Information.

To study the effectiveness of our local measurement scheme, we choose to test with an eight-dimensional algebraic quantum state as our target state $|\psi\rangle$. The fidelity of the reconstructed state is 99.9998% after 300 iterations, and can converge to 100% by increasing the number of iterations. Furthermore, we randomly generate 40 quantum states and show the reconstruction results in Fig. 2. A key finding is that when the $\varepsilon_{\text{Prob}}$ is small, the reconstructed quantum state has a fidelity approximating 100%. This indicates that our scheme can be verified if $\varepsilon_{\text{Prob}}$ is small enough. We choose the iteration processes with $\varepsilon_{\text{Prob}}$ below 8×10^{-5} from all results and plot them in Fig. 2(a). In addition, we make two plots with data from the 100,000 reconstructed states in order to have a clear picture of the results, as shown in Fig. 2(b)(c). Fig. 2(b) shows that when the $\varepsilon_{\text{Prob}}$ is above 8×10^{-5} , the fidelity can be both above and below 0.99, but when the $\varepsilon_{\text{Prob}}$ is below 8×10^{-5} , all the fidelity can be greater than 0.99. In other words, this result excludes the existence of multiple solutions and shows the uniqueness

FIG. 2. Numerical results of the local-measurement-bases scheme. We study the error in probability distribution ϵ_{Prob} (defined in Eq. (6)), the average fidelity and their relationship in the state reconstruction. The algebraic numbers and transcendental numbers are simulated on a computer using low-precision numbers and high-precision numbers, respectively, as computers can only store data in finite decimal places. The numbers of decimal places for the modulus r_k , the phases $\cos \varphi_k$ and $\sin \varphi_k$ are denoted as C_1 , C_2 , and C_3 , respectively, and are set to be 3. The numbers of decimal places for the second measurement basis and the measured probability distributions are set to be 15. The target state $|\psi\rangle$ and the simulated state $|\psi'\rangle$ are set at the same level of precision. **a**, The error in probability distribution ϵ_{Prob} in reconstructing the target random states (left) and 20-qubit W-like state (inset). We randomly generate 40 quantum states with dimension 8, and reconstruct each quantum state 2500 times using the two-local-measurement-bases scheme. To find the state, we use the Monte Carlo method to sample an initial guess and use the simulated annealing method to optimise ϵ_{Prob} . The dark blue dots in the figure indicate the average values of ϵ_{Prob} , and the shaded area represent the standard deviation of the random states during the reconstruction. The figure inset shows the fidelity during the reconstruction process of the 20-qubit W-like state. **b,c**, the relationship between the average fidelity and ϵ_{Prob} . The results in **b** and **c** indicate that a small ϵ_{Prob} results in high average fidelity which verifies the success of our reconstruction scheme. **b** The horizontal coordinate represents the index of the 40 random states. The blue dots represent all reconstruction results with fidelity less than or equal to 0.99, while the orange dots represent all reconstruction results with fidelity greater than 0.99. The red line represents $\epsilon_{\text{Prob}} = 8 \times 10^{-5}$. **c**, the fidelity of the target pure state and the reconstructed pure state. The red and blue dots represent the average fidelity of all reconstruction results for a fixed target state with $\epsilon_{\text{Prob}} < 10^{-5}$, and $10^{-2} < \epsilon_{\text{Prob}} < 10^{-1}$, respectively. The upper and lower bounds of the shaded area are the locations that deviate from the average values by one standard deviation.

of the state. Fig. 2(c) shows that the average fidelity is close to 100% when the ϵ_{Prob} is sufficiently small. These simulation results illustrate that the reconstructed state can converge to the target state when the ϵ_{Prob} of the reconstructed state is small enough, thus verifying the effectiveness of two bases. We further study the performance of our scheme with different levels of precision when dealing with the target states and the measurement bases. These results validate the necessity of introducing the algebraic space. Importantly, it shows the separation of the results for algebraic states and transcendental states (see Figure 4 in Methods).

To test the robustness of our measurement scheme, we add measurement bit-flip noise with the noise rate p in measurements, and construct the states from the noisy measurement outcomes. Fig. 3(a) shows that the average fidelity of all reconstructed data decreases as the statistical noise increases in small increments. If we observe the data with low ϵ_{Prob} , e.g., ϵ_{Prob} below 0.8×10^{-5} , the average fidelity of the reconstructed data maintains sufficiently high. These investigations provide a response to the limitations set up by our information-theoretic approach.

Finally, we show that our scheme can be extended to mixed-state cases, where depolarising noise is added to the target state $|\psi\rangle$ of the form $\rho = (1 - p) |\psi\rangle\langle\psi| + \frac{p}{d} I$,

where p is the coefficient of the depolarising noise, d is the dimension of the quantum states, and I is the identity operator. The pure quantum state is reconstructed from the probability distributions under two bases using the same algorithms, shown in Fig. 3(b). It can be seen that the average fidelity of all reconstructed data is decreasing as the depolarising noise rate increases in small increments. However, we can see that the fidelity of the reconstruction results is all close to 100% when ϵ_{Prob} is below 0.8×10^{-5} . These results indicate that our scheme can be extended to mixed-state tomography. In Methods, we study the performance when adding another measurement basis. Intuitively, adding more bases will make our scheme more robust because the states are more likely to be distinguished with more measurement results. We find that when the depolarising noise rate reaches 0.10, the fidelity is above 95% (see more discussions in Methods).

Discussions

This work asks a fundamental question of what the largest set of state spaces is for which two measurement bases are sufficient. We find that the largest possible set is the algebraic state space, which includes, for example, states generated from the discretised fault-tolerant gate set (e.g. Clifford + T gate set), CNOT + Pauli

FIG. 3. **Verification of the local measurement bases scheme with measurement and device statistical error.** 40 quantum states (of dimension 8) are randomly generated, and measurement results under two bases are produced. Each state is reconstructed 2500 times. The setting for the decimal numbers is set the same as in Fig. 2. **a**, The bit-flip noise is added to the measurement results. **b**, The depolarising noise is added to the state. The red, blue, and green dots represent the average fidelity of all reconstruction results for a fixed target state with $\epsilon_{\text{Prob}} < 0.8 \times 10^{-5}$, $\epsilon_{\text{Prob}} < 4 \times 10^{-5}$, and $\epsilon_{\text{Prob}} < 10^{-4}$, respectively.

rotation gates (commonly used in quantum chemistry simulation [11–14]), and any constructed states with finite precision which are concerned in the task of state tomography. We rigorously demonstrate that two measurement bases are sufficient to determine any pure algebraic state (both qudit and qubit states). Further, the two-local-measurement-bases scheme is numerically investigated for any pure algebraic qubit states. The two-measurement scheme is closely connected to the essence of quantum mechanics which requires complex amplitudes. Even though the pure state itself can not be accurately achieved experimentally, we are interested in the heart of quantum mechanics and the pure state is mostly concerned with quantum mechanical problems in theory, as well as quantum states that can be generated from quantum circuits in the fault-tolerant regime. We remark that the two measurements result only holds for determining $|\psi\rangle \in \mathbb{P}_A$, which has zero measure with respect to

the full state space, but is asymptotically equivalent to the full set of pure states. We show that a certain class of states is strictly informationally complete with respect to the full space under the two-local-measurement-bases scheme.

We extend the scheme to mixed states and provide the theoretical guarantee for the determination of mixed states with certain types of noise. We validate our method for both pure states and mixed states through numerical simulations, where the reconstruction algorithms are simulated annealing algorithms with the Monte Carlo method. We scale up numerical simulation by considering the reconstruction with a large problem size of up to 20 qubits. The simulation results show that the quantum state can be uniquely constructed from the measurement outcomes in two local bases and the fidelity can reach more than 99.99%, and thus validates our information-theoretic result. A critical question is whether the two-measurement scheme is still valid when considering a practical setup where measurement errors are present. We observe that under measurement noise or depolarising noise, the reconstructed state can still achieve high fidelity, thus further validating the robustness of our scheme.

While this work focuses on the uniqueness of quantum state determination, our results can be applied to classical problems. The essence of the two-measurement scheme is to perform measurements on a computational base and a transformed Fourier base. Similar operations can be realised in the classical world: The Fourier transformation is widely used in classical problems such as image processing and analysis of communication systems. For example, an image is placed in front of a positive lens and illuminated with parallel monochromatic coherent light, at which point the measurement on the back focal plane of the lens is the measurement of the image in the Fourier base [43]. Moreover, many problems at the classical level are treated discretely; for example, in image processing, the number of possible colours of a pixel is finite, which can be viewed as a result of high coarse-graining. As such, this classic problem is a special case of Problem 1, and we can directly apply our scheme to determine the target classical state.

From the foundational perspective, the fundamental formulae of quantum mechanics encompass two key facets: quantum states and their evolution. Initially, we approached these concepts by representing them as unit complex vectors and complex unitary operations, constraining our discussions within this framework. Our work suggests that through plausible simplifications by narrowing our focus to unit algebraic numbers and algebraic unitary operations, we may get better results. This refinement allows us to streamline our analysis while maintaining the essence of quantum mechanics. Our result indicates that focusing on a subset of the pure state space may simplify other quantum mechanical problems. In addition, the extension of our scheme to algebraic channel tomography is possible. Besides, an in-

interesting question is whether one can infer properties of an unknown quantum state, such as quantum entanglement [44], from just measurement outcomes of two bases without full state tomography.

METHODS

In Section A, we first give some formal descriptions of asymptotic equivalence and information completeness. In Section B, we introduce the linear independence lemmas, which will be used to prove Theorem 1. In Section C, we show the condition for constructing the two local measurement bases such that they are informationally complete for a subset of pure algebraic states. We provide proof for the strict information completeness for certain states with two bases in Section D (Theorem 2) and discuss the general cases in Section E. In Section F, we provide more details about the numerical setup, algorithm and results to support the effectiveness of our scheme. In Section G, we show how to understand previous works within our framework and summarise the advancements so far.

A. Asymptotic equivalence and information completeness

We first show the asymptotic equivalence between $\mathbb{P}_A$ and $\mathbb{P}$ which are defined in the main text.

Remark 1 (Asymptotic equivalence between $\mathbb{P}_A$ and $\mathbb{P}$). $\mathbb{P}_A$ can represent any states in $\mathbb{P}_A$ with arbitrary precision. In other words, $\mathbb{P}_A$ is asymptotically equivalent to $\mathbb{P}$ if the precision is large enough.

Proof. For any transcendental states $|\psi\rangle$ in the set $\mathbb{P}_A$, we can construct a series of algebraic states $\{|\phi_n\rangle\}_{n=1}^{\infty} \in \mathbb{P}_A$ such that

$$\lim_{n \rightarrow \infty} \|\phi_n\rangle - |\psi\rangle\| = 0. \quad (7)$$

The proof of Eq. (7) is the following. We express $|\psi\rangle \in \mathbb{P}_A$ with its vector form $(\psi_0, \dots, \psi_{d-1})$ under the computational basis. The state-vector norm $\|\psi\rangle - |\phi\rangle\|^2$ is defined as $\sum_{k=0}^{d-1} |\psi_k - \phi_k|^2$. For each transcendental number ψ_k , there always exists a sequence of algebraic numbers $\{b_{kj}\}_{j=1}^{\infty}$ to approximate it. That is to say, for any given $\epsilon > 0$, there always exists an integer N_k such that, $|b_{kj} - \psi_k|^2 < \epsilon/d$ when $j > N_k$. Find the maximal number N among N_k , $k = 0, \dots, d-1$. Thus we can construct a series of unnormalised algebraic vector $|\psi_n\rangle = (b_{0n}, \dots, b_{d-1,n})$. The states $|\psi_n\rangle$ is approximate to $|\psi\rangle$ when $n \geq N$. On the other hand, informally, we know that $\sum_k |b_{kn}|^2 \rightarrow \sum_k |\psi_k|^2 = 1$ when $n \rightarrow \infty$. Therefore, the normalised algebraic vector $|\psi_n\rangle = \frac{1}{\sum_j |b_{jn}|^2} |\psi_n\rangle$ is close to $|\psi\rangle$ when $n \rightarrow \infty$. Thus,

the algebraic state $|\psi_n\rangle$ is close to vector $|\psi\rangle$ when n is large enough. $\square$

An operation O is algebraic if its expression $O_{jk} = \langle j|O|k\rangle$ under basis $\mathcal{B}_1$ is algebraic for all indices $j, k = 0, \dots, d-1$. If both the state $|\phi\rangle$ and O are algebraic, then $O|\phi\rangle$ is also algebraic.

A corollary from this is that any finite sequence of Clifford + T gates yields an algebraic unitary operation. This is because each element of the matrix spanned by these elementary gates contains only algebraic number elements.

Remark 2. Any state that is generated from the gate set of Clifford + T gates or circuits consisting of single-qubit rotating gates commonly used in quantum simulation (the rotation angle should be $\beta\pi$, where β is a rational number, and $\beta = 1/4$ for the T gate) + CNOT gates with finite depth belongs to the set $\mathbb{P}_A$.

In the regime of fault-tolerant quantum computing, it is natural to consider the states in $\mathbb{P}_A$ only. It may also be interesting to discuss the certification and decomposition of algebraic operations. Since the discussion is restricted to $\mathbb{P}_A$ (a subset of $\mathbb{P}$), we introduce the following definition of information completeness.

Remark 3. The definition of an algebraic state $|\psi\rangle = \sum_{k=0}^{d-1} \gamma_k |k\rangle$ where γ_k are all algebraic numbers, is equivalent to $|\psi\rangle = \sum_{k=0}^{d-1} r_k e^{i\phi_k\pi} |k\rangle$ where r_k are algebraic numbers and ϕ_k are rational numbers.

The reason is as follows. Any rational number can be expressed as $\frac{N}{M}$, where N and M are integers. Suppose $e^{i\phi\pi} = e^{i\frac{N}{M}\pi}$. Then we have $(e^{i\frac{N}{M}\pi})^M = \cos(N\pi) = \pm 1$. Thus, $e^{i\frac{N}{M}\pi}$ must be an algebraic number. When combined with r_k , it can be denoted as a new algebraic number γ_k .

Definition 1 (Information completeness with respect to a given set [34]). Suppose the state space Λ_A is a subset of state space Λ . Consider projective measurements onto several sets of eigenbases $\{|\phi_j^k\rangle\}$ for $j = 0, 1, \dots, d-1$.

If the following condition is satisfied

$$\forall j, k, \quad |\langle \psi_1 | \phi_j^k \rangle|^2 = |\langle \psi_2 | \phi_j^k \rangle|^2 \Rightarrow |\psi_1\rangle = |\psi_2\rangle \quad (8)$$

1. for all $|\psi_1\rangle \in \Lambda$, and $|\psi_2\rangle \in \Lambda$, these projections $\{|\phi_j^k\rangle\langle \phi_j^k|\}$ are called informationally complete with respect to Λ .

2. for all $|\psi_1\rangle \in \Lambda_A$, and $|\psi_2\rangle \in \Lambda$, these projections $\{|\phi_j^k\rangle\langle \phi_j^k|\}$ are called strictly informationally complete with respect to a subset Λ_A of all pure states Λ .

3. for all $|\psi_1\rangle, |\psi_2\rangle \in \Lambda_A$, these projections $\{|\phi_j^k\rangle\langle \phi_j^k|\}$ are called informationally complete with respect to a subset Λ_A of all pure states Λ .

While all valid quantum pure states are unit vectors in a Hilbert space, the pure states that are typically manipulated in practical scenarios form a small subset of the

entire Hilbert space. We define a subspace, referred to as the algebraic number space, which effectively covers the vast majority of quantum pure states encountered in practical applications and can approximate any quantum state to arbitrary precision. By selecting a computational basis within this space, along with an additional set of bases from its complement, the transcendental number space, these quantum pure states in the algebraic number space can be uniquely determined.

Intuitively, this problem and its solution can be understood as bearing some resemblance to Gödel's incompleteness theorem: in mathematics, certain "truths" always lie beyond the scope of a given system, much like how a language cannot fully encapsulate all the rules that govern itself. By leveraging the complementarity of algebraic and transcendental numbers, problems defined within the algebraic number space can be addressed in a broader mathematical framework. For instance, extending from the field of rational numbers to real numbers enables solutions to many previously unsolvable problems. Similarly, a set of bases in the transcendental space provides the capacity to encode all phases of quantum pure states defined in the algebraic number space.

B. Linear Independence Theorem

Here we introduce two main lemmas for the proofs of our theorems.

Lemma 1 (Lindemann–Weierstrass theorem [45–47]). *If $\alpha_1, \alpha_2, \dots, \alpha_m$ are distinct algebraic numbers, then the exponentials $e^{\alpha_1}, e^{\alpha_2}, \dots, e^{\alpha_m}$ are linearly independent over the field of all algebraic numbers.*

Lemma 2 (Linear Independence Theorem). *Linear independence of sine and cosine functions with different angles over algebraic numbers: For a set of algebraic numbers $\theta_1, \theta_2, \dots, \theta_n$ that are not equal in absolute value to each other, $\cos \theta_1, \sin \theta_1, \cos \theta_2, \sin \theta_2, \dots, \cos \theta_n, \sin \theta_n$ are linear independent over the field of algebraic numbers.*

Lemma 2 can be proved by **Lemma 1**. Below, we provide the complete proof.

Proof: For a set of algebraic numbers $\theta_1, \theta_2, \dots, \theta_n$ that are not equal in absolute value to each other, suppose $\cos \theta_1, \sin \theta_1, \cos \theta_2, \sin \theta_2, \dots, \cos \theta_n, \sin \theta_n$ are not linear independent over the field of algebraic numbers, which means that it must satisfy:

$$k_1 \cos \theta_1 + k_2 \sin \theta_1 + k_3 \cos \theta_2 + k_4 \sin \theta_2 + \dots + k_{2m-1} \cos \theta_m + k_{2m} \sin \theta_m = 0, \quad (9)$$

while $k_1, k_2, \dots, k_{2m}$ are algebraic numbers that are not all zeros. We can rewrite $\cos \theta_j, \sin \theta_j, j = 1, 2, \dots, m$ as:

$$\begin{cases} \cos \theta_j = \frac{1}{2}e^{-i\theta_j} + \frac{1}{2}e^{i\theta_j} \\ \sin \theta_j = \frac{i}{2}e^{-i\theta_j} - \frac{i}{2}e^{i\theta_j} \end{cases} \quad (10)$$

Then we get:

$$\frac{k_1 + ik_2}{2}e^{-i\theta_1} + \frac{k_1 - ik_2}{2}e^{i\theta_1} + \frac{k_3 + ik_4}{2}e^{-i\theta_2} + \frac{k_3 - ik_4}{2}e^{i\theta_2} + \dots + \frac{k_{2m-1} + ik_{2m}}{2}e^{-i\theta_m} + \frac{k_{2m-1} - ik_{2m}}{2}e^{i\theta_m} = 0. \quad (11)$$

From the Lindemann–Weierstrass theorem, it follows that if a set of algebraic numbers $\theta_1, \theta_2, \dots, \theta_n$ that are not equal in absolute value to each other, we can know that

$$c_1 e^{-i\theta_1} + c_2 e^{i\theta_1} + \dots + c_{2m-1} e^{-i\theta_m} + c_{2m} e^{i\theta_m} \neq 0, \quad (12)$$

while algebraic numbers $c_1, c_2, \dots, c_{2m}$ are not all zeros. Then there is only one case satisfying the Eq. (11), e.g.

$$c_{2j-1} = \frac{k_{2j-1} + ik_{2j}}{2} = 0, c_{2j} = \frac{k_{2j-1} - ik_{2j}}{2} = 0, \quad (13)$$

where $j = 1, 2, \dots, m$. Thus, one has

$$k_l = 0, l = 1, 2, \dots, 2m. \quad (14)$$

This result contradicts the hypothesis that $k_1, k_2, \dots, k_{2m}$ are not all zeros. As a result, for a set of algebraic numbers $\theta_1, \theta_2, \dots, \theta_n$ that are not equal in absolute value to each other, $\cos \theta_1, \sin \theta_1, \cos \theta_2, \sin \theta_2, \dots, \cos \theta_n, \sin \theta_n$ are linear independent over the field of algebraic numbers.

C. Construction of the two local measurement bases and condition for information completeness

In this subsection, we provide the condition for constructing the two local measurement bases such that they are informationally complete.

Let us take a look at the global phase operation involved in the bases $\bigotimes_{j=1}^n R_j$. By expanding the tensor products of each diagonal operator R_j , we observe that this is a diagonal operation, which can be formally expressed as $\bigotimes_{j=1}^n R_j = \sum_{m=0}^{2^n} e^{i\alpha'_m} |m\rangle \langle m|$ with $\alpha'_m = \sum_{p=1}^n \alpha_p m_p$ and $|m\rangle = |m_n m_{n-1} \dots m_1\rangle$. Instead of restricting the absolute phase of the basis, an innovation here is that we propose to restrict its relative phase, i.e., $\alpha'_m - \alpha'_k$ for $m \neq k$. Without loss of generality, any relative phase can be expressed $\sum_{m \in M} (-1)^{x_m} \alpha_m$, where M is the subset of the set of positive integer numbers $N = \{1, 2, 3, \dots, n\}$. Given any two different strings $\vec{x} \neq \vec{x}'$ with $\vec{x} = \{x_m\}$, the constraints on algebraic numbers $\{\alpha_m\}$ is

$$\left| \sum_{m \in M} (-1)^{x_m} \alpha_m \right| \neq \left| \sum_{m \in M} (-1)^{x'_m} \alpha_m \right|. \quad (15)$$

This condition ensures that the linear independence theorem can be used in analysing the information completeness of a set of pure algebraic states (more detailed analysis can be found in the Supplementary Information).

Although this condition looks more complicated than the qudit cases, it is easy to find a set of bases that satisfy this condition. Similar to the qudit case, a simple example satisfying the above relationship is $\alpha_k = 2^{k-1} z_0$ for any $k \leq n$, where z_0 is an arbitrary algebraic number. Another example is $\alpha_k = \sqrt{q_k}$ where q_k is the k th prime number sorted from smallest to largest.

D. Proof of Theorem 2

Proof. Without loss generality, we suppose $|\psi\rangle = \sum_{i=0}^{2^n-1} r_i |i\rangle \in \Lambda$ where r_i is real number and $r \geq 0$. Obviously, if $|\psi'\rangle \in \mathbb{P}$ can simulate the measurement results of $|\psi\rangle$ under computational basis $\{|i\rangle\}$, $|\psi'\rangle$ should have the following form: $|\psi'\rangle = \sum_{i=0}^{2^n-1} r_i e^{i\phi_i} |i\rangle \in \mathbb{P}$ where $\{\phi_i\} \in [0, 2\pi)$ are undefined. For ease of presentation, we denote the j th measurement outcome of the $\{H^{\otimes n} |i\rangle\}$ basis for $|\psi\rangle$ and $|\psi'\rangle$ as T_j and T'_j respectively. If $|\psi'\rangle$ can produce the same measurement outcomes T of $|\psi\rangle$, one has $T_j = T'_j$, that is

$$\begin{aligned} \Delta T_j &= T_j - T'_j \\ &= \frac{1}{2^{n-1}} \sum_{s < l} (-1)^{h(j,s)+h(j,l)} r_s r_l [1 - \cos(\phi'_s - \phi'_l)] = 0. \end{aligned} \quad (16)$$

For $j = 0$, $\Delta T_0 = 2^{-(n-1)} \sum_{s < l} r_s r_l [1 - \cos(\phi'_s - \phi'_l)]$. Since $r_s r_l \geq 0$ and $1 - \cos(\phi'_s - \phi'_l) \geq 0$, $\Delta T_0 \geq 0$. $T_0 = 0$

if and only if all $\phi'_i = 0$, i.e., $|\psi\rangle = |\psi'\rangle$. Therefore, there is no $|\psi'\rangle \in \mathbb{P}$ and $|\psi'\rangle \neq |\psi\rangle$ that can simulate $|\psi\rangle$. $\square$

E. Discussions on strict information completeness

Suppose the to-be-determined target state is $|\psi\rangle \in \mathbb{P}_A$. In the above section, we have shown that two measurement bases are informationally complete with respect to $\mathbb{P}_A$, but they are not strictly informationally complete. The following theorem shows that there exist multi-solutions belong to $\mathbb{P}_{\bar{A}}$ that can simulate the measurement outcomes **P** and **Q**.

Theorem 3 (The existence of multi-solutions with the same measurement outcomes, i.e., not strictly informationally complete with respect to $\mathbb{P}_A$). *1. There exists $|\psi\rangle \in \mathbb{P}_A$ with the measurement outcome **P** and **Q**, and there exist many states $|\psi'\rangle \in \mathbb{P}_{\bar{A}}$ such that the measurement outcomes of $|\psi'\rangle$ are **P** and **Q**.*

*2. There exist infinitely many states $|\psi\rangle$ such that $|\psi'\rangle \in \mathbb{P}_{\bar{A}}$ has the same measurement outcomes as **P** and **Q**, and $|\langle \psi' | \psi \rangle| < 1 - \beta$ with a nonvanishing β .*

Here we give a simple example to illustrate Theorem 3. Consider the n -qubit GHZ-like state as the unknown target state

$$|\psi\rangle = a_0 |0\rangle^{\otimes n} + a_{2^n-1} e^{i\varphi_{2^n-1}} |1\rangle^{\otimes n}. \quad (17)$$

There is one solution in $\mathbb{P}_{\bar{A}}$ that may meet **P** and **Q** if two measurement bases are given. The solution is $|\psi'\rangle = a_0 |0\rangle^{\otimes n} + a_{2^n-1} e^{i(-\varphi_{2^n-1} + 2\alpha'_{2^n-1})} |1\rangle^{\otimes n}$, where α'_{2^n-1} is the parameter corresponding to **Q** basis. Obviously, this solution may be far away from $|\psi\rangle$. This is rooted in the fact that the quantum states in $\mathbb{P}_{\bar{A}}$, Lemma 2 no longer apply. The proof is shown in the Appendix.

Theorem 3 indicates that there are many distinct states that can simulate the target state. Universal quantum computation only requires the implementation of circuits such as Clifford + T circuits, or circuits consisting of single-qubit Pauli rotation gates (the rotation angle should be $\beta\pi$, where β is a rational number and T gate is $\beta = 1/4$) + CNOT gates. These circuits still make the evolving quantum state in $\mathbb{P}_A$, within which our scheme is valid, although the set of these states has a zero measure compared to the full set of pure states. Finally, we conclude by showing a certain class of pure states can be uniquely determined by two local measurements, that is, two local measurements are strictly informationally complete with respect to $\mathbb{P}$ for a certain class of pure states.

F. Numerical setup, algorithm, and simulation

1. Generating algebraic states

In the numerical simulation, the algebraic numbers and transcendental numbers are simulated on a computer us-

ing low-precision numbers and high-precision numbers, respectively, because computers can only store data in finite decimal places. We set that the target states are represented using numbers with M_1 decimal places, while the simulated states are represented using numbers with M_2 decimal places. The $e^{i\alpha}$ in the single-qubit rotation gates of the second basis are transcendental numbers with X decimal places in target states, and X' decimal places in simulated states. The numbers in probability distributions of target states $\mathbf{P}$, $\mathbf{Q}$ are numbers with Y decimal places, and probability distributions of simulated states $\mathbf{P}'$, $\mathbf{Q}'$ with Y' decimal places. We require the measurements to be represented in high precision, and thus X , X' , Y and Y' are set to be greater than M_1 and M_2 . It is worth noting that if we do a truncation of M decimal places on the target state or the simulated state directly, it will result in the final reconstructed quantum state not being unique. In this case, the truncation error of amplitude normalisation is $O(2^n 10^{-M})$, which grows exponentially as the number of qubits n increases. However, if we consider amplitude normalisation and phase normalisation, this error can be reduced, where a unique reconstructed state can be obtained.

The target state can be expressed as

$$|\psi\rangle = \sum_{k=0}^{2^n-1} r_k e^{i\varphi_k} |k\rangle = \sum_{k=0}^{2^n-1} (r_k \cos \varphi_k + i r_k \sin \varphi_k) |k\rangle, \quad (18)$$

and the simulated state can be similarly expressed as

$$|\phi\rangle = \sum_{k=0}^{2^n-1} r'_k e^{i\varphi'_k} |k\rangle = \sum_{k=0}^{2^n-1} (r'_k \cos \varphi'_k + i r'_k \sin \varphi'_k) |k\rangle. \quad (19)$$

In our setup, we do truncation on r_k , $\cos \varphi_k$, $\sin \varphi_k$ (r'_k , $\cos \varphi'_k$, $\sin \varphi'_k$), with the decimal places of the truncation set to C_1, C_2, C_3 (C'_1, C'_2, C'_3). In this work, $C_2 = C_3 = C'_2 = C'_3$ is set. It is obvious that $M_1 = C_1 + C_2$, $M_2 = C'_1 + C'_2$. In addition, the quantum state needs to satisfy amplitude normalisation and phase normalisation in Eq. (G4) and Eq. (G5).

2. Algorithm for pure state reconstruction

The goal is to find quantum states that are as close as possible to the two sets of probability distributions $\mathbf{P}$ and $\mathbf{Q}$. To do so, we use the Monte Carlo algorithm and simulated annealing algorithm [41, 42] to post-process the measured data in our two-bases scheme as a way to obtain the amplitudes and phases of the reconstructed state. We first generate a simulated state (a state whose matrix elements are randomly drawn from a certain distribution, and then the state is normalised) and compute its probability distributions $\mathbf{P}'$, $\mathbf{Q}'$ under the two measurement bases. Recall that we calculate the error of probability distributions by $\varepsilon_{\text{Prob}}$.

If the $\varepsilon_{\text{Prob}}$ of this simulated state is less than the $\varepsilon_{\text{Prob}}$ of the last randomly generated simulated state, the stored result is updated to the current simulated state. Otherwise, if the $\varepsilon_{\text{Prob}}$ of this simulated state is greater than or equal to the $\varepsilon_{\text{Prob}}$ of the last randomly generated simulated state, the stored result is updated to the current simulated state with a probability p , and the stored result is not updated with a probability $1 - p$. Repeat the above steps enough times. With a sufficiently large number of repetitions, this update scheme will eventually converge to the quantum state corresponding to the minimum value of the $\varepsilon_{\text{Prob}}$ [48, 49].

The classical post-processing for constructing the target states is efficient for sparse states. We consider sparse states with k nonzero amplitudes. The measurement results of the computational basis allow us to obtain the amplitude coefficients and to know the position of the nonzero component of the quantum state. In this case, the number of unknown phases is k instead of 2^n . Based on this analysis, we can reconstruct the k unknown phases by post-processing the measurement results of the second measurement basis.

We consider the effect of the number of decimal places of the second measurement base X' on the $\varepsilon_{\text{Prob}}$ and the average fidelity during the reconstruction process (see Fig. 4(a)). We also consider the effect of the number of decimal places of the simulated phases C'_2 on the $\varepsilon_{\text{Prob}}$ and average fidelity during the reconstruction process (see Fig. 4(b)). As we can obtain the quantum state amplitude directly from the first basis measurement, i.e., $\mathbf{r}_d = \sqrt{\mathbf{P}_d}$, the number of decimal places of the simulated amplitudes C'_1 has almost no effect on the $\varepsilon_{\text{Prob}}$ and average fidelity. Also, classical computers store floating-point numbers with 15 decimal places, so $Y = Y' = 15$ is set. As can be seen in both graphs, the error in probability distribution $\varepsilon_{\text{Prob}}$ fluctuates in a small range as the number of decimal places changes, but the average fidelity is stable around 99.999%.

3. Adding more measurement bases.

Moreover, we study the performance when adding another measurement basis. Intuitively, adding more bases will make our scheme more robust because the states are more likely to be distinguished with more measurement results. We find that adding a measurement base, such as $\{|k\rangle\} = \{H'|i\rangle\}$, $H' = H^{\otimes n}$, $i = 0, 1, \dots, 2^n - 1$ where H is the Hadamard gate, the robustness of our scheme against noise can be greatly enhanced. We randomly generate a 5-qubit pure state $|\psi\rangle$ and add depolarising noise. Then we obtain the probability distributions under three measurement bases, and post-process the noisy data. We extend the definition by

$$\varepsilon_{\text{Prob}} = \sum_{i=1}^3 \|\mathbf{P}'_i - \mathbf{P}_i\|_2,$$

FIG. 4. **The reconstruction error with respect to the precision of the bases and the phases of the state.** The precision (i.e. the number of decimal places) of the second measurement base X' and the simulated phases C'_2 during the reconstruction process are varied respectively, in order to test their effects on the ϵ_{Prob} and average fidelity of the reconstructed 3-qubit quantum state by using two local measurement bases scheme. The numbers of decimal places for the amplitudes are $C_1 = C'_1 = 3$, for the phases are $C_2 = 3$ and C'_2 changing from 3 to 8. The numbers of decimal places for the second measurement base are $X = 15$ and X' changing from 6 to 15, and for the measured probability distributions are $Y = Y' = 15$. Forty 3-qubit quantum states are randomly generated and each quantum state is reconstructed 2500 times. (a)(b) We choose the reconstruction result with the smallest ϵ_{Prob} for each state and average the ϵ_{Prob} and fidelity over the 40 states. **a**, The horizontal coordinate is the number of decimal places of the second measurement base X' , the blue dots reflect the values of ϵ_{Prob} , while the red dots reflect the values of the absolute values of 1 minus the average fidelity. **b**, The horizontal coordinate is the number of decimal places of the simulated phases C'_2 , the blue dots reflect the values of ϵ_{Prob} , while the red dots reflect the values of the absolute values of 1 minus the average fidelity.

where $\mathbf{P}_1, \mathbf{P}_2, \mathbf{P}_3$ represent the probability distributions under three measurement bases of the target states, and $\mathbf{P}'_1, \mathbf{P}'_2, \mathbf{P}'_3$ represent the probability distributions under three measurement bases of the simulated states. Another measure of the quality of the reconstruction process is the infidelity defined as $|1 - \text{Fidelity}| = |1 - |\langle \phi | \psi \rangle|^2|$. Fig. 5 shows ϵ_{Prob} and $|1 - \text{Fidelity}|$ versus the depolarising noise rate. When the depolarising noise rate reaches 0.10, the fidelity can still be 95.61%, indicating that the addition of a measurement base helps to greatly enhance the noise immunity of our measurement scheme.

G. Understanding previous works within our framework

The original concept of information completeness is for all quantum states. For a general positive operator-valued measure (POVM) $\{E_k\}$, we call them informationally complete if the following condition holds,

$$\forall k, \text{tr}(E_k \rho_1) = \text{tr}(E_k \rho_2) \Rightarrow \rho_1 = \rho_2, \quad (20)$$

for all $\rho_1, \rho_2 \in \mathbb{A}$, where $\mathbb{A}$ corresponds to the set of all density matrices. This needs the measurement operators $\{E_k\}$ to span the whole Hermitian matrix space. Thus an

informationally complete POVM should contain at least d^2 operators. It is proven that $d + 1$ mutually unbiased bases (MUBs) are minimal and optimal. The symmetric informationally complete POVM (SIC-POVM) contains d^2 measurement outcomes [50]. But the existence of $d + 1$ MUBs and SIC-POVM for arbitrary dimension d is still unknown up to now. The existence problems are selected as the first two open questions of quantum information theory by Horodecki *et al.* [51].

In order to decrease the number of measurement outcomes, prior knowledge of the unknown state is taken into consideration. That is to say, the target unknown states are some subset of the whole space $\mathbb{A}$. The prior information could be matrix product states [15, 16], permutation invariant states [17, 18], and subsets from a fiducial state [52] and so on. When the set for prior information of pure states is restricted $\mathbb{P} - E$, where E is a set of measure zero, Flammia *et al.* proved that any POVM with $2d - 1$ outcomes is not enough. Two special kinds of POVM are constructed: One is with $2d$ elements and the other is with $3d - 2$ rank-1 elements [5]. Later, it is proven that POVM with $2d$ rank-1 elements is also enough [39]. It is proven that five projective measurements onto orthonormal bases are also enough [6]. Adding an auxiliary qubit, the number of orthonormal bases can decrease to 2 or three, while the number of total measurement outcomes is the same or $4d$ [53]. Three orthonormal bases

FIG. 5. **Fidelity improvement when adding the third basis.** A 5-qubit pure state is randomly generated and depolarising noise is added to produce its probability distributions under three measurement bases. Then we use the measurement results to reconstruct the pure state. The horizontal coordinate is the coefficient of the depolarising noise added to the randomly generated pure state, the blue dots reflect the values of ϵ_{prob} , while the red dots reflect the values of the absolute values of 1 minus the fidelity.

are designed for this task, where totally $2^d - 1$ different pure states match the probability distributions. [7]. For dimension $d = 4$, it is proven that infinite candidates can match the probability distribution of Peres's two unbiased bases [9]. For n -qubit systems, $mn + 1$ separable bases [20] and $2n + 1$ Pauli observables are considered [19].

When the set of prior information of pure states is $\mathbb{P}$, it is proven that the POVM should contain at least $4d - 3 - c(d)\alpha(d)$ elements, where $c(d) \in [1, 2]$ and $\alpha(d)$ is the number of ones appearing in the binary expansion of $d - 1$ [34]. In other words, a POVM must consist of at least $4d - 5$ elements to distinguish a pure state from any other pure quantum states. While the four orthonormal bases are theoretically enough [8]. There is also a hot topic about directly reconstructing pure quantum states. With an auxiliary pointer and sequential weak measurements, two unbiased bases are enough [22]. The ancilla can be removed from σ -quench measurement [23].

For certain schemes, the reconstruction method entails

utilizing convex optimization to derive a density matrix that best matches the measurement data. Then theoretically, it should avoid another density matrix that matches the data of pure states. This needs the POVM $\{E_k\}$ to be strictly informationally complete with pure states, i.e.,

$$\forall k, \quad \text{tr}(E_k |\phi\rangle\langle\phi|) = \text{tr}(E_k \rho) \Rightarrow |\phi\rangle\langle\phi| = \rho, \quad (21)$$

for all $|\phi\rangle \in \mathbb{P}$ and $\rho \in \mathbb{A}$. To ensure strict information completeness with pure states, five eigenbases are sufficient [27]. At least $5d - 7$ operators should be considered [10]. Namely, a POVM must consist of at least $5d - 7$ elements to distinguish a pure state from any other quantum states, pure or mixed. For 2-qubit pure states, a total of 11 Pauli measurements are required, while for 3-qubit pure states, 31 Pauli measurements are needed [24]. Pure states correspond to rank-1 density matrices. The definition of strict information completeness with pure states is generalised to strictly rank- r complete [54], by replacing the set $\mathbb{P}$ with $\mathbb{A}_r$, where $\mathbb{A}_r$ corresponds to the set of all rank- r density matrices. The compressed sensing method shows that randomly chosen $O(rn^2 2^n)$ Pauli observables can reconstruct unknown rank- r density matrix with high probability [25].

The current results can be summarised as follows.

1. For all $|\psi_1\rangle, |\psi_2\rangle \in \mathbb{P} - E$, where E is a measure zero set, any 2 sets of eigenbases are not informationally complete [5].
2. For all $|\psi_1\rangle, |\psi_2\rangle \in \mathbb{P}$, the minimal number of eigenbases is 3 for $d = 2$. When $d = 3$ or $d \geq 5$, the minimal number is 4. The problem is still open for $d = 3$, where 4 sets of eigenbases are enough by not clear whether 3 sets of eigenbases are also enough [26].
3. For all $|\psi_1\rangle, |\psi_2\rangle \in \mathbb{P} - E$, where E is a measure zero set, 5 sets of eigenbases are constructed [6], $mn + 1$ sets of eigenbases [20] and $2n + 1$ Pauli bases are enough.

Another relevant topic is pure state verification. Rather than reconstructing unknown states belonging to a subset, the aim is to ascertain whether the states produced by a device are, on average, sufficiently close to the given target state $|\phi\rangle$. Various types of pure states are explored, including bipartite pure states, stabiliser states, hypergraph states, weighted graph states, Dicke states, answer vectors of linear equations, and more [28, 30, 33, 55–60].

SUPPLEMENTARY INFORMATION FOR "TWO MEASUREMENT BASES ARE ASYMPTOTICALLY INFORMATIONALLY COMPLETE FOR ANY PURE STATE TOMOGRAPHY"

Appendix A: Proof of the uniqueness for the qudit case in [Theorem 1](#)

1. Derivation of probability distributions for a qudit state

A general qudit state can be written as

$$|\psi\rangle = \sum_{k=0}^{d-1} r_k e^{i\varphi_k} |k\rangle, \quad (\text{A1})$$

where $\sum_{k=0}^{d-1} r_k^2 = 1$ and $r_k \geq 0$. Clearly, one can determine all r_k based on the results of the probability distribution of the computational basis (the first measurement base in our scheme). The unitary of the second measurement base of our scheme is given as

$$S'^{\dagger} = F^{\dagger} D^{\dagger}, \quad (\text{A2})$$

where $F = \sum_{m,n=0}^{d-1} \frac{1}{\sqrt{d}} e^{\frac{2\pi i m n}{d}} |m\rangle \langle n|$ is the d -dimensional quantum Fourier transform and $D^{\dagger} = \sum_{m=0}^{d-1} e^{-i\theta_m} |m\rangle \langle m|$ which is a diagonal phase gate. Since $D^{\dagger}$ is a diagonal matrix, it alters only the phase of the quantum state, leaving the amplitude unchanged. Consequently, any qudit state will retain its form, apart from the phase shift induced by D . To ease the discussion, we begin by examining the action of $F^{\dagger}$ on a general qudit state.

A quantum state $|\psi\rangle = \sum_{k=0}^{d-1} r_k e^{i\varphi_k} |k\rangle$ after applying $F^{\dagger}$ is given by

$$|\psi^F\rangle = F^{\dagger} |\psi\rangle = \sum_{j=0}^{d-1} \psi_j^F |j\rangle, \quad (\text{A3})$$

where $\psi_j^F = \frac{1}{\sqrt{d}} \sum_{k=0}^{d-1} r_k e^{i\varphi_k} e^{-\frac{2\pi i j k}{d}} = \frac{1}{\sqrt{d}} \sum_{k=0}^{d-1} r_k e^{i(\varphi_k - \frac{2\pi j k}{d})}$. The j -th amplitude of the state now becomes

$$Q_j(F^{\dagger} |\psi\rangle) = |\langle j | \psi^F \rangle|^2 = \psi_j^F \psi_j^{F\dagger} = \frac{1}{d} + \frac{2}{d} \sum_{s < l} r_s r_l \cos \left[\varphi_s - \varphi_l - \frac{2\pi j (s-l)}{d} \right]. \quad (\text{A4})$$

Since Eq. (A4) holds for a general state, the probability distribution when measuring in our second base is

$$Q_j(F^{\dagger} D^{\dagger} |\psi\rangle) = Q_j(F^{\dagger} |\phi\rangle) = \frac{1}{d} + \frac{2}{d} \sum_{s < l} r_s r_l \cos \left[(\varphi_s - \varphi_l) - (\theta_s - \theta_l) - \frac{2\pi j (s-l)}{d} \right], \quad (\text{A5})$$

where $|\phi\rangle = F^{\dagger} |\psi\rangle = \sum_{k=0}^{d-1} e^{-i\theta_k} |k\rangle \langle k | \psi \rangle = \sum_{j=0}^{d-1} r_j e^{i(\varphi_j - \theta_j)} |j\rangle$. This is because the measurement result under the second basis is equivalent to shifting the phase of the quantum state from φ_j to $\varphi_j - \theta_j$ in the Eq. (A4).

2. Proof of uniqueness of qudit states $\in \mathbb{P}_A$

In our scheme, the vectors $\mathbf{P}$ and $\mathbf{Q}$ represent the measurement distributions of the two bases for an unknown quantum state $|\psi\rangle = \sum_{j=0}^{d-1} r_j e^{i\varphi_j} |j\rangle$. Specifically, $P_j = r_j^2$ denoting the j th component of $\mathbf{P}$ and $Q_j = Q_j(F^{\dagger} D^{\dagger} |\psi\rangle)$ (see Eq. (A5)) denoting the j th component of $\mathbf{Q}$. In the following, we prove the uniqueness of our two measurement bases for any algebraic pure state (i.e. r_j , $\cos(\phi_j)$ and $\sin(\phi_j)$ are algebraic numbers) using a proof by contradiction.

Specifically, suppose there exists one or more algebraic states $|\psi'\rangle \in \mathbb{P}_A$ that is different from the target algebraic state $|\psi\rangle \in \mathbb{P}_A$, yet has the same probability distributions $\mathbf{P}$ and $\mathbf{Q}$ in our two measurement bases as the target state $|\psi\rangle$. The set consisting of all $|\psi'\rangle$ is called the null space, indicating that the tomography scheme will fail within this null space.

Let us analyze the conditions that $|\psi'\rangle \in \mathbb{P}_A$ should satisfy. First $|\psi'\rangle$ can simulate the unknown algebraic state $|\psi\rangle$ under the computational base. Without losing generality, we set $|\psi\rangle = \sum_{j=0}^{d-1} r_j e^{i\varphi_j} |j\rangle$ and $|\psi'\rangle = \sum_{j=0}^{d-1} r_j e^{i\varphi'_j} |j\rangle$, where $r_j \geq 0$, $\varphi, \varphi' \in [0, 2\pi)$. Given that the global phase has no physical observation effect, we first choose g from

the set $V = \{k | r_k \neq 0\}$, where k is an integer that varies from 0 to $d-1$ and simultaneously satisfies $r_k \neq 0$. Here, g represents the smallest ordinal number of the non-zero amplitudes. We then set its corresponding phase $\varphi_g = 0$ and $\varphi'_g = 0$, which means that we use it as the reference standard to define the remaining phases. It is important to note that if the amplitude of a component is zero, the value of its phase is meaningless. Therefore a more accurate description of the unknown quantum state should be

$$|\psi\rangle = \sum_{j \in V} r_j e^{i\varphi_j} |j\rangle = \sum_{j \in V, j \neq g} r_j e^{i\varphi_j} |j\rangle + r_g |g\rangle. \quad (\text{A6})$$

The corresponding quantum state $|\psi'\rangle$ that simulates the measurement result of unknown quantum state $|\psi\rangle$ under the computational base is

$$|\psi'\rangle = \sum_{j \in V} r_j e^{i\varphi'_j} |j\rangle = \sum_{j \in V, j \neq g} r_j e^{i\varphi'_j} |j\rangle + r_g |g\rangle. \quad (\text{A7})$$

We have assumed that $|\psi'\rangle$ is different from $|\psi\rangle$ at the beginning of our proof, so at this point, there is at least one different phase with nonzero amplitude between $|\psi\rangle$ and $|\psi'\rangle$.

Let us analyse whether $|\psi'\rangle$ can simulate the unknown algebraic state $|\psi\rangle$ under the second basis. If it is true, we have $\Delta Q_j = Q_j - Q'_j = 0$, where Q'_j donates the measurement outcome of the simulated state $|\psi'\rangle$. Let us calculate the difference of the probability, e.g.

$$\Delta Q_j = Q_j - Q'_j = \frac{2}{d} \sum_{s < l \in V} r_s r_l \left\{ \cos \left[(\varphi_s - \varphi_l) - (\theta_s - \theta_l) - \frac{2\pi j(s-l)}{d} \right] - \cos \left[(\varphi'_s - \varphi'_l) - (\theta_s - \theta_l) - \frac{2\pi j(s-l)}{d} \right] \right\}. \quad (\text{A8})$$

Expanding ΔQ_j yields:

$$\begin{aligned} \Delta Q_j &= \frac{2}{d} \sum_{s < l \in V} r_s r_l \left\{ \cos \left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d} \right] \cos(\theta_s - \theta_l) + \sin \left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d} \right] \sin(\theta_s - \theta_l) \right. \\ &\quad \left. - \cos \left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d} \right] \cos(\theta_s - \theta_l) - \sin \left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d} \right] \sin(\theta_s - \theta_l) \right\} \\ &= \frac{2}{d} \sum_{s < l \in V} r_s r_l \left\{ \left\{ \cos \left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d} \right] - \cos \left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d} \right] \right\} \cos(\theta_s - \theta_l) \right. \\ &\quad \left. + \left\{ \sin \left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d} \right] - \sin \left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d} \right] \right\} \sin(\theta_s - \theta_l) \right\} \\ &= \sum_{s < l \in V} C_{sl}^{(j)} \cos(\theta_s - \theta_l) + S_{sl}^{(j)} \sin(\theta_s - \theta_l), \end{aligned} \quad (\text{A9})$$

where

$$\begin{aligned} C_{sl}^{(j)} &= \frac{2}{d} r_s r_l \left\{ \cos \left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d} \right] - \cos \left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d} \right] \right\}, \\ S_{sl}^{(j)} &= \frac{2}{d} r_s r_l \left\{ \sin \left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d} \right] - \sin \left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d} \right] \right\}. \end{aligned}$$

Given the definitions and properties of algebraic numbers, we know that algebraic numbers remain algebraic under addition, subtraction, multiplication, and division by another algebraic number. Therefore, for the states $|\psi\rangle$ and $|\psi'\rangle$ in the set $\mathbb{P}_A$, the following holds true: (1) The amplitudes r_k and r'_k are algebraic numbers. (2) The trigonometric functions of the phases, $\cos \varphi_k$, $\sin \varphi_k$, $\cos \varphi'_k$, and $\sin \varphi'_k$ are algebraic numbers. (3) $\cos \left[\frac{2\pi j(s-l)}{d} \right]$, $\sin \left[\frac{2\pi j(s-l)}{d} \right]$ are algebraic numbers where j, s, l, d are integers. As such, it is easy to prove $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are algebraic numbers.

Consider the conditions we mentioned in the main text:

1. A.1, $\theta_l - \theta_k$ is an algebraic number for $0 \leq l < k \leq d-1$.
2. A.2, $|\theta_l - \theta_k|$ is not equal to $|\theta_{l'} - \theta_{k'}|$ for any different pair (l, k) and (l', k') , where $0 \leq l < k \leq d-1$ and $0 \leq l' < k' \leq d-1$.

If the above two conditions hold, we can deduce that $\{\cos(\theta_l - \theta_k), \sin(\theta_l - \theta_k)\}$ are linearly independent over the field of all algebraic numbers by Lemma 2. That is, if $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are not all 0, there must be

$$\Delta Q_j = \sum_{s < l \in V} C_{sl}^{(j)} \cos(\theta_s - \theta_l) + S_{sl}^{(j)} \sin(\theta_s - \theta_l) \neq 0.$$

For the case where $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are all 0, one has $\Delta Q_j = 0$. We shall see that this results in $\varphi_i = \varphi'_i$, i.e. $|\psi\rangle = |\psi'\rangle$. This is because all $C_{sl}^{(j)} = 0$ and $S_{sl}^{(j)} = 0$ suggest

$$\begin{aligned} \cos\left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d}\right] - \cos\left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d}\right] &= 0, \\ \sin\left[\varphi_s - \varphi_l - \frac{2\pi j(s-l)}{d}\right] - \sin\left[\varphi'_s - \varphi'_l - \frac{2\pi j(s-l)}{d}\right] &= 0. \end{aligned}$$

There exists $s \in V$. Let us choose to set $s = g$ and we have $\varphi_s = \varphi_g = 0 = \varphi'_s = \varphi'_g$. The above equations become

$$\cos\left[-\varphi_l - \frac{2\pi j(g-l)}{d}\right] = \cos\left[-\varphi'_l - \frac{2\pi j(g-l)}{d}\right], \quad \sin\left[-\varphi_l - \frac{2\pi j(g-l)}{d}\right] = \sin\left[-\varphi'_l - \frac{2\pi j(g-l)}{d}\right]. \quad (\text{A10})$$

Since $\varphi_s, \varphi'_s \in [0, 2\pi)$, the solution for Eq. (B13) is $\varphi_s = \varphi'_s$. This analysis hold for any $s \in V$. Therefore, there is no quantum state $|\psi'\rangle \in \mathbb{P}_A$ can simulate the measurement outcome $\mathbf{P}$ and $\mathbf{Q}$ of a state $|\psi\rangle \in \mathbb{P}_A$ given $|\psi\rangle \neq |\psi'\rangle$.

In other words, satisfying the conditions A.1 and A.2, our two-measurement-bases scheme is informationally complete with respect to all algebraic pure states. A simple example satisfying the above relationship is $\alpha_k = 2^{k-1}z_0$ where z_0 is an arbitrary algebraic number for all k . Another example is $\theta_k = \sqrt{\alpha_k}$ where $\{\alpha_k : k = 0, \dots, d-1\}$ are positive prime numbers.

Appendix B: Proof of the uniqueness for qubit systems

1. Derivation of probability distributions for multi-qubit states

Similar to the qudit case, a general n -qubit pure state can be written as

$$|\psi\rangle = \sum_{k=0}^{2^n-1} r_k e^{i\varphi_k} |k\rangle, \quad (\text{B1})$$

where $\sum_{k=0}^{2^n-1} r_k^2 = 1$ and $r_k \geq 0$. The coefficient r_k can be determined the probability distribution of the computational basis (the first measurement base in our scheme). The unitary of the second measurement base of our scheme is given as

$$S'^{\dagger} = \bigotimes_{j=1}^n S_j^{\dagger} = \left(\bigotimes_{j=1}^n H^{\dagger}\right) D^{\dagger} = H'^{\dagger} D^{\dagger}. \quad (\text{B2})$$

where $D^{\dagger} = \sum_{m=0}^{d-1} e^{-i\theta_m} |m\rangle\langle m|$,

$$H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}, \text{ and } H' = \bigotimes_{j=1}^n H. \quad (\text{B3})$$

Here we first derive the quantum state after acting n -qubit Hadamard gates. For a single-qubit case, $H^{\dagger}|j\rangle = \frac{1}{\sqrt{2}}(|0\rangle + (-1)^j|1\rangle) = \frac{1}{\sqrt{2}}\sum_{p=0}^1 (-1)^{jp}|p\rangle$. Extending to n qubits case, we have

$$\begin{aligned} H'^{\dagger}|j\rangle &= (H^{\dagger})^{\otimes n}|j\rangle = \frac{1}{\sqrt{2^n}} \left[|0\rangle + (-1)^{j_n}|1\rangle\right] \otimes \left[|0\rangle + (-1)^{j_{n-1}}|1\rangle\right] \otimes \dots \otimes \left[|0\rangle + (-1)^{j_1}|1\rangle\right] \\ &= \frac{1}{\sqrt{2^n}} \sum_{p_1, p_2, \dots, p_n=0}^1 (-1)^{\sum_{m=1}^n j_m p_m} |p_n p_{n-1} \dots p_1\rangle \\ &= \frac{1}{\sqrt{2^n}} \sum_{p_1, p_2, \dots, p_n=0}^1 (-1)^{\sum_{m=1}^n j_m \delta_{p_m, 1}} |p_n p_{n-1} \dots p_1\rangle, \end{aligned} \quad (\text{B4})$$

where $|j\rangle = |j_n j_{n-1} \cdots j_1\rangle$, $j_1, j_2, \dots, j_n \in \{0, 1\}$. Apply to the general form of quantum state (Eq. (B1)) we get

$$|\psi^H\rangle = H'^\dagger |\psi\rangle = \sum_{j=0}^{2^n-1} \psi_j^H |j\rangle, \quad (\text{B5})$$

where $\psi_j^H = \frac{1}{\sqrt{2^n}} \sum_{k=0}^{2^n-1} (-1)^{j_1 \delta_{k_1,1} + j_2 \delta_{k_2,1} + \cdots + j_n \delta_{k_n,1}} r_k e^{i\varphi_k}$, $|j\rangle = |j_n j_{n-1} \cdots j_1\rangle$, $|k\rangle = |k_n k_{n-1} \cdots k_1\rangle$. The square of the j -th amplitude of the state now becomes

$$Q_j(H'^\dagger |\psi\rangle) = |\langle j | \psi^H \rangle|^2 = \psi_j^H \psi_j^{H\dagger} = \frac{1}{2^n} + \frac{1}{2^{n-1}} \sum_{s < l} (-1)^{h(j,s)+h(j,l)} r_s r_l \cos(\varphi_s - \varphi_l), \quad (\text{B6})$$

while $h(j, s) = j_1 \delta_{s_1,1} + j_2 \delta_{s_2,1} + \cdots + j_n \delta_{s_n,1}$, $h(j, l) = j_1 \delta_{l_1,1} + j_2 \delta_{l_2,1} + \cdots + j_n \delta_{l_n,1}$, $|s\rangle = |s_n s_{n-1} \cdots s_1\rangle$, $|l\rangle = |l_n l_{n-1} \cdots l_1\rangle$.

Now the probability distribution of our second measurement base is given as

$$\begin{aligned} Q_j(S'^\dagger |\psi\rangle) &= Q_j(H'^\dagger |\phi\rangle) = \frac{1}{2^n} + \frac{1}{2^{n-1}} \sum_{s < l} (-1)^{h(j,s)+h(j,l)} r_s r_l \cos(\varphi_s - \theta_s - \varphi_l + \theta_l) \\ &= \frac{1}{2^n} + \frac{1}{2^{n-1}} \sum_{s < l} (-1)^{h(j,s)+h(j,l)} r_s r_l \cos[(\varphi_s - \varphi_l) - (\theta_s - \theta_l)], \end{aligned} \quad (\text{B7})$$

where $|\phi\rangle = D^\dagger |\psi\rangle = \sum_{k=0}^{2^n-1} e^{-i\theta_k} |k\rangle \langle k | \psi \rangle = \sum_{j=0}^{2^n-1} r_j e^{i(\varphi_j - \theta_j)} |j\rangle$. It can be seen that the measurement results of the second basis are equivalent to shifting the phases of the quantum state from φ_j to $\varphi_j - \theta_j$ in the Eq. (B6).

2. Proof of uniqueness of multi-qubit states $\in \mathbb{P}_A$

Suppose that there exists such an algebraic state $|\psi'\rangle \in \mathbb{P}_A$ can simulate the measurement outcomes $\mathbf{P}$ and $\mathbf{Q}$ of proposed two measurement bases of $|\psi\rangle \in \mathbb{P}_A$. Here we assume $|\psi\rangle = \sum_{j=0}^{2^n-1} r_j e^{i\varphi_j} |j\rangle$ and set $P_j = r_j^2$ denoting the j th component of $\mathbf{P}$ and $Q_j = Q_j(S'^\dagger |\psi\rangle)$ (see Eq. (B7)) denoting the j th component of $\mathbf{Q}$.

Let us analyze the conditions that $|\psi'\rangle \in \mathbb{P}_A$ should satisfy. First $|\psi'\rangle$ can simulate the unknown algebraic state $|\psi\rangle$ under the computational base, e.g. $P'_j = P_j$. Therefore, without losing generality, we suppose $|\psi\rangle = \sum_{j=0}^{2^n-1} r_j e^{i\varphi_j} |j\rangle$ and $|\psi'\rangle = \sum_{j=0}^{2^n-1} r'_j e^{i\varphi'_j} |j\rangle$, where $r_j \geq 0$, $\varphi, \varphi' \in [0, 2\pi)$ ($r_j, r'_j, \cos(\varphi_j), \cos(\varphi'_j), \sin(\varphi_j)$ and $\sin(\varphi'_j)$ are algebraic numbers). Given that the global phase has no physical observation effect, we first choose g from the set $V = \{k | r_k \neq 0\}$, where k is an integer that varies from 0 to $2^n - 1$ and simultaneously satisfies $r_k \neq 0$. Here, g represents the smallest ordinal number of the non-zero amplitudes. We then set its corresponding phase $\varphi_g = 0$ and $\varphi'_g = 0$, which means that we use it as the reference standard to define the remaining phases. It is important to note that if the amplitude of a component is zero, the value of its phase is meaningless. Therefore a more accurate description of the unknown quantum state should be

$$|\psi\rangle = \sum_{j \in V} r_j e^{i\varphi_j} |j\rangle = \sum_{j \in V, j \neq g} r_j e^{i\varphi_j} |j\rangle + r_g |g\rangle. \quad (\text{B8})$$

The corresponding quantum state $|\psi'\rangle$ that simulates the measurement result of unknown quantum state $|\psi\rangle$ under the computational base is

$$|\psi'\rangle = \sum_{j \in V} r'_j e^{i\varphi'_j} |j\rangle = \sum_{j \in V, j \neq g} r'_j e^{i\varphi'_j} |j\rangle + r'_g |g\rangle. \quad (\text{B9})$$

Since $|\psi'\rangle$ is assume to be a state different from $|\psi\rangle$, there is at least one different phase with nonzero amplitude between $|\psi\rangle$ and $|\psi'\rangle$.

Let analyse whether $|\psi'\rangle$ can simulate the unknown algebraic state $|\psi\rangle$ under the second basis. If it is true, we have $\Delta Q_j = Q_j - Q'_j = 0$, where Q'_j donates the measurement outcome of the simulated state $|\psi'\rangle$. Now we calculate the difference of the probability, e.g.

$$\Delta Q_j = Q_j - Q'_j = \frac{1}{2^{n-1}} \sum_{s < l \in V} (-1)^{h(j,s)+h(j,l)} r_s r_l \{ \cos[(\varphi_s - \varphi_l) - (\theta_s - \theta_l)] - \cos[(\varphi'_s - \varphi'_l) - (\theta_s - \theta_l)] \}. \quad (\text{B10})$$

Expanding ΔQ_j yields:

$$\begin{aligned}\Delta Q_j &= \frac{1}{2^{n-1}} \sum_{s < l \in V} (-1)^{h(j,s)+h(j,l)} r_s r_l \{ [\cos(\varphi_s - \varphi_l) - \cos(\varphi'_s - \varphi'_l)] \cos(\theta_s - \theta_l) + [\sin(\varphi_s - \varphi_l) - \sin(\varphi'_s - \varphi'_l)] \sin(\theta_s - \theta_l) \} \\ &= \sum_{s < l \in V} C_{sl}^{(j)} \cos(\theta_s - \theta_l) + S_{sl}^{(j)} \sin(\theta_s - \theta_l),\end{aligned}\tag{B11}$$

where

$$\begin{aligned}C_{sl}^{(j)} &= \frac{1}{2^{n-1}} (-1)^{h(j,s)+h(j,l)} r_s r_l [\cos(\varphi_s - \varphi_l) - \cos(\varphi'_s - \varphi'_l)], \\ S_{sl}^{(j)} &= \frac{1}{2^{n-1}} (-1)^{h(j,s)+h(j,l)} r_s r_l [\sin(\varphi_s - \varphi_l) - \sin(\varphi'_s - \varphi'_l)].\end{aligned}\tag{B12}$$

Note that (1) The amplitudes r_k and r'_k are algebraic numbers. (2) The trigonometric functions of the phases, $\cos \varphi_k$, $\sin \varphi_k$, $\cos \varphi'_k$, and $\sin \varphi'_k$ are algebraic numbers. Similar to the qudit case, it is easy to prove $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are algebraic numbers. Consider the following conditions:

1. A.1, $\theta_l - \theta_k$ is an algebraic number for $0 \leq l < k \leq 2^n - 1$.
2. A.2, $|\theta_l - \theta_k|$ is not equal to $|\theta_{l'} - \theta_{k'}|$ for any different pair (l, k) and (l', k') , where $0 \leq l < k \leq 2^n - 1$ and $0 \leq l' < k' \leq 2^n - 1$.

If the above two conditions hold, we can deduce that $\{\cos(\theta_l - \theta_k), \sin(\theta_l - \theta_k)\}$ are linearly independent over the field of all algebraic numbers by [Lemma 2](#). That is, if $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are not all 0, there must be

$$\Delta Q_j = \sum_{s < l \in V} C_{sl}^{(j)} \cos(\theta_s - \theta_l) + S_{sl}^{(j)} \sin(\theta_s - \theta_l) \neq 0.$$

For the case where $C_{sl}^{(j)}$ and $S_{sl}^{(j)}$ are all 0, one has $\Delta Q_j = 0$. We shall see that this results in $\varphi_i = \varphi'_i$, i.e. $|\psi\rangle = |\psi'\rangle$. This is because all $C_{sl}^{(j)} = 0$ and $S_{sl}^{(j)} = 0$ suggest

$$\cos(\varphi_s - \varphi_l) - \cos(\varphi'_s - \varphi'_l) = 0,$$

$$\sin(\varphi_s - \varphi_l) - \sin(\varphi'_s - \varphi'_l) = 0.$$

There exist $s \in V$. Let us choose to set $s = g$ and we have $\varphi_s = \varphi_g = 0 = \varphi'_s = \varphi'_g$. The above equations become

$$\cos(-\varphi_l) = \cos(-\varphi'_l), \quad \sin(-\varphi_l) = \sin(-\varphi'_l).\tag{B13}$$

Since $\varphi_s, \varphi'_s \in [0, 2\pi)$, the solution for Eq. (B13) is $\varphi_s = \varphi'_s$. This analysis holds for any $s \in V$. Therefore, there is no quantum state $|\psi'\rangle \in \mathbb{P}_A$ can simulate the measurement outcome $\mathbf{P}$ and $\mathbf{Q}$ of a state $|\psi\rangle \in \mathbb{P}_A$ given $|\psi\rangle \neq |\psi'\rangle$.

In other words, satisfying the conditions A.1 and A.2, our two-measurement-bases scheme is informationally complete with respect to all algebraic pure states. A simple example satisfying the above relationship is $\alpha_k = 2^{k-1} z_0$ where z_0 is an arbitrary algebraic number for all k . Another example is $\theta_k = \sqrt{\alpha_k}$ where $\{\alpha_k : k = 0, \dots, d-1\}$ are positive prime numbers.

3. Uniqueness for Sparse state $\in \mathbb{P}_A$

Our above proof shows for any pure algebraic state, two measurement bases are informationally complete. However, as the state dimension increases, the complexity of implementing the second measurement basis also grows. For an n -qubit system, where $d = 2^n$, the implementation of a global phase gate becomes exponentially complex in the general case.

Given the measurement distribution of the first basis, the implementation of the second basis can be significantly simplified. This is because applying phase operations to components that are zero in the computational basis is

unnecessary. Consequently, if the number of nonzero components r_k of the quantum state in the computational basis scales polynomially with n , i.e. $O(\text{poly}(n))$, the operation $D^\dagger$ for the second basis can be defined as follows:

$$D^\dagger = \sum_{m=0}^{d-1} e^{-i\theta_m(1-\delta_{r_m,0})} |m\rangle\langle m| = \sum_{m \in V} e^{-i\theta_m} |m\rangle\langle m| + \sum_{m \neq V} |m\rangle\langle m| \quad (\text{B14})$$

where $\delta_{r_m,0}$ is the delta function and V is defined as the set with a non-zero component of the quantum state (see Eq. (B8)). This indicates that $D^\dagger$ can be realised by polynomial elementary gates.

One can verify that the uniqueness of the sparse state $\in \mathbb{P}_A$ with simplified implementation also holds since the proof is the same as the general one.

Appendix C: Discussions the uniqueness of a set of $\mathbb{P}_A$ for two-local measurement bases

For the local measurement bases case, one may use $\bigotimes_{j=1}^n R^\dagger(\alpha_j)$ to replace the entangled diagonal phase gate $D^\dagger$, i.e.

$$(D')^\dagger = \bigotimes_{j=1}^n R^\dagger(\alpha_j) = \sum_{m=0}^{2^n-1} e^{-i\alpha'_m} |m\rangle\langle m|, \quad (\text{C1})$$

where $|m\rangle = |m_n m_{n-1} \cdots m_1\rangle$ and $\alpha'_m = \sum_{p=1}^n \alpha_p m_p = \sum_{p=1}^n \alpha_p \delta_{m_p,1}$. Here $R(\alpha_j) = R_j$ is defined as follows,

$$R_j = \begin{bmatrix} 1 & 0 \\ 0 & e^{i\alpha_j} \end{bmatrix}.$$

Thus, the unitary of the second bases is equivalent to acting a diagonal phase gate $\bigotimes_{j=1}^n R^\dagger(\alpha_j) = \sum_{m=0}^{2^n-1} e^{-i\alpha'_m} |m\rangle\langle m|$ on the quantum state and then applying the Hadamard gate on each qubit.

Similar to the analysis in Sec. B, expanding ΔQ_j yields:

$$\begin{aligned} \Delta Q_j &= \frac{1}{2^{n-1}} \sum_{s < l \in V} (-1)^{h(j,s)+h(j,l)} r_s r_l \{ [\cos(\varphi_s - \varphi_l) - \cos(\varphi'_s - \varphi'_l)] \cos(\alpha'_s - \alpha'_l) + [\sin(\varphi_s - \varphi_l) - \sin(\varphi'_s - \varphi'_l)] \sin(\alpha'_s - \alpha'_l) \} \\ &= \sum_{\Delta_t} f_1(j|\Delta_t) \cos \Delta_t + f_2(j|\Delta_t) \sin \Delta_t, \end{aligned} \quad (\text{C2})$$

where $\Delta_t = \alpha'_s - \alpha'_l$ represents t -th different relative phases (for local bases, there may exist many relative phases of $\{\alpha'_s\}$ that are the same), and we have:

$$\begin{aligned} f_1(j|\Delta_t) &= \frac{1}{2^{n-1}} \sum_{s < l \in V} (-1)^{h(j,s)+h(j,l)} r_s r_l [\cos(\varphi_s - \varphi_l) - \cos(\varphi'_s - \varphi'_l)]_{\Delta_t = \alpha'_s - \alpha'_l}, \\ f_2(j|\Delta_t) &= \frac{1}{2^{n-1}} \sum_{s < l \in V} (-1)^{h(j,s)+h(j,l)} r_s r_l [\sin(\varphi_s - \varphi_l) - \sin(\varphi'_s - \varphi'_l)]_{\Delta_t = \alpha'_s - \alpha'_l}. \end{aligned} \quad (\text{C3})$$

Here, we essentially merge terms that have the same relative phase. Note that there is a difference between this arrangement and the qudit case. In the qudit case, the measurement phase of the second basis can be arbitrary. However, in the case of local measurements, the phase corresponding to the measurement basis is a partial or full summation of the individual local phases.

For our local basis, $\alpha'_m - \alpha'_{m'} = \sum_{p=1}^n \alpha_p m_p - \sum_{q=1}^n \alpha_q m'_q$ (see Eq. (C1)). Generally, any relative phase can be expressed as the following general formula:

$$\sum_{m \in M} (-1)^{x_m} \alpha_m, \quad (\text{C4})$$

where M is the subset of the set $N = \{1, 2, 3, \dots, n\}$. The restrictions of $\{\alpha_m\}$ is that given $\vec{x} = \{x_m\}$ is not equal to $\vec{x}' = \{x'_m\}$,

$$\left| \sum_{m \in M} (-1)^{x_m} \alpha_m \right| \neq \left| \sum_{m \in M} (-1)^{x'_m} \alpha_m \right|, \quad (\text{C5})$$

where all α_m are algebraic number. That is $\Delta_t \neq \Delta_{t'}$ if $t \neq t'$. Note that $|\psi\rangle, |\psi'\rangle \in \mathbb{P}_A$, $f_1(j|\Delta_t)$ and $f_2(j|\Delta_t)$ are algebraic numbers or 0. We can deduce that $\{\cos \Delta_t, \sin \Delta_t\}$ are linearly independent over the field of all algebraic numbers by [Lemma 2](#). That is, if $f_1(j|\Delta_t)$ and $f_2(j|\Delta_t)$ are not all 0, there must be

$$\Delta Q_j = \sum_{\Delta_t} f_1(j|\Delta_t) \cos \Delta_t + f_2(j|\Delta_t) \sin \Delta_t \neq 0.$$

For the case where $f_1(j|\Delta_t)$ and $f_2(j|\Delta_t)$ are all 0, one has $\Delta Q_j = 0$. In this case, the situation is complicated, and whether $\varphi_j = \varphi'_j$ with $j \in V$ is an open problem. Thus, satisfying the above restriction of $\{\alpha_i\}$, our two-local measurement scheme is informationally complete with respect to a set of algebraic pure states (satisfying $f_1(j|\Delta_t)$ and $f_2(j|\Delta_t)$ are not all 0).

Similar to the qudit case, a simple example satisfying the above constraints is $\alpha_k = 2^{k-1}z_0$ for any k , where z_0 is an arbitrary algebraic number. Another example is $\alpha_k = \sqrt{q_k}$ where q_k is the k th prime number sorted from smallest to largest.

1. Information Completeness: W-like States and GHZ-like States

Here we demonstrate that two local bases are sufficient to characterise two special classes of sparse algebraic states: W-like algebraic states and GHZ-like algebraic states.

A general W-like algebraic state can be defined as

$$|\text{W-like}\rangle = \sum_{j=1}^n r_j e^{i\varphi_j} |0\rangle^{\otimes(j-1)} \otimes |1\rangle \otimes |0\rangle^{\otimes(n-j)}. \quad (\text{C6})$$

The W-like state has n amplitudes that are nonzero. After performing local phase gate $\bigotimes_{j=1}^n R_j^\dagger$ ($R_j^\dagger = |0\rangle\langle 0| + e^{-i\alpha_j} |1\rangle\langle 1|$), the state becomes

$$\bigotimes_{j=1}^n R_j^\dagger |\text{W-like}\rangle = \sum_{j=1}^n r_j e^{i(\varphi_j - \alpha_j)} |0\rangle^{\otimes(j-1)} \otimes |1\rangle \otimes |0\rangle^{\otimes(n-j)}. \quad (\text{C7})$$

One can see that this phase-shifted state has the same form as the state after the global phase gate $D^\dagger = \sum_{m=1}^{d-1} e^{-i\theta_m} |m\rangle\langle m|$, i.e. $D^\dagger |\psi_W\rangle = \sum_{j=1}^n r_j e^{i(\varphi_j - \theta_j)} |0\rangle^{\otimes(j-1)} \otimes |1\rangle \otimes |0\rangle^{\otimes(n-j)}$. Since R_j is local we may set α_j independently. Setting α_l is algebraic number and $|\alpha_l - \alpha_s| \neq |\alpha_i - \alpha_j|$ for any $l, s \neq ij$, the [Eq. \(C3\)](#) becomes

$$\begin{aligned} f_1(j|\Delta_t) &= \frac{1}{2^{n-1}} (-1)^{h(j,s)+h(j,l)} r_s r_l [\cos(\varphi_s - \varphi_l) - \cos(\varphi'_s - \varphi'_l)], \\ f_2(j|\Delta_t) &= \frac{1}{2^{n-1}} (-1)^{h(j,s)+h(j,l)} r_s r_l [\sin(\varphi_s - \varphi_l) - \sin(\varphi'_s - \varphi'_l)], \end{aligned} \quad (\text{C8})$$

which is exactly same as [Eq. \(B12\)](#). Thus, the uniqueness is guaranteed by the linear independence theorem [Lemma 2](#).

Similarly, GHZ-like algebraic states defined as

$$|\text{GHZ-like}\rangle = r_0 |0\rangle^{\otimes n} + r_1 e^{i\varphi} |1\rangle^{\otimes n}, \quad (\text{C9})$$

and its phase-shifted state

$$\bigotimes_{j=1}^n R_j^\dagger |\text{GHZ-like}\rangle = r_0 |0\rangle^{\otimes n} + r_1 e^{i(\varphi - \sum_j \alpha_j)} |1\rangle^{\otimes n}. \quad (\text{C10})$$

GHZ-like states also satisfy the uniqueness of two local bases. We note that the second local basis may be further simplified to $R_1 \otimes I^{\otimes n-1}$. This is because a GHZ-like state only has two components and a single local phase gate is enough to shift the phase of the second component.

Moreover, we can use a similar technique to find other sparse algebraic states that can be determined by two local bases. We need to consider the nonzero terms such that the phase-shifting for all nonzero amplitudes r_l and r_k satisfy the conditions A1 and A.2.

Appendix D: Proof of Theorem 3

Proof. It has been rigorously demonstrated that at least four measurement bases are required to uniquely determine a pure state, so if only two measurement bases are used, there exists a group of pure states which can not be uniquely determined.

We prove the second statement by an example. Consider the n -qubit GHZ-like state as the unknown target state

$$|\psi\rangle = a_0|0\rangle^{\otimes n} + a_{2^n-1}e^{i\varphi_{2^n-1}}|1\rangle^{\otimes n}. \quad (D1)$$

Consider the n -qubit simulated state as

$$|\psi'\rangle = \sum_{j=0}^{2^n-1} a'_j e^{i\varphi'_j} |j\rangle, \quad (D2)$$

and set the global phase $\varphi'_0 = 0$. From the measurement results of the first measurement base we can get

$$a'_0 = a_0, a'_{2^n-1} = a_{2^n-1}, a'_l = a_l = 0, l = 1, 2, \dots, 2^n - 2. \quad (D3)$$

That is, the structure of the simulated state at this point becomes

$$|\psi'\rangle = a_0|0\rangle^{\otimes n} + a_{2^n-1}e^{i\varphi'_{2^n-1}}|1\rangle^{\otimes n}. \quad (D4)$$

Next, by taking the measurements of the second measurement base and calculating $\Delta Q_j = Q_j - Q'_j$, we can get

$$\cos(\varphi_{2^n-1} - \alpha'_{2^n-1}) - \cos(\varphi'_{2^n-1} - \alpha'_{2^n-1}) = 0. \quad (D5)$$

At this point it can be solved that

$$\varphi'_{2^n-1} = \varphi_{2^n-1} \text{ or } \varphi'_{2^n-1} = -\varphi_{2^n-1} + 2\alpha'_{2^n-1}. \quad (D6)$$

These two solutions may be far apart. It is easy to verify the inner product of these solutions is $a_0^2 + a_{2^n-1}^2 e^{i(2\varphi_{2^n-1} - 2\alpha'_{2^n-1})}$, which can be small.

However, if we assume that both the target state and the simulated state are algebraic states, then it is natural to obtain the unique solution $\varphi'_{2^n-1} = \varphi_{2^n-1}$. This is because another solution $\varphi'_{2^n-1} = -\varphi_{2^n-1} + 2\alpha'_{2^n-1}$ will let

$$\cos(\varphi'_{2^n-1}) = \cos(-\varphi_{2^n-1} + 2\alpha'_{2^n-1}) = \cos(\varphi_{2^n-1})\cos(2\alpha'_{2^n-1}) + \sin(\varphi_{2^n-1})\sin(2\alpha'_{2^n-1}), \quad (D7)$$

$$\sin(\varphi'_{2^n-1}) = \sin(-\varphi_{2^n-1} + 2\alpha'_{2^n-1}) = -\sin(\varphi_{2^n-1})\cos(2\alpha'_{2^n-1}) + \cos(\varphi_{2^n-1})\sin(2\alpha'_{2^n-1}). \quad (D8)$$

This suggest the simulated state is not an algebraic state, which in turn is excluded.

□

While Theorem 3 seems a bit negative, it indeed is concerned with a different objective of tomography. The existence of multiple solutions is because this is a question of asking if there exist states that can re-produce the probability distribution. However, universal quantum computation only requires the implementation of circuits such as Clifford + T circuits, or circuits consisting of single-qubit rotating gates (the rotation angle should be $\beta\pi$, where β is a rational number) + CNOT gates, which are the building blocks of broad applications in quantum chemistry simulation. These circuits still make the evolving quantum state in $\mathbb{P}_A$. In these scenarios our scheme is valid.

Appendix E: Extension to mixed states with known types of noise

Our two-bases scheme remains valid for mixed states with known type of noise. The measurement and reconstruction process is shown in Eq. (E1) and Eq. (E2). We measure it under two measurement bases to obtain two sets of probability distributions $\mathbf{P}$, $\mathbf{Q}$, where $P_j = \rho_{jj}$, $Q_j = \rho'_{jj}$, while the mixed state is later reconstructed by post-processing. The difference from the case of pure state is that the target quantum state is added with known type of noise, so in the reconstruction process we can set the form of simulated quantum state with known type of noise.

$$\begin{aligned} I\rho I &= \rho \xrightarrow{\text{measurement}} \mathbf{P} \\ S'^{\dagger}\rho S' &= \rho' \xrightarrow{\text{measurement}} \mathbf{Q} \end{aligned} \quad (E1)$$

$$\left. \begin{matrix} \mathbf{P} \\ \mathbf{Q} \end{matrix} \right\} \xrightarrow{\text{reconstruction}} \rho \quad (\text{E2})$$

First, consider the Werner-like state which involves depolarising noise. It means that we already know both the target state and simulated state take the following form

$$\rho = p|\psi\rangle\langle\psi| + (1-p)\frac{I}{d}. \quad (\text{E3})$$

Suppose that the depolarisation coefficient p is a nonzero algebraic number but the exact magnitude is unknown. Like the contradiction analysis for a pure state, first assuming that there exists a simulated mixed state $\rho' = p'|\psi'\rangle\langle\psi'| + (1-p')\frac{I}{d}$ different from the true mixed state $\rho = p|\psi\rangle\langle\psi| + (1-p)\frac{I}{d}$, the same probability distributions of measurements $\mathbf{P}, \mathbf{Q}$ can be obtained under the $I, S'^{\dagger}$ measurement operations. Note that $|\psi\rangle = \sum_j r_j e^{i\varphi_j} |j\rangle, |\psi'\rangle = \sum_j r'_j e^{i\varphi'_j} |j\rangle, d = 2^n$. First the simulated mixed state ρ' can simulate the unknown mixed state ρ under the computational base. There should be $P'_j = P_j$, and thus we could get

$$p(r_j)^2 = P_j - \frac{1-p}{d}, \quad p'(r'_j)^2 = P_j - \frac{1-p'}{d}. \quad (\text{E4})$$

Next ρ' can simulate the unknown mixed state ρ under the second basis. From the results under the second measurement base, we can analogize the result of the pure state in the Eq. (B7) and get the difference of the probability distributions

$$\begin{aligned} \Delta Q_j &= \Delta \rho'_{jj} = Q_j - Q'_j \\ &= \frac{1}{2^{n-1}} \sum_{s < l} (-1)^{h(j,s)+h(j,l)} \{pr_s r_l \cos[(\varphi_s - \varphi_l) - (\alpha'_s - \alpha'_l)] - p'r'_s r'_l \cos[(\varphi'_s - \varphi'_l) - (\alpha'_s - \alpha'_l)]\} = 0, \end{aligned} \quad (\text{E5})$$

and we notice that the summation term in Eq. (E5) can be expanded as

$$\begin{aligned} &pr_s r_l \cos[(\varphi_s - \varphi_l) - (\alpha'_s - \alpha'_l)] - p'r'_s r'_l \cos[(\varphi'_s - \varphi'_l) - (\alpha'_s - \alpha'_l)] \\ &= pr_s r_l \cos(\varphi_s - \varphi_l) \cos(\alpha'_s - \alpha'_l) + pr_s r_l \sin(\varphi_s - \varphi_l) \sin(\alpha'_s - \alpha'_l) - p'r'_s r'_l \cos(\varphi'_s - \varphi'_l) \cos(\alpha'_s - \alpha'_l) - p'r'_s r'_l \sin(\varphi'_s - \varphi'_l) \sin(\alpha'_s - \alpha'_l) \\ &= [pr_s r_l \cos(\varphi_s - \varphi_l) - p'r'_s r'_l \cos(\varphi'_s - \varphi'_l)] \cos(\alpha'_s - \alpha'_l) + [pr_s r_l \sin(\varphi_s - \varphi_l) - p'r'_s r'_l \sin(\varphi'_s - \varphi'_l)] \sin(\alpha'_s - \alpha'_l). \end{aligned} \quad (\text{E6})$$

If the exact value of depolarising noise p is known, which means that $p' = p$, then the amplitude of the quantum state can be uniquely determined through Eq. (E4). Meanwhile, the noise coefficient in Eq. (E5) can be eliminated, and thus, the equation becomes the same form as Eq. (A9). Same as our analysis of the pure state, we get $|\psi'\rangle = |\psi\rangle$. Overall if it is known that $p' = p$, we must have $\rho' = \rho$ in this case.

Consider a general form of noise

$$\rho = p|\psi\rangle\langle\psi| + (1-p)\sigma, \quad (\text{E7})$$

where σ may be a thermal state or other mixed state is known a priori. Suppose the exact magnitude of the noise coefficient and the noise type are known. In that case, the scenario is the same as our analysis for the case of (I), where the amplitude of the quantum state can be uniquely determined and the difference of the probability distributions under the second measurement base becomes the same form as Eq. (A9). In this case, our scheme can uniquely determine the mixed state.

Appendix F: Comments

This work is mainly concerned with information completeness and is not concerned with measurement problems. Intuitively, the uniqueness is easy to hold with respect to a relatively small set of the full pure state space. In a more practical setup, when the level of control in the precision of the single-qubit rotation for measurement settings is higher than that of the gate operations in the circuit, the reconstructed state is unique. Moreover, the set of states generated by discretised gate sets (e.g., Clifford + T gates) is a subset of $\mathbb{P}_A$, and it is not a continuous set compared to $\mathbb{P}_A$. Therefore, compared to the general case, it is easier to find the appropriate rotation angles such that the state can be uniquely constructed.

The proof of uniqueness is based on the linear independence of the equations obtained from measurements, which is purely information-theoretic. The sufficiency of two bases hinges on the fact that (1) ideal measurement probability

distribution can be obtained perfectly, and (2) the measurement bases can be set to have transcendental angles. With these perfect assumptions, we will not encounter measurement issues in which statistical errors have to be considered. A critical question is whether the two-local-measurement-bases scheme is still valid in a practical setup with measurement errors. Although we cannot prove the sufficiency of two bases in this practical situation, we investigate this point through numerics. We take the statistical errors into account and show that our method can still faithfully reconstruct the state uniquely. These investigations provide a response to the limitations set up by our information-theoretic approach.

Appendix G: Numerical Results

1. Numerical setup

Let us re-express the quantum state as

$$|\psi\rangle = \sum_{k=0}^{2^n-1} r_k e^{i\varphi_k} |k\rangle = \sum_{k=0}^{2^n-1} (a_k + ib_k) |k\rangle. \quad (\text{G1})$$

The relationships between r_k, φ_k and a_k, b_k are

$$r_k^2 = a_k^2 + b_k^2, \quad \cos \varphi_k = \frac{a_k}{\sqrt{a_k^2 + b_k^2}}, \quad \sin \varphi_k = \frac{b_k}{\sqrt{a_k^2 + b_k^2}}. \quad (\text{G2})$$

Three conditions need to be satisfied in the ideal two-bases scheme:

- (1) Both target states and simulated states are algebraic states, i.e., the state components a_k, b_k, a'_k, b'_k of $|\psi\rangle = \sum_{k=0}^{2^n-1} (a_k + ib_k) |k\rangle$ and $|\psi'\rangle = \sum_{k=0}^{2^n-1} (a'_k + ib'_k) |k\rangle$ are **algebraic numbers**.
- (2) All the $e^{i\alpha}$ in the single-qubit gates

$$T = \begin{bmatrix} 1 & 0 \\ 0 & e^{i\alpha} \end{bmatrix}. \quad (\text{G3})$$

of the second basis are **transcendental numbers**. We note that this transcendental operation is achievable in physical implementation but not classical computer. All the α we choose are square root of different prime numbers.

- (3) The values of the probability distribution measured under the first basis are algebraic numbers, and the values of the probability distribution measured under the second basis are mostly **transcendental numbers**.

In these cases, the reconstruction of the target state can be realized with two bases. However, for the three requirements mentioned above, the second and third points cannot be fulfilled on existing classical computers. In fact, computers can only store up to a finite number of digits after the decimal point (we set the number of digits as X). For a 64-bit computer, the number of decimal places with respect to the floating-point number is 15 [61], which is widely used in software for algorithm design and simulation. We can also sacrifice computing speed to get a larger X by programming the calculation process on classical computers. Based on this, we propose an experimental-friendly two-bases scheme that can be easily implemented on a classical computer. The above three conditions are simplified into the following:

- (1') a_k, b_k are numbers with M_1 decimal places, while a'_k, b'_k are numbers with M_2 decimal places. Equally important is the fact that a_k, b_k and a'_k, b'_k both satisfy amplitude normalisation and phase normalisation with N_1, N_2 and N_3, N_4 decimal places respectively, which means that

$$\left| \sum_k r_k^2 - 1 \right| < \frac{1}{2} \times 10^{-N_1}, \quad |\cos^2 \varphi_k + \sin^2 \varphi_k - 1| < \frac{1}{2} \times 10^{-N_2}, \quad (\text{G4})$$

and

$$\left| \sum_k (r'_k)^2 - 1 \right| < \frac{1}{2} \times 10^{-N_3}, \quad |\cos^2 \varphi'_k + \sin^2 \varphi'_k - 1| < \frac{1}{2} \times 10^{-N_4}. \quad (\text{G5})$$

The conversion between a_k, b_k, a'_k, b'_k and $r_k, \varphi_k, r'_k, \varphi'_k$ is given by Eq. (G2).

- (2') All the $e^{i\alpha}$ in the single-qubit gates of the second basis are numbers with X decimal places in target states, and X' decimal places in simulated states (Both X and X' are greater than M_1 and M_2).

- (3') The numbers in probability distributions of target states $\mathbf{P}, \mathbf{Q}$ are numbers with Y decimal places, and probability distributions of simulated states $\mathbf{P}', \mathbf{Q}'$ with Y' decimal places (Both Y and Y' are greater than M_1 and M_2).

FIG. 6. **10-qubit and 20-qubit W-like states reconstruction.** The blue triangular dots represent changes in fidelity during the reconstruction process of the 10-qubit W-like state. The red square dots represent changes in fidelity during the reconstruction process of the 20-qubit W-like state. Infidelity: $1 - \text{Fidelity}$. The orange line: fidelity over 99.99%. The algebraic numbers and transcendental numbers are simulated on a computer using low-precision numbers and high-precision numbers, respectively, as computers can only store data in finite decimal places. The numbers of decimal places for the modulus r_k , the phases $\cos \varphi_k$ and $\sin \varphi_k$ are denoted as C_1 , C_2 , and C_3 , respectively, and are set to be 3. The numbers of decimal places for the second measurement base are $X = 15$, and for the measured probability distributions are $Y = 15$. The target state $|\psi\rangle$ and the simulated state $|\psi'\rangle$ are set at the same level of precision.

2. Numerical simulations

We randomly generate an eight-dimensional algebraic state as our target state $|\psi\rangle$. The real and imaginary parts of the density matrix of the target state are shown in Fig. 7(a)(b). The real and imaginary parts of the density matrix of the reconstructed state are shown in Fig. 7(c)(d). The fidelity of the reconstructed state is 99.9998% and can further approach 100% by increasing the number of iterations.

Then, we scale up the simulation by considering the reconstruction with a large problem size of up to 20 qubits. To enable the numerical simulation, we choose to set the unknown quantum state in the form of an n -qubit W-like state defined above. The aim is to recover the phase information from the probability distribution under two measurement bases. The randomly selected phase values of the target state in the form of a 10-qubit W-like state and the phase values of its reconstructed state are shown in Fig. 8(a) and Fig. 8(b), respectively. Meanwhile, the randomly selected phase values of the target state in the form of a 20-qubit W-like state and the phase values of its reconstructed state are shown in Fig. 8(c) and Fig. 8(d), respectively. The fidelity changes of the reconstructed states during the iteration process for the 10-qubit W-like state and 20-qubit W-like state are shown in Fig. 6 in the main text. The fidelity of the reconstructed states can all reach more than 99.99%.

FIG. 7. The set-up is the same as that in Fig. 2 in the main text. The numbers of decimal places for the amplitudes are $C_1 = C'_1 = 3$, for the phases are $C_2 = C'_2 = 3$, and we set $C_2 = C_3$ ($C'_2 = C'_3$). The numbers of decimal places for the second measurement base are $X = X' = 15$, and for the measured probability distributions are $Y = Y' = 15$. (a)(b) Real and imaginary parts of the target quantum state. (c)(d) Real and imaginary parts of the reconstructed quantum state.

FIG. 8. 10-qubit and 20-qubit W-like states reconstruction results. **a,b**, Phase values of the target state and the reconstructed simulated state in the form of a 10-qubit W-like state. **c,d**, Phase values of the target state and the reconstructed simulated state in the form of a 20-qubit W-like state. Accurate noise estimation is essential for fault-tolerant quantum computing, as decoding performance depends critically on the fidelity of circuit-level noise parameters. We introduce a differentiable Maximum Likelihood Estimation (dMLE) framework to optimize these parameters directly from experimental syndrome data via gradient descent. By mapping syndrome likelihoods to statistical mechanical models, we achieve exact, efficient evaluation using planar solvers for repetition codes and Tensor Networks (TNs) for surface codes, maintaining tractability up to distance 5. Validating across three distinct experimental superconducting datasets, our approach reduces logical error rates by up to 30.6(3)% for repetition codes. Crucially, on the Sycamore $d = 3$ surface code, our optimized TN decoder matches state-of-the-art AlphaQubit performance using only standard syndromes, requiring no auxiliary leakage data. Finally, on the larger $d = 5$ surface code, we secure an 7.1(8)% improvement over recent reinforcement learning method. By explicitly capturing the true physical error distribution, dMLE yields provably optimal, decoder-independent priors, offering a robust noise estimation tool for unlocking the full potential of error-corrected quantum processors.

Fault-tolerant quantum computing (FTQC) promises to unlock computational capabilities far beyond classical reach, from simulating many-body quantum systems to solving industrially relevant optimization problems [1–3]. Realizing this promise hinges on quantum error correction (QEC), which protects fragile logical information by encoding it redundantly across many physical qubits and continuously measuring error syndromes [4, 5]. The effectiveness of QEC, however, is only as good as the decoder that interprets these syndromes—and the decoder, in turn, is only as good as the noise model it assumes [6]. In practice, the noise affecting a quantum processor is described by a detector error model (DEM) that assigns prior probabilities to each possible error mechanism in the circuit [7, 8]. When these priors deviate from the true physical noise, decoding quality deteriorates sharply: Google’s landmark surface code experiment demonstrated that accurately estimated circuit-level noise parameters were essential to achieving below-threshold error suppression [5], and subsequent studies have shown that even modest prior inaccuracies can erode the exponential suppression expected from increasing code distance [9]. Accurately estimating DEM priors from experimental data is therefore the critical bottleneck standing between today’s noisy hardware and the full error-suppression power of QEC.

The challenge of noise estimation lies in the inverse nature of the problem: physical errors are not directly observable; only their degenerate mappings, syndromes, are measured. Consequently, the task is to infer the underlying error probabilities that maximize the likelihood of the observed syndrome statistics. While this is fun-

damentally a parameter estimation problem, the high-dimensional space of error configurations makes direct inference computationally intractable for general codes.

Previous efforts primarily rely on correlation analysis and reinforcement learning (RL). Correlation-based methods efficiently estimate error rates from local syndrome statistics [4, 5, 10–15]. However, these approaches do not optimize a global likelihood over the full joint distribution; they are fundamentally restricted to pairwise interactions, thereby struggling with codes characterized by higher stabilizer weights, such as color codes [16]. Furthermore, such methods are prone to generating unphysical negative probabilities [9]. Alternatively, RL optimizes decoder priors using the logical error rate as a reward [9, 17], which means it necessitates running a fast, often sub-optimal decoder in its training loop. While adaptable, RL parameters lack clear correspondence to physical error mechanisms and critically depend on a high-quality initialization such as correlation analysis [9]. Furthermore, as we demonstrate, the resulting priors overfit to this specific decoder and exhibit significantly degraded performance when transferred to higher-fidelity algorithms.

In this Letter, we propose a physics-inspired framework to estimate the DEM prior via differentiable Maximum Likelihood Estimation (dMLE). By mapping syndrome likelihoods to partition functions of statistical mechanical spin models, we compute them exactly using the *Planar* solver [18] for repetition codes and Tensor Networks (TNs) for surface codes. This enables direct, gradient-based optimization of physical error probabilities. Unlike heuristic or RL-based methods, dMLE explicitly minimizes the mismatch between the estimated and true error distributions, yielding physically meaningful and highly generalizable parameters. Validating our method across three distinct experimental supercon-

FIG. 1. **Differentiable Maximum Likelihood Noise Estimation (dMLE) Framework.** (1) Initialization: Observed detection events $\mathbf{s}$ and parameters θ are mapped to dual spin models (Repetition codes) or Tensor Networks (Surface codes). (2) Evaluation: The NLL loss is derived from the partition function $\mathcal{Z}$ or TN contraction. (3) Update: Since all of the above processes are differentiable, parameters are iteratively refined via gradient descent until convergence to the maximum likelihood estimate.

ducting datasets, we first achieve logical error rate reductions of up to 30.6(3)% for repetition codes. Transitioning to surface codes, our optimized TN decoder matches the state-of-the-art AlphaQubit on the Sycamore $d = 3$ dataset [19] using only standard syndromes data. Finally, on the larger $d = 5$ dataset [20], we secure an 7.1(8)% performance gain. These results demonstrate superior, decoder-agnostic generalizability compared to both correlation-analysis and RL-based approaches.

Maximum Likelihood Noise Estimation.— In circuit-level noise scenarios, conventional Pauli error models on qubits often fail to capture the intricate dynamics of fault-tolerant protocols. To address this, we employ the Detector Error Model (DEM), which characterizes the probabilistic relationships between error mechanisms and detectors (combinations of syndromes) within a space-time circuit [8]. A DEM is formally represented as a hypergraph: nodes correspond to detectors, while hyperedges denote independent error mechanisms e_i occurring with probabilities θ_i . This abstraction is particularly advantageous for decoding, as it provides a direct mapping from physical errors to the observed syndrome history.

Assuming the underlying noise process is decomposed into n independent mechanisms, an error configuration is represented by $\mathbf{e} \in \{0, 1\}^n$. Our goal is to estimate the prior parameters $\theta = \{\theta_i\}$ from a dataset of observed syndromes $\{\mathbf{s}^{(k)}\}$. The probability of observing a specific syndrome $\mathbf{s}$ is the sum of the probabilities of all error configurations $\mathbf{e}$ consistent with $\mathbf{s}$:

$$p_{\theta}(\mathbf{s}) = \sum_{\mathbf{e} \in \mathcal{C}(\mathbf{s})} p_{\theta}(\mathbf{e}), \quad (1)$$

where $\mathcal{C}(\mathbf{s})$ denotes the set of all errors that cause $\mathbf{s}$. In the context of maximum likelihood decoding, this quantity corresponds to the summation of all logical coset

probabilities. By identifying error probabilities with Boltzmann weights, this summation is mathematically equivalent to computing the partition function of a statistical mechanical spin model [21]. We formulate this as a maximum likelihood estimation task, updating θ via gradient descent to minimize the negative log-likelihood (NLL) loss:

$$\mathcal{L}(\theta) = -\mathbb{E}_{\mathbf{s} \sim p_{\text{data}}(\mathbf{s})} [\log p_{\theta}(\mathbf{s})]. \quad (2)$$

The primary challenge lies in the efficient computation of Eq. (1), which is generally #P-complete [18, 21, 22]. However, for planar DEMs typically found in repetition codes, the *Planar* method [18] exactly evaluates this partition function in polynomial time using a dual spin model as shown in Fig. 1(a). Furthermore, to extend our optimization framework to complex surface codes where the *Planar* method becomes inapplicable, we seamlessly transition to Tensor Networks (TNs). In the TN architecture, the summation over consistent configurations maps directly to a product-sum contraction [5, 23–25].

As illustrated in Fig. 1(b) for a surface code memory experiment, each detector is represented by an XOR tensor that enforces even parity across its connected legs. Detection event constraints are incorporated via red dangling edges, effectively halving the error configuration space. The probability tensors encode the error mechanisms, assigning weights θ_i and $1 - \theta_i$ to triggered and non-triggered states, respectively. Contracting this TN yields the exact $p_{\theta}(\mathbf{s})$.

Crucially, both the *Planar* and TN exact summations are fully differentiable with respect to their input parameters. This enables end-to-end gradient-based refinement, $\theta \leftarrow \theta + \eta \nabla_{\theta} \mathcal{L}(\theta)$, reliably guiding the parameters to the maximum likelihood estimate that explicitly characterizes the true underlying physical noise distribution.

FIG. 2. **Simulation results.** Estimated mean error rates versus true error rates for a $d = 3$, $r = 5$ surface code (base depolarizing error rate 0.005) with 1000000 shots. We compared three distinct initial conditions: empirical assignment (Emp., uniform 0.005), local perturbation (Per.), and completely random initialization (Ran.). The color gradient illustrates the evolutionary trajectory of the parameters over successive training epochs.

Numerical Results.— We first evaluated our approach via numerical simulations on small-scale models. The objective of these simulations was twofold: to confirm that dMLE can reconstruct the true underlying distribution of the syndromes, and to investigate its robustness against various initialization conditions. We simulated a $d = 3$, $r = 5$ surface code with a base depolarizing error rate of 0.005 using Stim [7]. We investigated three distinct initialization strategies for the DEM priors. As depicted in Fig. 2, remarkably, across all three disparate initialization scenarios, the estimated parameters consistently converge toward the ideal $y = x$ line, accompanied by a rapid decay in the total Mean Relative Error (MRE). This pronounced insensitivity to initial conditions highlights a fundamental theoretical advantage of our dMLE approach. Because we establish an exact and fully differentiable mapping from the DEM priors directly to the global syndrome likelihood, the resulting optimization landscape is inherently well-behaved. Consequently, provided that the Monte Carlo gradients are accurately evaluated, the gradient descent mechanism is mathematically guided to bypass local minima and reliably reconstruct the true underlying physical noise distribution, eliminating the requirement for fine-tuned initial guesses.”

Having validated the effectiveness of our optimization scheme through numerical simulations, we devote the remainder of this section to processing real experimental data, thereby demonstrating our framework’s capability to handle the complex noise inherent in experimental devices.

We first utilized repetition code data from the superconducting platform at the Beijing Academy of Quantum Information Sciences (BAQIS) [18]. Fig. 3 (a) presents the logical error probability per round as a function of code distance. As illustrated, our method consistently reduces the logical error rates for both the Minimum

Weight Perfect Matching (MWPM) [27, 28] and *Planar* decoders across all distances. This signifies that the optimized prior distribution aligns more closely with the actual noise characteristics.

Notably, the optimization yields a more pronounced gain for the *Planar* decoder, as indicated by the broader shaded region between the initial and optimized curves compared to MWPM. This observation is quantitatively supported by the inset, which details the relative improvement percentage. While the MWPM decoder shows a modest improvement of up to 8.6(6)%, the *Planar* decoder achieves a substantial performance boost, with improvements reaching up to 30.6(3)% at larger distances. These results confirm that our gradient-based optimization can effectively extract more accurate noise information from experimental data, thereby enhancing the decoder’s error suppression capability.

Furthermore by leveraging TNs, we extended our evaluation to Google’s Sycamore surface code ($d = 3$) dataset [19] to challenge our scheme in a realistic hardware environment. As shown in Fig. 3 (b), the TN (optimized) results, obtained after optimizing the prior distribution via dMLE, demonstrate a logical error rate per round (ϵ_L) that is on par with the state-of-the-art AlphaQubit decoder. Crucially, while AlphaQubit relies significantly on auxiliary experimental information—specifically leakage data—to achieve high accuracy, our approach attains comparable performance without utilizing any such extra physical overhead. This performance is entirely driven by our statistical physics-based optimization, which ensures the DEM prior closely captures the real syndrome data distribution. Beyond its direct decoding advantage, the high-quality DEM optimized by our framework can serve as a robust generative model to produce realistic pre-training data for neural network decoders like AlphaQubit, potentially further enhancing

FIG. 3. **Numerical results on experimental datasets.** (a) Validation on BAQIS superconducting repetition codes. Logical error probability per round versus code distance $d \in \{3, 5, 7, 9\}$. Dashed lines correspond to initial parameters derived from correlation analysis [4], while solid lines represent performance after our optimization. Inset: Relative improvement percentages, highlighting a significant gain for the *Planar* decoder at larger distances. (b) Decoding performance on the Google’s first Sycamore ($d = 3$) surface code dataset [19]. The logical observable $1 - 2P_L$ (where P_L is the logical error rate) is plotted as a function of syndrome measurement rounds. The ϵ_L is extracted via exponential fitting. Baseline results for TN (Google), Belief Matching (MWPM-BP), and Correlated Matching (MWPM-Corr) decoders are obtained directly from the Google dataset. The theoretical curve for AlphaQubit is reconstructed using the ϵ_L reported in the original reference [26]. Crucially, the TN (optimized) result represents our contribution (red error bars and dashed line): decoding is performed by an exact TN decoder after the prior distribution has been optimized via our dMLE method based on this experimental dataset. (c) Optimization on Google surface code ($d = 5$) dataset used for RL method [20]. Logical error rates per round compared across three decoders TN, Tesseract, Belief Matching (BM) using DEMs derived from three distinct sources: our TN-based optimization, RL-based Belief Matching, and correlation analysis. The BM results are obtained from the original dataset.

their training efficiency and generalization [26].

Finally, we evaluated experimental data from the $d = 5$ Sycamore surface code (5 to 25 QEC rounds) used in Google’s RL study [20] (note that even though both datasets were collected from Sycamore chip, their details are quite different [5]). This large-scale analysis is enabled by a novel TN architecture [25] that drastically simplifies the DEM likelihood computation. By decomposing XOR tensors via Walsh-Hadamard transformations (detailed in the Supplementary Material [29]), the network topology is reduced to only Hadamard matrices and one-dimensional probability vectors. Combined with state-of-the-art contraction path optimization [30–33], the contraction complexity remains manageable across all rounds, avoiding the prohibitive costs of previous boundary MPS schemes [29, 34]. Crucially, this fully differentiable pipeline [35] permits end-to-end gradient optimization. For efficiency, we optimized on 5-round data and broadcasted the parameters to larger rounds, exploiting the time-translation symmetry of memory experiments [9, 36].

We initialized our optimization using the SI1000 DEM [37] from Google’s dataset. After training, we compared the TN, Tesseract [38], and Belief Matching [39] decoders across three DEMs: our TN-optimized DEM, the Belief Matching-based RL DEM (the best performer in Ref. [9]), and the correlation analysis baseline Fig. 3(c). For the TN decoder, our DEM reduces the logical error rate by an average of 7.1(8)%

and 4.7(8)% compared to the RL and correlation baselines, respectively. Tesseract shows similar reductions of 5.2(3)% and 2.9(4)%. Conversely, Belief Matching shows only marginal improvement over correlation and no gain over RL. This highlights that while matching-based decoders often yield sub-optimal solutions, coupling a superior minimum-weight decoder like Tesseract, with our maximum-likelihood-estimated DEM consistently achieves the lowest logical error rates. Importantly, these results expose a fundamental limitation of RL-based schemes: they tend to overfit the specific training decoder, thereby lacking broad generalizability. By directly optimizing the prior to reflect the true physical distribution, our dMLE method ensures robust, generalized enhancements across diverse decoding algorithms.

Notably, restricted by computational resources, we evaluated a subset of the data (10 randomly and 14 sequentially sampled datasets) rather than the full 53 datasets. While this introduces minor statistical variations, the relative improvements of dMLE-optimized TN and Tesseract over other two DEM baselines are consistently positive as shown in the Fig. 3(c), ensuring our overall conclusions remain robust (see Supplementary Material [29] for details).

Conclusion.— In this work, we have shown that the problem of noise estimation in quantum error correction can be cast as a maximum likelihood estimation task, where syndrome log-likelihoods are computed exactly via statistical mechanical mappings and tensor network

methods. This physics-motivated formulation provides a principled, decoder-agnostic route to learning circuit-level error parameters directly from experimental syndrome data.

Our optimized priors consistently outperform both correlation-analysis and RL-based alternatives. Crucially, these gains share across all tested decoders—Planar, TN, Matching-based decoders, and Tesseract—without retraining. When evaluated on the Google Sycamore $d = 3$ surface code dataset, our optimized TN decoder achieved a decoding performance on par with the state-of-the-art AlphaQubit, remarkably doing so using only standard syndrome measurements without requiring auxiliary experimental information such as leakage data. Furthermore, in the larger $d = 5$ dataset, employing the highest-fidelity Tensor Network (TN) decoder in conjunction with the optimal DEM yielded an average 10.1(3)% performance improvement compared to the former state-of-the-art RL-optimized Belief-Matching.

Although exact surface code validation is currently bounded at distance $d = 5$, scaling to larger codes by exploiting spatial translation symmetry i.e. subsampling strategies. While this scheme of partitioning a large code into smaller ones introduces additional ap-

proximations, making the optimization no longer strictly global, its effectiveness has been demonstrated in several works [9, 36]. Therefore, scaling up to larger codes will be an important direction for our future work. Furthermore, recent studies have demonstrated that higher-quality noise priors significantly benefit the pre-training of neural-network decoders [26, 40–43]. Consequently, our optimized DEMs hold great promise for generating experimentally aligned training data to bridge the simulation-experiment gap in machine learning-based QEC. Finally, future investigations will explore scalable likelihood approximations and leverage the framework’s inherent differentiability for gate- or pulse-level noise estimation [17], paving the way for joint optimization of physical controls and QEC performance.

Abstract. We open a feasible pathway to realize polylog-time parallel minimum-weight perfect matching (MWPM) decoding for surface-code fault-tolerant quantum computation, by developing an overflow-safe algorithm for MWPM decoding with explicit failure detection and bitwise operations suited to FPGA. We reduce the required arithmetic bit length by more than 99.9% and show that this approach, which previously remained an asymptotic theoretical algorithm, can be realized in practical proof-of-principle experiments. These results enable both polylog-time decoding and a theoretical guarantee of error suppression in early FTQC regime, breaking the conventional trade-off in surface-code decoding and creating a major step toward demonstrating low-overhead FTQC.

Keywords: Quantum error correction, minimum-weight perfect matching, polylogarithmic time, surface code, fault-tolerant quantum computation

Practical validation of theoretically established methods with finite-size devices, even when demonstrated in a small testbed, has played an important role in the development of quantum error correction (QEC). Demonstrations of the threshold theorem in surface code at small code distances of $d = 3, 5, 7$, for example, have a significant impact [1, 2], and their progress has also been highlighted in the QEC2025 conference. Such small-scale validations serve as important milestones toward scalable fault-tolerant quantum computation (FTQC). Recently, Takada and Yamasaki proposed a minimum-weight perfect matching (MWPM) decoder with polylogarithmic parallel runtime [10], which substantially improves the conventional polynomial scaling of the runtime of MWPM decoders based on the blossom algorithms [5, 4, 3, 11, 6]. The MWPM decoder proposed in Ref. [10] is based on the algorithm of Mulmuley et al. [8, 9], which constructs matrices from the detector graph and computes the least significant bits (LSBs) of the binary representations of their determinants. The matrix entries are integers whose magnitudes can be exponential in the detector-graph edge weights, and hence their binary representations can require bit lengths that are polynomial in those weights. Moreover, because the algorithm requires the MWPM to be unique, random perturbations are used to isolate a unique MWPM, which can further amplify the effective weights, thereby increasing the required

arithmetic bit length. In the same spirit as the proof-of-principle demonstrations of error suppression in QEC, demonstrating the practical feasibility of this asymptotically nontrivial decoding method, even at small code distances, is important for the continued advancement of QEC. However, the practical implementation of this approach faces two fundamental challenges. First, the determinant-based formulation involves integer arithmetic over matrix entries whose magnitudes can be exponential in the detector-graph edge weights, potentially requiring an impractically large number of bits to represent intermediate values during the determinant computation. Second, under finite-precision hardware constraints, overflow can compromise the computation of the determinant. If overflow occurs silently, it corrupts intermediate values and breaks the algorithm's theoretical correctness guarantee. If overflow is instead detected by an overflow flag and the output is simply discarded, the resulting detect-and-discard strategy is highly wasteful: it throws away computations even though the algorithm eventually requires only certain LSBs of the determinants. To make such a strategy practical, however, the hardware would have to support sufficiently many bits to avoid overflows in the full determinant computation and its intermediate values, reintroducing the need for excessively large arithmetic precision and thereby making the finite-bit hardware implementation impractical.

In this work, we address these two challenges by extending the determinant-based MWPM-decoding

method.

First, we develop an algebraic framework that analytically guarantees the correctness of our decoding method under a given finite-bit-length constraint. We reformulate the determinant computation over a truncated polynomial ring, where finite-bit arithmetic corresponds to polynomial truncation. In this framework, overflow becomes mathematically well-defined and naturally detectable during the decoding method. We establish the following two guarantees: correctness within the representable range and explicit failure detection beyond it. Specifically, if the MWPM weight is sufficiently smaller than the finite-bit representable threshold imposed by the hardware, our algorithm outputs the same MWPM as the previous MWPM-decoding method [10], with high probability. Otherwise, when the MWPM weight exceeds this representable range and overflow would occur during the determinant computation on fixed finite-bit hardware, the algorithm does not return a corrupted result; instead, it explicitly outputs a failure indicator.
