Theorem 1 (Correctness) *Let w^* denote the weight of an MWPM for the input graph $\bar{G} = (\bar{V}, \bar{E})$ with edge weights $\tilde{w} : \bar{E} \rightarrow \mathbb{Z}$, and let w_{th} denote the finite-bit representable threshold determined by the hardware constraints. If*

$$w^* < \frac{w_{\text{th}}}{2}, \quad (1)$$

then our algorithm outputs a correct MWPM with probability at least $1 - |\bar{V}|/W_{\text{max}}$, where W_{max} denotes the range parameter of the random perturbation.

Theorem 2 (Failure detection) *Let w^* denote the weight of an MWPM for the input graph $\bar{G} = (\bar{V}, \bar{E})$ with edge weights $\tilde{w} : \bar{E} \rightarrow \mathbb{Z}$, and let w_{th} denote the finite-bit representable threshold determined by the hardware constraints. If*

$$w^* \geq \frac{w_{\text{th}}}{2}, \quad (2)$$

then our algorithm outputs a failure indicator.

All arithmetic operations reduce to bitwise XOR and shift operations, making our approach naturally suitable for FPGA-style parallel architectures while asymptotically preserving polylogarithmic parallel depth, as theoretically proposed in Ref. [10].

Second, we remove dominant sources of bit-length blowup inherent in the previous procedure

Figure 1: (a) Threshold arithmetic bit length for determinant computation required to make the decoding failure probability negligible compared with the logical error rate, shown as a function of the path-graph size. The green curve indicates that a few hundred bits suffice for typical path-graph sizes in proof-of-principle demonstrations. (b) Decoding failure probability as a function of the arithmetic bit length. With an arithmetic bit length of $3 \times 10^2 - 5 \times 10^2$, our method sufficiently suppresses the decoding failure probability, as indicated by the green curve.

in Ref. [10]. We first eliminate the costly weight-amplification step introduced in the previous procedure with regard to the random perturbations used to isolate a unique MWPM. Building upon this, we further introduce a variable-precision scheme that first performs a costly part, i.e., computes MWPM candidates, with low precision, and later efficiently verifies them with high precision, where the verification is at a low cost. Together, these refinements substantially reduce the required arithmetic bit length while maintaining the desired suppression of the logical error rate.

With numerical simulations on surface codes with code distance $d = 5$ for proof-of-principle demonstrations, we reduce the required arithmetic bit length for polylog-time MWPM decoding from $\approx$

6×10^5 bits in the previous method [10] to $\lesssim 5 \times 10^2$ bits, i.e., by up to 99.9%, making it compatible with machines supporting 512-bit computing while keeping the decoding failure probability below the logical error rate for $d = 5$ (Fig. 1; see the technical version [7] for details). The required number of classical processors remains sub-linear in the size of the detector graph.

We establish an overflow-safe and hardware-feasible realization of asymptotically polylog-time parallel MWPM decoding, narrowing the gap between asymptotic optimality and practical implementation in FTQC architectures. Our results provide concrete evidence that such an asymptotically fast decoder can be implemented at proof-of-principle experimental scales under realistic hardware constraints, overcoming the conventional polynomial-time runtime bottleneck of MWPM decoding. Together with prior results showing that polylog-time parallel decoding implies doubly-polylog-time-overhead FTQC [10], our work opens a route toward demonstrating highly time-efficient FTQC in the early FTQC regime.

Fault-tolerant quantum computation (FTQC) requires fast and accurate decoding of quantum errors, which is often formulated as a minimum-weight perfect matching (MWPM) problem. A determinant-based approach has been proposed as a novel method to surpass the conventional polynomial runtime of MWPM decoding via the blossom algorithm, asymptotically achieving polylogarithmic parallel runtime. However, the existing approach requires an impractically large bit length to represent intermediate values during the computation of the matrix determinant; moreover, when implemented on a finite-bit machine, the algorithm cannot detect overflow, and therefore, the mathematical correctness of such algorithms cannot be guaranteed. In this work, we address these issues by presenting a polylog-time MWPM decoder that detects overflow in finite-bit representations by employing an algebraic framework over a truncated polynomial ring. Within this framework, all arithmetic operations are implemented using bitwise XOR and shift operations, enabling efficient and hardware-friendly implementation. Furthermore, with algorithmic optimizations tailored to the structure of the determinant-based approach, we reduce the arithmetic bit length required to represent intermediate values in the determinant computation by more than 99.9%, making it possible to implement it on machines supporting 512-bit computing while preserving the decoder's polylog runtime scaling. These results open the possibility of a proof-of-principle demonstration of the polylog-time MWPM decoding in the early FTQC regime.

I. INTRODUCTION

A. Background and motivation

Practical validation of theoretically established methods with finite-size devices, even when demonstrated in a small testbed, has played an important role in the development of quantum error correction (QEC). Fault-tolerant quantum computation (FTQC) provides a framework for reliable quantum computation in the presence of noise, and among quantum error-correcting codes, the surface code is regarded as one of the leading approaches [1] due to its high error tolerance and practical implementability. In theory, the threshold theorem guarantees that the logical error rate can be suppressed exponentially as we increase the distance d of the surface code [2, 3]. More recently, experimental demonstrations of this error-suppression scaling in surface code at small code distances of $d = 3, 5, 7$ have had a significant impact [4, 5]. Such small-scale validations serve as important milestones toward scalable FTQC.

* ryo-223606@g.ecc.u-tokyo.ac.jp

† hayata.yamasaki@gmail.com

In practice, such demonstrations require a solid theoretical foundation for decoding. The surface code preserves logical quantum states by extracting syndromes that indicate where errors have occurred and correcting those errors accordingly [2]. QEC is performed by running classical decoding algorithms. The time overhead of the classical decoder has a non-negligible impact on the overall runtime of FTQC [6, 7], while its decoding performance directly affects the logical error rate of the computation. In general, degenerate quantum maximum likelihood decoding (DQMLD), while achieving the optimal error-correction performance, is computationally hard [8, 9]. In contrast, for the surface code, a decoding method based on minimum-weight perfect matching (MWPM) runs in polynomial time and provides a theoretical guarantee on the error suppression [2, 3]. There are other decoders with similar theoretical guarantees, such as the union-find (UF) decoder [10, 11], the cellular-automaton (CA) decoder [12–18], and the renormalization-group (RG) decoder [19], but their error suppression is weaker than MWPM decoding. Heuristic decoders, such as belief propagation with ordered statistic decoding (BPOSD) [20, 21] and neural-network decoders [22], may achieve strong error suppression but do not provide the theoretical guarantee. As a result, MWPM decoding for the surface code plays an important role in validating and demonstrating the feasibility of FTQC with the surface code.

A well-known limitation of conventional MWPM decoding is its large polynomial runtime exponent, which constrains decoding throughput and can become a bottleneck for the time overhead of FTQC [7]. Conventionally, the decoder solves the MWPM problem using Edmonds’ blossom algorithm [23, 24]. The blossom algorithm proposed by Edmonds has a computational complexity of $O(|V|^4)$, where $|V|$ denotes the number of vertices in the graph. Micali and Vazirani [25, 26] achieved a complexity of $O(\sqrt{|V|} \cdot |E|)$ by introducing techniques to accelerate the search for augmenting paths, where $|E|$ denotes the number of edges. Kolmogorov [27] developed a faster implementation that is effective in practice by incorporating dual variables and priority queues. In the context of surface-code decoding, representative implementations of MWPM decoders, such as sparse blossom [28] and fusion blossom [29], are also based on variants of the blossom algorithm. Reference [30] considered the problem of solving the MWPM decoding for the surface code within a short average parallel runtime, but in the worst case, it still requires a polynomial time complexity in $|V|$. None of these blossom-algorithm-based methods can achieve polylog time complexity; even with parallelization, no blossom-algorithm-based method is currently known to achieve polylog parallel running time.

More recently, Ref. [7] proposed an alternative algorithm for the MWPM decoding that asymptotically achieves polylog parallel runtime, substantially improving the conventional polynomial scaling of the runtime of MWPM decoders based on the blossom algorithms.

FIG. 1: Conceptual comparison between Takada-Yamasaki [7] and the proposed bitwise algorithm.

The MWPM decoder proposed in Ref. [7] is based on the algorithm of Mulmuley et al. [31, 32], computing determinants of matrices obtained from the detector graph, where the matrix entries are integers that may take values exponential in the detector graph’s edge weights (i.e., polynomial in the bit length).

The practical implementation of this polylog-time MWPM decoding, however, faces two fundamental challenges. First, the determinant-based formulation assumes integer arithmetic that may require an impractically large number of bits to represent intermediate values during the computation of the matrix determinant. Second, under finite-precision hardware constraints, overflow may silently corrupt intermediate values, thereby breaking the algorithm’s theoretical correctness guarantee. Despite the challenges, in the same spirit as the proof-of-principle demonstrations of error suppression in QEC [4, 5], demonstrating the practical feasibility of this asymptotically nontrivial runtime scaling of MWPM decoding, even at small code distances, is valuable for the continued advancement of QEC.

B. Summary of main results

In this work, we address these challenges in the existing polylog-time parallel MWPM-decoding method by constructing and analyzing an approach that is feasible to implement at the same scale as current surface-code experiments. Our method generalizes the previous determinant-based framework from integer arithmetic to bitwise polynomial arithmetic, which is fully implementable using bitwise operations while asymptotically preserving polylog time complexity. To clarify the distinction between our method and the previous approach in Ref. [7], we summarize the key contrasts in Fig. 1.

Our contributions are summarized as follows.

1. We develop an algebraic framework that analytically guarantees the correctness of our determinant-based decoding method under a given finite-bit-length constraint. We reformulate the determinant computation over a truncated polynomial ring, where finite-bit arithmetic corresponds to polynomial truncation. In this framework, overflow becomes mathematically well-defined and naturally detectable during the decoding method. We prove that whenever the MWPM weight lies within the representable range, our decoding algorithm outputs exactly the same result as the previous MWPM-decoding method [7]; otherwise, i.e., if intermediate values during the determinant computation overflow on a fixed finite-bit machine, it explicitly signals a logical error. All arithmetic operations reduce to bitwise XOR and shift operations, making our approach naturally suitable for FPGA-style parallel architectures while asymptotically preserving polylog parallel depth, as theoretically proposed in Ref. [7].
2. Second, we remove dominant sources of bit-length blowup inherent in the previous procedure in Ref. [7]. First, we eliminate a costly weight-amplification procedure, a key modification from the previous procedure. Building upon this, we further introduce a variable-precision scheme that first performs a costly part, i.e., computing candidates of MWPMs, with low precision, and later efficiently verifies them with high precision, where the verification is at a low cost. Together, these refinements substantially reduce the required arithmetic bit length while maintaining the desired suppression of the logical error rate. In a proof-of-principle numerical simulation on surface codes with code distance $d = 5$, we reduce the required arithmetic bit length for polylog-time MWPM decoding from $\lesssim 6 \times 10^5$ bits in the previous method [7] to $\lesssim 5 \times 10^2$ bits, i.e., by up to 99.9%, while keeping the decoding failure probability below the logical error rate for $d = 5$. The required number of classical processors remains sub-linear in the size of the detector graph.

Our results establish the overflow-safe, hardware-feasible realization of asymptotically polylog-time parallel MWPM decoding, narrowing the gap between asymptotic optimality and practical implementation in FTQC architectures. Combined with prior results showing that polylog-time parallel decoding implies doubly-polylog-time-overhead FTQC [7], our work strengthens the practical feasibility of such highly time-efficient FTQC, opening up the possibility of its proof-of-principle demonstration in the early FTQC regime.

C. Organization of the paper

The remainder of this paper is organized as follows. In Sec. II we construct our determinant-based polylog-time MWPM decoding algorithm, analyze its correctness, and present numerical results to evaluate its parameter choice. In Sec. III, we further optimize this algorithm by introducing heuristic techniques for substantially reducing the required arithmetic bit length, where we do not analytically provide the conditions on securing correctness, while also presenting the results of numerical simulations to support its correctness and propose appropriate parameter choices. Finally, in Sec. IV, we discuss the implications of our results for low-overhead FTQC and outlines directions for future research.

II. OVERFLOW-SAFE POLYLOG-TIME MWPM DECODER

In this section, we first describe the proposed decoding algorithm based on polynomial arithmetic over a truncated polynomial ring in Sec. II A. In Sec. II B, we analyze its theoretical properties, including correctness and failure detectability under finite-bit representations. In Sec. II C, we provide numerical simulations to estimate the bit precision for reliable decoding.

A. Description of the polylog-time parallel algorithm for MWPM decoding

We describe the details of our polylog-time parallel algorithm, building on the approach that was introduced in Ref. [7] (see also Appendix A for the details of the approach in Ref. [7]). In Sec. II A 1, we describe the decoding task for the surface code. In Sec. II A 2, we introduce a mathematical framework that serves as the foundation of our methods. In Sec. II A 3, we propose our polylog-time parallel algorithm for MWPM decoding.

1. Task of decoding

We summarize the decoding task for the surface code, which can be, in the context of FTQC, formulated as

an MWPM problem on a weighted graph (see also, e.g., Ref. [7] for the details of the problem formulation). The surface code performs error correction by repeatedly applying syndrome extraction, which is represented as a syndrome-extraction circuit composed of state preparations, gates, measurements, and idle operations on physical qubits. We refer to each operation in this circuit as a location. Following the convention of Ref. [33], we assume a local stochastic Pauli error model. Namely, each location j has an error parameter p_j , and for any set A of locations, the probability that all locations in A are faulty is upper bounded as

$$\Pr[\text{all locations in } A \text{ are faulty}] \leq \prod_{j \in A} p_j. \quad (1)$$

Pauli errors may occur at faulty locations.

A syndrome measurement consists of measuring stabilizer generators, each of which is represented as a tensor product of Pauli operators, yielding a classical single-bit outcome, i.e., 0 or 1. The syndrome-extraction circuit provides detectors, which are the parities of pairs of consecutive syndrome measurement outcomes used for error correction. The detector is 0 if there is no error, and physical errors may flip a set of detectors into 1, which are called active detectors. Using the detectors as vertices, we form a detector graph in which error chains are represented as paths over detectors. However, error chains may also terminate on spatial or time-like boundaries of the decoding window in the syndrome-extraction circuit. Such boundaries are addressed by introducing boundary vertices in the detector graph, which can serve as endpoints of error chains. In the surface code, an error at a given location in the syndrome-extraction circuit may flip either one or two detectors; these cases are represented by edges connecting a detector to a boundary vertex, or connecting a pair of detectors, respectively.

Using these detectors and boundary vertices, we define a detector graph [28]

$$G := (V, E), \quad (2)$$

where each vertex represents either a detector or a boundary vertex. An edge $e \in E$ connects either one detector and one boundary, or two detectors. Edge weights $w(e)$ are defined by

$$w(e) := \left\lceil -C \ln \left(\sum_j p_j \right) \right\rceil, \quad (3)$$

where $C \geq 1$ is a scaling factor used for integer rounding, $\lceil \cdot \rceil$ denotes the ceiling function, p_j denotes the error parameter of a location j in (1), and the sum is taken over multiple possible locations that may flip the detectors incident with the edge e . This form corresponds to the negative log-likelihood of the error and ensures that the MWPM problem is equivalent to finding the most probable set of error chains.

From a detector graph, we construct a path graph (see also, e.g., Ref. [7] for the formal description of this procedure)

$$\overline{G} = (\overline{V}, \overline{E}). \quad (4)$$

The weights of the path graph $w : \overline{E} \rightarrow \mathbb{Z}$ are obtained from the weights of the detector graph using Dijkstra's algorithm [34]. Each edge in the path graph corresponds to a possible error chain between two detection events or between a detection event and a boundary vertex.

Given a path graph $\overline{G} = (\overline{V}, \overline{E})$ with integer weights w , the decoding task is to find a perfect matching $M^* \subseteq \overline{E}$ that minimizes the total weight

$$M^* = \operatorname{argmin}_{M \subseteq \overline{E}} \sum_{e \in M} w(e). \quad (5)$$

The MWPM M^* corresponds to the most probable configuration of physical errors consistent with the observed detection events and thus determines the appropriate recovery operation on the code block.

To summarize, the inputs to the decoding algorithm are a path graph $\overline{G} = (\overline{V}, \overline{E})$ and a weight function $w : \overline{E} \rightarrow \mathbb{Z}$, and the output is an MWPM M^* . Finding such a matching feasibly in polylog parallel time is the goal of decoding in this work.

2. Finite-digit binary numbers and truncated polynomial rings

In a modern computer, numbers are represented as finite-digit binary values. Due to hardware constraints, digits beyond a certain length are truncated as overflow. Such behavior does not occur in the ring of integers; therefore, the assumption that overflow never occurs underlies the guarantee of mathematical correctness in the previous analysis [7], which may indeed be violated in practical implementations due to finite arithmetic bit lengths.

To preserve mathematical consistency under such practical constraints, we introduce the following natural correspondence

$$\begin{aligned} & a_{n-1}a_{n-2} \cdots a_0(2) \\ & \rightarrow a_{n-1}X^{n-1} + a_{n-2}X^{n-2} + \cdots + a_0. \end{aligned} \quad (6)$$

Here, the left-hand side represents the binary representation of an integer, where $a_i \in \{0, 1\}$ and the representable bit length is n . The fact that digits beyond n bits are discarded due to overflow corresponds to the condition that $X^n = 0$ holds, or equivalently, to taking the remainder upon the division of a polynomial by X^n . Therefore, a finite-digit binary number can be rigorously represented as the remainder of a polynomial over the finite field $\mathbb{F}_2 = \{0, 1\}$ modulo X^n . The set of all such polynomials forms a ring denoted by $\mathbb{F}_2[X]/(X^n)$.

Using this algebraic structure, arithmetic operations such as addition and multiplication over the integers can be consistently defined as addition and multiplication in $\mathbb{F}_2[X]/(X^n)$, respectively, incorporating overflow in an algebraically coherent manner. Although arithmetic in the ring of integers and that in the polynomial ring generally differ, as shown later in Theorem 3, our algorithm produces identical results under this correspondence. Consequently, computations with finite-bit representations on actual hardware can be modeled in a mathematically rigorous manner, thereby ensuring the overall correctness of our algorithm.

Although our algorithm will be described using polynomials, it can be implemented using bitwise operations, as shown by the following theorem.

Theorem 1 (Bit-Level Computability). *For any constant positive integers $w_{\text{th}} \in \{1, 2, \dots\}$, polynomial arithmetic over $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$ can be implemented by bitwise XOR and shift operations.*

Proof. We first show that any element in $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$ can be represented as a bit string. Since the coefficients in this polynomial ring take values in $\{0, 1\}$, and since $X^w = 0$ for any $w \geq w_{\text{th}}$, each polynomial has finitely many terms. Therefore, by directly mapping each coefficient to its corresponding bit, with 1 indicating the presence and 0 the absence of a term, every element can be expressed as a bit string of length w_{th} . We then show that addition and multiplication operations can be implemented using bitwise operations.

Addition. For $a, b \in \mathbb{F}_2[X]/(X^{w_{\text{th}}})$ and for each $0 \leq n < w_{\text{th}}$,

$$(a + b)[X^n] = \begin{cases} 1 & (a[X^n] \neq b[X^n]), \\ 0 & (a[X^n] = b[X^n]), \end{cases} \quad (7)$$

where $p[X^n]$ denotes the coefficient of X^n in p . This relation is equivalent to

$$a + b = a_{\text{bit}} \oplus b_{\text{bit}}, \quad (8)$$

where p_{bit} denotes the corresponding bitwise representation of p , and $\oplus$ denotes the bitwise XOR. Thus, the addition in $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$ corresponds exactly to a bitwise XOR operation.

Multiplication. For $a, b \in \mathbb{F}_2[X]/(X^{w_{\text{th}}})$, we have

$$a \times b = \sum_{i=0}^{w_{\text{th}}-1} (a \cdot b[X^i]X^i). \quad (9)$$

This can be rewritten as

$$a \times b = \bigoplus_{i: b[X^i] = 1} (a_{\text{bit}} \ll i), \quad (10)$$

where $\ll$ denotes the left-shift operation. Since whether $b[X^i] = 1$ can be determined directly from b_{bit} , multiplication is realized by a sequence of bitwise shifts and XORs.

Thus, all operations over $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$ can be implemented solely using bit-level XOR and shift operations, demonstrating that computations in this ring are implementable directly on bits. $\square$

3. A parallel algorithm for finding an MWPM via polynomial arithmetic

Given a path graph $\bar{G} = (\bar{V}, \bar{E})$ with edge weights $w : \bar{E} \rightarrow \mathbb{Z}$, we propose a parallel algorithm for finding an MWPM in $\bar{G}$ based on polynomial arithmetic over a truncated polynomial ring $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$ with a fixed constant w_{th} . In this framework, the truncation threshold w_{th} is set in advance, prior to computation, based on the available computational resources and hardware constraints.

Our algorithm is described as follows.

1. Adjust each edge weight and replace w by $\tilde{w}$ for each $e \in \bar{E}$ as

$$\tilde{w}(e) := \tilde{C}w(e) + W(e), \quad (11)$$

where we take the factor $\tilde{C}$ and the perturbation function W as

$$\tilde{C} := \frac{|\bar{V}|}{2}(W_{\max} - 1) + 1, \quad (12)$$

$$W : \bar{E} \rightarrow \mathbb{N}, \quad (13)$$

$$1 \leq W(e) \leq W_{\max}, \quad (14)$$

$$W_{\max} := \max_{e \in \bar{E}} \{W(e)\}. \quad (15)$$

Here, for each $e \in \bar{E}$, the perturbation $W(e)$ is drawn independently and uniformly at random from the integer set $\{1, \dots, W_{\max}\}$. With this perturbation, with high probability, one of the MWPMs in $\bar{G}$ becomes a unique MWPM in the resulting weighted graph. As will be shown later in Theorem 3, if the resulting weighted graph has a unique MWPM, then the algorithm's output subset M represents this unique MWPM, which is one of the MWPMs of $\bar{G}$, similar to the previous algorithm in Ref. [7] based on integer arithmetic.

2. Let A be a Tutte matrix with its element $A_{i,j}$ given by

$$A_{i,j} = \begin{cases} x_{i,j} & (i < j, \{i, j\} \in \bar{E}), \\ -x_{i,j} & (i > j, \{i, j\} \in \bar{E}), \\ 0 & \text{otherwise,} \end{cases} \quad (16)$$

where $x_{i,j}$ is a variable. Then, for each edge $\{i, j\} \in \bar{E}$, we assign

$$x_{i,j} = X^{\tilde{w}(\{i,j\})}, \quad (17)$$

where X is the indeterminate of $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$. Since we are working on $\mathbb{F}_2$ when computing the

coefficient of X^w , we then obtain a matrix B defined as

$$B_{i,j} = \begin{cases} X^{\tilde{w}(\{i,j\})} & \{i,j\} \in \bar{E}, \\ 0 & \text{otherwise,} \end{cases} \quad (18)$$

from an assignment (17).

3. Compute the determinant $\det(B)$ of B and obtain

$$w^* := \frac{\deg_{\min}(\det(B))}{2}, \quad (19)$$

where $\deg_{\min}(f)$ denotes the minimum exponent of X appearing in the polynomial f . Note that the determinant of ring-valued matrices can be computed in polylog parallel runtime by the Samuelson-Berkowitz algorithm [35] (see also Sec. S2 of Ref. [7] for the details of this method).

4. For each edge, calculate a minor $M_{i,j}^B = \det(B^{(i,j)})$, where $B^{(i,j)}$ is defined as an $(|\bar{V}| - 1) \times (|\bar{V}| - 1)$ submatrix obtained from B by removing the i th row and the j th column. Finally, we obtain

$$M = \left\{ \{i,j\} \mid \deg_{\min}(M_{i,j}^B \cdot X^{\tilde{w}(\{i,j\})}) = w^* \right\} \subseteq \bar{E}. \quad (20)$$

When step 3 computes $w^* = 0$, the algorithm terminates and outputs a failure indicator, which is interpreted as a logical error.

The following theorem shows that this algorithm can be parallelized to achieve a polylog parallel runtime.

Theorem 2 (Parallelizability). *Given a path graph of size $\bar{V}$ and a perturbation range $W_{\max}$, all computational steps of the algorithm are parallelizable with polylog depth $O(\text{polylog}(|\bar{V}|, |W_{\max}|))$ using bitwise operations.*

Proof. We show that the proposed algorithm can be parallelized in polylog time. First, in Step 4, each minor is computed independently and can therefore be evaluated in parallel using $O(|\bar{V}|^2)$ processors. Thus, it suffices to show that the determinant of an $O(|\bar{V}|) \times O(|\bar{V}|)$ matrix can be computed in parallel within polylog time.

As indicated above, it is known that the determinant of such a matrix with entries in polynomial rings can be computed in $O(\log^2 |\bar{V}|)$ parallel time using $O(\text{poly}(|\bar{V}|))$ processors, as achieved by the Samuelson-Berkowitz algorithm [35]. Since this algorithm does not require division, it can also be applied to matrices B in (18) whose entries are polynomials over $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$.

From Theorem 1, each polynomial in $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$ can be represented as a bit string, and both addition and multiplication over this ring can be implemented using bitwise operations as the standard arithmetic operations. As the addition and multiplication of N -bit integers can be performed in $O(\log N)$ parallel time using $O(\text{poly}(N))$

processors, the same parallel complexity applies to operations in $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$. In our case, from (11), we have $N = O(\text{poly}(|\bar{V}|, W_{\max}))$.

Therefore, the total runtime for finding the unique MWPM is

$$O(\text{polylog}(|\bar{V}|, |W_{\max}|)), \quad (21)$$

and the required number of processors is

$$O(\text{poly}(|\bar{V}|, |W_{\max}|)). \quad (22)$$

□

B. Theoretical analysis of the proposed method

We analyze the theoretical properties of the proposed method, focusing on its correctness in Theorem 3 and failure detectability in Theorem 4.

First, the following theorem shows that our algorithm produces results identical to those of the existing MWPM decoder in Ref. [7] if no overflow occurs.

Theorem 3 (Correctness). *Let w^* denote the MWPM weight for the input graph $\bar{G} = (\bar{V}, \bar{E})$ with edge weights $\tilde{w} : \bar{E} \rightarrow \mathbb{Z}$. If*

$$w^* < \frac{w_{\text{th}}}{2}, \quad (23)$$

then our algorithm outputs a unique and correct MWPM with high probability at least $1 - |\bar{V}|/W_{\max}$.

Proof. We will check the correctness of each algorithmic step.

Step 1. In this step, the edge weights are adjusted. Let M^* denote the MWPM of $\bar{G} = (\bar{V}, \bar{E})$ with weights $\tilde{w}$, and let M' be any perfect matching that is not an MWPM of $\bar{G}$ with weights w . Noting that $|M^*| = |M'| = |\bar{V}|/2$ and from (14), we have

$$\sum_{e \in M^*} \tilde{w}(e) \leq \tilde{C} \sum_{e \in M^*} w(e) + \frac{|\bar{V}|}{2} W_{\max}, \quad (24)$$

$$\sum_{e \in M'} \tilde{w}(e) \geq \tilde{C} \sum_{e \in M'} w(e) + \frac{|\bar{V}|}{2}. \quad (25)$$

Thus, for M' and M^* , it holds that

$$\begin{aligned} & \sum_{e \in M'} \tilde{w}(e) - \sum_{e \in M^*} \tilde{w}(e) \\ & \geq \tilde{C} \left(\sum_{e \in M'} w(e) - \sum_{e \in M^*} w(e) \right) - \frac{|\bar{V}|}{2} (W_{\max} - 1) \end{aligned} \quad (26)$$

$$\geq \tilde{C} - \frac{|\bar{V}|}{2} (W_{\max} - 1) \quad (27)$$

$$\geq 1. \quad (28)$$

This inequality shows that M^* has a smaller weight than any other perfect matching, guaranteeing that M^* is one of the MWPMs in $\bar{G}$ with weights w .

By the isolation lemma [31, 32], we also have

$$\Pr[\text{Isolation fails to hold}] \leq \frac{|\bar{V}|}{W_{\max}}, \quad (29)$$

implying that, with high probability, the MWPM in $\bar{G}$ with weights $\tilde{w}$ is unique. From here onward, we assume $\tilde{w}(e)$ as the working weights, and the MWPM is unique.

Step 2. We construct the matrix B as defined in (18).

Step 3. For this step of computing $\det(B)$ to determine the weight of the MWPM, we will show that (19) indeed yields the weight. Recall that

$$\det(B) = \sum_{\sigma} \text{sign}(\sigma) \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)}, \quad (30)$$

where σ is a permutation, $\text{sign}(\sigma)$ is its sign, and $b_{i,j}$ denotes the (i,j) -th entry of B . Since we are working on $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$, we have

$$\det(B) = \sum_{\sigma} \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)}. \quad (31)$$

Each σ corresponds to a subgraph of $\bar{G}$, since $\{i, \sigma(i)\}$ represents an edge and every permutation contains at least one cycle. We partition the set of permutations into S_2 , the subset consisting entirely of 2-cycles, and $S_{>2}$, the subset containing permutations with cycles of length greater than 2.

Then we have

$$\det(B) = \sum_{\sigma \in S_2} \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)} + \sum_{\sigma \in S_{>2}} \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)}.$$

For $\sigma_{>2} \in S_{>2}$, there exists another permutation $\sigma'_{>2}$ obtained by reversing a cycle. Since $b_{i,j} = b_{j,i}$, we have

$$\prod_{i=1}^{|\bar{V}|} b_{i,\sigma_{>2}(i)} = \prod_{i=1}^{|\bar{V}|} b_{i,\sigma'_{>2}(i)}. \quad (32)$$

Recalling that $1 + 1 = 0$ over $\mathbb{F}_2$, we see that the contributions from $S_{>2}$ cancel out

$$\sum_{\sigma \in S_{>2}} \text{sign}(\sigma) \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)} = 0. \quad (33)$$

Computing the rest, we have

$$\sum_{\sigma \in S_2} \text{sign}(\sigma) \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)} = \sum_{\sigma \in S_2} X^{\sum_{i=1}^{|\bar{V}|} \tilde{w}_{i,\sigma(i)}} \quad (34)$$

$$= \sum_{\sigma \in S_2} X^{2w^* + \epsilon(\sigma)}. \quad (35)$$

Here, w^* denotes the weight of the MWPM in $\bar{G}$ with weights $\tilde{w}$, and $\epsilon(\sigma)$ over $\sigma \in S_2$ is defined as

$$\epsilon(\sigma) := \sum_{i=1}^{|\bar{V}|} \tilde{w}_{i,\sigma(i)} - 2w^*. \quad (36)$$

Considering the graph corresponding to each permutation in S_2 , from the properties of the MWPM, we have $\epsilon(\sigma) \in \mathbb{Z}$ and

$$\epsilon(\sigma) = \begin{cases} 0 & (\sigma = \sigma_M), \\ > 0 & (\sigma \neq \sigma_M), \end{cases} \quad (37)$$

where σ_M denotes the permutation corresponding to the MWPM. This holds because a permutation composed of 2-cycles corresponds to a perfect matching in the graph. Then we have

$$\det(B) = X^{2w^*} \sum_{\sigma \in S_2} X^{\epsilon(\sigma)}. \quad (38)$$

Under the assumption that the MWPM is unique, there exists exactly one permutation σ such that $\epsilon(\sigma) = 0$. Moreover, because $w_{\text{th}} > 2w^*$, the term X^{2w^*} remains in the truncated polynomial ring $\mathbb{F}_2[X]/(X^{w_{\text{th}}})$. Therefore, w^* indeed corresponds to the MWPM weight.

Step 4. We compute the minors for each edge and use the result from Step 3 to identify edges belonging to the MWPM. From the Laplace expansion

$$|M_{i,j}^B| \cdot X^{\tilde{w}(\{i,j\})} = \sum_{\sigma: \sigma(i)=j} \text{sign}(\sigma) \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)}, \quad (39)$$

we have

$$M_{i,j}^B \cdot X^{\tilde{w}(\{i,j\})} = \sum_{\sigma: \sigma(i)=j} \prod_{i=1}^{|\bar{V}|} b_{i,\sigma(i)}. \quad (40)$$

The contribution from permutations with cycles of length greater than 2 cancels out with that of its reverse, as argued above. Thus, we have

$$M_{i,j}^B \cdot X^{\tilde{w}(\{i,j\})} = X^{2w^*} \sum_{\sigma \in S_2: \sigma(i)=j} X^{\epsilon(\sigma)}, \quad (41)$$

where S_2 denotes the set of permutations consisting of 2-cycles. Recalling the definition of $\epsilon(\sigma)$, for σ that satisfy $\sigma(i) = j$, we have

$$\epsilon(\sigma) = \begin{cases} 0 & (\sigma = \sigma_M), \\ > 0 & (\sigma \neq \sigma_M), \end{cases} \quad (42)$$

where σ_M denotes the permutation corresponding to the MWPM. This implies that $\epsilon(\sigma)$ can be 0 if and only if $\sigma_M(i) = j$. Since the MWPM is unique, focusing on the lowest-degree term, we correctly identify the MWPM

edges according to (20). This confirms that our algorithm yields the same MWPM as the algorithm in Ref. [7] as long as $w_{\text{th}} > 2w^*$.

Hence, if $w_{\text{th}} > 2w^*$, our algorithm outputs a unique and correct MWPM with high probability. $\square$

We also show that if the overflow occurs, our algorithm can naturally detect it, as shown below.

Theorem 4 (Failure Detection). *Let w^* denote the weight of the MWPM for the input graph $\bar{G} = (\bar{V}, \bar{E})$ with edge weights $\tilde{w} : \bar{E} \rightarrow \mathbb{Z}$. If*

$$w^* \geq \frac{w_{\text{th}}}{2}, \quad (43)$$

the algorithm outputs a failure indicator.

Proof. From Theorem 3, we have

$$\det(B) = X^{2w^*} \sum_{\sigma \in S_2} X^{\epsilon(\sigma)}, \quad (44)$$

$$M_{i,j}^B \cdot X^{\tilde{w}(\{i,j\})} = X^{2w^*} \sum_{\sigma \in S_2: \sigma(i)=j} X^{\epsilon(\sigma)}. \quad (45)$$

Since $2w^* \geq w_{\text{th}}$ and $\epsilon(\sigma) \geq 0$, all terms vanish, causing both expressions to become zero. In this situation, (19) evaluates to zero, the algorithm correctly outputs a failure indicator, signaling that the MWPM weight exceeds the representable range. $\square$

C. Numerical estimation of required parameters

Here, we numerically evaluate the proposed MWPM decoder from the perspective of scaling accuracy. In particular, since the edge weights are discretized as in (3), we investigate how much scaling precision is sufficient to ensure that the decoded matching remains identical to the one obtained using floating-point weights. Although our decoding problem is formulated in terms of integer-weighted path graphs as in (3), our numerical estimates aim to determine the arithmetic bit length required for these integer weights to achieve error-suppression performance comparable to that of conventional MWPM decoding methods based on floating-point weights, such as the ones in Refs. [28, 29].

The numerical simulation was conducted for the $[[n, k = 1, d = \sqrt{n}]]$ two-dimensional rotated surface codes [36] under the independent and identically distributed (IID) circuit-level depolarizing error model with a physical error rate of $p = 10^{-3}$. After preparation of $|0\rangle$, a bit flip may occur with probability p . After a single-qubit gate, Pauli errors $X, Y \propto XZ$, and Z may occur with probability $p/3$, respectively, where identity gates also suffer from errors. After a two-qubit CNOT gate, $X \otimes I, I \otimes X, X \otimes X, \dots, Z \otimes Z$ may occur with probability $p/15$, respectively, where I is the identity matrix. Before a measurement in the Z basis, a bit flip may occur with

FIG. 2: MWPM error rate as a function of the code distance for different discretization precisions of integerized edge weights. Each curve corresponds to a different number that represents a binary digit of the minimum discretized edge weight of a detector graph. The error rate indicates the fraction of trials where the MWPM solution obtained from the integer-weight graph differs from that obtained using the floating-point weights. Error bars indicate the standard error computed over the 10^7 trials.

probability p . We simulated memory experiments consisting of d rounds of syndrome extraction, starting from a codeword of logical $|0\rangle$ and ending with measurements in the Z basis.

Under this setting, we estimate the scale of the discretized weights in (3) required to reproduce the same MWPM as that obtained with floating-point weights. In the simulation, we used Stim [37] to generate the syndrome extraction circuits. The detector error model obtained from Stim was converted into a graph using PyMatching [28]. To prepare a version of the graph with integer edge weights, we further converted it into a NetworkX [38] graph. For the detector graph on NetworkX, we multiplied an integer scaling factor C to the edge weights, where C is defined as the smallest integer such that the minimum weight obtained from (3) becomes a b -digit binary number. This ensures that all edge weights have at least b significant binary digits. The resulting integer-weighted detector graph was then converted back into a PyMatching graph, producing both floating-point and integer-weight versions of the same graph. We sampled errors using Stim and performed MWPM decoding with PyMatching for both the floating-point and integer-weight graphs to check whether they produced identical matchings. This process was repeated 10^7 times for each code distance $d \in \{3, 5, \dots, 29\}$ and for each binary precision $b \in \{5, 6, \dots, 11\}$ to determine the minimum number of binary digits required to reproduce the same MWPM as that obtained from the floating-point graph.

In Fig. 2, we plot the fraction of mismatched MWPMs between the floating-point and discretized-weight graphs as a function of the code distance for various dis-

cretization precisions. As the binary precision increases, the mismatch rate decreases rapidly, and for $b \geq 10$, the mismatch rate becomes zero, up to the statistical error below the logical error rate across small code distances $d = 5, 7, 9$. This result demonstrates that a precision of approximately 10 binary digits is sufficient to reproduce the same MWPM as the floating-point version under the considered noise model and parameter regime for small code distances. For sufficiently large code distances, the mismatch rate can be reduced below the logical error rate by increasing the binary precision.

The trend observed in Fig. 2 can be interpreted as follows. The MWPM algorithm depends only on the relative ordering of edge weights, not their absolute values. Therefore, discretization can change the MWPM result only when two or more competing matching paths have total weights that are very close. As the discretization precision increases, the relative ordering of these weights becomes stable, leading to the disappearance of mismatches. Overall, these results indicate that MWPM decoding outcomes with floating-point weights can be faithfully reproduced by using only integer-weight graphs with a feasibly small binary precision for the scaled edge weights.

III. HEURISTIC MODIFICATIONS FOR PRACTICAL BIT-LENGTH REDUCTION

In this section, we propose heuristic modifications to our MWPM-decoding algorithm presented in Sec. II and numerically evaluate the practical feasibility of its implementation. In Sec. III A, we introduce heuristic modifications aimed at reducing the required arithmetic bit length, including a modified isolation strategy and a variable-precision scheme. Their performance is numerically evaluated in Sec. III B. In Sec. III C, we propose practical parameter choices for hardware implementation.

A. Description of the heuristic improvements on the overflow-safe polylog-time MWPM decoding

In this section, we present two strategies for reducing the required arithmetic bit length. In Sec. III A 1, we remove the dominant source of bit-length blowup by modifying isolation. In Sec. III A 2, we further introduce the variable-precision scheme that efficiently verifies the MWPM.

1. Modification of isolation

The randomized algorithm described in Sec. II A isolates the MWPM by scaling every edge weight according to (11), where the amplification factor $\tilde{C}$ in (12) guarantees that, once the perturbed MWPM becomes unique,

it coincides with the MWPM under the original weights $w : \bar{E} \rightarrow \mathbb{Z}$. Although this construction ensures correctness with high probability, the large magnitude of $\tilde{C}$ substantially increases the bit length required to compute the determinant of matrix B in (18), creating a substantial bottleneck for practical implementations.

Here, we propose an alternative perturbation strategy by omitting the multiplication of the scaling factor $\tilde{C}$, which considerably reduces the required bit length. In particular, the algorithm proceeds identically to the procedure in Sec. II A, except for the perturbation rule and the selection of the final output. We describe the modified step below.

Modified step. Instead of constructing the amplified weights $\tilde{w}$ in (11), we define perturbed weights without amplification by

$$\hat{w}(e) := w(e) + W(e), \quad (46)$$

where $W(e)$ is drawn in the same manner as in Sec. II A. All subsequent steps—construction of the matrix B in 18, computation of $\det(B)$, extraction of minimum-degree terms, and evaluation of minors to obtain the set representing the unique MWPM—are performed exactly as in Sec. II A, with the replacement of $\tilde{w}(e)$ in (11) with $\hat{w}(e)$ in (46) throughout. In addition to this, for each matching obtained from $\hat{w}(e)$, the true weight of the matching with respect to the original, unperturbed weight function w is computed. When the perturbation procedure is repeated multiple times, we select as the final output the set M corresponding to the perturbation whose resulting matching attains the minimum weight with respect to the original weights w .

2. Modification of accuracy scaling

As described in Sec. III A 1, the heuristic method outputs an estimate of the optimal solution by recomputing the weight of each MWPM candidate using the original weights. In this process, graphs of the same precision are used both to generate MWPM candidates and to evaluate the final weights. As a result, while the probability of obtaining candidates that include the correct MWPM increases, the bit length required for determinant computations increases to maintain high precision, which may still make the implementation impractical.

Here, we further extend this method by allowing the discretization precisions in (3) to vary and adapting them at each step. The algorithm proceeds identically to the procedure in Sec. III A 1, except for the weight functions used in the computation. We describe the modified step below.

Modified step. Let $\bar{G} = (\bar{V}, \bar{E})$ be the path graph. First, we define the discretized weight as

$$w_C(e) := \left\lceil -C \ln \left(\sum_j p_j \right) \right\rceil, \quad (47)$$

by explicitly introducing the scaling factor C , where the notation follows that of (3). We introduce two scaling factors that satisfy $C_{\text{high}} > C_{\text{low}}$ and prepare the corresponding weight functions

$$w_{C_{\text{high}}} : \bar{E} \rightarrow \mathbb{Z}, \quad (48)$$

$$w_{C_{\text{low}}} : \bar{E} \rightarrow \mathbb{Z}. \quad (49)$$

With these definitions, the proposed method can be described as the following replacement of weight functions in the existing algorithm. In the step of generating MWPM candidates, namely in the computation of the MWPM in Sec. II A, the weight function $w_{C_{\text{low}}}$ is used. On the other hand, in the step of selecting the final output, that is, in the additional weight evaluation introduced in Sec. III A 1, the weight function $w_{C_{\text{high}}}$ is used.

B. Numerical evaluation of the heuristic decoder

Here, we evaluate the proposed improvements on our MWPM decoder from the following perspectives.

1. **Required bit length:** In Sec. II A and Sec. III A, we presented two approaches: a theoretically correct formulation and its heuristic, yet practically optimized variant with reduced bit length. In Sec. III B 1, we estimate the required arithmetic bit length w_{th} to reliably obtain the correct MWPM without affecting the logical error rates.
2. **Correctness of the MWPM:** In the method described in Sec. III A, MWPM candidates are obtained via heuristic approximations. In Sec. III B 2, we numerically evaluate how w_{th} affects the correctness of the MWPM and how the number of perturbation trials influences the probability of obtaining the correct MWPM.

All the numerical simulations were conducted in the same setting as in Sec. II C.

1. Required bit length

We estimate the threshold bit length w_{th} in Sec. II A required to obtain the correct MWPM with high probability.

In this simulation, we used the same procedure as in Sec. II C to generate circuits with Stim, construct the detector graph using PyMatching, and produce its integer-weight version for MWPM decoding using NetworkX. For efficiency, we fixed the code distance to $d = 5$. Although larger code distances require a digit length of at least 10 for sufficient numerical precision, a binary precision of $b = 8$ is sufficient for $d = 5$, and we therefore used $b = 8$ as a high binary precision. To evaluate the method in Sec. III A 2, we also adopted a reduced binary precision, or low binary precision, of $b = 4$ in order to

FIG. 3: Required w_{th} to obtain the correct MWPM for each number $\{2, 4, \dots, 28\}$ with a code distance of 5, and a high binary precision of 8 bits and a low binary precision of 4 bits. The three curves represent the lower bounds of w_{th} obtained from MWPM weights using the respective edge-weight scalings, where the plotted values correspond to the maximum w_{th} observed over 10^7 trials

further suppress the required bit length to a practically feasible level. Under this setting, we sampled errors using Stim and performed MWPM decoding with PyMatching on the graphs to obtain the total weight of the resulting MWPM. From this MWPM weight, we applied the two scaling procedures corresponding to (11) and (46), respectively, thereby generating the two types of scaled weights, $\tilde{w}_{\text{total}}$ and $\hat{w}_{\text{total}}$. In summary, we compare three cases: the original scaling $\tilde{w}$, the proposed scaling $\hat{w}$ with high binary precision, and the same scaling $\hat{w}$ with low binary precision.

To ensure that the perturbed weights lead to a correct MWPM, we adopted the perturbation range

$$1 \leq W(e) \leq W_{\text{max}} (= \lceil 0.8 n^{0.8} \rceil), \quad (50)$$

where n denotes the size of a path graph. We chose a looser bound than that in Ref. [7] to ensure a sufficient margin. The effect of the perturbation was incorporated by using the maximum value over this allowed range. We then computed $2\tilde{w}_{\text{total}} + 1$ (or the corresponding quantity for $\hat{w}_{\text{total}}$) for each trial. From Theorem 3, this value provides a lower bound on the required threshold bit length w_{th} . This process was repeated 10^7 times to determine and compare the lower bounds of the required threshold bit length w_{th} for the two algorithms described in Secs. II A and III A.

In Fig. 3, we plot lower bounds of the required threshold bit length w_{th} , obtained from the maximum w_{th} that we found within 10^7 trials for each path graph size. Note that, by construction, the path graph size is restricted to even integers, as illustrated in Ref. [7]. As the path graph size increases, the gap between the curves corresponding to $\tilde{w}$ and $\hat{w}$ becomes larger. For instance, at a path graph size of $n = 28$, the scaling method based on (11) requires a threshold bit length of about 6×10^5 ,

whereas the method described in (46) requires only about 4×10^3 when using high binary precision. Furthermore, using the low binary precision $b = 4$, we achieve further reduction in the required threshold bit length, down to approximately 5×10^2 , corresponding to a reduction of more than 99.9% relative to 6×10^5 .

These results indicate that the method described in Sec. III A requires a bit length that may still require impractically large for FPGA-based implementations, whereas the bit-reduction techniques introduced in Secs. III A 1 and III A 2 bring the required threshold bit length within a feasible range for FPGA hardware that supports 512-bit computing.

2. Correctness of the MWPM

We estimate the probability that the algorithm presented in Sec. III A does not output the correct MWPM.

In this simulation, we used the same procedure as in Sec. III B 1 to generate circuits with Stim, construct the detector graph using PyMatching, and produce its integer-weight version for MWPM decoding using NetworkX, where we fixed the code distance to $d = 5$, chose a high binary precision of $b = 8$, and a low binary precision of $b = 4$. We performed a Monte Carlo simulation to evaluate the probability that our algorithm fails to output an MWPM of the same weight as that of the conventional blossom algorithm [28].

In this simulation, we first constructed a lookup table from the detector graph using NetworkX. We then sampled detection events with Stim and constructed the corresponding path graph by reading the lookup table. The Mersenne Twister [39] was used as the pseudo-random function to generate random numbers for perturbation. The seed values are chosen uniformly at random from the set of 32-bit unsigned integers. For each perturbation set, we constructed the weight-perturbed path graph following Sec. III A 1 and computed the determinant. For this computation, we used an implementation based on Ref. [7], modified to retain only the first w_{th} digits during arithmetic to evaluate the success probability as a function of w_{th} . For every perturbation set, we checked whether the value w^* obtained from (19) coincides with the weight computed from (20); those satisfying this condition are regarded as MWPM candidates. Following the methods described in Sec. III A, we evaluated the correctness of the algorithm using the following two methods.

a. Base modified method: isolation-based bit reduction. For each MWPM candidate that is obtained from the high-binary-precision path graph, its weight on the original high-binary-precision path graph is recomputed, and the one with the minimum weight is selected.

b. Extended modified method: low-precision candidate generation with high-precision verification. To further reduce the required bit length, we additionally consider a variant in which MWPM candidates are generated using the low-binary-precision path graph. For each

MWPM candidate obtained in this way, its weight on the original high-binary-precision path graph is recomputed, and the one with the minimum weight is selected.

We then verified whether its weight coincides with the MWPM weight obtained by PyMatching, i.e., whether it corresponds to the correct MWPM on the integer-scaled path graph.

These entire procedures were repeated 10^6 times for each chosen number of perturbation samples, allowing us to estimate how many perturbation samples are sufficient for our bit-reduction methods. Since the failure probability only needs to be kept below the logical error rate, we decoded path graphs of size at most 28. Following Ref. [7], we adopted W_{max} , which denotes the upper bound of the perturbation range, as the number of perturbation sets, which also indicates the number of weight-perturbed path graphs. As in Sec. III B 1, we used $\lceil 0.8n^{0.8} \rceil$ to ensure that the correct MWPM can be obtained. Using this value as the base perturbation, we conducted additional experiments by doubling the number of perturbation sets while keeping the perturbation range fixed. Note that, throughout our experiments, we did not directly check whether the MWPM is uniquely isolated or not, since the isolation is only a sufficient condition, not a necessary condition, for finding the correct MWPM.

In Fig. 4, we plot the failure probability for each threshold bit length w_{th} . Figure 4a shows the results for the base isolation-based bit-reduction method, while Fig. 4b shows the results for the extended method using low-precision MWPM candidate generation. In both figures, the gap between the curves is zero up to the error bar for small values of w_{th} . As w_{th} increases, the gap gradually becomes more pronounced. In Fig. 4a, we observe that the failure probability for the base value remains almost constant below the logical error rate in the range $3000 \lesssim w_{\text{th}} \lesssim 4000$, while for the doubled value, the failure probability drops to zero at $w_{\text{th}} \approx 4000$. In Fig. 4b, we observe a trade-off between the failure probability and the set size: at the doubled set size, the failure probability remains below the logical error rate, and when the set size is octupled, it drops to zero.

Based on the results presented in Sec. III B 1 and the numerical simulation above, the base isolation-based bit-reduction method requires a threshold bit length of $w_{\text{th}} \approx 4 \times 10^3$, whereas the original method requires $w_{\text{th}} \approx 6 \times 10^5$. This corresponds to an estimated improvement in bit length of about 99.3% compared with the previous work [7]. By additionally using the extended method with low-precision MWPM candidate generation, the required threshold bit length is further reduced to approximately 3×10^2 – 5×10^2 . This range is consistent with the numerics in Sec. III B 1, and the numerics here confirm that it keeps the failure probability below the logical error rate. As in Sec. III B 1, this corresponds to an improvement of about 99.9% compared with the original method in Ref. [7].

(a) Base modification

(b) Extended modification

FIG. 4: Failure probability as a function of the threshold bit length w_{th} for a code distance of 5, a high binary precision of 8 bits, and a low binary precision of 4 bits. The failure probability represents the fraction of trials, among those with path graph size at most 28, in which the decoding process fails, or the decoded MWPM of the perturbed path graph does not coincide with any of the correct MWPMs of the original path graph. Error bars indicate the standard error computed over 10^6 trials. (a) Isolation-based bit-reduction method using high-binary-precision MWPM candidate generation. (b) Extended method using low-binary-precision MWPM candidate generation with high-binary-precision verification. For each panel, the dashed horizontal line indicates the logical error rate. The blue curve denotes the baseline number of perturbation samples required by the conventional method, while orange, green, and red denote $2\times$, $4\times$, and $8\times$ that number, respectively. Our method sufficiently suppresses the decoding failure probability with arithmetic bit lengths of 3×10^2 – 5×10^2 , as indicated by the green curve.

C. Proposal of parameter choice for implementation

Based on the theoretical analysis and numerical simulations presented in the previous sections, we summarize practical guidelines for parameter selection when implementing the proposed decoder on hardware, with particular emphasis on proof-of-principle demonstrations at code distance $d = 5$:

- arithmetic bit length: $w_{th} \geq 5 \times 10^2$ bits;
- low binary precision: 4 bits;
- high binary precision: ≥ 8 bits;
- range of perturbations: $\geq \lceil 0.8 n^{0.8} \rceil$;
- the number of perturbation sets: $\geq 8W_{max}$.

IV. DISCUSSION

In this work, we address fundamental implementability challenges associated with the determinant-based algorithm for solving MWPM in polylog parallel time. We have established a framework that guarantees the mathematical correctness of this approach under finite bit-length arithmetic. Furthermore, we have mitigated the large bit-length requirements of the previous determinant-based algorithm in Ref. [7] by identifying and removing computational bottlenecks, thereby

substantially reducing the arithmetic bit length required for its implementation. These results close a practical gap between asymptotically fast MWPM decoding theory and its finite-precision hardware implementation.

Conventionally, MWPM decoders are regarded as having polynomial-time complexity, and achieving polylog runtime for MWPM decoding has been challenging even with parallelization. By contrast, the polylog-time parallel MWPM decoder proposed in Ref. [7] offers a route toward doubly-polylog-time-overhead FTQC, substantially reducing the time overhead of FTQC. However, the approach in Ref. [7] has been hard to implement in practice because of an extremely large arithmetic bit length. Our contribution is to provide concrete evidence that this asymptotically fast MWPM-decoding approach can be implemented at an experimental scale within realistic hardware constraints. Analogous to recent surface-code experiments that validated exponential error suppression at increasing code distances [4, 5], our results enable proof-of-principle demonstrations in the early-FTQC regime that can experimentally validate the possibility of asymptotically sublinear runtime scaling of the MWPM decoding.

Beyond the near-term regime, further optimization of the determinant-based MWPM-decoding methods and a thorough comparison with those based on variants of the blossom algorithm remain interesting directions for future work. Indeed, variants of the blossom algorithm, such as the sparse blossom [28] and the fusion

blossom [29], explicitly leverage the problem structure of surface-code decoding to reduce the computational complexity to approximately $O(n^{1.3})$, compared with naively invoking a general-purpose blossom-algorithm-based MWPM solver. Similarly, the use of the problem structure may also reduce the computational complexity of the determinant-based approach. Given the poly-log runtime scaling of the determinant-based approach, which is asymptotically faster than blossom-based methods, it would be interesting to estimate the crossover point at which it becomes faster in practice, accounting for such algorithmic optimizations.

Appendix A: A parallel algorithm for finding an MWPM via conventional integer arithmetic

For completeness, we summarize the determinant-based polylog-time parallel algorithm in Ref. [7]. In particular, given a path graph $\bar{G} = (\bar{V}, \bar{E})$ with edge weights $w : \bar{E} \rightarrow \mathbb{Z}$, we describe an algorithm for finding an MWPM in $\bar{G}$.

1. Adjust each edge weight and replace w by $\tilde{w}$ for each $e \in \bar{E}$ as

$$\tilde{w}(e) := \tilde{C}w(e) + W(e), \quad (\text{A1})$$

where we take the factor $\tilde{C}$ and the perturbation function W as

$$\tilde{C} := \frac{|\bar{V}|}{2}(W_{\max} - 1) + 1, \quad (\text{A2})$$

$$W : \bar{E} \rightarrow \mathbb{N}, \quad (\text{A3})$$

$$1 \leq W(e) \leq W_{\max}, \quad (\text{A4})$$

$$W_{\max} := \max_{e \in \bar{E}} \{W(e)\}. \quad (\text{A5})$$

With this perturbation, with high probability, one of the MWPMs in $\bar{G}$ becomes a unique MWPM in the resulting weighted graph.

2. Use a Tutte matrix A with its element $A_{i,j}$ given

by

$$A_{i,j} = \begin{cases} x_{i,j} & i < j, \{i,j\} \in \bar{E}, \\ -x_{i,j} & i > j, \{i,j\} \in \bar{E}, \\ 0 & \text{otherwise,} \end{cases} \quad (\text{A6})$$

where $x_{i,j}$ is a variable. Then, for each edge $\{i,j\} \in \bar{E}$, we assign

$$x_{i,j} = 2^{\tilde{w}(\{i,j\})}, \quad (\text{A7})$$

and obtain a matrix B defined as

$$B_{i,j} = \begin{cases} 2^{\tilde{w}(\{i,j\})} & i < j, \{i,j\} \in \bar{E}, \\ -2^{\tilde{w}(\{i,j\})} & i > j, \{i,j\} \in \bar{E}, \\ 0 & \text{otherwise,} \end{cases} \quad (\text{A8})$$

3. Compute $\det(B)$ and obtain

$$w^* := \max \left\{ w \in \mathbb{Z} \left| \frac{\det(B)}{2^{2w}} \in \mathbb{N} \right. \right\}. \quad (\text{A9})$$

Note that the determinant can be computed in polylog parallel runtime by the Samuelson-Berkowitz algorithm [35] (see also Sec. S2 of Ref. [7] for the details of this method).

4. For each edge, in parallel, calculate a minor $M_{i,j}^B = \det(B^{(i,j)})$, where $B^{(i,j)}$ is defined as an $(|\bar{V}| - 1) \times (|\bar{V}| - 1)$ matrix obtained from B by removing the i th row and the j th column. Finally, we obtain

$$M = \left\{ \{i,j\} \left| \frac{M_{i,j}^B \cdot 2^{\tilde{w}(\{i,j\})}}{2^{2w^*}} \text{ is odd} \right. \right\} \subseteq \bar{E}. \quad (\text{A10})$$

This subset M represents the unique MWPM of $\bar{G}$.

Hamiltonian dynamics from pure dissipation

Zhong-Xia Shang*

Daniel Stilck França†

Abstract

Quantum simulation usually distinguishes coherent Hamiltonian evolution from dissipative open-system dynamics. We show that this boundary is unexpectedly porous: purely dissipative Lindbladians, with no Hamiltonian term, can approximate time- t Hamiltonian evolution generated by H to diamond-norm error ε using purely dissipative evolution time $T = O(\|H\|_\infty^2 t^2/\varepsilon)$. The construction is explicit. A single jump $F = I - i\delta H$ yields a generator equal to a slowed Hamiltonian term $-i\delta[H, \rho]$ plus only $O(\delta^2)$ dissipation; choosing δ appropriately and rescaling time produces the target dynamics. For local many-body Hamiltonians $H = \sum_\ell H_\ell$, local jumps $F_\ell = I - i\delta H_\ell$ give the corresponding local bound $T = O((\sum_\ell \|H_\ell\|_\infty^2) t^2/\varepsilon)$. We also prove that this scaling is optimal under a natural uniform-in-time notion of simulation: for a family of Hamiltonians, any purely dissipative simulator with m jump operators of norm at most C must satisfy $T = \Omega(\|H\|_\infty^2 t^2/(mC^2\varepsilon))$. The lower bound is geometric: dissipation can generate effective rotation only at the price of radial contraction and decoherence. These results sharpen the boundary between closed and open dynamics and have consequences for dissipative computation, Zeno physics, and Lindbladian simulation algorithms.

Overview. For a finite-dimensional quantum system with Hilbert space $\mathcal{H} \cong \mathbb{C}^d$, the most general Markovian evolution is governed by a Lindbladian

$$\mathcal{L}(\rho) = -i[H, \rho] + \sum_j \left(F_j \rho F_j^\dagger - \frac{1}{2} \{F_j^\dagger F_j, \rho\} \right), \quad (1)$$

*Department of Mathematical Sciences, University of Copenhagen. Email: zhongxia.shang@math.ku.dk

†Department of Mathematical Sciences, University of Copenhagen. Email: dsfranca@math.ku.dk

where H generates coherent dynamics and the jump operators F_j describe coupling to an environment [1, 2]. The standard viewpoint is that Hamiltonian and dissipative dynamics are fundamentally different resources: the first is reversible and internal, the second irreversible and externally driven. Our starting question is whether dissipation can reproduce coherent dynamics *on the original system*, without appealing to a Stinespring dilation that enlarges the Hilbert space and absorbs the environment into a larger closed system [3]. We show that the answer is yes, and that the exact overhead is surprisingly efficient: quadratic in the simulated time and inverse-linear in the target accuracy.

This question is directly relevant to the boundary between open and closed quantum systems. Especially, a recent wave of dissipation-based quantum algorithms has emerged, spanning Gibbs state [4, 5] and ground state [6, 7, 8] preparation, solving differential equations [9], and optimization [10]. The performance, advantages, and inherent limitations of these dissipative approaches, especially when compared to traditional coherent algorithms [11], are deeply rooted in how open and closed dynamics interface and diverge.

Hamiltonian dynamics from a purely dissipative jump. Set the coherent Hamiltonian part to zero and consider the single-jump purely dissipative generator

$$\mathcal{D}_F(\rho) = F\rho F^\dagger - \frac{1}{2}\{F^\dagger F, \rho\}. \quad (2)$$

Choosing

$$F = I - i\delta H \quad (3)$$

for Hermitian H gives the identity

$$\mathcal{D}_F(\rho) = -i\delta[H, \rho] + \delta^2 \left(H\rho H - \frac{1}{2}\{H^2, \rho\} \right). \quad (4)$$

Thus pure dissipation already contains a first-order copy of Hamiltonian evolution; the price is a second-order dissipative term. If the target Hamiltonian channel is $e^{s\mathcal{L}_H}$ with $\mathcal{L}_H(\rho) =$

$-i[H, \rho]$, then running $\mathcal{D}_F$ for total dissipative time $T = t/\delta$ yields a rescaled generator

$$\frac{T}{t} \mathcal{D}_F = \mathcal{L}_H + \delta \mathcal{D}_H, \quad (5)$$

where $\mathcal{D}_H(\rho) = H\rho H - \frac{1}{2}\{H^2, \rho\}$. A standard Duhamel estimate then implies

$$\sup_{0 \leq s \leq t} \left\| e^{\frac{T}{t}s\mathcal{D}_F} - e^{s\mathcal{L}_H} \right\|_{\diamond} \leq t\delta \|\mathcal{D}_H\|_{\diamond}, \quad (6)$$

so choosing $\delta \asymp \varepsilon/(t\|H\|_{\infty}^2)$ gives

$$T = O\left(\|H\|_{\infty}^2 t^2/\varepsilon\right). \quad (7)$$

The construction is simple, explicit, and robust: the dissipative simulator has no coherent term at all, yet it tracks the full Hamiltonian trajectory uniformly in time.

The same idea localizes. If

$$H = \sum_{\ell=1}^L H_{\ell} \quad (8)$$

is a decomposition into local many-body terms, then choosing local jumps

$$F_{\ell} = I - i\delta H_{\ell} \quad (9)$$

produces a purely dissipative simulator with

$$T = O\left(\left(\sum_{\ell=1}^L \|H_{\ell}\|_{\infty}^2\right) t^2/\varepsilon\right). \quad (10)$$

This version is especially relevant for platforms with local dissipative control, and it shows that coherent many-body dynamics can be generated from local open-system primitives with only polynomial overhead.

Why the t^2/ε overhead is unavoidable.

The upper bound is optimal under a natural uniform-in-time notion of simulation. Suppose a purely dissipative Lindbladian

$$\mathcal{L}_D(\rho) = \sum_{j=1}^m \left(F_j \rho F_j^{\dagger} - \frac{1}{2} \{F_j^{\dagger} F_j, \rho\} \right), \quad \|F_j\|_{\infty} \leq C \quad (11)$$

approximates a target Hamiltonian trajectory up to time t with error ε in the sense that

$$\sup_{0 \leq s \leq t} \left\| e^{\frac{T}{t}s\mathcal{L}_D} - e^{s\mathcal{L}_H} \right\|_{\diamond} \leq \varepsilon. \quad (12)$$

We prove that there exist families of Hamiltonians for which any such simulator must satisfy

$$T = \Omega\left(\frac{\|H\|_{\infty}^2 t^2}{mC^2\varepsilon}\right). \quad (13)$$

The proof is geometric and is already visible on a single qubit. For the target $H = \nu\sigma_z/2$, any purely dissipative qubit generator has Bloch form

$$\dot{r} = Br + c, \quad B = S + [\omega \times], \quad (14)$$

where $S = S^{\top} \preceq 0$ is the contraction part and $[\omega \times]$ is the antisymmetric matrix that generates effective rotation. The key structural fact is

$$|\omega|^2 \leq mC^2 (-\text{Tr} S). \quad (15)$$

This inequality captures the basic obstruction: a purely dissipative generator can create angular motion only by paying with radial contraction. Under the uniform-in-time requirement (12), the channel must remain close to a unitary orbit at every intermediate time, which forces two simultaneous conditions. First, purity loss must stay tiny, giving roughly

$$-\text{Tr}(S) \lesssim \varepsilon/T. \quad (16)$$

Second, the dissipative path must keep up with the length of the Hamiltonian orbit, which forces

$$|\omega| \gtrsim \|H\|_{\infty} t/T. \quad (17)$$

Combining these inequalities with (15) yields the lower bound (13). In other words, the second-order dissipative cost in (4) is not an artifact of the construction; it is the fundamental decoherence cost of simulating reversible motion through irreversible dynamics.

Uniqueness of the construction.

Beyond the explicit construction, we prove a rigidity statement showing that this mechanism is essentially the only smooth way to obtain Hamiltonian motion from pure dissipation. Suppose $\{\mathcal{L}_{D,\delta}\}_{\delta>0}$ is a smooth family of purely dissipative Lindbladians such that $e^{\frac{s}{\delta}\mathcal{L}_{D,\delta}}$ converges uniformly on $0 \leq s \leq t_0$ to the target unitary evolution $e^{s\mathcal{L}_H}$. Then necessarily

$$\mathcal{L}_{D,\delta} = \delta\mathcal{L}_H + O(\delta^2) \quad (18)$$

in diamond norm. At the jump-operator level, every term contributing at first order must have the form

$$F_{j,\delta} = \sqrt{\gamma_j}(I - \delta A_j) + O(\delta^2), \quad (19)$$

with $\sum_j \gamma_j(A_j - A_j^\dagger)/(2i) = H$; jumps that vanish at $\delta = 0$ only contribute at order $O(\delta^2)$. Thus, up to Lindblad gauge freedom and higher-order corrections, the “identity plus small anti-Hermitian piece” ansatz is not merely convenient but forced.

Implications for open-system quantum simulation. The construction has several direct consequences. First, it gives a purely dissipative normal form for general Lindbladians. Indeed, for

$$\mathcal{L}(\rho) = -i[H, \rho] + \sum_j \left(F_j \rho F_j^\dagger - \frac{1}{2} \{F_j^\dagger F_j, \rho\} \right), \quad (20)$$

one may introduce a purely dissipative generator with jumps $F'_0 = I - i\delta H$ and $F'_j = \sqrt{\delta} F_j$. This reproduces $\delta\mathcal{L}$ up to $O(\delta^2)$ corrections, showing that arbitrary Markovian dynamics can be rewritten using dissipation alone with polynomial overhead.

Second, the same mechanism yields a state-independent Zeno cancellation effect. By adding a strong dissipator whose first-order contribution is the reverse Hamiltonian, one can suppress the evolution of *any* input state, rather than only states in a pre-existing Zeno subspace [12].

Third, the result shows that purely dissipative dynamics is algorithmically as expressive as coherent dynamics up to polynomial overhead, which has implications for dissipative computation (BQP-completeness for dissipative dynamics beyond the previous fixed point results [13, 14, 15]) and for no-super-quadratic-fast-forwarding statements in special classes of Lindbladians.

Finally, our construction highlights the importance of Lindblad gauge freedom for digital simulation: equivalent Lindblad representations can have very different operator norms, and therefore very different simulation costs [16, 17, 18, 19, 20, 21, 22, 23, 24]. From an

algorithm-design perspective, changing gauge before simulation may be as important as the simulation primitive itself.

Summary. We show that Hamiltonian dynamics can be generated, to arbitrary accuracy, by purely dissipative Lindbladians with no coherent term, and we determine the optimal simulation overhead. The explicit upper bound and the matching geometric lower bound sharpen the conceptual boundary between closed and open dynamics while also providing a concrete new tool for quantum simulation. For QSim, the work sits at the interface of simulation algorithms, verification, open-system control, and many-body physics: it identifies dissipation not only as noise to be mitigated or as a route to fixed points, but as a precise dynamical resource capable of emulating coherent quantum evolution.

Hamiltonian dynamics from pure dissipation

Zhong-Xia Shang^{1,*} and Daniel Stilck França^{1,†}

¹*Department of Mathematical Sciences, University of Copenhagen, Universitetsparken 5, 2100 Denmark*

The fundamental difference between closed and open quantum dynamics lies in their environmental interaction: closed systems are perfectly isolated and evolve reversibly under unitary Hamiltonian dynamics, whereas open systems continuously couple to an external bath, resulting in irreversible dissipation and information loss. In this work, we show internal Hamiltonian dynamics can be “faked” via external pure dissipation, i.e., Lindbladians without a coherent Hamiltonian part. More concretely, we show that, in a GKSL representation with zero explicit Hamiltonian term but non-traceless jump operators, bounded-norm dissipative generators can approximate Hamiltonian dynamics within ϵ error in diamond norm using $\mathcal{O}(t^2/\epsilon)$ evolution time. We further prove that for time-independent dynamics this $\mathcal{O}(t^2/\epsilon)$ scaling is in the worst case, necessary and optimal from a geometric perspective, which captures the fundamental decoherence cost for catching up with the speed of Hamiltonian dynamics. Our construction leads to various implications, including the BQP-completeness of purely dissipative dynamics even before reaching approximate equilibrium, a Zeno-adjacent state-independent freezing effect, the no super-quadratic fast-forwarding theorem of a class of purely dissipative dynamics, and reducing Lindbladian simulation cost via gauge changing.

Introduction.—The dynamics of any physical systems are governed by a combination of internal interactions and external coupling to an environment. For a quantum system described by a d -dimensional Hilbert space $\mathcal{H} \cong \mathbb{C}^d$, the most general trace-preserving and completely positive Markovian evolution is described by the Gorini–Kossakowski–Sudarshan–Lindblad master equation (Lindbladian) [1, 2]

$$\frac{d\rho}{dt} = -i[H, \rho] + \sum_i \left(F_i \rho F_i^\dagger - \frac{1}{2} \{ \rho, F_i^\dagger F_i \} \right). \quad (1)$$

Here, the first term captures the internal, coherent evolution driven by the system Hamiltonian $H \in \mathbb{C}^{d \times d}$, while the second term captures the external interactions mediated by the jump operators $\{F_i\} \subset \mathbb{C}^{d \times d}$. When external interactions are completely absent, the system is closed; it evolves unitarily and reversibly, preserving all quantum information. Conversely, the inclusion of the jump operators defines an open quantum system, where continuous interaction with a bath drives irreversible dissipation and decoherence [3].

Understanding how to simulate quantum systems and the effect of dissipation or decoherence is a central theoretical pursuit in quantum mechanics, with profound practical implications for quantum information and quantum computing. Especially, a recent wave of dissipation-based quantum algorithms has emerged, spanning Gibbs state [4–6] and ground state [7–9] preparation, solving differential equations [10], and optimization [11]. The performance, advantages, and inherent limitations of these dissipative approaches, especially when compared to traditional coherent algorithms [12], are deeply rooted in how open and closed dynamics interface and diverge [6].

To interrogate this boundary, we ask: *can coherent Hamiltonian dynamics be approximately reproduced by purely dissipative interactions, and if so, at what cost?* While Stinespring dilation [13] allows open systems to be modeled via closed dynamics, it does so by artificially expanding the Hilbert space to encompass the entire bath, thereby redefining the system-environment partition and converting external interactions into internal ones. However, if we restrict our view to the system alone, the fundamentally distinct physical origins and time-reversal properties of these two mechanisms suggest they cannot substitute for one another. Even though the gauge invariance [3] of the Lindbladian allows a certain level of freedom of interconversions, finding F_i such that

$$\sum_i \left(F_i \rho F_i^\dagger - \frac{1}{2} \{ \rho, F_i^\dagger F_i \} \right) = -i[H, \rho] \quad (2)$$

holds exactly is impossible for any nonzero H , even if we allow for F_i that have a nonzero trace [14].

In this work, we demonstrate that the internal, coherent Hamiltonian interactions can be well mimicked by strictly external, dissipative ones. Specifically, we prove that purely dissipative Lindbladians (i.e. Lindbladians with only $\{F_i\}$ and no H in eq. (1)) can achieve approximate ideal t -time Hamiltonian evolution within an error ϵ in diamond norm using an evolution time of $\mathcal{O}(t^2/\epsilon)$. This scaling shows that this imitation is not only possible but also efficient with no exponential overheads in time, system size or precision. Since the purely dissipative dynamics is fundamentally irreversible, we further show that this $\mathcal{O}(t^2/\epsilon)$ Lindbladian evolution time is actually necessary and optimal to simulate the reversible Hamiltonian dynamics in the worst case. We prove this via geometry: how to maximize the rotational speed (Hamiltonian dynamics) while minimizing the radial one (decoherence). Later, we show several implications of our results for various topics, including the complexity class of dissipative dynamics, Zeno effect, fast-forwarding dis-

sipative dynamics, and Lindbladian simulations.

FIG. 1. The physical meaning of theorem 1. Our construction essentially says that for any closed quantum system characterized by the Hamiltonian H with zero external dissipation, we can always find a purely dissipative open quantum system with zero internal Hamiltonian to efficiently mimic its dynamics.

Hamiltonian dynamics via dissipation. Our construction is simple and direct. Consider a purely dissipative, single-jump Lindbladian

$$\frac{d\rho}{dt} = \mathcal{L}[\rho] = F\rho F^\dagger - \frac{1}{2}\{F^\dagger F, \rho\}, \quad (3)$$

i.e. in GKSL form with only one jump (albeit not necessarily traceless). If we set $F = I - i\delta H$, then we will have

$$\frac{d\rho}{dt} = -i\delta[H, \rho] + \delta^2 \left(H\rho H - \frac{1}{2}\{H^2, \rho\} \right), \quad (4)$$

where the first term is a δ -strength Hamiltonian dynamics and the second term is δ^2 -strength dissipation when viewing H as a jump operator, which has recently been found to have deep connections with quantum phase estimation [15]. Based on eq. (4), we obtain the following theorem.

Theorem 1. *By setting $\delta = \epsilon/t$, the purely dissipative, single-jump Lindbladian eq. (3) can approximate the Hamiltonian dynamics $e^{\mathcal{L}_H t}[\rho] = e^{-iHt}\rho e^{iHt}$ within ϵ error in diamond distance [16] in the sense that $\sup_{0 \leq s \leq t} \|e^{\mathcal{L}_H s} - e^{\mathcal{L} s}\|_\diamond \leq \epsilon$, by an evolution time*

$$T = \mathcal{O}(\|H\|_\infty^2 t^2 \epsilon^{-1}). \quad (5)$$

We give detailed proofs in App. A, which uses Duhamel's Identity [17] to bound the distance between dynamics via the distance between the Liouvillian operators. The theorem 1 is surprising in terms of the physical picture as shown in fig. 1. Closed quantum systems have zero dissipation and non-zero internal Hamiltonians, while purely dissipative open quantum systems have zero internal Hamiltonians but non-zero dissipation. Therefore, these two types of systems are exactly the opposite of

each other and should have fundamentally different dynamics. However, our result here shows that in fact the purely dissipative one can efficiently mimic the other with only an overhead that matches the first-order product formula-based Hamiltonian simulation method [18].

The design of the jump operator is not unique, and we show two generalizations. First, as long as $F = I - \delta A + \mathcal{O}(\delta^2)$ and the anti-Hermitian part of A is H , then the Lindbladian evolution time to achieve the same goal in theorem 1 requires

$$T = \mathcal{O}(\|A\|_\infty^2 t^2 \epsilon^{-1}). \quad (6)$$

A direct example of such a jump is $F = e^{-iH\delta}$, which is unitary short-time Hamiltonian dynamics itself.

Second, one may argue $F = I - i\delta H$ is not physical since H is a global operator, whereas physical jumps should be local. But note that we can actually localize jumps by increasing their number. Suppose H has the decomposition $H = \sum_i H_i$, with H_i local, then for each term, we can assign a jump operator $F_i = I - i\delta H_i$, and the resulting multi-jump purely dissipative Lindbladian can approximate the Hamiltonian dynamics by an evolution time

$$T = \mathcal{O}\left(\sum_i \|H_i\|_\infty^2 t^2 \epsilon^{-1}\right). \quad (7)$$

This version is especially relevant for platforms with local dissipative control [19], and it shows that coherent many-body dynamics can be generated from local open-system primitives with only polynomial overhead.

One may notice that in all the above constructions, the jumps have the form $I + \delta O + \mathcal{O}(\delta^2)$ with O some operator. In fact, we can prove this is the only possible form for smooth, purely dissipative Lindbladians that mimic the Hamiltonian dynamics.

Proposition 1 (Uniqueness up to $\mathcal{O}(\delta^2)$). *Let $\{\mathcal{L}_{D,\delta}\}_{0 \leq \delta < \delta_0}$ be a smooth family of purely dissipative Lindbladians on a finite-dimensional system, and let*

$$\mathcal{L}_H(\rho) := -i[H, \rho]. \quad (8)$$

Assume that there exists $t_0 > 0$ such that

$$\varepsilon(\delta) := \sup_{0 \leq s \leq t_0} \|e^{\frac{s}{\delta} \mathcal{L}_{D,\delta}} - e^{s \mathcal{L}_H}\|_\diamond \xrightarrow{\delta \rightarrow 0} 0. \quad (9)$$

Then

$$\mathcal{L}_{D,\delta} = \delta \mathcal{L}_H + \mathcal{O}(\delta^2) \quad (10)$$

in diamond norm.

We refer to App. C for the detailed proof. But note that our proof boils down to showing that Eq. (9) implies constraints on how the family of smooth Lindbladians $\mathcal{L}_{D,\delta}$ must behave at different orders of δ . An interesting remark here is that while shifting the Hamiltonian (adding identity) is trivial and only introduces a

global phase, shifting the jump operator can fundamentally change the dynamics.

We finish this section by introducing a corollary of theorem 1. Since Hamiltonian dynamics can be recast as dissipation, therefore, we can actually convert any Lindbladian into a pure dissipation form. For the general form eq. (1), we can construct a purely dissipative Lindbladian with jump operators F' where we let $F'_0 = I - i\delta H$ and let $F'_i = \sqrt{\delta}F_i$, then by setting $\delta = \epsilon/t$, to simulate the original Lindbladian for an evolution time t within error ϵ , the required new Lindbladian evolution time is

$$T = \mathcal{O}(\|H\|_\infty^2 t^2 \epsilon^{-1}). \quad (11)$$

FIG. 2. **Left:** Hamiltonian dynamics via dissipation can be compared to driving a top via a whip. Since we want to rotate the top (Hamiltonian dynamics) via an external whip (environment), the rotation of a δ -strength is inevitably accompanied by radial disturbance (dissipation) of δ^2 -strength. **Right:** Under the uniform-in-time error restriction eq. (13), the dissipative trajectory (blue) should be close to the Hamiltonian trajectory (red). As results, the radial distance between the ideal state and the Lindbladian evolved state should be within ϵ , and the trajectory length of the dissipative dynamics (l_D) should be close to the trajectory length of the Hamiltonian dynamics (l_H).

Geometric Lower Bound. Now, we want to show that since the dissipation is irreversible and fundamentally different from the Hamiltonian dynamics after all, the $\mathcal{O}(t^2/\epsilon)$ cost is what you have to pay in the worst case, as illustrated in the theorem below:

Theorem 2. *There exist families of Hamiltonians $H \in \mathbb{C}^{2 \times 2}$ such that if a purely dissipative Lindbladian of the form*

$$\mathcal{L}_D(\rho) = \sum_{j=1}^m \left(F_j \rho F_j^\dagger - \frac{1}{2} \{ F_j^\dagger F_j, \rho \} \right), \quad \|F_j\|_\infty \leq C, \quad (12)$$

can simulate the target Hamiltonian dynamics for an evolution time t within an diamond-distance error ϵ uniformly in time

$$\sup_{0 \leq s \leq t} \left\| e^{\mathcal{L}_D \frac{T}{t} s} - e^{\mathcal{L}_H s} \right\|_\diamond \leq \epsilon, \quad (13)$$

then the total Lindbladian evolution time T must satisfy the lower bound

$$T = \Omega \left(\frac{\|H\|_\infty^2}{mC^2} t^2 \epsilon^{-1} \right). \quad (14)$$

We have two remarks for theorem 2. First, the mC^2 factor in eq. (14) matches the block encoding cost in the digital Lindbladian simulation algorithms on quantum computers [20–28]. Second, the reason we ask the uniform-in-time error assumption is to avoid the adversarial cheating where the Lindbladian doesn't actually simulate the Hamiltonian dynamics but only approximates the unitary map $e^{\mathcal{L}_H t}$ at the specific time t .

The proof idea of theorem 2 is from a geometric point of view. Since the lower bound cares about the worst case, we can analyze the lower bound via a single-qubit system where we consider approximating $H = \nu \sigma_z/2$ via eq. (12). By mapping the qubit's density matrix to a Bloch vector $r \in \mathbb{R}^3$, the purely dissipative Lindbladian eq. (12) can be recast as an affine Bloch equation of the form $\dot{r} = Br + c$ [13] with

$$B = S + [\omega \times]. \quad (15)$$

The matrix $[\omega \times]$ (representing cross product by ω) is real and antisymmetric, representing the effective rotational speed that attempts to mimic the target Hamiltonian dynamics. The matrix S is real, symmetric, and strictly negative semi-definite ($S \preceq 0$). This component drives the inevitable radial contraction, pulling the state away from the boundary of the Bloch sphere and representing irreversible decoherence.

Since both $[\omega \times]$ and S emerge from eq. (12), we prove that they have the relation

$$|\omega|^2 \leq mC^2 (-\text{Tr} S). \quad (16)$$

This indicates that one cannot increasing the rotational speed without increasing the radial decoherence. The $|\omega|^2$ versus $-\text{Tr} S$ have been seen in eq. (4) with the δ -strength Hamiltonian part and the δ^2 -strength dissipative part. We can also understand this from fig. 2 left, where we can imagine the Hamiltonian dynamics via dissipation as rotating a top via a whip. Since the internal Hamiltonian is zero, top cannot rotate by itself, and can only rely on the external force of whip, therefore, it is impossible to rotate the top without radial disturbance.

Under the uniform-in-time requirement eq. (13), we want the dissipative trajectory on the Bloch sphere to be close to the Hamiltonian trajectory as shown in fig. 2 right. This leads to two further consequences. First, S should be small such that the decoherence won't make the radial distance between the Bloch surface and the Lindbladian evolved state from a pure initial state to go beyond ϵ . We prove S must satisfy

$$-\text{Tr}(S) \leq \frac{6\epsilon}{T}. \quad (17)$$

Second, $|T\omega|$ should be large such that the length of the dissipative trajectory l_D can catch the length of the Hamiltonian trajectory $l_H = \nu t$, which relates to the so-called quantum speed limit [29–31]. We prove that $|\omega|$ must satisfy

$$|\omega| \geq \frac{\nu t}{8T}. \quad (18)$$

By combining eq. (16), eq. (17), and eq. (18), we proof theorem 2. Detailed proofs can be found in App. B.

Implications.—We now show several direct implications of our results.

1. *Purely dissipative dynamics is BQP-complete.*—A direct implication of our result is that purely dissipative dynamics is BQP-complete [32] beyond the fixed point. Since Hamiltonian dynamics is BQP-complete, theorem 1 indicates the purely dissipative Lindbladian is BQP-hard, which combining with the fact that Lindbladian can be efficiently simulated by repeated short-time unitary transformations plus tracing out operations via Stinespring dilation [13, 20, 22], leads to the BQP-complete result. An important remark here is that, previously, the BQP-complete results [6, 33, 34] of dissipation are all about the fixed point where the universal quantum computation is embedded into the steady states of the dissipative Lindbladian. Our result is different from the existing ones on BQP completeness of Lindbladians in the literature [6, 33, 34] in the sense that we do not encode the computation into properties of a (quasi)stationary state of the dynamics. Other results [35] achieve universality of Lindbladian dynamics by introducing auxiliary ‘timer gadgets’ to orchestrate sequential measurement-based operations. However, this typically requires significant spatial overhead in the form of complex lattice geometries and auxiliary clock qubits, overheads which are not present in our simple construction.

2. *A novel Zeno-adjacent freezing mechanism.* Quantum Zeno effect [36] states that strong and frequent measurements (or jump operators with large norms in the language of Lindbladian) can sometimes freeze the system’s evolution. The mechanism of the traditional Zeno effect is to construct strong dissipators $\mathcal{L}_D[\rho] = \sum_i (F_i \rho F_i^\dagger - \frac{1}{2} \{\rho, F_i^\dagger F_i\})$, which is so strong, such that the system can ignore the internal Hamiltonian and is forced to stay in the steady subspace where $\mathcal{L}_D[\rho] = 0$, also known as the Zeno subspace [37]. Our theorem 1 also leads to a fundamentally different mechanism of quantum Zeno effect. Suppose the system Hamiltonian is H , and we know H , then to freeze the dynamics, we can simply introduce a jump operator $F = \delta^{-1/2}(I + i\delta H)$. Then we have

$$\frac{d\rho}{dt} = -i[H, \rho] + F\rho F^\dagger - \frac{1}{2} \{\rho, F^\dagger F\} = \mathcal{O}(\delta). \quad (19)$$

Thus, setting $\delta = \epsilon/t$ can make sure $\|\rho(0) - \rho(t)\|_1 = \mathcal{O}(\epsilon)$. The idea of this new mechanism is to actively generate the reversal time evolution via dissipation to cancel

out the system evolution. While both require large dissipation, the biggest difference between these two mechanisms is that the traditional mechanism can only freeze states that are inside the Zeno subspace, while ours can freeze any state.

3. *No super-quadratic fast forwarding for a class of Lindbladians.*—A central result in Hamiltonian simulation is the no fast-forwarding theorem [38, 39], which states that there exist no universal (meaning for any H) Hamiltonian simulation algorithms that can simulate t -time Hamiltonian dynamics within a constant precision $\epsilon = 1/4$ using sublinear costs in t . For the class of purely dissipative Lindbladian we considered ($F = I - i\delta H$), we can simply let H be the sparse parity check Hamiltonian [38, 40] used in the Hamiltonian no-fast-forwarding proof and set $\delta = \epsilon/t = 1/4T$, then we have $T = \mathcal{O}(t^2)$. If this Lindbladian can be super-quadratically fast-forwarded, i.e. $o(\sqrt{T})$, we will conflict with the query lower bound of the parity check problem, implying this class of Lindbladians cannot be fast-forwarded beyond quadratic. On the other hand, this also indicates that this class of Lindbladians has the possibility to be quadratically fast-forwarded in some cases, which, if true, will be another class of fast-forwardable Lindbladians beyond the recent progress [15, 41, 42]. We want to emphasize that we cannot simply use the t -time Hamiltonian dynamics to simulate the T -time Lindbladian evolution and claim achieving the quadratic fast-forwarding since the δ^2 -strength of the dissipation is fixed and prevents the simulation error to be arbitrarily small. This raises the question of how to construct fast-forwarding algorithms for these Lindbladians.

4. *Reducing Lindbladian simulation cost via gauge changing.*—One way to understand theorem 1 is via the gauge freedom of Lindbladians. For H and F_i in eq. (1), we can do a gauge transform [3] while keeping the Liouvillian operator and therefore, the dynamics unchanged

$$\text{Jump: } F_i \rightarrow F'_i = \sum_j U_{ij} F_j + c_i I, \quad (20)$$

$$\text{Hamiltonian: } H \rightarrow H' = -\frac{i}{2} \sum_i (c_i^* F'_i - c_i F_i'^\dagger), \quad (21)$$

where U is unitary, c_i are arbitrary complex numbers. If we let $H = 0$ and $F_i = I - i\delta H$, then by setting $U = I$ and $c_i = -1$ we will have $H' = \delta H$ and $F'_i = -i\delta H$, which recovers eq. (4). In the context of simulating Lindbladian on quantum computers, given the Hamiltonian H and jump operators F_i , the algorithmic cost is then proportional to $\|H\|_\infty + \sum_i \|F_i\|_\infty^2$ [20–28]. For the Lindbladian we considered in theorem 1, we have $\|F\|_\infty = \mathcal{O}(1)$ while $\|H'\|_\infty + \sum_i \|F'_i\|_\infty^2 = \mathcal{O}(\delta)$. Therefore, while the gauge transform of the Lindbladian doesn’t change the actual dynamics, it indeed can drastically change the simulation cost. This suggests that, if we want to simulate a Lindbladian on a quantum computer, instead of directly putting the Hamiltonian and jumps into the simulation algorithms, we can first find a better gauge with smaller

norms and simulating the Lindbladian in that gauge will result in a lower cost.

Discussions.—In this work, we show the Hamiltonian dynamics can be efficiently simulated via pure dissipation via explicit construction (theorem 1) and prove it matches the $\Omega(t^2/\epsilon)$ lower bound (theorem 2). It is worth contrasting our result with a line of work on emergent unitary dynamics from dissipation initiated by [43, 44] and extended by [45]. These works consider a strongly dissipative Lindbladian $\mathcal{L}_0$ admitting a non-trivial manifold of steady states, perturbed by a weak Hamiltonian term λH . In the limit $\lambda \rightarrow 0$ with time rescaled as $\tau = \lambda t$, the effective dynamics projected onto the steady-state manifold becomes unitary, generated by a projected Hamiltonian *PHP*. The setup we consider here is fundamentally different in three respects. First, our Lindbladian has no Hamiltonian term at all: the coherent dynamics is generated entirely by the dissipator. Second, our construction does not rely on the existence of a non-trivial steady-state manifold: the target unitary evolution is approximated on the entire Hilbert space, not on a projected subspace. Third, we provide a quantitative error bound with matching upper and lower bounds of order t^2/ϵ , whereas the dissipation-projected dynamics literature is primarily concerned with the qualitative

emergence of unitarity and its geometric structure. Our $\Omega(t^2/\epsilon)$ lower bound is also naturally dual to the $\mathcal{O}(t^2/\epsilon)$ overhead identified by [22] for the reverse direction of simulating Lindblad evolution via Hamiltonian evolution on a dilated system, with a similar scaling appearing in the repeated-interactions simulation of [27].

Several directions can be further explored. For example, whether and when it is possible and how to achieve the quadratic fast-forwarding for our considered Lindbladians as explained in Implication 3. Also, while in Implication 4, we explain the importance of choosing gauge in Lindbladian simulations, accurately estimating $\|H\|_\infty + \sum_i \|F_i\|_\infty^2$ is actually QMA-hard [46]. This raises the question of how to find a better gauge in a practical way.

Appendix A: Proof of theorem 1 and related results

On $F = I - \delta A$: To avoid ambiguity, in the following, we will use $\|\cdot\|_\infty$ to represent the spectral norm $\|\cdot\|$ in the main text. When we set the jump operator to be $F = I - \delta A$ with $A = G + iH$, we have

$$\begin{aligned}
 F\rho F^\dagger &= (I - \delta(G + iH))\rho(I - \delta(G - iH)) \\
 &= \rho - \delta(G + iH)\rho - \delta\rho(G - iH) + \delta^2(G + iH)\rho(G - iH) \\
 &= \rho - \delta\{G, \rho\} - i\delta[H, \rho] + \delta^2(G + iH)\rho(G - iH).
 \end{aligned} \tag{A1}$$

Also, because we have

$$\begin{aligned}
 F^\dagger F &= (I - \delta(G - iH))(I - \delta(G + iH)) \\
 &= I - \delta(G - iH) - \delta(G + iH) + \delta^2(G - iH)(G + iH) \\
 &= I - 2\delta G + \delta^2(G - iH)(G + iH),
 \end{aligned} \tag{A2}$$

therefore, we have

$$\begin{aligned}\frac{1}{2}\{F^\dagger F, \rho\} &= \frac{1}{2}\{I - 2\delta G + \delta^2(G - iH)(G + iH), \rho\} \\ &= \rho - \delta\{G, \rho\} + \frac{1}{2}\delta^2\{(G - iH)(G + iH), \rho\}.\end{aligned}\tag{A3}$$

Thus, the derivative of the density matrix has the form

$$\begin{aligned}\frac{d\rho}{dt} &= \mathcal{D}_F[\rho] = F^\dagger \rho F - \frac{1}{2}\{F^\dagger F, \rho\} \\ &= \rho - \delta\{G, \rho\} - i\delta[H, \rho] + \delta^2(G + iH)\rho(G - iH) - \rho + \delta\{G, \rho\} - \frac{1}{2}\delta^2\{(G - iH)(G + iH), \rho\} \\ &= -i\delta[H, \rho] + \delta^2\mathcal{D}_A[\rho],\end{aligned}\tag{A4}$$

where we denote $\mathcal{D}_O[\rho] = O\rho O^\dagger - \frac{1}{2}\{O^\dagger O, \rho\}$.

Now, to bound the error of simulating the Hamiltonian dynamics, we first introduce the following lemma

Lemma 1. *Given two Lindbladians with the Liouvillian operators $\mathcal{L}_1$ and $\mathcal{L}_2$ respectively, the diamond distance between the two Lindbladians for an evolution time t has the upper bound*

$$\|e^{\mathcal{L}_1 t} - e^{\mathcal{L}_2 t}\|_\diamond \leq t\|\mathcal{L}_1 - \mathcal{L}_2\|_\diamond.\tag{A5}$$

Proof. Using the Duhamel Identity [17], we have

$$e^{\mathcal{L}_1 t} - e^{\mathcal{L}_2 t} = \int_0^t e^{\mathcal{L}_2(t-s)}(\mathcal{L}_1 - \mathcal{L}_2)e^{\mathcal{L}_1 s} ds,\tag{A6}$$

which leads to

$$\begin{aligned}\|e^{\mathcal{L}_1 t} - e^{\mathcal{L}_2 t}\|_\diamond &\leq \int_0^t \|e^{\mathcal{L}_2(t-s)}\|_\diamond \|\mathcal{L}_1 - \mathcal{L}_2\|_\diamond \|e^{\mathcal{L}_1 s}\|_\diamond ds \\ &\leq \int_0^t \|\mathcal{L}_1 - \mathcal{L}_2\|_\diamond ds = t\|\mathcal{L}_1 - \mathcal{L}_2\|_\diamond,\end{aligned}\tag{A7}$$

where we use $\|e^{\mathcal{L}t}\|_\diamond \leq 1$. □

Now, using lemma 1, we have

$$\|e^{\mathcal{D}_F t/\delta} - e^{\mathcal{L}_H t}\|_\diamond \leq t\delta\|\mathcal{D}_A\|_\diamond,\tag{A8}$$

where we use $\mathcal{L}_H$ to denote the Liouvillian operator of Hamiltonian dynamics under H . To have an approximation with an error ϵ , we can simply ask

$$t\delta\|\mathcal{D}_A\|_\diamond \leq \epsilon \rightarrow \delta \leq \frac{\epsilon}{t\|\mathcal{D}_A\|_\diamond}.\tag{A9}$$

Since the Lindbladian evolution time T is $T = t/\delta$, thus, we obtain

$$T \geq \|\mathcal{D}_A\|_\diamond t^2/\epsilon.\tag{A10}$$

Since $\|\mathcal{D}_A\|_\diamond = \mathcal{O}(\|A\|_\infty^2)$, we finish the proof

$$T = \mathcal{O}(\|A\|_\infty^2 t^2/\epsilon).\tag{A11}$$

When $A = iH$, we recover theorem 1.

On $F_i = I - i\delta H_i$: Similarly, when $H = \sum_i H_i$, and set jump operators $F_i = I - i\delta H_i$, we have

$$\begin{aligned}\frac{d\rho}{dt} &= \sum_i \mathcal{D}_{F_i}[\rho] = \sum_i \left(F_i^\dagger \rho F_i - \frac{1}{2}\{F_i^\dagger F_i, \rho\} \right) \\ &= -i\delta \left[\sum_i H_i, \rho \right] + \sum_i \delta^2 \mathcal{D}_{H_i}[\rho].\end{aligned}\tag{A12}$$

Using lemma 1, we have

$$\|e^{\sum_i \mathcal{D}_{F_i} t/\delta} - e^{\mathcal{L}_H t}\|_\diamond \leq t\delta \left\| \sum_i \mathcal{D}_{H_i} \right\|_\diamond \leq t\delta \sum_i \|\mathcal{D}_{H_i}\|_\diamond, \quad (\text{A13})$$

which leads to

$$T = \mathcal{O} \left(\sum_i \|H_i\|_\infty^2 t^2 / \epsilon \right). \quad (\text{A14})$$

On General Lindbladian via dissipation: To simulate the general Lindbladian

$$\frac{d\rho}{dt} = \mathcal{L}[\rho] = -i[H, \rho] + \sum_i \left(F_i \rho F_i^\dagger - \frac{1}{2} \{ \rho, F_i^\dagger F_i \} \right), \quad (\text{A15})$$

via dissipation, we construct a purely dissipative Lindbladian $\mathcal{L}'$ with jumps $F'_0 = I - i\delta H$ and $F'_i = \sqrt{\delta} F_i$. Since we have

$$\begin{aligned} \frac{d\rho}{dt} &= \mathcal{L}'[\rho] = F_0'^\dagger \rho F_0' - \frac{1}{2} \{ F_0'^\dagger F_0', \rho \} + \sum_i \left(F_i'^\dagger \rho F_i' - \frac{1}{2} \{ F_i'^\dagger F_i', \rho \} \right) \\ &= -i\delta[H, \rho] + \delta \sum_i \left(F_i^\dagger \rho F_i - \frac{1}{2} \{ F_i^\dagger F_i, \rho \} \right) + \delta^2 \mathcal{D}_H[\rho] \\ &= \delta \mathcal{L}[\rho] + \delta^2 \mathcal{D}_H[\rho], \end{aligned} \quad (\text{A16})$$

therefore, following the similar procedures as above, we obtain

$$T = \mathcal{O} \left(\|H\|_\infty^2 t^2 / \epsilon \right). \quad (\text{A17})$$

Appendix B: Proof of theorem 2

In this note we prove a rigorous lower bound under the *stronger* simulation requirement that the dissipative evolution must approximate the target Hamiltonian evolution *for every intermediate time* between 0 and t , not just at the final time. The result is proved for a simple qubit family, which is enough to establish the desired $\Omega(t^2/\epsilon)$ scaling in the worst-case sense.

a. Simulation notion. Let

$$\mathcal{L}_D(\rho) = \sum_{j=1}^m \left(F_j \rho F_j^\dagger - \frac{1}{2} \{ F_j^\dagger F_j, \rho \} \right), \quad \|F_j\|_\infty \leq C, \quad (\text{B1})$$

be a purely dissipative Lindbladian on a qubit, and let $\Phi_\tau = e^{\tau \mathcal{L}_D}$. For a target Hamiltonian H , define the unitary channel

$$\mathcal{U}_s(\rho) = e^{-iHs} \rho e^{iHs}. \quad (\text{B2})$$

We say that Φ_τ simulates $\mathcal{U}_s$ up to time t in total dissipative time T if

$$\sup_{0 \leq s \leq t} \left\| \Phi_{\frac{T}{t}s} - \mathcal{U}_s \right\|_\diamond \leq \epsilon. \quad (\text{B3})$$

This is the natural uniform-in-time strengthening of the endpoint condition and matches the linear time reparametrization used by the constructive upper bound.

Theorem 3 (Uniform-in-time lower bound for a hard qubit family). *Let*

$$H = \frac{\nu}{2} \sigma_z, \quad \Theta := |\nu|t. \quad (\text{B4})$$

Assume that (B3) holds and that

$$0 < \epsilon \leq \frac{1}{100} \min\{1, \Theta\}. \quad (\text{B5})$$

Then

$$T \geq \frac{\Theta^2}{384 m C^2 \epsilon} = \frac{\nu^2 t^2}{384 m C^2 \epsilon}. \quad (\text{B6})$$

Equivalently, since $\|H\|_\infty = |\nu|/2$,

$$T \geq \frac{\|H\|_\infty^2 t^2}{96 m C^2 \epsilon}. \quad (\text{B7})$$

In particular, for any fixed-norm hard family with $\|H\|_\infty = \Theta(1)$, uniform-in-time pure-dissipative simulation requires

$$T = \Omega(t^2/\epsilon). \quad (\text{B8})$$

Proof. We write the qubit state as

$$\rho = \frac{1}{2}(I + \mathbf{r} \cdot \boldsymbol{\sigma}), \quad \mathbf{r} \in \mathbb{R}^3, \quad (\text{B9})$$

and represent channels in Bloch form.

b. Step 1: Bloch form of a purely dissipative qubit generator. Write each jump operator as

$$F_j = a_j I + \mathbf{u}_j \cdot \boldsymbol{\sigma}, \quad a_j \in \mathbb{C}, \quad \mathbf{u}_j \in \mathbb{C}^3. \quad (\text{B10})$$

A standard Pauli-basis calculation gives the affine Bloch equation [13]

$$\dot{\mathbf{r}} = B\mathbf{r} + \mathbf{c}, \quad B = S + [\boldsymbol{\omega} \times], \quad (\text{B11})$$

where $S = S^\top$ is real symmetric, $[\boldsymbol{\omega} \times]$ is the real antisymmetric matrix for the cross product by $\boldsymbol{\omega}$, and

$$S = 2 \sum_{j=1}^m \left(\text{Re}(\mathbf{u}_j \mathbf{u}_j^\dagger) - |\mathbf{u}_j|^2 I_3 \right), \quad (\text{B12})$$

$$\boldsymbol{\omega} = -2 \sum_{j=1}^m \text{Im}(a_j^* \mathbf{u}_j). \quad (\text{B13})$$

The translation vector $\mathbf{c}$ will not be needed explicitly.

Two consequences are immediate. First, $S \preceq 0$. Indeed, for every real $\mathbf{x} \in \mathbb{R}^3$,

$$\mathbf{x}^\top S \mathbf{x} = 2 \sum_{j=1}^m \left(|\mathbf{x} \cdot \mathbf{u}_j|^2 - |\mathbf{u}_j|^2 |\mathbf{x}|^2 \right) \leq 0. \quad (\text{B14})$$

Hence

$$\|S\|_\infty \leq -\text{Tr}(S). \quad (\text{B15})$$

Second, taking the trace in (B12) gives

$$-\text{Tr}(S) = 4 \sum_{j=1}^m |\mathbf{u}_j|^2. \quad (\text{B16})$$

Using $|a_j| \leq \|F_j\|_\infty \leq C$ and Cauchy–Schwarz,

$$|\boldsymbol{\omega}| \leq 2 \sum_{j=1}^m |a_j| |\mathbf{u}_j| \leq 2C \sqrt{m \sum_{j=1}^m |\mathbf{u}_j|^2} \quad (\text{B17})$$

$$= C \sqrt{m(-\text{Tr} S)}, \quad (\text{B18})$$

where the last equality uses (B16). Thus

$$|\boldsymbol{\omega}|^2 \leq m C^2 (-\text{Tr} S). \quad (\text{B19})$$

c. *Step 2: Uniform channel closeness implies uniform Bloch-matrix closeness.* Let $A_\tau = e^{\tau B}$ denote the linear part of Φ_τ in Bloch form, so that

$$\mathbf{r} \mapsto A_\tau \mathbf{r} + \mathbf{b}_\tau. \quad (\text{B20})$$

The target channel generated by $H = \frac{\nu}{2}\sigma_z$ acts on Bloch vectors by the rotation

$$R_z(\alpha\tau), \quad \alpha := \frac{\nu t}{T} = \frac{\Theta}{T}. \quad (\text{B21})$$

Since the trace distance between qubit states equals the Euclidean distance between their Bloch vectors, (B3) implies that for every unit vector $\mathbf{r} \in \mathbb{R}^3$ and every $\tau \in [0, T]$,

$$|A_\tau \mathbf{r} + \mathbf{b}_\tau - R_z(\alpha\tau)\mathbf{r}| \leq \epsilon. \quad (\text{B22})$$

Applying (B22) to both $\mathbf{r}$ and $-\mathbf{r}$ and adding/subtracting the two inequalities yields

$$\|A_\tau - R_z(\alpha\tau)\|_\infty \leq \epsilon, \quad |\mathbf{b}_\tau| \leq \epsilon, \quad 0 \leq \tau \leq T. \quad (\text{B23})$$

d. *Step 3: Uniform closeness forces very small total contraction.* Taking $\tau = T$ in (B23), Weyl's inequality [47] for singular values implies that every singular value of A_T lies in $[1 - \epsilon, 1 + \epsilon]$, because all singular values of the rotation $R_z(\Theta)$ are equal to 1. Therefore

$$\det(A_T) \geq (1 - \epsilon)^3. \quad (\text{B24})$$

Since $A_T = e^{TB}$ and $\text{Tr}([\omega \times]) = 0$,

$$\det(A_T) = e^{T\text{Tr}(B)} = e^{T\text{Tr}(S)}. \quad (\text{B25})$$

Hence, for $\epsilon \leq 1/2$,

$$-\text{Tr}(S) \leq \frac{3}{T} \log \frac{1}{1 - \epsilon} \leq \frac{6\epsilon}{T}. \quad (\text{B26})$$

By (B15),

$$\|S\|_\infty \leq \frac{6\epsilon}{T}. \quad (\text{B27})$$

e. *Step 4: Uniform closeness to the rotating orbit forces a macroscopic path length.* Let

$$\mathbf{u}(\tau) := R_z(\alpha\tau)\mathbf{e}_x, \quad \mathbf{v}(\tau) := A_\tau \mathbf{e}_x, \quad (\text{B28})$$

where $\mathbf{e}_x = (1, 0, 0)^\top$. By (B23),

$$|\mathbf{v}(\tau) - \mathbf{u}(\tau)| \leq \epsilon, \quad 0 \leq \tau \leq T. \quad (\text{B29})$$

We claim that the Euclidean arc length $L(\mathbf{v})$ of $\mathbf{v}(\tau)$ satisfies

$$L(\mathbf{v}) \geq \frac{\Theta}{5}. \quad (\text{B30})$$

Indeed:

Case 1: $0 < \Theta \leq 1$. Since length dominates endpoint distance,

$$L(\mathbf{v}) \geq |\mathbf{v}(T) - \mathbf{v}(0)| \geq |\mathbf{u}(T) - \mathbf{u}(0)| - 2\epsilon \quad (\text{B31})$$

$$= 2 \sin(\Theta/2) - 2\epsilon \geq \Theta/2 - 2\epsilon \geq \Theta/4, \quad (\text{B32})$$

where in the last step we used (B5).

Case 2: $\Theta \geq 1$. Let $N = \lfloor \Theta \rfloor$, so $N \geq \Theta/2$. For $k = 0, 1, \dots, N$, define $\tau_k = k/\alpha$. Then consecutive target points are separated by one radian, hence

$$|\mathbf{u}(\tau_{k+1}) - \mathbf{u}(\tau_k)| = 2 \sin(1/2) > 0.95. \quad (\text{B33})$$

Using (B29) and (B5),

$$|\mathbf{v}(\tau_{k+1}) - \mathbf{v}(\tau_k)| \geq |\mathbf{u}(\tau_{k+1}) - \mathbf{u}(\tau_k)| - 2\epsilon > 0.93. \quad (\text{B34})$$

Therefore

$$L(\mathbf{v}) \geq \sum_{k=0}^{N-1} |\mathbf{v}(\tau_{k+1}) - \mathbf{v}(\tau_k)| > 0.93N \geq 0.46\Theta > \frac{\Theta}{5}. \quad (\text{B35})$$

This proves (B30).

f. Step 5: Convert path length into a lower bound on the effective rotation rate. Since $\dot{\mathbf{v}}(\tau) = B\mathbf{v}(\tau)$, we have

$$L(\mathbf{v}) = \int_0^T |\dot{\mathbf{v}}(\tau)| d\tau \leq \int_0^T \|B\|_\infty |\mathbf{v}(\tau)| d\tau \quad (\text{B36})$$

$$\leq (1 + \epsilon)T(|\boldsymbol{\omega}| + \|S\|_\infty), \quad (\text{B37})$$

where we used $\|[\boldsymbol{\omega} \times]\|_\infty = |\boldsymbol{\omega}|$ and $|\mathbf{v}(\tau)| \leq |\mathbf{u}(\tau)| + \epsilon = 1 + \epsilon$. Combining (B30), (B37), and (B27), we obtain

$$|\boldsymbol{\omega}| \geq \frac{\Theta}{5(1 + \epsilon)T} - \frac{6\epsilon}{T}. \quad (\text{B38})$$

Under (B5), the second term is at most $0.06 \Theta/T$ and the first term is at least $0.19 \Theta/T$, so in particular

$$|\boldsymbol{\omega}| \geq \frac{\Theta}{8T}. \quad (\text{B39})$$

g. Step 6: Finish the lower bound. Combining (B39), (B19), and (B26), we find

$$\frac{\Theta^2}{64T^2} \leq |\boldsymbol{\omega}|^2 \leq mC^2(-\text{Tr}S) \leq \frac{6mC^2\epsilon}{T}. \quad (\text{B40})$$

Rearranging gives

$$T \geq \frac{\Theta^2}{384mC^2\epsilon}, \quad (\text{B41})$$

which is exactly (B6). $\square$

Appendix C: Uniqueness of construction for smooth Lindbladians

In this section we discuss to what extent our construction is unique, showing that any smooth family of semigroups that can approximate Hamiltonian dynamics to arbitrary precision (potentially at the cost of increased simulation time), must have a form similar to our evolution up to second order.

Proposition 2 (Uniqueness up to $O(\delta^2)$). *Let $\{\mathcal{L}_{D,\delta}\}_{0 \leq \delta < \delta_0}$ be a smooth family of purely dissipative Lindbladians on a finite-dimensional system, and let*

$$\mathcal{L}_H(\rho) := -i[H, \rho]. \quad (\text{C1})$$

Assume that there exists $t_0 > 0$ such that

$$\varepsilon(\delta) := \sup_{0 \leq s \leq t_0} \|e^{\frac{s}{\delta}\mathcal{L}_{D,\delta}} - e^{s\mathcal{L}_H}\|_\diamond \xrightarrow{\delta \rightarrow 0} 0. \quad (\text{C2})$$

Then

$$\mathcal{L}_{D,\delta} = \delta\mathcal{L}_H + O(\delta^2) \quad (\text{C3})$$

in diamond norm. In particular, the first-order term is uniquely fixed by H . Equivalently, if $\tilde{\mathcal{L}}_{D,\delta}$ is another smooth purely dissipative family satisfying (C2) for the same Hamiltonian H , then

$$\mathcal{L}_{D,\delta} - \tilde{\mathcal{L}}_{D,\delta} = O(\delta^2). \quad (\text{C4})$$

Moreover, assume that for some fixed m one can choose jump operators smoothly so that

$$\mathcal{L}_{D,\delta}(\rho) = \sum_{j=1}^m \left(F_{j,\delta} \rho F_{j,\delta}^\dagger - \frac{1}{2} \{F_{j,\delta}^\dagger F_{j,\delta}, \rho\} \right), \quad F_{j,\delta} = F_{j,0} + \delta G_j + O(\delta^2). \quad (\text{C5})$$

Then $F_{j,0} = c_j I$ for some scalars c_j , and

$$H = \sum_{j=1}^m \frac{c_j G_j^\dagger - c_j^* G_j}{2i}. \quad (\text{C6})$$

Hence, modulo the usual Lindblad gauge freedom and up to $O(\delta^2)$, every nontrivial first-order jump has the form

$$F_{j,\delta} = \sqrt{\gamma_j}(I - \delta A_j) + O(\delta^2), \quad \sum_j \gamma_j \frac{A_j - A_j^\dagger}{2i} = H, \quad (\text{C7})$$

while jumps with $F_{j,0} = 0$ contribute only at order $O(\delta^2)$.

Proof. Set

$$\Phi_{\delta,s} := e^{\frac{s}{\delta}\mathcal{L}_{D,\delta}}, \quad U_s := e^{s\mathcal{L}_H}. \quad (\text{C8})$$

We first show that $\mathcal{L}_{D,0} = 0$. Fix any $a > 0$. For all sufficiently small δ , we have $a\delta \leq t_0$, and therefore (C2) implies

$$\|e^{a\mathcal{L}_{D,\delta}} - e^{a\mathcal{L}_H}\|_\diamond \leq \varepsilon(\delta). \quad (\text{C9})$$

Now let $\delta \rightarrow 0$. Since $\mathcal{L}_{D,\delta}$ is smooth at $\delta = 0$, we get

$$e^{a\mathcal{L}_{D,0}} = I. \quad (\text{C10})$$

Since this holds for every $a > 0$, differentiating at $a = 0$ yields

$$\mathcal{L}_{D,0} = 0. \quad (\text{C11})$$

Because the family is smooth, there exists a bounded superoperator $\mathcal{M}$ such that

$$\mathcal{L}_{D,\delta} = \delta\mathcal{M} + O(\delta^2), \quad \mathcal{M} = \partial_\delta \mathcal{L}_{D,\delta}|_{\delta=0}. \quad (\text{C12})$$

Define

$$A_\delta := \delta^{-1}\mathcal{L}_{D,\delta} = \mathcal{M} + O(\delta). \quad (\text{C13})$$

By Duhamel's formula,

$$e^{sA_\delta} - e^{s\mathcal{M}} = \int_0^s e^{(s-u)A_\delta} (A_\delta - \mathcal{M}) e^{u\mathcal{M}} du. \quad (\text{C14})$$

Hence, for $0 \leq s \leq t_0$,

$$\begin{aligned} \|e^{sA_\delta} - e^{s\mathcal{M}}\|_\diamond &\leq s e^{s(\|A_\delta\|_\diamond + \|\mathcal{M}\|_\diamond)} \|A_\delta - \mathcal{M}\|_\diamond \\ &= O(\delta), \end{aligned} \quad (\text{C15})$$

uniformly on $[0, t_0]$. Since $e^{sA_\delta} = e^{\frac{s}{\delta}\mathcal{L}_{D,\delta}}$, combining this with (C2) gives

$$\sup_{0 \leq s \leq t_0} \|e^{s\mathcal{M}} - e^{s\mathcal{L}_H}\|_\diamond \leq \|e^{s\mathcal{M}} - e^{\frac{s}{\delta}\mathcal{L}_{D,\delta}}\|_\diamond + \|e^{\frac{s}{\delta}\mathcal{L}_{D,\delta}} - e^{s\mathcal{L}_H}\|_\diamond = O(\delta + \varepsilon(\delta)). \quad (\text{C16})$$

Letting $\delta \rightarrow 0$ we conclude that:

$$\sup_{0 \leq s \leq t_0} \|e^{s\mathcal{M}} - e^{s\mathcal{L}_H}\|_\diamond = 0. \quad (\text{C17})$$

Therefore

$$e^{s\mathcal{M}} = e^{s\mathcal{L}_H} \quad \text{for all } 0 \leq s \leq t_0. \quad (\text{C18})$$

Differentiating at $s = 0$ yields

$$\mathcal{M} = \mathcal{L}_H. \quad (\text{C19})$$

This proves (C3).

We now prove the jump statement. Write

$$\mathcal{D}_F(\rho) := F\rho F^\dagger - \frac{1}{2}\{F^\dagger F, \rho\}, \quad \mathcal{L}_{D,\delta} = \sum_{j=1}^m \mathcal{D}_{F_{j,\delta}}. \quad (\text{C20})$$

Since $\mathcal{L}_{D,0} = 0$, we have

$$0 = \mathcal{L}_{D,0} = \sum_{j=1}^m \mathcal{D}_{F_{j,0}}. \quad (\text{C21})$$

Let $\rho = |\psi\rangle\langle\psi|$ be pure. Then

$$\begin{aligned} 0 &= \text{Tr}(\rho \mathcal{L}_{D,0}[\rho]) \\ &= - \sum_{j=1}^m \left(\langle\psi|F_{j,0}^\dagger F_{j,0}|\psi\rangle - |\langle\psi|F_{j,0}|\psi\rangle|^2 \right). \end{aligned} \quad (\text{C22})$$

Each summand is nonnegative, so every summand must vanish for every $|\psi\rangle$. Hence each $F_{j,0}$ has zero variance on every pure state, which implies

$$F_{j,0} = c_j I \quad (\text{C23})$$

for some scalar c_j .

Now write

$$F_{j,\delta} = c_j I + \delta G_j + O(\delta^2). \quad (\text{C24})$$

A direct expansion gives

$$\begin{aligned} \mathcal{D}_{F_{j,\delta}}[\rho] &= \delta \left(c_j^* G_j \rho + c_j \rho G_j^\dagger - \frac{1}{2} \{c_j G_j^\dagger + c_j^* G_j, \rho\} \right) + O(\delta^2) \\ &= -i\delta \left[\frac{c_j G_j^\dagger - c_j^* G_j}{2i}, \rho \right] + O(\delta^2). \end{aligned} \quad (\text{C25})$$

Summing (C25) over j and comparing with (C3) proves

$$H = \sum_{j=1}^m \frac{c_j G_j^\dagger - c_j^* G_j}{2i}, \quad (\text{C26})$$

which is (C6).

Finally, if $c_j \neq 0$, write

$$G_j = -c_j A_j, \quad (\text{C27})$$

so that

$$F_{j,\delta} = c_j (I - \delta A_j) + O(\delta^2). \quad (\text{C28})$$

The overall phase of c_j is irrelevant because $\mathcal{D}_{e^{i\theta} F} = \mathcal{D}_F$. Thus, after removing the phase and defining $\gamma_j := |c_j|^2$, we may rewrite

$$F_{j,\delta} = \sqrt{\gamma_j} (I - \delta A_j) + O(\delta^2). \quad (\text{C29})$$

Then (C6) becomes

$$\sum_j \gamma_j \frac{A_j - A_j^\dagger}{2i} = H. \quad (\text{C30})$$

If $c_j = 0$, then $F_{j,\delta} = O(\delta)$ and hence

$$\mathcal{D}_{F_{j,\delta}} = O(\delta^2), \quad (\text{C31})$$

so such jumps do not contribute at first order. This proves (C7). $\square$

Classical Noise Inversion: A Practical and Optimal framework for Robust Quantum Applications

Dayue Qin,^{1,*} Ying Li,^{2,†} and You Zhou^{1,‡}

¹*Key Laboratory for Information Science of Electromagnetic Waves
(Ministry of Education), Fudan University, Shanghai 200433, China*

²*Graduate School of China Academy of Engineering Physics, Beijing 100193, China*

Quantum error mitigation is a critical technology for extracting reliable computations from noisy quantum processors, proving itself essential not only in the near term but also as a valuable supplement to fully fault-tolerant systems in the future. However, its practical implementation is hampered by two major challenges: the expansive cost of sampling from quantum circuits and the reliance on unrealistic assumptions, such as gate-independent noise. Here, we introduce Classical Noise Inversion (CNI), a framework that fundamentally bypasses these crucial limitations and is well-suited for various quantum applications. CNI effectively inverts the accumulated noise entirely during classical post-processing, thereby eliminating the need for costly quantum circuit sampling and remaining effective under the realistic condition of gate-dependent noise. Apart from CNI, we introduce noise compression, which groups noise components with equivalent effects on measurement outcomes, achieving the optimal overhead for error mitigation. We integrate CNI with the framework of shadow estimation to create a robust protocol for learning quantum properties under general noise. Our analysis and numerical simulations demonstrate that this approach substantially reduces statistical variance while providing unbiased estimates in practical situations where previous methods fail. By transforming a key quantum overhead into a manageable classical cost, CNI opens a promising pathway towards scalable and practical quantum applications.

EXTENDED ABSTRACT

Background.—Addressing noise is essential for the utility of quantum computers. Quantum error mitigation (QEM) [1–4], which tackles noise with minimal qubit overhead, is necessary for the reliability of near-term quantum devices [5]. In the meanwhile, QEM complements fault-tolerant architectures [6, 7] by suppressing the non-correctable logical errors [8–10], enhancing imperfect magic distillations [11, 12], circumventing decoding bottlenecks [13] and mitigating circuit compilation imperfections [8].

Quantum Error Mitigation (QEM) is highly necessary and useful, yet its real-world deployment is hindered by two key challenges. First, most QEM techniques suffer from prohibitive resource overhead, stemming from the exponential growth of required samples with circuit size [14–17] and severe latency issues where sampling and recompiling quantum circuits take far longer than quantum operations themselves [18, 19]. Second, existing QEM methods depend on restrictive assumptions about noise properties, such as invariant noise models under circuit modifications [1–3, 20–25], which are hard to satisfy in realistic scenarios with gate-dependent noise.

To directly address these dual challenges, we introduce **Classical Noise Inversion** (CNI), a QEM framework that fundamentally shifts the mitigation overhead from quantum to classical resources. CNI works by classically simulating the propagation of a noise model

through the circuit and then inverting its effect entirely in post-processing. This approach presents two immediate advantages: first, it eliminates the quantum-circuit-sampling cost entirely, reducing the overhead to the fundamental cost of acquiring measurement shots; second, it does not rely on any restrictive noise-structure assumptions required by prior methods, and thus is inherently applicable to gate-dependent noise. In addition to CNI, we introduce **Noise Compression** to further reduce the cost of QEM. This method groups distinct errors that exhibit identical effects on the measurement results. The CNI scheme (incorporated with noise compression, which will be illustrated later) is illustrated in Fig. 1(a).

Classical Noise Inversion.—In real experiments, quantum operations and measurements are noisy, and the intended quantum process $\mathcal{U}$ is replaced by $\tilde{\mathcal{U}} := \mathcal{E}\mathcal{U}$, where $\mathcal{E} = \tilde{\mathcal{U}}\mathcal{U}^\dagger$ captures the net effect of both circuit noise and computational-basis measurement noise. By applying the inverse of the compressed noise model $\mathcal{E}'^{-1}$ on the measurement outcomes, CNI eliminates the effect of noise with optimal cost without sampling quantum circuits.

The hardness of inverting $\mathcal{E}$ and $\mathcal{E}'$ are quantified by the factors γ and γ' respectively. Theorem 1 of our paper establishes that CNI yields unbiased estimates of ideal expectation values with precision ϵ using $O(\gamma'^2/\epsilon^2)$ measurement shots, outperforming conventional QEM methods that require $O(\gamma^2/\epsilon^2)$ quantum circuit samples and rely on unrealistic noise model assumptions, while also enabling variance reduction via purely classical postprocessing by increasing L without additional quantum circuit measurements.

We establish the validity CNI with Proposition 1 in our paper. Here, we illustrate the key result of this propo-

FIG. 1. Illustration of the framework of CNI and its applications. (a) The scheme CNI incorporated with noise compression. Both CNI and noise compression are implemented on a classical computer. The compression procedure transforms the actual hard-to-mitigate noise into easy-to-mitigate noise, further reducing the cost of QEM. Then, the noise effect is canceled by classically simulating the noise inversion using efficient methods such as Monte-Carlo or tensor-network-based methods. (b) Representative quantum applications amenable to the CNI approach. (c) Flowchart of the CNI-based robust shadow estimation protocol.

FIG. 2. A two qubit example of twirling and compression of noise models. (a) The Pauli transfer matrix of general quantum noise operation. Where every element of the matrix (plaquettes filled with color) can be non-zero (since we impose no physical constraints on the noise). (b) The $\mathbb{Z}$ -twirled Pauli transfer matrix. Some of the elements of the original matrix are transformed to zero (empty plaquettes). According to Proposition 1, the upper right block being zero is the necessary and sufficient condition for CNI validity. (c) After both $\mathbb{Z}$ - and $\mathbb{X}$ -twirling, i.e. Pauli twirling, the Pauli transfer matrix is diagonal. (d, e) Noise compression (Comp.) from the perspective in the Pauli transfer matrix, we only need to consider the $\mathbb{Z}$ -block, and neglect the non- $\mathbb{Z}$ -block elements (plaquettes filled with gray).

sition in Fig. 2 (b). This criterion is naturally satisfied by common noise models, such as the depolarizing noise model or phase damping noise model, and can be satisfied by any arbitrary noise model when the twirling technique is applied.

Noise Compression.— Noise compression achieves the optimal overhead for error mitigation by grouping noise components with equivalent effects on computational results. Since only the $\mathbb{Z}$ -block of the Pauli transfer matrix of a quantum channel can affect the measurement outcomes (as illustrated in Fig. 2 (d) and (e)), we can group different noise components with identical affects, and construct $\mathcal{E}'$ based the grouping that achieves lower overhead. In Proposition 2 of our paper, we prove that $\gamma' \leq \gamma$, and γ' is the minimum value for unbiased quantum error mitigation.

CNI-based robust quantum learning.—The most efficient regime for CNI arises when the classical simulation of noise propagation is tractable. This is notably the case for circuits comprising gates from classically simulable sets, such as Clifford [26] or matchgates [27, 28], as well as shallow-depth circuits [29, 30]. Importantly, this regime encompasses a wide array of practically important scenarios. As illustrated in Fig. 1(b), these include the simultaneous estimation of commuting observables in many-body Hamiltonian learning [31–33], the physical implementation of fault-tolerant logical measurements, and various randomized measurement protocols for system learning [34]. Furthermore, for more general circuits beyond this regime, CNI can be combined with approxi-

FIG. 3. Numerical comparison of our method and existing methods under multi-shot measurement scheme. In the figure, CNI stands for the proposed CNI-based robust shadow estimation, sRSE stands for standard robust shadow estimation and cPEC stands for conventional probabilistic error cancellation. The fidelity of 4-qubit GHZ state is estimated at a cost of $M = 10^3$, $K = 10^3$, $L = 1$ across varying error rates; this estimation procedure is repeated for 320 times. Data points represent the mean values of the repeated estimations, while the shaded areas indicates one standard deviation. The standard deviations are also plotted separately in the inset. The calibration cost for sRSE is $M = 3.2 \times 10^5$, $K = 1$, $L = 1$. (a) Local approach for uncorrelated noise. (b) Global approach for correlated noise.

mate classical simulation techniques, suggesting a versatile trade-off between computational resources and mitigation fidelity.

In this study, we focus on the application of quantum state learning by integrating CNI with classical shadow estimation [35, 36] to establish a robust and broadly applicable framework. As shown in Fig. 1(c), by applying CNI to every random measurement, CNI is integrated with thrifty shadow estimation [37, 38], a method that improves resource efficiency through circuit reuse. The CNI-based robust shadow framework is universally applicable to shadow estimation with all kinds of unitary ensembles [39–42], circuit structures [43–45] and shallow-circuit variants [46–48]. Meanwhile, the framework inher-

its the advantages of CNI: it achieves unbiased estimation even under challenging gate-dependent noise while maintaining low variance.

We employ both rigorous theoretical analysis and extensive numerical simulations to demonstrate the advantages of CNI over existing methods [23, 49]. For detailed theoretical results, please refer to Theorem 3 and Proposition 3 in the full paper. Regarding numerical simulations, we present a subset of the simulated results in Fig. 3; these results illustrate that our method achieves both low variance and unbiasedness, whereas competing methods either exhibit bias[23] or introduce significantly higher variance [49].

Abstract. The restriction of the Heisenberg Limit in quantum metrology, which says that the scaling of the measurement uncertainty is strictly bounded by $1/N$ with N representing the number of employed resources, has been circumvented by the quantum switch in the measurement of the Berry phase. Here, we construct a new quantum switch operation—the symmetric quantum switch—thereby for the first time realizing a measurement precision for a dimensional physical quantity (displacement) that attains the super-Heisenberg scaling of $1/N^2$. Moreover, by employing both a single-photon state and an entangled state as the input probe, we demonstrate that entanglement and our measurement scheme jointly enhance the measurement precision.

Keywords: Quantum Information, Quantum Metrology, Quantum switch

The scaling of measurement uncertainty Δ with the amount of resource N is a central topic in quantum metrology. It is widely accepted that, by exploiting quantum resources, Δ can be reduced at most as N^{-1} , known as the Heisenberg limit (HL), and that this limit cannot be violated. However, recent research has identified a new quantum resource capable of breaking the N^{-1} barrier of the HL. This resource is the ability to combine quantum processes in a superposition of alternative orders, introduced as the quantum switch. It has been rigorously proved in [1] that by applying the quantum switch, the measurement uncertainty of the Berry phase A can surpass the HL and scale as $\Delta(A) \propto N^{-2}$. And this theory has already been demonstrated experimentally in [2].

So far, such a super-Heisenberg limit (SHL) has only been achieved in the measurement of the Berry phase, which is a dimensionless parameter. For dimensional parameters, the measurement uncertainty remains bounded by the HL. In this Letter, we prove that with a new quantum metrological scheme—the symmetric quantum switch—the estimation of a dimensional parameter can also reach an SHL, and we demonstrate this scaling in a practical measurement task.

1 Theorem

Consider a scenario in which a continuous-variable degree of freedom experiences two sets of displacements conditioned on the polarization state. If the polarization is $|R\rangle$, the system first undergoes N position displacements and then N momentum displacements:

$$\prod_{i=1}^N e^{ip_i \hat{X}} \prod_{i=1}^N e^{-ix_i \hat{P}}; \text{ if the polarization is } |L\rangle, \text{ the order}$$

$$\text{is reversed: } \prod_{i=1}^N e^{-ix_i \hat{P}} \prod_{i=1}^N e^{ip_i \hat{X}}.$$

The distinguishing feature of our symmetric quantum

switch is that the encoding parameters x_i and p_i are no longer independent but obey the specific correlation $p_i = ax_i$ with a being a constant. The evolution therefore can be expressed as:

$$\begin{aligned} \hat{U} &= \prod_{i=1}^N e^{iax_i \hat{X}} \prod_{i=1}^N e^{-ix_i \hat{P}} \otimes |R\rangle \langle R| \\ &+ \prod_{i=1}^N e^{-ix_i \hat{P}} \prod_{i=1}^N e^{iax_i \hat{X}} \otimes |L\rangle \langle L| \\ &= e^{-iN\bar{x}\hat{P}} e^{iaN\bar{x}\hat{X}} \otimes (|L\rangle \langle L| + e^{iaN^2\bar{x}^2} |R\rangle \langle R|), \end{aligned} \quad (1)$$

where $\bar{x} = \frac{1}{N} \sum_{i=1}^N x_i$ is the parameter to be estimated.

Suppose the initial state is $|\psi\rangle \otimes (|R\rangle + |L\rangle)/\sqrt{2}$. After the evolution governed by the symmetric quantum switch in Eq. (1), the joint state becomes $e^{-iN\bar{x}\hat{P}} e^{iaN\bar{x}\hat{X}} |\psi\rangle \otimes \frac{1}{\sqrt{2}} (e^{iaN^2\bar{x}^2} |R\rangle + |L\rangle)$. Tracing out the continuous-variable mode, the effective polarization state yields the detection probability in the basis $|-\rangle = (|R\rangle - |L\rangle)/\sqrt{2}$ as $P = \sin^2(aN^2\bar{x}^2/2)$. Consequently, the precision for estimating $\bar{x}$, as given by the classical Fisher information F , is

$$\Delta x = \frac{1}{\sqrt{F}} = \frac{1}{2aN^2\bar{x}}, \quad (2)$$

which exhibits the super-Heisenberg scaling $\Delta x \propto 1/N^2$ for the average displacement $\bar{x}$.

2 Experiment

We found that such a symmetric quantum switch can be achieved by an operation named Controlled Fourier Transformation in experiment, as depicted in Fig.1.(b): A set of glass plates at the center introduces a displacement $-N\bar{x}$, where $\bar{x}$ is the parameter to be measured, N is the number of plates. For an incident beam with $|L\rangle$ polarization (red line), CFT gates 1, 3, 4, and 6 converge the beam, while gates 2 and 5 leave the spatial distribution unaffected. Consequently, the spatial distribution at the back focal plane undergoes a displacement of $N\bar{x}$ relative to the front focal plane. Conversely, an injected $|R\rangle$

*hxs990131@mail.ustc.edu.cn

†chengeng@ustc.edu.cn

state (blue line) undergoes the $4f$ system which contains CFT gates 2,5, therefore the spatial momentum shifts by $N\bar{p} = N \frac{2\pi}{\lambda(2f)} \bar{x}$. By querying the gate $\hat{U}_2$ in Fig.1.(b) twice, one can get the evolution with the same form in Eq.(1):

$$\begin{aligned} \hat{U}_1 = & \hat{D}_x(N\bar{x})\hat{D}_p\left(\frac{N\pi\bar{x}}{\lambda f}\right)|R\rangle\langle L| \\ & + \hat{D}_p\left(\frac{N\pi\bar{x}}{\lambda f}\right)\hat{D}_x(N\bar{x})|L\rangle\langle R|, \end{aligned} \quad (3)$$

In our experiment, we employ two distinct initial states as the light source: (i) a single-photon state $|\phi\rangle_{n=1} = |H\rangle = (|R\rangle + |L\rangle)/\sqrt{2}$ and (ii) an entangled two-photon state $|\phi\rangle_{n=2} = (|R\rangle \otimes |R\rangle + |L\rangle \otimes |L\rangle)/\sqrt{2}$. Both states are initialized in the TEM00 mode, where the index n denotes the degree of entanglement resources inherent in the initial state. After the evolution of Eq.(3), we examine the relation of detection probabilities P with displacement $\bar{x}$ under various number of plates N and entanglement resources n . The result is shown in Fig.3.(a) and (b). Notably, for both the single-photon and entangled two-photon sources, the detection probability as a function of $\bar{x}$ fits well to a $\sin^2(k\bar{x}^2)$ distribution, confirming the successful implementation of the quantum switch. Quantitative analysis reveals that, for a fixed entanglement resource n , the coefficient k exhibits a nonlinear quadratic relationship with the number of plates, specifically $k \propto N^2$ as predicted by Eq.(2). Furthermore, for a fixed N , the coefficient k for the two-photon source is approximately twice that of the single-photon source, demonstrating the enhancement afforded by entanglement.

From the detection probabilities, the precision Δx of estimating the displacement $\bar{x}$ is determined, as depicted in Fig. 2. The figure clearly demonstrates that, precision Δx exhibits a nonlinear quadratic scaling with N , namely $\Delta x \propto N^{-2}$, regardless of whether a single photon state or an entangled two photon state is employed. This observation validates our theory and offers compelling evidence that the measurement of displacement beats the Heisenberg Limit $\Delta x \propto N^{-1}$, as shown by the yellow dashed line in the figure, and that the source of this superiority lies in the quantum switch architecture, not in other resources such as entanglement. The figure also point out that, for the same plate number N , precision under the entangled two-photon resource achieves an enhancement of about 3.1dB relative to the single-photon case—which according to Eq. (2) should be 3dB theoretically—illustrating the benefit of entanglement for the improvement of precision, while the power-law dependence of the precision on N remains unchanged. Last, we calculate the theoretical bound (Cramer-Rao Bound) of the measuring precision and the Classical Fisher information of our devices. As depicted in Fig. 2. (a) and (b), our experimental results closely approach the bound, verifying the reliability of our apparatus and the correctness of the theoretical framework.

Figure 2: **Precision of measuring $\bar{x}$.** Here the x-axis stands for plates number N , while the y-axis represents the precision Δx of measuring a fixed displacement $\bar{x} = 14.2\mu m$. Measuring results of the two photon source $n = 2$ are exhibited by the blue dots, while those from the single photon source $n = 1$ are presented by the red dots, whereas the yellow dots demonstrate the standard measurement which only sequentially queries the N plates without quantum switch. The number of photons utilized remains the same across all three cases, being 2. The dashed lines are the linear fitted curves of the results on the logarithmic coordinates, while the solid lines depict the theoretical Cramer-Rao Bound.

3 Conclusion

The importance of this work lies in offering a practical solution to measuring a dimensional physical parameter surpassing the Heisenberg Limit. Crucially, our symmetric quantum switch is a general protocol which can be utilized in various measurement tasks, by encoding the parameter to be measured and its Fourier transformation pair into the Berry phase, broadening the applications of super Heisenberg Limit sensing. Furthermore, with the assistance of entanglement resources, the precision of measurement can be further elevated, paving the way for more precise quantum-inspired sensing technologies.

Figure 1: (a). **Controlled Fourier transformation(CFT) gate**. The red plate is a plate lens(PL), When the incident light is right-hand circular polarized, PL will function as a concave lens with a nominal focal length $2f$, otherwise it will perform as a convex lens with the same focal length. By compacting the PL with a plano-convex lens of equal focal length, the transformation of the beam's TM mode under the combined element from the front to the back focal plane can be approximated by a CFT gate. (b). **Controlled displacement gate $\hat{U}_2$** . N glass plates at the center of the gate will cause a small displacement with $-N\bar{x}$ to the beam. After propagating through the gate, the injected beam with $|L\rangle$ experiences a displacement with $N\bar{x}$ on the patten, while the transverse momentum for $|R\rangle$ shifts with $N\bar{p}$, and their polarizations are exchanged.

Figure 3: (a). **The detected possibility P versus displacement for the entangled two-photon source**. The x-axis is for the magnitude of displacement. The solid lines are the fitted curves with the form of $\sin^2(kx^2)$. The plate numbers $N = 2, 4, 10$ are represented by colors blue, red, and yellow. Therefore, the curves with different colors demonstrate the elevation from the gate resources. The error bars are derived from the bootstrap method. (b). **The detected possibility P versus displacement for the single-photon source**. The elements in the picture have the same meanings as in (a). Notice that the period for the curve in (b) is longer than that with the same N in (a).

Unified Characterization of Optical Quantum States with Neural Networks

Abstract. Neural networks have enabled property prediction for specific optical quantum states, but a unified and reusable model across broad state families and tasks remains lacking. This limitation is especially acute for multimode non-Gaussian states, where labelled data are scarce due to the growing cost of classical simulation. Here, we introduce the first foundation model for optical quantum-state characterization. By organizing optical states through a complexity hierarchy of non-Gaussianity, mode number, and squeezing, a model pretrained on low-complexity homodyne statistics generalizes to higher-complexity states and transfers to challenging regimes including Schrödinger cat states, ten-mode systems, and squeezing up to 10.4 dB. With modest fine-tuning, it predicts key properties such as fidelity, Wigner negativity, and quantum Fisher information from limited measurements, providing a scalable framework for optical quantum computing, communication, and metrology.

Keywords: optical quantum states, homodyne measurement, machine learning, continuous variables

Optical continuous-variable systems provide a versatile platform for quantum communication, quantum metrology, and photonic quantum computing. In experimentally relevant regimes, however, the states of interest are often multimode and non-Gaussian, living in an infinite-dimensional Hilbert space whose effective dimension grows rapidly with the number of modes, photon number, and squeezing. As a result, full quantum state tomography becomes increasingly impractical precisely in the regimes where efficient characterization and certification are most needed.

Recent progress has shown that machine learning can help extract quantum information directly from experimentally accessible measurement data. Neural networks have been used to detect continuous-variable entanglement from homodyne correlation patterns [1], while physically motivated criteria and data-augmented learning further enable the characterization of multipartite non-Gaussian entanglement structures [2, 3]. These works demonstrate that neural networks can learn useful quantum features from limited measurements without reconstructing the full density matrix. Nevertheless, most existing models remain specialized to a particular task or data distribution, and therefore do not provide a reusable representation that can be trans-

ferred across different characterization problems.

Here we introduce an optical-state foundation model for unified quantum-state characterization [4]. The model is designed to learn compact and transferable representations of optical quantum states from homodyne measurement statistics. Its construction is guided by a physically meaningful complexity hierarchy described by three factors: the number of modes m , the maximal squeezing degree ξ , and the stellar rank r , which quantifies non-Gaussianity. Gaussian states correspond to $r = 0$, photon-subtracted and photon-added states have finite nonzero stellar rank, while Schrödinger cat states provide an important example with infinite stellar rank. Increasing any of these factors typically makes classical simulation and state characterization more demanding.

In the pretraining stage, the model receives a small set of local homodyne marginals as context. Each marginal distribution is paired with its measurement setting and encoded by a representation network into a latent vector; these vectors are then combined into a state representation. A generation network uses this representation to predict homodyne marginals at unobserved measurement settings. In this way, the model is pretrained using measurement statistics themselves, rather than labels associated with a specific downstream task such as Wigner negativity, fidelity, or quantum Fisher information.

*gaoxiaoting@pku.edu.cn

†wuyadong301@sjtu.edu.cn

‡qiongyihe@pku.edu.cn

After pretraining on relatively tractable optical states, the model is tested on states outside the pre-training distribution along the (m, ξ, r) complexity hierarchy. It remains accurate in predicting unseen homodyne statistics for more complex states, indicating that the learned representation captures transferable physical regularities rather than merely interpolating within the training set. The learned latent space also exhibits a physically meaningful structure: Gaussian and non-Gaussian states are separated, and finite-rank non-Gaussian states are organized consistently with the stellar hierarchy.

The pretrained representation can then be adapted to different quantum-property prediction tasks with modest fine-tuning. For multimode photon-subtracted and photon-added states with $m = 5, 7, 10$ modes, the model predicts Wigner negativity from limited homodyne data and outperforms both the same architecture trained from scratch and a shallow neural-network baseline. The same framework also transfers to state families far from the pretraining distribution: it predicts purity and fidelity for lossy N00N states with photon number up to $N = 8$, cat size and fidelity for Schrödinger cat states with infinite stellar rank, and fidelity and quantum Fisher information for highly squeezed states up to 10.4 dB.

These results establish a reusable representation-learning framework for optical quantum states. Rather than designing a separate model for each state family or target property, the proposed foundation model learns from homodyne measurement statistics and adapts through few-shot fine-tuning. This provides a scalable route for characterizing and certifying experimentally relevant optical quantum states, especially in multimode non-Gaussian regimes where both experimental data and classically simulated labels are scarce.

Abstract. We present a scalable method for detecting entanglement in dynamical many-body quantum systems. By tracking generalized stabilizers inspired by stabilizer-based simulation, we construct linear witnesses to detect bipartite and genuine multipartite entanglement across any target partition. Unlike exact classical simulation, our approach utilizes coarse-grained digitization and a heuristic Pauli-basis truncation technique to efficiently approximate the evolved stabilizer operators. Numerical simulations on representative Heisenberg-type Hamiltonians demonstrate that our method enables effective entanglement detection over relatively long evolution times. Notably, the resulting witness sizes scale polynomially with system size, significantly reducing the required experimental measurement resources compared to full state tomography.

Keywords: Entanglement detection, Hamiltonian simulation, Stabilizer theory

1 Introduction

Large-scale quantum devices are increasingly utilized to generate and probe many-body Hamiltonian dynamics. As system sizes scale up, the resulting evolved states host rich multipartite entanglement structures necessary for quantum advantages [1, 2, 3]. However, characterizing these states poses a severe challenge: full state tomography scales exponentially with system size, and exact classical tracking quickly becomes intractable due to the rapid growth of many-body correlations [4, 5, 6]. Fortunately, full state reconstruction is often unnecessary if the primary goal is to certify specific physical properties, such as entanglement. While efficient verification protocols exist, they are predominantly tailored to highly symmetric, fine-tuned target states (e.g., GHZ or W states [1, 2]). In contrast, states generated via generic Hamiltonian dynamics rapidly lose permutation or simple stabilizer symmetries, rendering conventional verification schemes inapplicable.

In this work, we develop a scalable framework to detect entanglement generated during generic Hamiltonian evolution. Given an initial state $|\psi_0\rangle$, a Hamiltonian H , and an evolution time t , the ideal target state is governed by the unitary dynamics $|\psi(t)\rangle = e^{-iHt}|\psi_0\rangle$. Aiming at constructing witnesses to detect (genuine multipartite) entanglement with respect to this state, rather than executing an accurate classical simulation, we find that a coarse-grained simulation of the state's evolved stabilizers provides sufficient information to construct effective linear entanglement witnesses (EWs).

2 Entanglement Witness Construction

We first describe the algorithm to construct an EW with respect to the target state in Hamiltonian evolution. To acquire relevant system information, instead of tracking the evolved state vector, we track the generalized stabilizers of the state as inspired by the stabilizer-based simulation algorithms [7, 8]. Consider a target evolution time t and take $t = Kt_0 + t_R$ with $0 \leq t_R < t_0$; we call t_0 a unit time and t_R the residue time. The EW is

constructed as

$$\begin{aligned} (|\psi_0\rangle, H, t) &\xrightarrow{\text{find stabilizers}} \bar{S}_i(0), S_\ell(0) := \sum_i \bar{S}_i(0) \\ &\xrightarrow{\text{evolve for } t_0 \text{ and truncate}} S_\ell(t_0) \cdots \rightarrow S_\ell(Kt_0) \\ &\xrightarrow{\text{residual time } t_R} S_\ell(t) \\ &\xrightarrow{\text{compute separable bound}} W_\ell(t) = \beta_\ell I - S_\ell(t). \end{aligned}$$

Here, the observables $\bar{S}_i(0)$ at time 0 are the stabilizers of the initial state such that $\bar{S}_i(0)|\psi_0\rangle = |\psi_0\rangle$. The unit-time update combines digitized Heisenberg evolution with Pauli truncation:

$$S_\ell(kt_0) = \Pi_\ell \left(\tilde{U}_{t_0} S_\ell((k-1)t_0) \tilde{U}_{t_0}^\dagger \right), k = 1, \dots, K,$$

where $\tilde{U}_{t_0}$ approximates e^{-iHt_0} as its truncated Taylor series expansion, and the truncation operation Π_ℓ for a fixed truncation threshold ℓ is defined as

$$\Pi_\ell \left(\sum_{P \in \mathbb{P}} c_P P \right) = \sum_{|c_P| > \ell \max_Q |c_Q|} c_P P$$

with $\mathbb{P}$ representing the Pauli basis that spans the operator space. In this way, less significant Pauli components are removed after an evolution time t_0 . We repeatedly apply the same truncation techniques after each unit time and also after the final residual time t_R . In this work, we refer the size of the entanglement witness to the number of retained Pauli strings in the decomposition of $S_\ell(t)$, which gives a direct upper estimate of the number of elementary Pauli observables to be measured in an experiment. In practice, mutually commuting Pauli strings may be grouped into one common measurement setting, so the actual number of settings can be further smaller.

After obtaining $S_\ell(t)$ through coarse-grained operator evolution and truncation, we design an EW with respect to it. The coefficient β_ℓ is chosen as the largest expectation value of $S_\ell(t)$ over a superset $\mathcal{R}$ of separable states:

$$\beta_\ell = \max_{\sigma \in \mathcal{R}} \text{tr}[\sigma S_\ell(t)].$$

Exact optimization over separable states is generally hard [9], so for bipartite entanglement detection

we choose $\mathcal{R}$ as a PPT-type relaxation of separable states [10, 11]. For GME detection, $\mathcal{R}$ is chosen as an analogous relaxation of biseparable states [12]. With this choice,

$$\text{tr}[W_\ell(t)\sigma] = \beta_\ell - \text{tr}[S_\ell(t)\sigma] \geq 0$$

for every $\sigma \in \mathcal{R}$; hence $W_\ell(t)$ is a valid EW. The truncation techniques do not affect the EW's validity but instead trade its entanglement detection capability with a reduction of resources: by discarding a certain level of fine-grained system information, the EW $W_\ell(t)$ can be easier to implement with much fewer measurement bases.

Finally, the threshold ℓ can be adjusted adaptively. If the constructed witness detects the target state but is decomposed into too many Pauli strings, ℓ can be increased for a more aggressive truncation. On the other hand, if it fails to detect entanglement in the target state, ℓ can be decreased to retain more operator information. The witness is accepted once it is able to detect entanglement in the target, ideally evolved state, and that its size in terms of the measurement bases for its implementation is below a prescribed threshold.

3 Numerical Simulation

We test the efficacy of our method numerically on several representative Hamiltonian models. We first illustrate the method on a power-law XY Hamiltonian with a longitudinal field:

$$H_{XY,\text{power}} = \sum_{i < j} |i - j|^{-2} (X_i X_j + Y_i Y_j) + 0.2 \sum_i Z_i. \quad (1)$$

For an n -qubit system, we investigate entanglement across the specific system partition between the first $\lfloor n/2 \rfloor$ qubits and the rest. Starting from a simple product state like $|01010 \dots\rangle$, Figure 1(a) shows that the evolution of $H_{XY,\text{power}}$ rapidly generates bipartite entanglement.

To demonstrate that entanglement certification can use far less operator information than full-state tracking, in Figure 1(b), we first observe that a slight truncation of the less significant terms in the stabilizers' Pauli-basis decomposition radically reduces the size of the optimized witness compared to the untruncated construction. Figure 2(a) shows how the EW sizes after truncation evolve for $n = 6-9$. The size remains moderate over nontrivial evolution times, indicating that the coarse-grained construction can keep the measurement cost controlled. After decomposing the EWs at an early time and near the stopping time on the Pauli basis, we compare the coefficients with the largest absolute values in Figures 2(b) and 2(c). The coefficient distribution is initially peaked at the beginning, but becomes more flattened at a later time. This explains both why truncation is effective at early and intermediate times, and why it eventually fails when discarded components carry important operator information.

We then test our method on several other representative Heisenberg-type models: power-law and nearest-neighbor couplings, XY and XYZ interactions, asymmetric fields, and randomized coupling coefficients.

The Hamiltonians are listed in detail in the Technical Manuscript. Figures 3(a) and 3(b) summarize the optimized performance for bipartite entanglement detection: the curves show the final witness size, while the bars show the maximal evolution time for which the optimized witness still detects entanglement. Across these models, the retained Pauli support remains far below the full Pauli basis under a polynomial-size constraint, and the detectable time remains nontrivial as the number of qubits increases.

The construction also extends to genuinely multipartite entanglement. Replacing the separability relaxation by a biseparability relaxation gives GME witnesses from the same coarse-grained stabilizer information. Figures 3(c) and 3(d) show the corresponding witness size and detectable evolution time for GME detection. The witness size remains controlled in this stronger certification task as well. Hence the method can detect not only the presence of entanglement, but also stronger multipartite entanglement structure generated by Hamiltonian dynamics.

4 Outlook

Our results suggest that entanglement certification in quantum dynamics can be substantially easier than full-state characterization when one tracks only the operator information relevant to the resource. The method is not intended to certify arbitrary long-time dynamics with small witnesses: once the Pauli coefficients spread over many components, more information must be retained. Nevertheless, the numerical evidence indicates that coarse-grained stabilizer evolution can produce compact, experimentally accessible witnesses over meaningful dynamical time scales. This viewpoint may be useful for scalable verification of quantum simulators and for designing analogous certification tools for other dynamical resources.

Figure 1: Evolution features of $H_{XY,\text{power}}$ in Eq. (1) (10 qubits). (a) System entanglement entropy. (b) Size of the optimized EW for the evolving state. We investigate the effect of the truncation threshold ($\ell = 0$ versus $\ell = 0.05$) on the EW size.

Figure 2: Change of the EW size in the evolution of the Hamiltonian model $H_{XY,power}$. (a) Change of the EW under different system sizes. We perform simulation with a system size ranging from 6 to 9 qubits. Simulation stops at the time when we cannot detect entanglement using the optimized EW. (b) The 20 coefficients with the largest absolute values in the Pauli-basis decomposition of the EW at time $t = t_0$. The system has a size of 6 qubits in this showcase, and we list the underlying Pauli strings of the coefficients. (c) The 20 coefficients with the largest absolute values in the Pauli-basis decomposition of the EW at time $t = 18t_0$.

Figure 3: EW performance with respect to the system size for five models. Under the constraint that the EW size is at most a polynomial function of the system size, we depict the EW size (curves) and the maximal entanglement detection time (bars) in the optimization for two parties entanglement in (a)(b) and GME in (c)(d) respectively.

Abstract. The effective Hamiltonian translates complex physical hardware into programmable quantum logic. However, deriving these models suffers from mathematical “gauge ambiguities,” leading to inconsistent predictions in strongly-coupled processors. We resolve this by establishing the Least Action Unitary Transformation (LAUT) principle, which selects the unique decoupling transformation with minimal geometric deformation. This variationally optimal approach guarantees long-time dynamical fidelity and inherently preserves system symmetries. Validated on superconducting architectures, our framework accurately captures driven multi-body interactions that standard methods fail to resolve. For full technical details and mathematical derivations, we refer the reader to our technical manuscript at arXiv:2602.03618.

Keywords: Effective Hamiltonian, Hamiltonian Engineering, Gauge Ambiguity, Least Action Principle, Superconducting Circuits

1 Introduction: The Interface Between Physics and Logic

At the heart of quantum information science lies a fundamental translation problem: how do we map the messy, infinite-dimensional reality of physical quantum hardware into the clean, finite-dimensional logic of qubits? The mathematical bridge that performs this translation is the *effective Hamiltonian*. By mathematically eliminating highly excited states, leakage channels, and environmental noise, the effective Hamiltonian distills the relevant low-energy dynamics into a programmable model.

Historically, effective Hamiltonians have been phenomenological tools. However, as the field of quantum computing rapidly scales, we are pushing hardware into regimes of strong coupling and near-degeneracy. Fast entangling gates, such as those relying on frequency-selective microwave drives or tunable couplers, require interaction strengths that increasingly rival the energy gaps separating the computational subspace from the rest of the physical system. In this regime, the standard theoretical frameworks used to build effective Hamiltonians are facing a crisis of ambiguity.

1.1 The Crisis of Gauge Ambiguity

The central difficulty is the mathematical non-uniqueness of block diagonalization. While the mathematical condition for decoupling a target computational subspace is precise, the unitary transformation that achieves this decoupling is not unique. It possesses an intrinsic “gauge freedom.”

Conceptually, imagine trying to separate a mixture of two fluids. There are infinitely many ways to draw the boundary, and depending on the mathematical path chosen, the internal coordinates of the extracted fluid are rotated differently. In quantum mechanics, this means that two theorists utilizing different standard techniques—such as standard Schrieffer-Wolff transformations (SWT)

or numerical Givens rotations—can arrive at distinct effective Hamiltonians for the exact same physical system.

This lack of a canonical geometric constraint leads to dire consequences for quantum hardware. It can result in spurious symmetry breaking, the loss of adiabatic continuity, and the generation of unphysical artifacts. Consequently, the extracted physical parameters (like qubit frequencies and coupling strengths) cease to be objective physical invariants and become artifacts of the chosen algorithm. For a detailed mathematical proof of this gauge freedom, see the technical version of this work (arXiv:2602.03618).

2 The Core Idea: The LAUT Principle

To resolve this ambiguity, we propose that the definition of an effective Hamiltonian is fundamentally incomplete without a variational, geometric constraint. We elevate the effective Hamiltonian from a procedural byproduct of block diagonalization to a variationally optimized physical entity.

We introduce the *Least Action Unitary Transformation (LAUT)* principle. Among the continuous, infinite manifold of all possible block-diagonalizing transformations, the true physical solution is the unique unitary that minimizes the geometric distance to the identity matrix.

In a non-technical sense, LAUT acts as a strict gauge-fixing condition that mandates the “shortest path.” Instead of taking a meandering mathematical trajectory that needlessly scrambles the internal states of the qubits, LAUT performs the absolute minimum amount of mathematical deformation required to isolate the computational subspace. By aligning with the principle of least information, the LAUT framework ensures that the resulting effective model contains no arbitrary gauge information or spurious correlations.

*dengxiuhao@iqasz.cn

3 Key Insights and Results

By adopting the LAUT principle, we reconcile variational optimality with analytical tractability, leading to three profound insights for quantum information processing.

1. The Guarantee of Dynamical Fidelity: While LAUT minimizes structural deviation statically, we have discovered a direct link to quantum dynamics. We proved that the transformation minimizing this geometric distance simultaneously maximizes the theoretical lower bound of long-time evolution fidelity. In simple terms: doing the least mathematical damage during the derivation guarantees the highest accuracy when simulating the quantum system over long gate times. This provides the missing physical justification for why the "shortest path" is the physically correct one.

2. Inherent Symmetry Preservation: Nature possesses fundamental symmetries (e.g., parity, exchange symmetry). Standard numerical methods, which blindly diagonalize matrices step-by-step, frequently introduce arbitrary phase artifacts that break these global symmetries, predicting unphysical behaviors in simulated materials or logical qubits. We demonstrate that because the LAUT solution is uniquely defined by a global variational minimum, it inherently respects and preserves all original symmetries of the physical system.

3. An Accessible Analytical Tool: While LAUT can be solved exactly via numerical methods, quantum engineers often require analytical formulas to design hardware. We bridge this gap by identifying the Bloch-Brandow (BB) formalism as the natural perturbative counterpart to the LAUT principle. Unlike standard SWT, which deviates from the optimal geometric path at higher orders, the BB approach remains variationally optimal and symmetry-preserving. This provides quantum architects with a practical, closed-form algebraic tool to engineer high-precision hardware.

4 Real-World Impact: Superconducting Circuits

To demonstrate the immediate practical importance of these results, we extensively validated the LAUT framework against experimental data from modern superconducting quantum processors (full data available at [arXiv:2602.03618](https://arxiv.org/abs/2602.03618)).

4.1 Rescuing the Cross-Resonance Gate

The cross-resonance (CR) gate is a cornerstone of fixed-frequency superconducting architectures. It operates by driving a control qubit at the frequency of a target qubit. Because the drive is strong and the detuning is small, standard perturbative methods (like SWT) catastrophically diverge, failing to predict the correct interaction rates.

By applying our LAUT-guided framework, we quantitatively reproduced experimental interaction rates across the entire drive range. The framework naturally captures the asymmetric virtual tunneling pathways—specifically, the transient occupation of highly excited, non-computational states—that govern the gate’s conditional logic, proving its superiority for practical gate calibration.

4.2 Discovering Hidden Multi-Body Physics

Beyond merely calibrating known gates, the LAUT framework serves as a powerful discovery tool. In complex, tunable-coupler architectures, standard approximations (like the Rotating-Wave Approximation) intentionally ignore counter-rotating terms.

By employing our method on a five-mode quantum circuit (Q-C-Q-C-Q), we systematically mapped out higher-order virtual transitions that standard methods blur. In doing so, we successfully identified and quantified a genuine, tunable three-body interaction ($XZX + YZY$) mediated by the central coupler. Previously dismissed by some models as a gauge artifact, the LAUT framework rigorously verifies that this multibody term is a physically real, engineerable quantity.

5 Importance to Quantum Information and Computation

The implications of this work extend far beyond the specific derivations of superconducting circuits. As the quantum information community moves from the Noisy Intermediate-Scale Quantum (NISQ) era toward fault tolerance, the precision of our theoretical models must match the increasing precision of our hardware.

High-Precision System Learning: Accurate Hamiltonian learning relies on comparing experimental data to a theoretical model. If the theoretical model is plagued by gauge ambiguities, the learning process will inherit those systematic errors. The LAUT principle provides a mathematically rigorous, canonical standard for model reduction, eliminating this source of systemic uncertainty.

Hardware Co-Design: The ability to analytically and accurately predict higher-order interactions—such as the discovered three-body term—allows for more creative hardware co-design. Engineers can intentionally leverage these "parasitic" multi-body interactions to implement complex quantum simulation algorithms natively, reducing circuit depth.

Conclusion: By providing a unique, physically justified, and symmetry-preserving method for constructing effective Hamiltonians, the LAUT framework resolves a longstanding theoretical crisis. It establishes an extensible and robust mathematical foundation for the design, calibration, and understanding of next-generation quantum computers and simulators.

Efficient circuit compression by multi-qudit entangling gates in linear optical quantum computation

Apurav Tehri¹ *

Jaskaran Singh¹ †

¹ *Center for Quantum Science and Technologies, Indian Institute of Technology, Mandi, Himachal Pradesh 175075, India*

Abstract. Linear optical quantum computation (LOQC) is fundamentally constrained by the probabilistic nature of non-local entangling gates. Qudit-based circuit compression mitigates this by encoding multiple qubits onto qudits, but becomes exponentially inefficient when only a subset of encoded qubits is required to participate in a non-local gate. We resolve this bottleneck by demonstrating the physical existence of multi-level entangling (controlled-Z) gates for spatially encoded qudits. We present two linear optical realizations: a state-dependent scheme achieving a constant 1/8 success probability independent of qudit dimension, and a state-independent scheme reducing the non-local gate count from $\mathcal{O}(2^{r_1+r_2})$ to $\mathcal{O}(2^{r_1} + 2^{r_2})$.

Keywords: Linear Optical Quantum Computation, Qudit Circuit Compression, Multi-level Entangling Gates

1 Introduction and Motivation

Linear optical quantum computation (LOQC) is a promising platform for scalable quantum processing, but it is limited by the probabilistic nature and the high resource cost of non-local two-qubit entangling gates [1, 2, 3, 4, 5, 6]. Qudit based quantum circuit compression schemes address this by mapping multiple qubits onto higher-dimensional qudits to convert non-local gates into deterministic local ones. However, they suffer from a critical limitation. Specifically, when only a subset of qubits encoded onto the two qudits is required to participate in a non-local controlled or multi-controlled gate, the number of necessary entangling gates effectively doubles for each non-participating qubit [7, 8, 9]. This selectivity issue arises because multiple qubits are encoded into a single physical system. Consequently, any operation on that physical system inherently affects all the qubits encoded within it, making it impossible to isolate and address a single qubit separately. The standard workaround is to perform the operation on the desired qubits for all possible states of the non-participating qubits encoded onto the qudit. This leads to an exponential blowup in the number of required operations, scaling as $\mathcal{O}(2^r)$, where r is the number of qubits excluded from the operation. This inefficiency stems from the non-existence of multi-level entangling gates, which could address arbitrary levels of the system. Moreover, due to the non-existence of native gates compatible with the qudit architecture for photons encoded in path degree of freedom, the standard two-qubit gate architecture (like the Ralph's CZ gate) has been customized in recent literature to account for the path modes not participating in the gate [7] (as two-qubit gates only address one path mode across each qubit). Those modes must be paired with additional beam splitters and dump modes to deliberately discard a fraction of photons, which increases the complexity of the photonic circuit.

In this work, we resolve this bottleneck by demonstrating the existence of multi-level control-Z (CZ) gates for spatial-mode LOQC. Unlike conventional implementations, our multi-level CZ gates impart conditional phase flips across any pre-defined combination of spatial modes across the two qudits. We present two linear optical schemes to realize this:

- **State-Dependent Scheme:** Achieves the multi-level entanglement with a constant success probability of 1/8, though it requires a priori knowledge of the input states.
- **State-Independent Scheme:** Functions without a priori knowledge of the input states and reduces the number of non-local two-qubit gates required to achieve the multi-level entangling operation to $\mathcal{O}(2^{r_1} + 2^{r_2})$, an exponential improvement over the standard $\mathcal{O}(2^{r_1+r_2})$ scaling, where r_1 and r_2 represent the number of non-participating qubits across the first and second qudits, respectively.

These constructions are compatible with the qudit architecture, as shown for photons encoded in orbital angular momentum in [10]. Combined with circuit compression, these realizations significantly enhance LOQC scalability by exponentially reducing gate overhead for selective multi-control operations.

2 The Conceptual Framework: Multi-Level Entangling Gates

In this section, we introduce the concept of multi-level entangling gates, as shown in our work [11]. In standard qudit compression schemes, a non-local entangling operation behaves as a two-level CZ gate that triggers exclusively when both qudits occupy their highest computational basis states (i.e., $|d-1\rangle_1|d-1\rangle_2$). This rigidity is what forces the exponential decomposition when specific qubits are isolated from the operation.

Figure 1: Schematic description of the qudit compression scheme. (a) Encoding g qubits into 2^g spatial modes. (b) Conversion of a non-local CZ gate into a local gate. (c) Implementation of a CCCZ gate on the 4 qubits using one qubit architecture CZ (on purple path modes) and using the two-level CZ gate compatible with the qudit architecture (on red path modes). (d) A compressed circuit illustrating the operation required when two control qubits are removed following the standard scheme (on purple path modes) and multi-level CZ operation (on red path modes).

Our multi-level CZ gates circumvent this bottleneck by imparting a conditional phase flip across an arbitrary, pre-defined combination of spatial modes between the two qudits. Because multiple qubits share the same physical system, ignoring a non-participating qubit conventionally requires the system to sequentially account for every possible state of that ignored qubit. Our scheme bypasses this by defining specific sets of “trigger modes” that simultaneously encompass all permutations of the non-participating qubits’ states. This allows the multi-level entangling operation to trigger across multiple spatial modes in a fewer number of steps.

Let us define the set of indices corresponding to the trigger modes (which can be chosen arbitrarily but are in general always known a priori to the application of the gate) in the first and second qudit by $\mathcal{C}_1 = \{c_0, c_1, \dots, c_{k_1-1}\}$ and $\mathcal{C}_2 = \{t_0, t_1, \dots, t_{k_2-1}\}$ respectively, where $k_1, k_2 < d$ (the dimension of the input qudits) such that each pair of indices $(c_i, t_j) \in \mathcal{C}_1 \times \mathcal{C}_2$ identifies the states $|c_i\rangle_1$ and $|t_j\rangle_2$ as the trigger modes for the application of the quantum gate. The action of the multi-level entangling gate is then given by the unitary matrix

$$U_{\text{MCZ}} = \mathbb{1} - 2 \sum_{m \in \mathcal{C}_1} \sum_{n \in \mathcal{C}_2} |m\rangle \langle m|_1 \otimes |n\rangle \langle n|_2, \quad (1)$$

where its action on the set of states $\{|m\rangle_1 |n\rangle_2 \mid (m, n) \in \mathcal{C}_1 \times \mathcal{C}_2\}$ is to apply a phase flip, mapping each state to $-|m\rangle_1 |n\rangle_2$ respectively, while the set of states $\{|m\rangle_1 |n\rangle_2 \mid m \notin \mathcal{C}_1 \text{ or } n \notin \mathcal{C}_2 \text{ (or both)}\}$ remain unchanged.

3 Physical Realizations and Resource Trade-offs

We present two distinct linear optical realizations that highlight a fundamental trade-off between the prior information held about the input quantum state and the physical resource scaling required for implementation.

State-Dependent Realization: Our primary scheme achieves the multi-level entangling effect in a single non-local step. The architecture relies on pairing the input

Figure 2: Schematic of the state-dependent multi-level CZ operation. The SMRs execute a partial swap on defined trigger sets. Ancillary qudits are mapped to a 2D subspace via unitaries O_1 and O_2 , followed by a Bell State Measurement (BSM) and local unitaries U_1, U_2 .

qudits with ancillary qudits and feeding them into Selective Mode Routers (SMRs). Constructed via Mach-Zehnder interferometers, the SMRs execute a partial swap exclusively on the pre-defined trigger modes. This effectively flags the state of the input qudit without collapsing it.

Following the SMRs, unitary transformations map the ancillary systems onto a two-dimensional subspace, followed by a Bell State Measurement (BSM) and appropriate feedforward corrections. This realization operates with a constant success probability of $1/8$, achieving an improvement over the standard LOQC two-qubit entangling success rate of $1/9$. Crucially, this success rate is independent of the qudit dimension and the number of qubits involved. The required trade-off is that preparing the ancillary qudits demands *a priori* knowledge of the initial input states.

Selective Mode Router: The SMR is physically realized using a parallel array of standard Mach-Zehnder interferometers (MZIs). Given that the input qudit state (d -dimensional) is known a priori, the ancilla is prepared in a balanced superposition of the input state and an additional independent vacuum mode, resulting in a $(d+1)$ -dimensional ancilla space. Although practical implementations suffice for the preparation of the ancilla to be

Figure 3: Schematic of the state-independent multi-level CZ gate. It uses $k_1 + k_2$ instances of two-level CZ gates, followed by a BSM and local unitaries U_1, U_2 .

accomplished by the balanced superposition of the trigger modes and the additional vacuum mode, we present a generalized $(d + 1)$ -dimensional ancilla to maintain complete flexibility in trigger mode selection. Optically, the i -th mode of the input qudit and the corresponding i -th mode of the ancilla are fed into the i -th MZI. The routing logic is completely dictated by the internal phase shift, θ_i . To designate the k -th mode as a trigger, the corresponding phase is set to $\theta_k = \pi$, while all non-trigger modes are set to $\theta_{i \neq k} = 0$. This discrete phase tuning ensures that only the trigger modes undergo a spatial swap between the input and ancilla paths, while non-trigger modes undergo identity operations (transmission). The additional independent mode bypasses the MZI array entirely. Because this decomposition relies strictly on standard, tunable MZIs, the SMR is readily implementable on existing programmable integrated photonic architectures.

The success of the SMR operation is heralded by a single-photon coincidence at the output of the SMR, limiting its success probability to $1/2$. The presence of two SMRs and a $1/2$ success probability of Bell state measurement using linear optics limit the success probability of the state-dependent scheme to $1/8$.

State-Independent Realization: To construct a universal quantum gate applicable to arbitrary unknown input states, we introduce a secondary scheme. This approach eliminates the need for prior state knowledge by sequentially building the requisite input-ancilla entanglement using qubit (rather than qudit) ancillas.

Because we cannot rely on a single non-local step, this scheme cascades instances of two-level CZ gates. For a compressed circuit requiring the removal of r_1 and r_2 control qubits from two respective qudits, this realization scales the required number of non-local entangling gates to $\mathcal{O}(2^{r_1} + 2^{r_2})$. Although the success probability of the operation scales down to $\frac{1}{2}(\frac{1}{8})^{2^{r_1} + 2^{r_2}}$, the scaling of resources represents an exponential improvement over the existing architectural limit of $\mathcal{O}(2^{r_1 + r_2})$, effectively extending the computational reach of qudit architectures.

4 Algorithmic Application: Quantum Full Adder

To demonstrate the concrete algorithmic impact of our proposed realizations, we apply the multi-level CZ framework to an optical realization of a 4-qubit Quantum Full Adder (QFA) circuit.

In standard LOQC, the necessary Toffoli gates decompose into multiple CNOT gates, raising the total non-local gate count to nine. By mapping the three input qubits onto a single $d = 8$ qudit, circuit compression converts all but one of these into local gates. However, the remaining non-local gate must account for a non-participating qubit. Using standard compression techniques, this would force a decomposition into two probabilistic CNOT gates, resulting in a lower success probability of $(1/9)^2$.

By employing our state-dependent multi-level CZ gate, this same compressed QFA circuit can be executed using only a single non-local operation. This brings the success probability to $1/8$. This physically demonstrates how multi-level entangling gates directly unblock the scalability limits of LOQC architectures for standard arithmetic circuits.

5 Conclusion and Impact

The fundamental barrier to scaling linear optical quantum computation is the probabilistic overhead of multi-qubit entangling gates. While qudit circuit compression theoretically mitigates this, it introduces a severe selectivity bottleneck during multi-control operations that negates its advantages.

By demonstrating the physical viability of multi-level CZ gates, our work provides a direct optical mechanism to bypass this exponential blowup. Our state-dependent realization offers a highly efficient protocol with a constant $1/8$ success probability, directly applicable to near-term applications where the input state is known a priori, such as variational quantum algorithms. Furthermore, our universal state-independent scheme fundamentally alters the resource scaling landscape. We also reduce the non-local gate requirement from an exponential product $\mathcal{O}(2^{r_1 + r_2})$ down to an exponential sum $\mathcal{O}(2^{r_1} + 2^{r_2})$, with all the gates compatible with the qudit architecture.

Ultimately, this architectural shift ensures that the theoretical depth-reduction advantages of qudit circuit compression can be physically realized on integrated photonic hardware, bridging a critical gap between abstract quantum compilation and practical optical implementation. The full technical details, including the optical realization of the Selective Mode Routers, full state derivations, and success probability calculation, are detailed in our technical manuscript (arXiv:2602.08394v1).

Abstract. Quantum data hiding encodes a hidden classical bit to a pair of quantum states that is difficult to distinguish using a particular set of measurement, denoted as M . In this work, we explore quantum data hiding in two contexts involving Gaussian operations or states. First, we consider the set M as Gaussian local quantum operations and classical communication. We hide one classical bit in two different mixture of displaced two-mode squeezed states. Second, we consider the set M as general Gaussian measurement and construct the data hiding states using two-mode thermal states, which is effective in the weak strength limit.

Keywords: Quantum data hiding, Quantum protocol, Gaussian quantum information

1 Introduction

Quantum data hiding conceals classical bits against a specific set of POVMs M by encoding the bits into quantum states, ensuring that the probability of successfully distinguishing between these states is no better than random guessing when only POVMs from the set M are employed. Originally introduced for local operations and classical communication (LOCC) measurements [1, 2], quantum data hiding showed that one bit of classical information can be hidden from local observers, initially using entangled states and later using separable states at the cost of losing perfect orthogonality [3]. The idea was subsequently extended to quantum information, showing that qubits can also be hidden in bipartite states inaccessible under LOCC [4], and higher-rate schemes were later developed using collective random unitary operations [5].

Beyond cryptography, quantum data hiding has become an important tool in entanglement theory, particularly through its connection to bound entangled states with secure key [6, 7, 8], which also underlie the superactivation of quantum channels [9]. However, most existing studies focus on discrete-variable systems, while continuous-variable (CV) quantum data hiding remains much less developed [10, 11]. A systematic CV framework is therefore needed to explore related phenomena, including secure key distillation from bound entanglement, in CV settings. In this work, we focus on the CV version of quantum data hiding. CV quantum informa-

tion utilizes quantum states of systems characterized by continuous degrees of freedom, such as position and momentum of light fields [12, 13, 14, 15]. We will discuss two set of POVM: (1) Gaussian local quantum operations assisted by classical communication (GLOCC) (2) general Gaussian operations.

2 Data Hiding from GLOCC

In the quantum data hiding protocol considered in this work, a sender encodes classical information $\vec{r}$ into a bipartite quantum state $\rho_{\vec{r}}$ and distributes it to two spatially separated receivers, Alice and Bob. Alice and Bob perform measurements collaboratively in order to recover the classical information $\vec{r}$. The data-hiding property requires that the encoded information remain inaccessible when Alice and Bob are restricted to a prescribed set of operations, M . The protocol nevertheless allows Alice and Bob to reliably decode the encoded classical information when they are permitted to perform measurements outside the restricted set M .

The intuition behind data hiding against GLOCC is based on the incompatibility between measurements of the position quadrature $\hat{x}$ and the momentum quadrature $\hat{p}$. If the sender prepares states such that recovering the encoded information requires simultaneous access to both the $\hat{x}_1$ and $\hat{p}_1$ quadratures for Alice, as well as the $\hat{x}_2$ and $\hat{p}_2$ quadratures for Bob, then the classical information cannot be locally extracted when Alice and Bob are restricted to Gaussian local operations. In the following, we first analyze information extraction from displaced two-mode squeezed states using GLOCC measurements, and then use this insight to construct states that are secure against GLOCC.

*y697wang@uwaterloo.ca

†graeme.smith@uwaterloo.ca

This extended abstract is based on our recent work, arXiv:2502.00670.

Assume Alice and Bob share a displaced two-mode squeezed state as described by

$$\rho_{\vec{r}} = (D_{a+ib} \otimes D_{c+id}) |\phi\rangle \langle\phi| (D_{a+ib} \otimes D_{c+id})^\dagger, \quad (1)$$

where $\vec{r} = [a, b, c, d]^T$, $D_\alpha = \exp(\alpha \hat{a}_i^\dagger - \alpha^* \hat{a}_i)$ is the displacement operation, $\hat{a}_i$ represents the annihilation operator for the corresponding mode on Alice's or Bob's sides, $|\phi\rangle = \exp(s(\hat{a}_1 \hat{a}_2 - \hat{a}_1^\dagger \hat{a}_2^\dagger)/2) |0\rangle$ is the two mode squeezed state with squeezing parameter s . The parameters a, b, c, d are encoded on the quadratures of $\rho_{\vec{r}}$. Assume these parameters follow a prior distribution described by

$$P(\vec{r}) = \frac{1}{(2\pi)^2 \sqrt{\det V_r}} \exp\left[-\frac{1}{2} \vec{r}^T V_r^{-1} \vec{r}\right], \quad (2)$$

where $V_r = \sigma^2 I$. Alice and Bob want to measure $\rho_{\vec{r}}$ with the POVM $\{M_x\}_x$ to decode the parameters a, b, c, d . We can treat this problem as a communication model with input a, b, c, d and output x . In the following, we want to show that the mutual information for a proper nonlocal Gaussian measurement is greater than any GLOCC.

Any Gaussian measurement can be written as the form [13, 14], $\Pi_{\vec{y}} = \frac{1}{\pi^2} D_{\vec{y}} \Pi_0 D_{\vec{y}}^\dagger$, where Π_0 is a density matrix of a general Gaussian state with vanishing displacement and covariance matrix V_Π . Note that the label $\vec{y}$ of the outcome is only related to the displacement of $\Pi_{\vec{y}}$. We can easily find

$$P(\vec{y}|\vec{r}) = \frac{1}{(2\pi)^2 \sqrt{\det V}} \exp\left[-\frac{1}{2} (\vec{y} - \vec{r})^T V^{-1} (\vec{y} - \vec{r})\right], \quad (3)$$

where $V = V_\Pi + V_\rho$. And the mutual information is

$$I(\vec{y}; \vec{r}) = \frac{1}{2} \log(\det(I + \sigma^2 V^{-1})), \quad V = V_\Pi + V_\rho. \quad (4)$$

where the covariance matrix of $\rho_{\vec{r}}$ is given by

$$V_\rho = \begin{bmatrix} \cosh 2sI & \sinh 2sZ \\ \sinh 2sZ & \cosh 2sI \end{bmatrix}. \quad (5)$$

We now aim to optimize V_Π to maximize the mutual information $I(\vec{y}; \vec{r})$ in the case of nonlocal Gaussian measurement and GLOCC.

Proposition 1 *There exists a nonlocal Gaussian measurement with outcome labeled by $\vec{y}$ on the two-mode squeezed state $\rho_{\vec{r}}$ given in Eq. 1 encoded with the parameter $\vec{r}$ that can achieve the mutual information scaling $I(\vec{y}; \vec{r}) = 2s$ to the leading order as $s \rightarrow \infty$.*

The nonlocal Gaussian measurement can be constructed as follows. Intuitively, for the two-mode squeezed state considered here, as $s \rightarrow \infty$, the intrinsic noise of the state in the variables $q_1 - q_2$ and $p_1 + p_2$ approaches zero. Due to this property, we should only be able to estimate $a - c$ and $b + d$. These are the linear combinations that can be extracted from the two-mode squeezed state with perfect precision at an infinite squeezing level. This corresponds to estimating $q_1 - q_2$ and $p_1 + p_2$ which is a nonlocal measurement implemented with beam splitter and homodyne detection.

Theorem 2 *Any GLOCC measurement with outcome labeled by $\vec{y}$ on the two-mode squeezed state $\rho_{\vec{r}}$ given in Eq. 1 encoded with the parameter $\vec{r}$ cannot achieve the mutual information scaling $I(\vec{y}; \vec{r}) = 2s$ to the leading order as $s \rightarrow \infty$.*

Intuitively, for Gaussian states, nonlocal Gaussian measurements can simultaneously estimate both $q_1 - q_2$ and $p_1 + p_2$ with perfect precision. In contrast, GLOCC can only estimate either $q_1 - q_2$ or $p_1 + p_2$ (or any linear combination of them), due to the incompatibility of the two quadratures. Building on this intuition, we propose using the sign of $\alpha = (a - c)(b + d)$ to encode one bit of classical information. This leads to the following data-hiding protocol against GLOCC.

Theorem 3 *Consider the data hiding states,*

$$\rho_{\text{even}} = 2 \int_{\text{even}} d\vec{r} P(\vec{r}) \rho_{\vec{r}}, \quad \rho_{\text{odd}} = 2 \int_{\text{odd}} d\vec{r} P(\vec{r}) \rho_{\vec{r}}, \quad (6)$$

where prefactor 2 is introduced for normalization, $\vec{r} = [\vec{r}^1, \vec{r}^2, \dots, \vec{r}^N]^T$, $\vec{r}^i = [a_i, b_i, c_i, d_i]^T$, $\rho_{\vec{r}} = \otimes_{i=1}^N \rho_{\vec{r}^i}$, each $\rho_{\vec{r}^i}$ is given in Eq. 1, $\int_{\text{even, odd}}$ denotes the integral over all the $\vec{r}$ such that the count of $\alpha_i = (a_i - c_i)(b_i + d_i) > 0$ is an even or odd number. And we assume prior distribution $P(\vec{r})$ is again Gaussian similar to Eq. 2 with $V_r = \sigma^2 I_{4N}$. The one bit of classical information is encoded in whether the state is ρ_{even} or ρ_{odd} . The states $\rho_{\text{even, odd}}$ can be distinguished with near 100% success probability using nonlocal Gaussian measurements. In contrast, when restricted to GLOCC, the success probability for correctly distinguishing $\rho_{\text{even, odd}}$ is close to 1/2, equivalent to making a random guess.

Just as motivated above by the calculation of the mutual information $I(\vec{y}; \vec{r})$, the nonlocal Gaussian measurement still aims to estimate $q_1 - q_2$ and $p_1 + p_2$. This can be achieved using a beam splitter followed by homodyne detection, allowing us to

identify each α_i . In this way, we can easily count the number of positive α_i . Determining the sign of each α_i requires access to both $q_1 - q_2$ and $p_1 + p_2$, which cannot be estimated using GLOCC with the same precision. We use N states to amplify the performance gap between the nonlocal Gaussian measurement and GLOCC by forcing Alice and Bob to determine the sign of each α_i . As a result, this one bit of classical information is almost inaccessible to GLOCC.

3 Data hiding from general Gaussian operations

In this section, we consider data hiding from general Gaussian operations. We begin by considering a two-mode weak thermal state with zero displacement, described by the P representation [16]

$$\begin{aligned}\rho &= \int \frac{d^2\alpha d^2\beta}{\pi^2 \det \Gamma} \exp(-\vec{\gamma}^\dagger \Gamma^{-1} \vec{\gamma}) |\vec{\gamma}\rangle \langle \vec{\gamma}|, \\ \vec{\gamma} &= [\alpha, \beta]^T, \quad \Gamma = \frac{\epsilon}{2} \begin{bmatrix} 1 & |g|e^{i\theta} \\ |g|e^{-i\theta} & 1 \end{bmatrix}, \\ |\vec{\gamma}\rangle &= \exp(\alpha \hat{a}^\dagger - \alpha^* \hat{a}) \exp(\beta \hat{b}^\dagger - \beta^* \hat{b}) |0\rangle,\end{aligned}\quad (7)$$

where ϵ is the mean photon number per temporal mode and assumed to be much less than one $\epsilon \ll 1$, $\hat{a}, \hat{b}$ are the annihilation operators for the two modes. The intuition behind this choice is that Gaussian measurements are not well suited for distinguishing vacuum and single-photon states, which are intrinsically non-Gaussian [17]. To hide one bit of classical information, we choose $|g| = 1$ and $\theta = 0, \pi$ in Eq. 7 as the two states $\rho_\pm$.

Proposition 4 *Consider the pair of data hiding states $\rho_+^{\otimes N}, \rho_-^{\otimes N}$, which is used to encode one bit of classical information. There exists a non-Gaussian measurement that can distinguish $\rho_+^{\otimes N}, \rho_-^{\otimes N}$ with success probability close to 100% when $N = \Theta(1/\epsilon)$.*

In the limit $\epsilon \rightarrow 0$, the thermal states are dominated by the vacuum and single-photon terms in its Fock basis expansion. To achieve the above success probability, we use a non-Gaussian measurement: the projective measurement on each copy of the state $\rho_\pm$. The corresponding probabilities of obtaining each outcome are

$$\begin{aligned}|00\rangle \langle 00|, \quad P &= 1 - \epsilon, \\ |\pm\rangle \langle \pm|, \quad P &= \frac{\epsilon}{2}(1 \pm |g| \cos \theta),\end{aligned}\quad (8)$$

where $|\pm\rangle = (|01\rangle \pm |10\rangle)/\sqrt{2}$, and $|0\rangle$ and $|1\rangle$ are the vacuum and single-photon states, respectively. We

perform the same measurement on N copies of the same state $\rho^{\otimes N}$. We find that, to achieve a success probability close to one, we need $N = \Theta(1/\epsilon)$.

Theorem 5 *Consider the pair of data hiding states $\rho_+^{\otimes N}, \rho_-^{\otimes N}$, which is used to encode one bit of classical information. Any Gaussian measurement can distinguish $\rho_+^{\otimes N}, \rho_-^{\otimes N}$ with error probability $P_{err} \geq \frac{1}{2}(1 - \sqrt{2N\epsilon})$ for $N = o(\epsilon^{-2})$. When $N = \Theta(\epsilon^{-1})$ and $\epsilon \rightarrow 0$, any Gaussian measurement performs almost no better than random guessing.*

If we choose $\epsilon \rightarrow 0$ and $N = \Theta(1/\epsilon)$, the data hiding states $\rho_+^{\otimes N}$ and $\rho_-^{\otimes N}$ cannot be distinguished by Gaussian measurements but can be distinguished by the non-Gaussian measurement. We have thus constructed the data hiding states for general Gaussian operations.

Let's check this discussion with some specific examples. Firstly, let's consider the local heterodyne detection at each mode, which needs at least $N = \Omega(\epsilon^{-2})$ to have nearly 100% success probability for distinguishing $\rho_\pm^{\otimes N}$. Secondly, let's consider the case when we first combine the light from $\hat{a}, \hat{b}$ modes on a balanced beam splitter and do homodyne detection on the two output ports. Note that this measurement is already a nonlocal measurement. Intuitively, we are projecting onto displaced two mode squeezed states with infinite squeezing. And with such a nonlocal measurement, we still at least need $N = \Omega(1/\epsilon^2)$ to have nearly 100% success probability for distinguishing $\rho_\pm^{\otimes N}$ as claimed.

4 Conclusion

In this paper, we investigate two distinct scenarios of data hiding within the CV context. First, we introduce data hiding with respect to a new class of operations, GLOCC. To establish the intuition, we identify the CV counterpart to the challenge of distinguishing Bell entangled states using LOCC, which is a key insight underlying the initial data hiding proposal [1, 2]. Building on this intuition, we construct data-hiding states under GLOCC using the mixture of displaced two-mode squeezed states.

Second, we explore data hiding against general Gaussian operations. We propose a novel example of data-hiding states utilizing multiple copies of two-mode thermal states in the weak-strength limit. Notably, this construction is closely related to the interferometric imaging described in Ref. [18, 19], which may also suggest a broader advantage of non-Gaussian operations in imaging applications.

Quantum data hiding encodes a hidden classical bit to a pair of quantum states that is difficult to distinguish using a particular set of measurement, denoted as M . In this work, we explore quantum data hiding in two contexts involving Gaussian operations or states. First, we consider the set of measurement M as Gaussian local quantum operations and classical communication, a new set of operations not previously discussed in the literature for data hiding. We hide one classical bit in the two different mixture of displaced two-mode squeezed states. Second, we consider the set of measurement M as general Gaussian measurement and construct the data hiding states using two-mode thermal states. This data hiding scheme is effective in the weak strength limit, providing a new example compared to existing discussions for the set of general Gaussian measurement.

I. INTRODUCTION

Discriminating between quantum states or channels is a fundamental task in quantum information science [1–6]. The fundamental lower bound of success probability of distinguishing the states is known as Helstrom bound [7–10]. The optimal measurement used to saturate the Helstrom bound is chosen from all physically allowed positive operator valued measure (POVM), which can be hard to implement. A practically interesting problem is whether we can limit the available measurement to a set M and ask for the success probability using this set [11–17]. For example, in the multipartite setting, local quantum operations assisted by classical communication (LOCC) is an interesting set M [18].

Quantum data hiding conceals classical bits against a specific set of POVMs M by encoding the bits into quantum states, ensuring that the probability of successfully distinguishing between these states is no better than random guessing when only POVMs from the set M are employed. This phenomenon was initially identified in Ref. [19, 20] for the set of LOCC. This discovery allows for the secure hiding of one bit of classical information from any attempts to cheat using LOCC. Since then, the concept of quantum data hiding has been extended in various ways. For instance, hiding classical bits in multipartite settings is discussed in Ref. [21]. Protocols for hiding quantum data in both bipartite and multipartite cases are constructed [22–24]. Data hiding in the presence of noise is considered [25]. It is shown that using many copies of specific data hiding states does not provide a disproportionate advantage over using a single copy [26]. Additionally, distinguishability norms have been introduced to study different sets of POVMs [27].

In this work, we focus on the continuous variable (CV) version of quantum data hiding. Unlike discrete-variable quantum information, which primarily relies on qubits as

the fundamental units of information, CV quantum information adopts a continuous-variable approach. This framework utilizes quantum states of systems characterized by continuous degrees of freedom, such as position and momentum of light fields [28–31]. The primary tools in CV quantum information processing are Gaussian states and Gaussian operations. Gaussian states are characterized by their representation through Gaussian functions, making them mathematically convenient and experimentally accessible. Gaussian operations, in turn, are transformations that map Gaussian states to other Gaussian states. We will discuss two set of POVM: (1) Gaussian local quantum operations assisted by classical communication (GLOCC) (2) general Gaussian operations. We note there exists some discussion of data hiding from Gaussian operations [32, 33].

For the first setting, data hiding from GLOCC, Ref. [33] discusses a closely related result under different conditions. They examine data hiding using CV states from LOCC, which includes non-Gaussian LOCC in their considered set M . They allow both the state and measurement to be non-Gaussian, but lacks concrete examples. In contrast, we consider GLOCC as the set M and provide a concrete example of data hiding state which is a mixture of Gaussian states.

For the second setting, data hiding from general Gaussian measurements, Ref. [33] provides an example using single-mode CV data hiding states known as even and odd thermal states. However, it is important to note that the state considered in their work is neither Gaussian nor a mixture of Gaussian states. Additionally, Ref. [32] demonstrated the existence of two Gaussian states with infinitely many modes, each being a mixture of a finite set of randomly chosen coherent states. In both examples, the two states cannot be distinguished by Gaussian measurements, while general measurements can achieve a success probability close to one. Their constructions rely on quite nonclassical states or random mixtures of coherent states, whereas our approach is based on simple thermal states, providing an example of derandomized and concrete data hiding states. Furthermore, while their discussion is rooted in information-theoretic arguments,

* y697wang@uwaterloo.ca

† graeme.smith@uwaterloo.ca

our work specifies the exact measurements required for the data hiding scheme.

II. DATA HIDING FROM GLOCC

In the following sections, we will begin with an instructive discussion on the performance of information extraction using GLOCC measurements on displaced two-mode squeezed states. Using this understanding, we will then construct data hiding states that are secure against GLOCC.

A. GLOCC measurements perform less effectively in decoding information from two-mode squeezed states

In this subsection, we aim to build some intuition about when nonlocal Gaussian measurements can outperform GLOCC measurements in decoding information. Assume Alice and Bob share a displaced two-mode squeezed state as described by

$$\rho_{\vec{r}} = (D_{a+ib} \otimes D_{c+id}) |\phi\rangle \langle\phi| (D_{a+ib} \otimes D_{c+id})^\dagger, \quad (1)$$

where $\vec{r} = [a, b, c, d]^T$, $D_\alpha = \exp(\alpha \hat{a}_i^\dagger - \alpha^* \hat{a}_i)$ is the displacement operation, $\hat{a}_i$ represents the annihilation operator for the corresponding mode on Alice's or Bob's sides, $|\phi\rangle = \exp(s(\hat{a}_1 \hat{a}_2 - \hat{a}_1^\dagger \hat{a}_2^\dagger)/2) |0\rangle$ is the two mode squeezed state with squeezing parameter s . The parameters a, b, c, d are encoded on the quadratures of $\rho_{\vec{r}}$. Assume these parameters follow a prior distribution described by

$$P(\vec{r}) = \frac{1}{(2\pi)^2 \sqrt{\det V_r}} \exp\left[-\frac{1}{2} \vec{r}^T V_r^{-1} \vec{r}\right], \quad (2)$$

$$= \frac{1}{4\pi^2 \sigma^4} \exp\{-(a^2 + b^2 + c^2 + d^2)/2\sigma^2\}.$$

Alice and Bob want to measure $\rho_{\vec{r}}$ with the POVM $\{M_x\}_x$ to decode the parameters a, b, c, d . We can treat this problem as a communication model with input a, b, c, d and output x . In the following, we want to show that the mutual information for a proper nonlocal Gaussian measurement is much greater than any GLOCC.

Any Gaussian measurement can be written as the form [29, 30]

$$\Pi_{\vec{y}} = \frac{1}{\pi^2} D_{\vec{y}} \Pi_0 D_{\vec{y}}^\dagger, \quad (3)$$

where Π_0 is a density matrix of a general Gaussian state with vanishing displacement and covariance matrix V_Π . Note that the label $\vec{y}$ of the outcome is only related to the displacement of $\Pi_{\vec{y}}$. We now want to find the probability distribution $P(\vec{y}|\vec{r}) = \text{tr}(\Pi_{\vec{y}} \rho_{\vec{r}})$, where $\vec{r}$ is the

information we want to send. Note for two operators A, B whose Wigner function is $W_A(\vec{q}, \vec{p}), W_B(\vec{q}, \vec{p})$, we have $\text{tr}[AB] \propto \int d\vec{q} d\vec{p} W_A(\vec{q}, \vec{p}) W_B(\vec{q}, \vec{p})$ [34]. The Wigner function for $\Pi_{\vec{y}}$ and $\rho_{\vec{r}}$ is given by

$$W_\Pi(q_1, p_1, q_2, p_2) = \frac{1}{\pi^2} \frac{\exp[-\frac{1}{2}(\vec{x} - \vec{y})^T V_\Pi^{-1}(\vec{x} - \vec{y})]}{(2\pi)^2 \sqrt{\det V_\Pi}}, \quad (4)$$

$$W_\rho(q_1, p_1, q_2, p_2) = \frac{\exp[-\frac{1}{2}(\vec{x} - \vec{r})^T V_\rho^{-1}(\vec{x} - \vec{r})]}{(2\pi)^2 \sqrt{\det V_\rho}}, \quad (5)$$

where $\vec{x} = [q_1, p_1, q_2, p_2]^T$, $\vec{y} = [y_1, y_2, y_3, y_4]^T$, the covariance matrix of $\rho_{\vec{r}}$ is given by

$$V_\rho = \begin{bmatrix} \cosh 2sI & \sinh 2sZ \\ \sinh 2sZ & \cosh 2sI \end{bmatrix}. \quad (6)$$

Since the integral is simply a Gaussian integral, we can easily find

$$P(\vec{y}|\vec{r}) = \frac{1}{(2\pi)^2 \sqrt{\det V}} \exp\left[-\frac{1}{2}(\vec{y} - \vec{r})^T V^{-1}(\vec{y} - \vec{r})\right], \quad (7)$$

where $V = V_\Pi + V_\rho$. And the mutual information is

$$I(\vec{y}; \vec{r}) = \frac{1}{2} \log(\det(I + \sigma^2 V^{-1})), \quad V = V_\Pi + V_\rho. \quad (8)$$

We now aim to optimize V_Π to maximize the mutual information $I(\vec{y}; \vec{r})$ in the case of nonlocal Gaussian measurement and GLOCC.

Proposition 1. There exists a nonlocal Gaussian measurement with outcome labeled by $\vec{y}$ in Eq. 3 on the two-mode squeezed state $\rho_{\vec{r}}$ given in Eq. 1 encoded with the parameter $\vec{r}$ that can achieve the mutual information scaling $I(\vec{y}; \vec{r}) = 2s$ to the leading order as $s \rightarrow \infty$.

Proof. We note the eigenspectrum of V_ρ are,

$$\lambda_{\rho 1} = \lambda_{\rho 2} = e^{2s}, \quad \lambda_{\rho 3} = \lambda_{\rho 4} = e^{-2s},$$

$$\omega_{\rho 1} = \frac{1}{\sqrt{2}}[0, -1, 0, 1]^T, \quad \omega_{\rho 2} = \frac{1}{\sqrt{2}}[1, 0, 1, 0]^T, \quad (9)$$

$$\omega_{\rho 3} = \frac{1}{\sqrt{2}}[0, 1, 0, 1]^T, \quad \omega_{\rho 4} = \frac{1}{\sqrt{2}}[-1, 0, 1, 0]^T.$$

Intuitively, the homodyne detection and beam splitter can estimate linear combinations of all the quadratures $q_1 = a + dq_1$, $p_1 = b + dp_1$, $q_2 = c + dq_2$, $p_2 = d + dp_2$, where a, b, c, d are the displacement, $dq_{1,2}, dp_{1,2}$ are the intrinsic noise depending on the quantum state. We emphasize that while homodyne detection enables perfect precision in estimating certain quadratures, this precision only implies that no additional noise is introduced by the measurement itself; the intrinsic noise inherent to the quantum state still persists. For the two mode squeezed state considered here, if $r \rightarrow \infty$, we know $dq_1 - dq_2$ and $dp_1 + dp_2$ are approaching zero. But for

example, if we just focus on dq_1 , it is totally random. Due to this property, we should only be able to estimate $a - c + dq_1 - dq_2 \rightarrow a - c$ and $b + d + dp_1 + dp_2 \rightarrow b + d$. These are the linear combinations that can be extracted from the two-mode squeezed state with perfect precision at an infinite squeezing level. This corresponds to estimating $q_1 - q_2$ and $p_1 + p_2$ which is a nonlocal measurement implemented with beam splitter and homodyne detection. The corresponding V_Π in the eigenbasis $\{\omega_{\rho i}\}_{i=1,2,3,4}$ of V_ρ is simply

$$V_\Pi = \lim_{\delta \rightarrow 0} \left[\frac{1}{\delta} (\omega_{\rho 1} \omega_{\rho 1}^T + \omega_{\rho 2} \omega_{\rho 2}^T) + \delta (\omega_{\rho 3} \omega_{\rho 3}^T + \omega_{\rho 4} \omega_{\rho 4}^T) \right]. \quad (10)$$

We can find that for this V_Π ,

$$\det(I + \sigma^2 V^{-1}) \propto e^{4s}, \quad I(\vec{y}; \vec{r}) = 2s + o(s), \quad (11)$$

to the leading order as $s \rightarrow \infty$ and $e^{-2s} \gg \delta$. $\square$

Theorem 1. Any GLOCC measurement with outcome labeled by $\vec{y}$ in Eq. 3 on the two-mode squeezed state $\rho_{\vec{r}}$ given in Eq. 1 encoded with the parameter $\vec{r}$ cannot achieve the mutual information scaling $I(\vec{y}; \vec{r}) = 2s$ to the leading order as $s \rightarrow \infty$.

Proof. We will prove any GLOCC cannot achieve $I(\vec{y}; \vec{r}) = 2s$ to the leading order as $s \rightarrow \infty$ by contradiction. Firstly, we want to prove that to have $I(\vec{y}; \vec{r}) = 2s + o(s)$, or $\det(I + \sigma^2 V^{-1}) \propto e^{4s}$, V_Π has exactly two eigenvalues approach zero ($\ll e^{-2s}$). Because if V_Π has less than two eigenvalues approach zero, based on Weyl's inequality for $n \times n$ matrices A, B [35]

$$\lambda_{i+j-1}(A+B) \leq \lambda_i(A) + \lambda_j(B) \leq \lambda_{i+j-n}(A+B), \quad (12)$$

where $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$. We have

$$\begin{aligned} \lambda_3(V_\Pi + V_\rho) &\geq \lambda_3(V_\Pi) + \lambda_4(V_\rho) \geq \lambda_3(V_\Pi) \sim O(e^{0r}), \\ \lambda_4(V_\Pi + V_\rho) &\geq \lambda_4(V_\Pi) + \lambda_4(V_\rho) \geq \lambda_4(V_\rho) \sim O(e^{-2s}). \end{aligned} \quad (13)$$

Then, $V = V_\Pi + V_\rho$ only has one small eigenvalues scaling as e^{-2s} , which shows $\det(I + \sigma^2 V^{-1})$ at most scales as e^{2s} . Furthermore, V_Π cannot have more than two eigenvalues approaching zero. Because for any real symmetric matrix V_Π , the requirement for it to be the covariance matrix is given by [29]

$$V_\Pi > 0, \quad V_\Pi + i\Omega \geq 0, \quad \Omega = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -1 & 0 \end{bmatrix}. \quad (14)$$

If $\lambda_{2,3,4}(V_\Pi) \rightarrow 0$, and we know the eigenvalues of $i\Omega$ are 1,1,-1,-1. We can find that

$$\lambda_4(V_\Pi + i\Omega) \leq \lambda_2(V_\Pi) + \lambda_3(i\Omega) \sim 0 - 1 < 0, \quad (15)$$

which violates the requirement that $V_\Pi + i\Omega \geq 0$. This actually shows that $\lambda_{1,2}(V_\Pi) \geq 1$.

Secondly, we aim to demonstrate that the eigenvectors of V_Π must correspond to the eigenvectors of V_ρ , as specified below. If the eigenvector ω_V of $V = V_\Pi + V_\rho$ has the corresponding eigenvalue $\lambda_V \rightarrow 0$, i.e. ω_V is one of $\omega_{V,3,4}$

$$V\omega_V = \lambda_V\omega_V. \quad (16)$$

We can multiply ω_V^T from the left on the both side of the equation, which gives

$$\omega_V^T V \omega_V = \lambda_V \rightarrow 0. \quad (17)$$

If we write the spectrum decomposition $V_\Pi = \sum_{i=1,2,3,4} \lambda_{\Pi i} \omega_{\Pi i} \omega_{\Pi i}^T$, $V_\rho = \sum_{i=1,2,3,4} \lambda_{\rho i} \omega_{\rho i} \omega_{\rho i}^T$, then we can find that

$$\begin{aligned} e^{-2s} [(\omega_V^T \omega_{\rho 3})^2 + (\omega_V^T \omega_{\rho 4})^2] + e^{2s} [(\omega_V^T \omega_{\rho 1})^2 \\ + (\omega_V^T \omega_{\rho 2})^2] + \sum_i \lambda_{\Pi i} (\omega_V^T \omega_{\Pi i})^2 = \lambda_V \rightarrow 0. \end{aligned} \quad (18)$$

Then, it is clear that $\omega_V^T \omega_{\Pi 1,2} \rightarrow 0$, $\omega_V^T \omega_{\rho 1,2} \rightarrow 0$. We must have $\omega_{\Pi 3,4}, \omega_{V 3,4}$ in the span $\{\omega_{\rho 3}, \omega_{\rho 4}\}$, $\omega_{\Pi 1,2}, \omega_{V 1,2}$ in the span $\{\omega_{\rho 1}, \omega_{\rho 2}\}$.

Finally, based on the observed requirements for V_Π to achieve $\det(I + \sigma^2 V^{-1}) \propto e^{4s}$ —namely, $\lambda_{V 3,4} \rightarrow 0$, with $\omega_{\Pi 3,4}$ confined to the span $\{\omega_{\rho 3}, \omega_{\rho 4}\}$ and $\omega_{\Pi 1,2}$ confined to the span $\{\omega_{\rho 1}, \omega_{\rho 2}\}$ —we are now prepared to demonstrate that V_Π cannot be GLOCC. This can be easily verified because if

$$\begin{aligned} V_\Pi &= \sum_{i=1,2,3,4} \lambda_{\Pi i} \omega_{\Pi i} \omega_{\Pi i}^\dagger, \quad \lambda_{\Pi 1,2} \geq 1, \quad \lambda_{\Pi 3,4} \ll 1, \\ \omega_{\Pi 1} &= x_1 \omega_{\rho 1} + \sqrt{1 - x_1^2} \omega_{\rho 2}, \quad \omega_{\Pi 2} = \sqrt{1 - x_1^2} \omega_{\rho 1} - x_1 \omega_{\rho 2}, \\ \omega_{\Pi 3} &= x_3 \omega_{\rho 3} + \sqrt{1 - x_3^2} \omega_{\rho 4}, \quad \omega_{\Pi 4} = \sqrt{1 - x_3^2} \omega_{\rho 3} - x_3 \omega_{\rho 4}, \end{aligned} \quad (19)$$

where $\omega_{\rho i}$ are the eigenvector of V_ρ given in Eq. 9, $|x_{1,3}| \leq 1$. V_Π follows the Positive Partial Transpose (PPT) criterion iff $TV_\Pi T + i\Omega \geq 0$ [29], where

$$T = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}, \quad (20)$$

and $TV_\Pi T$ corresponds to partial transpose. We can find one of eigenvalues of $TV_\Pi T + i\Omega$ is

$$\frac{1}{2} \left(\lambda_{\Pi 3} + \lambda_{\Pi 4} - \sqrt{4 + (\lambda_{\Pi 3} - \lambda_{\Pi 4})^2} \right). \quad (21)$$

It is clear that when $\lambda_{\Pi 3,4} \ll 1$, this eigenvalue is smaller than 0, which implies V_Π cannot be a GLOCC measurement. We have thus showed that GLOCC measurements can only have mutual information worse than $2s$. $\square$

Although the analytical proof shows that GLOCC cannot achieve $I(\vec{y}; \vec{r}) = 2s$, we are unable to analytically determine a tight upper bound for $I(\vec{y}; \vec{r})$ using GLOCC.

FIG. 1. The mutual information $I(\vec{y}; \vec{r})$ is presented as a function of the squeezing parameter s for both GLOCC and nonlocal Gaussian measurements. For GLOCC, $I(\vec{y}; \vec{r})$ is obtained through numerical optimization. In the case of nonlocal Gaussian measurements, $I(\vec{y}; \vec{r})$ is calculated based on the measurements of $q_1 - q_2$ and $p_1 + p_2$, as introduced in Proposition 1. The solid line represents the fitting function $I(\vec{y}; \vec{r}) = r$. Here, the parameter σ is set to 1.

We now aim to numerically optimize the GLOCC measurement to determine the optimal mutual information $I(\vec{y}; \vec{r})$. As illustrated in Fig. 1, for small squeezing parameters $s \ll 1$, optimal $I(\vec{y}; \vec{r})$ using GLOCC remains nearly constant. This behavior is expected, as in the absence of squeezing, the measurement effectively reduces to estimating the displacement of a coherent state. However, as the squeezing parameter s increases, the optimal mutual information $I(\vec{y}; \vec{r}) \approx s$ under GLOCC measurements. This numerical result aligns with and confirms the analytical findings in Theorem 1, demonstrating the limitations of GLOCC. For nonlocal Gaussian measurement, $I(\vec{y}; \vec{r}) \approx 2s$ as stated in Proposition 1.

The above results serve as the CV counterpart to the fact that in the discrete-variable case, LOCC cannot fully distinguish the four Bell states. Local projection onto $|0\rangle, |1\rangle$ can only distinguish the states $|00\rangle \pm |11\rangle$ or $|01\rangle \pm |10\rangle$. Similarly, local projection onto $|+\rangle, |-\rangle$ can distinguish either $|00\rangle + |11\rangle$ and $|01\rangle + |10\rangle$, or $|11\rangle - |00\rangle$ and $|01\rangle - |10\rangle$. For Gaussian states, nonlocal Gaussian measurements can simultaneously estimate both $q_1 - q_2$ and $p_1 + p_2$ with perfect precision. In contrast, GLOCC can only estimate either $q_1 - q_2$, or $p_1 + p_2$, (or any linear combination of them), by relying on local homodyne detection. This intuition also leads to a no-go theorem:

Theorem 2. If we want to estimate any single linear combination $t_1(a - c) + t_2(b + d)$ in Eq. 1, the performance of nonlocal Gaussian measurements and GLOCC measurements labeled by $\vec{y}$ as in Eq. 3 will be comparable in the sense that the mutual information for both cases are $I(\vec{y}; \vec{r}) = s$ to the leading order as $s \rightarrow \infty$.

Proof. Intuitively, this is because a local homodyne with an appropriate phase shift can estimate any linear combination $k_1a + k_2b$ and $k_3c + k_4d$, enabling us to find

$t_1(a - c) + t_2(b + d)$. To support this intuition, we can choose

$$P(\vec{r}) = \frac{1}{(2\pi)^2 \sqrt{\det V_r}} \exp\left[-\frac{1}{2} \vec{r}^T V_r^{-1} \vec{r}\right],$$

$$V_r = \sigma^2 \omega_1 \omega_1^T + \frac{1}{\delta^2} \sum_{i=2}^4 \omega_i \omega_i^T, \quad \delta \rightarrow 0, \quad (22)$$

$$\omega_1 = [t_1, t_2, -t_1, t_2]^T, \quad \omega_2 = [t_1, t_2, t_1, -t_2]^T,$$

$$\omega_3 = [-t_2, t_1, t_2, t_1]^T, \quad \omega_4 = [-t_2, t_1, -t_2, -t_1]^T,$$

where, without loss of generality, we choose $t_1^2 + t_2^2 = 1/2$ for normalization. We fix all other relationships between a, b, c, d by setting $\delta \rightarrow 0$, ensuring that all the information is encoded in the linear combination $t_1(a - c) + t_2(b + d)$. We find

$$I(\vec{y}; \vec{r}) = \frac{1}{2} \log(\det(I + \sigma^2 M V^{-1})),$$

$$V = V_\Pi + V_\rho, \quad M = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad (23)$$

where we write the matrix in the basis $\{w_i\}_{i=1,2,3,4}$ in Eq. 22. It is easy to verify that we can choose V_Π for both both GLOCC measurements and nonlocal measurement such that we have

$$V = \begin{bmatrix} e^{-2s} & 0 & 0 & 0 \\ 0 & * & 0 & 0 \\ 0 & 0 & * & 0 \\ 0 & 0 & 0 & * \end{bmatrix}, \quad (24)$$

in the basis $\{w_i\}_{i=1,2,3,4}$ in Eq. 22. For GLOCC measurement, we choose to estimate $t_1 q_1 + t_2 p_1$ and $-t_1 q_2 + t_2 p_2$. For nonlocal measurement, we can directly estimate both $q_1 - q_2$ and $p_1 + p_2$ using homodyne detection. So, both GLOCC measurements and nonlocal measurement have $I(\vec{y}; \vec{r}) = s + o(s)$. $\square$

B. Data hiding

Building on the intuition from the previous subsection, we aim to construct a data hiding scheme. GLOCC cannot simultaneously obtain $a - c$ and $b + d$ with high precision, whereas a nonlocal measurement can achieve precise estimation of both parameters. We propose to use the sign of $\alpha = (a - c)(b + d)$ to encode one bit of classical information.

Proposition 2. Consider the pair of data hiding states

$$\rho_+ = 2 \int_{\alpha > 0} d\vec{r} P(\vec{r}) \rho_{\vec{r}}, \quad \rho_- = 2 \int_{\alpha < 0} d\vec{r} P(\vec{r}) \rho_{\vec{r}}, \quad (25)$$

where the prefactor 2 is introduced for normalization, $\alpha = (a - c)(b + d)$, $\rho_{\vec{r}}$ is given in Eq. 1, $P(\vec{r})$ is given in

Eq. 2. The sign of α is used to encoded one bit of classical information. The sign of α can be determined using nonlocal Gaussian measurements, with the success probability approaching 100%. However, using only GLOCC measurements, the probability of correctly determining the sign of α will sufficiently deviate from 100%.

Proof. For two probability distribution $P_0(y)$ and $P_1(y)$ and outcome $\vec{y}$, the error probability of distinguishing the two distribution is given by [36, 37]

$$P_{\text{err}} = \frac{1}{2}(1 - TV),$$

$$TV = \frac{1}{2}||P_0 - P_1|| = \frac{1}{2} \sum_y |P_0(y) - P_1(y)|. \quad (26)$$

where TV is total variation distance between two probability distribution. Our aim is to maximize the total variation TV by designing the POVM $\{\Pi_{\vec{y}}\}_{\vec{y}}$. The total variation between two probability distributions $P(\vec{y}|\pm) = \text{tr}(\Pi_{\vec{y}}\rho_{\pm})$

$$TV = \frac{1}{2} \int d\vec{y} |P(\vec{y}|+) - P(\vec{y}|-)|$$

$$= \int d\vec{y} \left| \int_{\alpha>0} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) - \int_{\alpha<0} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) \right|$$

$$= \int_{\beta>0} d\vec{y} \left(\int_{\alpha>0} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) - \int_{\alpha<0} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) \right)$$

$$+ \int_{\beta<0} d\vec{y} \left(\int_{\alpha<0} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) - \int_{\alpha>0} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) \right)$$

$$= TV(++) - TV(-+) + TV(--), \quad (27)$$

where we assume $\beta = (y_1 - y_3)(y_2 + y_4)$, $TV(\pm\pm) = TV(\alpha = \pm, \beta = \pm)$ represents the four different integrals.

To do the above calculation, let's define $\vec{Y}$ and $\vec{R}$

$$U = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & -1 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 1 & 0 & 1 \end{bmatrix}, \quad (28)$$

$$\vec{Y} = U\vec{y}, \quad \vec{R} = U\vec{r}, \quad \Sigma = UVU^T.$$

And the integral can be written as

$$TV(++) = \left(\int_0^\infty dR_1 \int_0^\infty dR_4 + \int_{-\infty}^0 dR_1 \int_{-\infty}^0 dR_4 \right)$$

$$\times \left(\int_0^\infty dY_1 \int_0^\infty dY_4 + \int_{-\infty}^0 dY_1 \int_{-\infty}^0 dY_4 \right)$$

$$\times \int_{-\infty}^{+\infty} dR_2 \int_{-\infty}^{+\infty} dR_3 \int_{-\infty}^{+\infty} dY_2 \int_{-\infty}^{+\infty} dY_3 P(\vec{y}|\vec{r}) P(\vec{r}). \quad (29)$$

We further define $\vec{P} = \vec{Y} + \vec{R}$, $\vec{Q} = \vec{Y} - \vec{R}$, and have $P(\vec{y}|\vec{r}) = \exp\left[-\frac{1}{2}\vec{Q}^T \Sigma^{-1} \vec{Q}\right] / [(2\pi)^2 \sqrt{\det \Sigma}]$, $P(\vec{r}) = \exp\left[-\frac{1}{8}(\vec{Q} - \vec{P})^T V_r^{-1} (\vec{Q} - \vec{P})\right] / [(2\pi)^2 \sqrt{\det V_r}]$.

Through the procedure of changing variables and changing the order the integration, we do the integration for $\vec{P}$ first since we have a simple assumption that $V_r = \sigma^2 I$, which gives

$$TV(++) = \frac{1}{4} \int_{-\infty}^{+\infty} dQ_1 \int_{-\infty}^{+\infty} dQ_2 \int_{-\infty}^{+\infty} dQ_3 \int_{-\infty}^{+\infty} dQ_4$$

$$\times P(\vec{y}|\vec{r}) \left(2 - \text{erf}\left(\frac{|Q_1|}{\sqrt{2}\sigma}\right) - \text{erf}\left(\frac{|Q_4|}{\sqrt{2}\sigma}\right) \right)$$

$$+ \frac{1}{2} \left(\int_0^{+\infty} dQ_1 \int_0^{+\infty} dQ_4 + \int_{-\infty}^0 dQ_1 \int_{-\infty}^0 dQ_4 \right)$$

$$\times \int_{-\infty}^{+\infty} dQ_2 \int_{-\infty}^{+\infty} dQ_3 P(\vec{y}|\vec{r}) \text{erf}\left(\frac{|Q_1|}{\sqrt{2}\sigma}\right) \text{erf}\left(\frac{|Q_4|}{\sqrt{2}\sigma}\right). \quad (30)$$

Similarly, we can find $TV(+-), TV(--), TV(-+)$ and eventually get

$$TV = \int_{-\infty}^{+\infty} dQ_1 \int_{-\infty}^{+\infty} dQ_2 \int_{-\infty}^{+\infty} dQ_3 \int_{-\infty}^{+\infty} dQ_4$$

$$\times P(\vec{y}|\vec{r}) \left(1 - \text{erf}\left(\frac{|Q_1|}{\sqrt{2}\sigma}\right) \right) \left(1 - \text{erf}\left(\frac{|Q_4|}{\sqrt{2}\sigma}\right) \right). \quad (31)$$

To get larger TV , we hope $|Q_{1,4}|$ to be distributed around 0 following the distribution $P(\vec{y}|\vec{r})$, which requires at least two eigenvalues of $\Sigma = U(V_\rho + V_\Pi)U^T$ to approach zero. Note that

$$UV_\rho U^T = \begin{bmatrix} e^{-2s} & 0 & 0 & 0 \\ 0 & e^{2s} & 0 & 0 \\ 0 & 0 & e^{2s} & 0 \\ 0 & 0 & 0 & e^{-2s} \end{bmatrix}. \quad (32)$$

Following the argument in the proof of Theorem 1, GLOCC cannot have V_Π such that at least two eigenvalues of Σ approach zero, TV of GLOCC is constant with sufficient deviation from 1. But for nonlocal measurement it is possible to achieve $TV \rightarrow 1$ using the measurement constructed in Eq. 10. $\square$

Although the analytical proof shows that GLOCC cannot achieve $TV \rightarrow 1$, we are unable to analytically determine a tight upper bound for TV using GLOCC. We now numerically optimize the GLOCC measurement to determine the optimal total variation TV . As shown in Fig. 2, as the squeezing parameter s increases, the TV for the nonlocal Gaussian measurement approaches 1, whereas the TV for the GLOCC measurement remains significantly below 1 as claimed in Proposition 2.

So far, we have demonstrated the gap in error probability when inferring the single bit of classical information encoded in the sign of α using GLOCC and nonlocal Gaussian measurement. Similar to the approach of Ref. [19], we aim to further reduce the success probability of obtaining this bit of information using GLOCC to nearly 1/2, equivalent to a random guess. This can be accomplished by sending states with more modes to amplify the difference between the success probability.

FIG. 2. The total variation distance TV is presented as a function of the squeezing parameter s for both GLOCC and nonlocal Gaussian measurements. For GLOCC, TV is obtained through numerical optimization. In the case of nonlocal Gaussian measurements, TV is calculated based on the measurements of $q_1 - q_2$ and $p_1 + p_2$, as introduced in Proposition 1. Here, the parameter σ is set to 1.

Theorem 3. Consider the data hiding states,

$$\rho_{\text{even}} = 2 \int_{\text{even}} d\vec{r} P(\vec{r}) \rho_{\vec{r}}, \quad \rho_{\text{odd}} = 2 \int_{\text{odd}} d\vec{r} P(\vec{r}) \rho_{\vec{r}}, \quad (33)$$

where prefactor 2 is introduced for normalization, $\vec{r} = [\vec{r}^1, \vec{r}^2, \dots, \vec{r}^N]^T$, $\vec{r}^i = [a_i, b_i, c_i, d_i]^T$, $\rho_{\vec{r}} = \otimes_{i=1}^N \rho_{\vec{r}^i}$, each $\rho_{\vec{r}^i}$ is given in Eq. 1, $\int_{\text{even,odd}}$ denotes the integral over all the $\vec{r}$ such that the count of $\alpha_i = (a_i - c_i)(b_i + d_i) > 0$ is an even or odd number. And we assume prior distribution $P(\vec{r})$ is again Gaussian similar to Eq. 2 with $V_r = \sigma^2 I_{4N}$. The one bit of classical information is encoded in whether the state is ρ_{even} or ρ_{odd} . The states $\rho_{\text{even,odd}}$ can be distinguished with near 100% success probability using nonlocal Gaussian measurements. In contrast, when restricted to GLOCC, the success probability for correctly distinguishing $\rho_{\text{even,odd}}$ is close to 1/2, equivalent to making a random guess.

Proof. The covariance matrix of the state $\rho_{\vec{r}}$ is

$$V_{\rho}^N = \bigoplus_{i=1}^N V_{\rho}, \quad (34)$$

where V_{ρ} is given in Eq. 6. And the total variation be-

tween $P(\vec{r}|\text{even,odd}) = \text{tr}(\rho_{\text{even,odd}} \Pi_{\vec{r}})$ is given by

$$\begin{aligned} TV^N &= \frac{1}{2} \int d\vec{y} |P(\vec{r}|\text{even}) - P(\vec{r}|\text{odd})| \\ &= \int d\vec{y} \left| \int_{\text{even}} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) - \int_{\text{odd}} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) \right| \\ &= \int_{\text{even}} d\vec{y} \left(\int_{\text{even}} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) - \int_{\text{odd}} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) \right) \\ &\quad + \int_{\text{odd}} d\vec{y} \left(\int_{\text{odd}} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) - \int_{\text{even}} d\vec{r} P(\vec{y}|\vec{r}) P(\vec{r}) \right) \\ &= TV^N(e, e) - TV^N(o, e) + TV^N(o, o) - TV^N(e, o), \end{aligned} \quad (35)$$

where $\vec{y} = [\vec{y}^1, \vec{y}^2, \dots, \vec{y}^N]^T$, $\vec{y}^i = [y_1^i, y_2^i, y_3^i, y_4^i]^T$, the even or odd labeled for the integral interval means the number of $\alpha_i = (a_i - c_i)(b_i + d_i)$ or $\beta_i = (y_1^i - y_3^i)(y_2^i + y_4^i)$ is even or odd. $TV(e, e)$ represents the count of $\alpha_i > 0$ or $\beta_i > 0$ is an even number, with similar definitions for $TV(e, o)$, $TV(o, e)$, and $TV(o, o)$. We again change variables and switch the order of integral in a similar fashion, which allows us to simplify the equations as

$$\begin{aligned} TV^N(e, e) &= \sum_{\substack{\# \alpha_i > 0 \text{ even} \\ \# \beta_i > 0 \text{ even}}} \left(\prod_{i=1}^N \int_{\beta_i} d\vec{y}^i \int_{\alpha_i} d\vec{r}^i P(\vec{r}^i) \right) P(\vec{y}|\vec{r}) \\ &= \sum_{\substack{\# \alpha_i > 0 \text{ even} \\ \# \beta_i > 0 \text{ even}}} \prod_{i=1}^N \hat{f}(\alpha_i, \beta_i) P(\vec{y}|\vec{r}). \end{aligned} \quad (36)$$

where $\sum_{\# \alpha_i > 0 \text{ even}}$ denotes a summation over all cases where the count of $\alpha_i > 0$ is an even number. We emphasize that $\hat{f}(\alpha_i, \beta_i)$ is not a function as it includes an integral involving $P(\vec{y}|\vec{r})$.

$$\begin{aligned} TV^N(e, e) - TV^N(e, o) &= \left(\sum_{\substack{\# \alpha_i > 0 \text{ even} \\ \# \beta_i > 0 \text{ even}}} - \sum_{\substack{\# \alpha_i > 0 \text{ odd} \\ \# \beta_i > 0 \text{ even}}} \right) \left(\prod_{i=1}^N \hat{f}(\alpha_i, \beta_i) \right) P(\vec{y}|\vec{r}) \\ &= \sum_{\# \beta_i > 0 \text{ even}} \prod_{i=1}^N \left(-\hat{f}(\alpha_i > 0, \beta_i) + \hat{f}(\alpha_i < 0, \beta_i) \right) P(\vec{y}|\vec{r}), \end{aligned} \quad (37)$$

$$\begin{aligned} TV^N(o, o) - TV^N(o, e) &= \left(\sum_{\substack{\# \alpha_i > 0 \text{ odd} \\ \# \beta_i > 0 \text{ odd}}} - \sum_{\substack{\# \alpha_i > 0 \text{ even} \\ \# \beta_i > 0 \text{ odd}}} \right) \left(\prod_{i=1}^N \hat{f}(\alpha_i, \beta_i) \right) P(\vec{y}|\vec{r}) \\ &= - \sum_{\# \beta_i > 0 \text{ odd}} \prod_{i=1}^N \left(-\hat{f}(\alpha_i > 0, \beta_i) + \hat{f}(\alpha_i < 0, \beta_i) \right) P(\vec{y}|\vec{r}), \end{aligned} \quad (38)$$

$$\begin{aligned}
TV^N &= \prod_{i=1}^N \left[\hat{f}(\alpha_i > 0, \beta_i > 0) - \hat{f}(\alpha_i > 0, \beta_i < 0) \right. \\
&\quad \left. - \hat{f}(\alpha_i < 0, \beta_i > 0) + \hat{f}(\alpha_i < 0, \beta_i < 0) \right] P(\vec{y}|\vec{r}) \\
&= \prod_{i=1}^N \left[\int_{-\infty}^{+\infty} dQ_1^i \int_{-\infty}^{+\infty} dQ_2^i \int_{-\infty}^{+\infty} dQ_3^i \int_{-\infty}^{+\infty} dQ_4^i \right. \\
&\quad \left. \times \left[1 - \operatorname{erf} \left(\frac{|Q_1^i|}{\sqrt{2}\sigma} \right) \right] \left[1 - \operatorname{erf} \left(\frac{|Q_4^i|}{\sqrt{2}\sigma} \right) \right] \right] P(\vec{y}|\vec{r}). \tag{39}
\end{aligned}$$

For each i , we need two eigenvalues approaching zero to have $TV^N \rightarrow 1$, which cannot be achieved using GLOCC. Because for any of the i th mode, if we have $|Q_{1,4}^i| \rightarrow 0$, this requires both $\omega_{\rho 3}^i = [0, \dots, 0, \omega_{\rho 3}, 0, \dots, 0]$ and $\omega_{\rho 4}^i = [0, \dots, 0, \omega_{\rho 4}, 0, \dots, 0]$ to be eigenvectors of $V^N = V_{\rho}^N + V_{\Pi}^N$ with eigenvalues approaching zero, where $\omega_{\rho 3,4}$ is given in Eq. 9. Since $\omega_{\rho 3,4}$ are already the eigenvectors of V_{ρ}^N with eigenvalues e^{-2s} , this means $\omega_{\rho 3,4}$ must also be the eigenvectors of V_{Π}^N with vanishing eigenvalues. We now want to check whether $T_N V_{\Pi}^N T_N + i\Omega_N \geq 0$, where $\Omega_N = \bigoplus_{i=1}^N \Omega$, $T_N = \bigoplus_{i=1}^N T$. Since $\omega_{\rho 3,4}^i$ are eigenvectors of V_{Π}^N with vanishing eigenvalues, $T_N \omega_{\rho 3,4}^i$ are eigenvectors of $T_N V_{\Pi}^N T_N$ with vanishing eigenvalues. Note that $T_N \omega_{\rho 3}^i + iT_N \omega_{\rho 4}^i$ is an eigenvector of $i\Omega_N$ with eigenvalues -1 . This means $T_N V_{\Pi}^N T_N + i\Omega_N$ is not positive-semidefinite and hence the measurement is not PPT. For each i , TV^N of GLOCC will get a factor deviating from 1 due to the integral of $Q_{1,4}^i$, which means $TV^N \rightarrow 0$ as $N \rightarrow \infty$. But nonlocal measurement can have $TV^N \rightarrow 1$, which can be achieved by implementing the measurement in Eq. 10 for each $\rho_{\vec{r}_i}$. We have thus constructed an example of data hiding based on the displaced two mode squeezed states from GLOCC. $\square$

III. DATA HIDING FROM GENERAL GAUSSIAN OPERATIONS

In this section, we consider data hiding from general Gaussian operations. We begin by considering a two-mode weak thermal state with zero displacement, described by the P representation [38]

$$\begin{aligned}
\rho &= \int \frac{d^2 \alpha d^2 \beta}{\pi^2 \det \Gamma} \exp(-\vec{\gamma}^\dagger \Gamma^{-1} \vec{\gamma}) |\vec{\gamma}\rangle \langle \vec{\gamma}|, \\
\vec{\gamma} &= [\alpha, \beta]^T, \quad \Gamma = \frac{\epsilon}{2} \begin{bmatrix} 1 & |g|e^{i\theta} \\ |g|e^{-i\theta} & 1 \end{bmatrix}, \tag{40} \\
|\vec{\gamma}\rangle &= \exp(\alpha \hat{a}^\dagger - \alpha^* \hat{a}) \exp(\beta \hat{b}^\dagger - \beta^* \hat{b}) |0\rangle,
\end{aligned}$$

where ϵ is the mean photon number per temporal mode and assumed to be much less than one $\epsilon \ll 1$, $\hat{a}, \hat{b}$ are the annihilation operators for the two modes. The motivation for selecting this state comes from Ref. [39], which

shows that nonlocal schemes for estimating θ outperform any LOCC, highlighting the advantage of nonlocal measurements. This inspired us to encode information in the phase θ of a two-mode weak thermal state for quantum data hiding, effectively concealing the information from LOCC. However, while this was our initial motivation, we made an unexpected discovery: Gaussian measurements, including nonlocal ones, perform worse than proper non-local non-Gaussian measurements. This reveals a scheme to hide one classical bit of information from any Gaussian measurement using only a separable state.

To hide one bit of classical information, we choose $|g| = 1$ and $\theta = 0, \pi$ in Eq. 40 as the two states $\rho_{\pm}$, which have the following covariance matrices

$$V_{\pm} = \begin{bmatrix} 1 + \epsilon & 0 & \pm\epsilon & 0 \\ 0 & 1 + \epsilon & 0 & \pm\epsilon \\ \pm\epsilon & 0 & 1 + \epsilon & 0 \\ 0 & \pm\epsilon & 0 & 1 + \epsilon \end{bmatrix}. \tag{41}$$

For non-Gaussian measurement, it is easier to expand Eq. 40 in Fock basis as a series of ϵ ,

$$\rho = (1 - \epsilon) |00\rangle \langle 00| + \frac{\epsilon}{2} \begin{bmatrix} 1 & |g|e^{i\theta} \\ |g|e^{-i\theta} & 1 \end{bmatrix} + o(\epsilon). \tag{42}$$

Proposition 3. Consider the pair of data hiding states $\rho_+^{\otimes N}, \rho_-^{\otimes N}$, which is used to encode one bit of classical information. There exists a non-Gaussian measurement that can distinguish $\rho_+^{\otimes N}, \rho_-^{\otimes N}$ with success probability close to 100% when $N = \Theta(1/\epsilon)$.

Proof. We first consider the success probability of a non-local non-Gaussian measurement on one copy of state ρ in Eq. 40. The projective measurement and the corresponding probability of obtaining each outcome is

$$\begin{aligned}
|00\rangle \langle 00|, \quad P &= 1 - \epsilon, \\
|\pm\rangle \langle \pm|, \quad P &= \frac{\epsilon}{2} (1 \pm |g| \cos \theta), \tag{43}
\end{aligned}$$

where $|\pm\rangle = (|01\rangle \pm |10\rangle)/\sqrt{2}$, $|0\rangle, |1\rangle$ are the vacuum and single photon states. We do the same measurement for N copies of the same state $\rho^{\otimes N}$, which has the probability

$$\begin{aligned}
P(k, m | |g|, \theta) &= C_N^k C_{N-k}^m (1 - \epsilon)^k \\
&\times \left(\frac{\epsilon}{2} (1 + |g| \cos \theta) \right)^m \left(\frac{\epsilon}{2} (1 - |g| \cos \theta) \right)^{N-m-k}, \tag{44}
\end{aligned}$$

where $k = 0, 1, 2, \dots, N$ labels the number of times of getting $|00\rangle$, $m = 0, 1, 2, \dots, N - k$ labels the number of times we get $|\pm\rangle$. The total variation between the probability of measuring the two data hiding states $\rho_{\pm}^{\otimes N}$

and $\rho_-^{\otimes N}$ is

$$\begin{aligned}
TV &= \frac{1}{2} \sum_{k=0}^N \sum_{m=0}^{N-k} |P(k, m|+) - P(k, m|-)| \\
&= \frac{1}{2} \sum_{k=0}^N \sum_{m=0}^{N-k} C_N^k C_{N-k}^m (1-\epsilon)^k \\
&\quad \times |\epsilon^m 0^{N-k-m} - 0^m \epsilon^{N-k-m}| \\
&= \sum_{k+m=N, m \neq 0} C_N^k (1-\epsilon)^k \epsilon^m \\
&= 1 - (1-\epsilon)^N \approx N\epsilon + o(\epsilon).
\end{aligned} \tag{45}$$

So, to achieve a success probability close to one, we need $N = \Theta(1/\epsilon)$. $\square$

Theorem 4. Consider the pair of data hiding states $\rho_+^{\otimes N}, \rho_-^{\otimes N}$, which is used to encode one bit of classical information. Any Gaussian measurement can distinguish $\rho_+^{\otimes N}, \rho_-^{\otimes N}$ with error probability $P_{\text{err}} \geq \frac{1}{2}(1 - \sqrt{2N\epsilon})$ for $N = o(\epsilon^{-2})$. When $N = \Theta(\epsilon^{-1})$ and $\epsilon \rightarrow 0$, any Gaussian measurement performs almost no better than random guessing.

Proof. For any Gaussian measurement, the total variation distance between two probability $P(\vec{y}|\pm) = \text{tr}(\rho_{\pm}^{\otimes N} \Pi_{\vec{y}})$ is

$$\begin{aligned}
TV &= \frac{1}{2} \int d\vec{y} |P(\vec{y}|+) - P(\vec{y}|-)|, \\
P(\vec{y}|\pm) &= \frac{1}{(2\pi)^2 \sqrt{\det V_N}} \exp\left(-\frac{1}{2} \vec{y}^T V_N^{-1} \vec{y}\right),
\end{aligned} \tag{46}$$

where $V_N = V_{\pm} \otimes I_N + V_{\Pi}$, V_{Π} is the covariance matrix describing the POVM of a Gaussian measurement, $\vec{y}$ consists of $\vec{y}^i = [y_1^i, y_2^i, y_3^i, y_4^i]^T$ as in Eq. 35. We again define $\vec{Y}^i = U \vec{y}^i$ as in Eq. 28 and get

$$P(\vec{y}|\pm) = P(\vec{Y}|\pm) = \frac{1}{(2\pi)^2 \sqrt{\det \Sigma_N}} \exp\left(-\frac{1}{2} \vec{Y}^T \Sigma_N^{-1} \vec{Y}\right),$$

$$\Sigma_N = \Sigma_{\pm} + \Sigma_{\Pi}, \quad \Sigma_{\pm} = (UV_{\pm} U^T) \otimes I_N,$$

$$\Sigma_{\Pi} = (U \otimes I_N) V_{\Pi} (U \otimes I_N)^T,$$

$$UV_+ U^T = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1+2\epsilon & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1+2\epsilon \end{bmatrix},$$

$$UV_- U^T = \begin{bmatrix} 1+2\epsilon & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1+2\epsilon & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix},$$

(47)

where I_N is the identity matrix added for the direct product of N copies of states. The total variation can be upper bounded by Pinsker's inequality [36, 37]

$$TV(P, Q) \leq \sqrt{\frac{1}{2} D_{KL}(P||Q)}, \tag{48}$$

where $D_{KL}(P||Q)$ is Kullback-Leibler divergence for two probability distribution P, Q . For the Gaussian probability distribution $P = \mathcal{N}(\mu_1, \Sigma_1)$, $Q = \mathcal{N}(\mu_2, \Sigma_2)$ [36, 37]

$$\begin{aligned}
D_{KL}(\mathcal{N}(\mu_1, \Sigma_1)||\mathcal{N}(\mu_2, \Sigma_2)) \\
&= \frac{1}{2} \left[\text{tr}(\Sigma_2^{-1} \Sigma_1) + (\mu_2 - \mu_1)^T \Sigma_2^{-1} (\mu_2 - \mu_1) \right. \\
&\quad \left. - M + \ln \left(\frac{\det \Sigma_2}{\det \Sigma_1} \right) \right],
\end{aligned} \tag{49}$$

where M is the dimension of the matrix $\Sigma_{1,2}$. For our case

$$\begin{aligned}
\Sigma_1 &= \Sigma_+ + \Sigma_{\Pi} = A + \epsilon B_1, \\
\Sigma_2 &= \Sigma_- + \Sigma_{\Pi} = A + \epsilon B_2, \\
A &= I_{4N} + \Sigma_{\Pi}, \quad \mu_{1,2} = \vec{0}, \quad M = 4N, \\
B_1 &= \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 2I_N & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2I_N \end{bmatrix}, \\
B_2 &= \begin{bmatrix} 2I_N & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 2I_N & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}.
\end{aligned} \tag{50}$$

For $\Sigma = A + \epsilon B$, we can have the following expansion [40]

$$\begin{aligned}
\Sigma_2^{-1} \Sigma_1 &= I + \epsilon A^{-1} (B_1 - B_2) \\
&\quad + \epsilon^2 A^{-1} B_2 A^{-1} (B_2 - B_1) + o(\epsilon^2),
\end{aligned} \tag{51}$$

$$\begin{aligned}
\ln \left(\frac{\det \Sigma_2}{\det \Sigma_1} \right) &= \epsilon \text{tr} [A^{-1} (B_2 - B_1)] \\
&\quad + \epsilon^2 \text{tr} (A^{-1} B_1 A^{-1} B_1 - A^{-1} B_2 A^{-1} B_2) + o(\epsilon^2),
\end{aligned} \tag{52}$$

$$D_{KL} = \frac{\epsilon^2}{4} \text{tr} (A^{-1} (B_1 - B_2) A^{-1} (B_1 - B_2)). \tag{53}$$

So, now the problem is the maximization of $\text{tr} (A^{-1} (B_1 - B_2) A^{-1} (B_1 - B_2))$, which can be easily bounded by

$$\text{tr} (A^{-1} (B_1 - B_2) A^{-1} (B_1 - B_2)) \leq \text{tr} (A^{-2}). \tag{54}$$

Note that $A = I_{4N} + \Sigma_{\Pi}$, where $\Sigma_{\Pi} \geq 0$, we have

$$0 \leq A^{-1} \leq I. \tag{55}$$

We then have

$$D_{KL} \leq 4\epsilon^2 N, \quad TV \leq \sqrt{2N\epsilon}. \tag{56}$$

The required N to achieve nearly 100% success probability of distinguishing $\rho_{\pm}^{\otimes N}$ is at least $\Omega(1/\epsilon^2)$. $\square$

If we choose $\epsilon \rightarrow 0$ and $N = \Theta(1/\epsilon)$, the data hiding states $\rho_+^{\otimes N}$ and $\rho_-^{\otimes N}$ cannot be distinguished by Gaussian measurements but can be distinguished by the non-Gaussian measurement described in Eq. 43. We have thus constructed the data hiding states for general Gaussian operations. Let's check this discussion with some specific examples. Firstly, let's consider the local heterodyne detection at each mode, which has $\Sigma_{\Pi} = I_{4N}$, and

$$D_{KL, hetero} = N\epsilon^2, \quad (57)$$

which shows we need at least $N = \Omega(\epsilon^{-2})$ to have nearly 100% success probability for distinguishing $\rho_{\pm}^{\otimes N}$.

Secondly, let's consider the case when we first combine the light from $\hat{a}, \hat{b}$ modes on a balanced beam splitter and do homodyne detection on the two output ports. This measurement is described by

$$\Sigma_{\Pi} = \lim_{s \rightarrow \infty} \begin{bmatrix} e^{-2s} I_N & 0 & 0 & 0 \\ 0 & e^{2s} I_N & 0 & 0 \\ 0 & 0 & e^{2s} I_N & 0 \\ 0 & 0 & 0 & e^{-2s} I_N \end{bmatrix}, \quad (58)$$

$$D_{KL} = 2N\epsilon^2. \quad (59)$$

Note that for the second case, the measurement is already a nonlocal measurement. Intuitively, we are projecting onto displaced two mode squeezed states with infinite squeezing. And with such a nonlocal measurement, we still at least need $N = \Omega(1/\epsilon^2)$ to have nearly 100% success probability for distinguishing $\rho_{\pm}^{\otimes N}$ as claimed.

In the above two example, we do not yet saturate the upper bound for D_{KL} . This is because, we only use the fact that $\Sigma_{\Pi} \geq 0$ in the derivation of upper bound. But as a valid POVM, Σ_{Π} also need to satisfy some condition from the uncertainty principle [29]. Indeed, we can easily read from the proof that, the following Σ_{Π} achieves the upper bound

$$\Sigma_{\Pi} = \lim_{s \rightarrow \infty} e^{-2s} I_{4N}. \quad (60)$$

This measurement essentially asks for the perfect estimation of all quadratures at the same time, which is not physically allowed.

IV. CONCLUSION

In this paper, we investigate two distinct scenarios of data hiding within the CV context. First, we introduce data hiding with respect to a new class of operations, GLOCC. To establish the intuition, we identify the CV counterpart to the challenge of distinguishing Bell entangled states using LOCC, which is a key insight underlying the initial data hiding proposal [19, 20]. Building on this intuition, we construct data-hiding states under GLOCC using the mixture of displaced two-mode squeezed states.

Second, we explore data hiding against general Gaussian operations. We propose a novel example of data-hiding states utilizing multiple copies of two-mode thermal states in the weak-strength limit. Notably, this construction is closely related to the interferometric imaging described in Ref. [39, 41]. As such, the demonstrated advantage of non-Gaussian operations for data hiding may also suggest a broader advantage of non-Gaussian operations in imaging applications.

Several questions remain unanswered. Our data hiding states from GLOCC are mixtures of displaced two-mode squeezed states, which are non-Gaussian. It is intriguing to consider whether we can construct data hiding states from GLOCC using only Gaussian states. Additionally, our current data hiding scheme only hides one bit of classical information. Given that we are working with CV states, it is worth exploring whether we can hide a classical continuous variable.

Abstract. Magic state distillation is a central primitive for universal fault-tolerant quantum computation, but conventional logical-level distillation requires large space-time overhead. This overhead is particularly restrictive in early fault-tolerant quantum computation, where only a limited number of logical qubits may be available. We propose a zero-level distillation protocol that directly generates a logical CCZ magic state using physical qubits on a two-dimensional square lattice with nearest-neighbor interactions [1]. The protocol uses the transversal $T/T^\dagger$ implementation of the $[[8, 3, 2]]$ code to fault-tolerantly encode $\overline{CCZ}|+++ \rangle$ and then teleports the three logical qubits into surface-code patches by lattice surgery. A key ingredient is adaptively initialized teleportation (AIT), which temporarily initializes the target surface code so that it supports a short logical- Z operator compatible with the weight-two logical- Z operators of the $[[8, 3, 2]]$ code. Numerical simulations under a circuit-level depolarizing noise model show that the logical error rate scales as $p_L \simeq 300p^2$, giving about one and two orders of magnitude improvement over a seven- T implementation at $p = 10^{-3}$ and $p = 10^{-4}$, respectively. The circuit uses only 22 physical qubits for distillation, three output logical qubits, and circuit depth 24, reducing the space-time overhead by a factor of approximately 5–10 compared with representative previous approaches. Our results indicate that direct physical-level CCZ -state distillation is a practical route to supplying non-Clifford resources in early fault-tolerant architectures.

Keywords: early fault-tolerant quantum computation, magic state distillation, CCZ state, surface code, lattice surgery, zero-level distillation

1 Motivation and background

Fault-tolerant quantum computation (FTQC) requires non-Clifford gates in addition to fault-tolerant Clifford operations. In surface-code architectures, Clifford operations can be implemented efficiently by code deformation, lattice surgery, or Pauli-frame updates, whereas non-Clifford gates such as the T and CCZ gates are commonly supplied by magic states and gate teleportation [2]. Magic state distillation is therefore one of the main bottlenecks for scalable FTQC because it consumes many logical qubits and many rounds of syndrome extraction before a sufficiently high-fidelity non-Clifford resource becomes available [3].

This bottleneck is especially severe in early fault-tolerant quantum computation, where the number of available logical qubits is limited and the dominant objective is to obtain useful non-Clifford resources with minimal space-time overhead. Recent low-overhead physical-level distillation protocols aim to reduce this overhead by constructing magic state distillation circuits directly from physical qubits under realistic noise models and hardware connectivity constraints. [4, 5]. These approaches can output surface-code magic states with very small footprint when the physical error rate is around 10^{-3} – 10^{-4} . However, most previous work has focused on T -state generation. Direct preparation of a CCZ magic state remains comparatively

*itogawa.tomohir@fujitsu.com

Figure 1: Overview of the proposed zero-level CCZ distillation protocol. The protocol first prepares an encoded $CCZ|+++ \rangle$ state in the $[[8,3,2]]$ code, then performs adaptively initialized teleportation and syndrome extraction to output three surface-code logical qubits.

less developed, despite the fact that CCZ is a particularly useful non-Clifford resource because it can implement Toffoli-type classical reversible logic.

In this work [1], we develop a low-overhead physical-level protocol for preparing a logical CCZ magic state under a hardware model motivated by superconducting-qubit architectures, where physical qubits are arranged on a two-dimensional square lattice and only nearest-neighbor two-qubit gates are allowed. Our goal is to generate a high-fidelity logical CCZ state directly from physical qubits, without using a large logical-level distillation factory, while keeping both the circuit depth and the number of logical qubits small. The proposed protocol combines three key ingredients: the transversal non-Clifford structure of the $[[8,3,2]]$ code, a verification-based fault-tolerant encoding circuit for $CCZ|+++ \rangle$, and a lattice-surgery interface that transfers the encoded state into three surface-code logical qubits.

2 Protocol and main results

Our protocol begins with a fault-tolerant encoding of a $|+++ \rangle$ state into the $[[8,3,2]]$ CSS code, which encodes three logical qubits into eight physical qubits. After that, a transversal layer of T and $T^\dagger$ gates implements the logical CCZ operation, producing the encoded magic state $\overline{CCZ}|+++ \rangle$. Since the $[[8,3,2]]$ code has distance two and is not itself a scalable memory, the prepared state is subsequently teleported into three surface-code logical qubits.

The first technical component is a fault-tolerant encoding procedure for $|+++ \rangle$ in the $[[8,3,2]]$ code. We begin with a depth-three non-fault-tolerant encoding circuit and convert it into a verified preparation by using transversal CNOT operations with an ancilla block, followed by decoding and X -basis

Figure 2: Circuit-level structure of the protocol. A verified encoding procedure prepares $|+++ \rangle$ in the $[[8,3,2]]$ block, transversal $T/T^\dagger$ gates implement logical CCZ , and lattice surgery teleports the resulting state to three surface-code patches.

checks. The construction is designed so that all required two-qubit gates respect nearest-neighbor connectivity on a square lattice. This verification suppresses leading-order harmful faults while keeping the physical circuit shallow, which is crucial for zero-level distillation because the circuit itself is executed below the logical layer.

The second technical component is adaptively initialized teleportation (AIT). A direct lattice-surgery measurement between the $[[8,3,2]]$ code and a large-distance surface code is difficult under nearest-neighbor connectivity constraints, because the corresponding surface-code logical Z operator is supported on many physical qubits and cannot be measured directly using only local two-qubit gates. In AIT, the target surface-code patch is initialized in a tailored intermediate state: one stabilizer is temporarily left unmeasured so that the logical- Z support relevant for the surgery is shortened. This makes the logical ZZ measurement between the two codes local. After the teleportation measurement, the remaining stabilizers are measured to complete the full surface-code patch. AIT therefore acts as a code-interface primitive that transfers a state from a small code with short logical operators to a larger surface code.

The third component is a superdense syndrome extraction circuit for the $[[8,3,2]]$ block. By using a GHZ-type ancilla, the circuit simultaneously measures one X -type and three Z -type stabilizers with circuit depth 8. Nontrivial syndromes are treated as detection events and lead to postselection. This design avoids the need to distinguish data errors from hook errors, because the protocol aims to output an accepted high-fidelity state rather than correct every detected fault.

We evaluate the protocol by numerical simulation under a circuit-level noise model in which single-

Figure 3: Numerical performance under circuit-level noise. The logical error rate scales approximately as $p_L \simeq 300p^2$, while the success probability remains high in the 10^{-4} – 10^{-3} physical-error-rate regime.

qubit gates and idle operations are followed by single-qubit depolarizing noise with probability p , state preparation and measurement suffer flip noise with probability p , and two-qubit gates are followed by two-qubit depolarizing noise with probability p . A logical failure is declared when any of the three output surface-code logical qubits has a logical error. The resulting logical error rate follows

$$p_L \simeq 300p^2. \quad (1)$$

At $p = 10^{-3}$ this gives $p_L \simeq 3 \times 10^{-4}$, about an order-of-magnitude improvement over a conventional seven- T implementation whose leading contribution scales as $7p$. At $p = 10^{-4}$ the improvement reaches about two orders of magnitude. The success probability is approximately 30–40% at $p = 10^{-3}$ and about 90% at $p = 10^{-4}$.

The resource footprint is also small. The distillation part uses 22 physical qubits, and the output consists of three surface-code logical qubits. The total circuit depth is 24, corresponding to only three rounds of surface-code syndrome extraction in the proposed layout. Comparing the product of the number of logical qubits and the number of surface-code syndrome-measurement rounds, the proposed protocol reduces the space-time overhead by a factor of approximately 5–10 relative to representative approaches based on T states prepared by zero-level distillation or CCZ distillation using eight T states. Although some alternatives can achieve a smaller logical-error prefactor, they require substantially larger space-time overhead; our protocol therefore provides a favorable trade-off in the resource-limited early-FTQC regime.

In summary, this work [1] demonstrates that direct zero-level CCZ distillation is possible with nearest-neighbor physical operations on a square lattice. Beyond the particular CCZ protocol, the

Figure 4: Space-time overhead versus success probability. Each point corresponds to a different degree of parallelization, where multiple distillation blocks are executed simultaneously and the output is accepted if at least one block succeeds. Larger parallelization increases the success probability at the cost of larger space-time overhead. The proposed zero-level CCZ protocol reaches a target success probability with substantially smaller space-time overhead than representative alternatives.

verified encoding method and AIT may be useful as general tools for preparing and transferring states between small CSS codes and surface-code patches. Future work includes combining this zero-level CCZ state with higher-level logical distillation to reach lower target error rates, and adapting the construction to architectures with different connectivity, such as neutral atoms or trapped ions.

Abstract. We demonstrate superadditivity of one-shot zero-error classical capacity in an asymmetric communication setting where a noisy classical channel is used in parallel with a perfect quantum channel. Each channel individually supports only finitely many perfectly distinguishable messages, yet their joint use enables transmission of more messages than allowed by the product of their individual capacities. We present explicit constructions achieving this enhancement and show that replacing the perfect quantum channel with a perfect classical channel removes the effect. Finally, we identify a structural criterion governing this phenomenon and establish that the resulting quantum advantage is rooted in Kochen–Specker contextuality.

Keywords: Zero-error communication, channel capacity, superadditivity, Kochen–Specker contextuality.

1 Introduction

The question of whether combined performance of imperfect resources can exceed the sum of their individual contributions traces back to Aristotle’s philosophical inquiries. In information theory, this manifests as the study of channel capacity *superadditivity*. While classical intuition suggests that two noisy classical channels used together should achieve a joint capacity equal to the sum of their individual capacities [1], quantum information theory reveals striking violations of this principle.

Superadditivity has been rigorously established for quantum and private capacities of quantum channels [2, 3, 4, 5], with indications of similar phenomena for classical capacity [6]. Zero-error information theory, introduced by Shannon [7], addresses communication under absolute certainty, allowing no probability of error. Remarkably, even classical channels can exhibit superadditive behavior in this regime [7, 8, 9, 10].

Recent developments in quantum zero-error information theory have emerged as an active research area [11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24]. Notably, Cubitt et al. [11] demonstrated that entanglement assistance can enhance zero-error capacity for certain noisy classical channels, with the criterion being that the channel hypergraph must be $\{0, 1\}$ -uncolorable, and also corresponds to *disjoint* Kochen–Specker basis set [22].

Our contribution. We present a novel instance of superadditivity in zero-error communication regime. Specifically, we show that a *noisy classical* channel, when paired in parallel with a *perfect quantum* channel, exhibits superadditive one-shot zero-error capacity. The joint capacity supersedes the sum of individual capacities.

Crucially, this enhancement is fundamentally quantum: replacing the perfect quantum channel with a perfect classical channel eliminates the superadditive advantage entirely.

Our work differs from previous results in several key aspects:

- *Protocol structure:* In contrast to the entanglement-assisted scheme of Cubitt et al. [11], which achieves zero-error capacity enhancement through shared entanglement, we demonstrate superadditivity by augmenting the noisy classical channel with a parallel *perfect quantum channel*.
- *Broader applicability:* We demonstrate superadditivity beyond the disjoint KS-basis-set regime considered by Cubitt et al. [11, 22]. In particular, our construction applies not only to channels built from the 18-vector Cabello set, whose 18-vector form does not suffice for the Cubitt et al. protocol without completion to Peres’s 24-vector KS set, but also to channels arising from state-independent contextuality sets that are not KS proofs, such as the qutrit family of Xu et al. [25].
- *Structural characterization:* We derive general criteria characterizing when such superadditive behavior occurs, connecting it to the foundational notion of Kochen–Specker contextuality through exclusivity graphs [26, 27].

Framework and Definitions.— A discrete memoryless classical channel $\mathcal{N}$ is specified by input alphabet $\mathcal{X}$, output alphabet $\mathcal{Y}$, and conditional probabilities $P(y|x)$. The support of input x is $\Gamma(x) := \{y \in \mathcal{Y} \mid P(y|x) > 0\}$. Two inputs $x, x' \in \mathcal{X}$ are *confusable* if $\Gamma(x) \cap \Gamma(x') \neq \emptyset$, and *perfectly distinguishable* if $\Gamma(x) \cap \Gamma(x') = \emptyset$.

A *one-shot zero-error code* is a subset $C \subseteq \mathcal{X}$ such that all pairs of distinct inputs in C are perfectly distinguishable.

*p24iqc001@iitj.ac.in

†anushko12@gmail.com

‡agarwalkunika9@gmail.com

§rakeshdas17082002@gmail.com

¶amitm@iitj.ac.in

able. The size $|C|$ represents the number of messages transmittable with certainty in a single channel use.

The *confusability graph* $G(\mathcal{N})$ has vertex set $\mathcal{X}$, with edges connecting confusable input pairs. A zero-error code corresponds to an independent set in $G(\mathcal{N})$. The one-shot zero-error capacity is $C_0(\mathcal{N}) = \alpha(G(\mathcal{N}))$, the independence number of $G(\mathcal{N})$. Although the one-shot zero-error capacity is commonly defined as the logarithm of the maximum number of messages that can be transmitted with certainty in a single channel use, throughout this work we instead take it to mean the maximum number of such messages, not its logarithm. A noisy classical channel N can equivalently be represented by its channel hypergraph, denoted as $H(N)$. A vertex set of $H(N)$ is the input alphabet $\mathcal{X}$ of the channel. The output symbol $y \in \mathcal{Y}$, is a hyperedge h_y which consists of vertex subset $\{x \in \mathcal{X} \mid P(y|x) > 0\} \subseteq \mathcal{X}$. Two inputs are confusable if and only if they belong to a common hyperedge. The confusability graph $G(N)$ is obtained from $H(N)$ by connecting each pair of vertices with an edge that appear together in at least one hyperedge.

For parallel channel use $\mathcal{N} \otimes \mathcal{N}'$, the joint confusability graph is the strong product $G(\mathcal{N}) \boxtimes G(\mathcal{N}')$. Vertices (u, i) and (v, j) are adjacent if: (i) $u = v$ and $i \sim j$ in $G(\mathcal{N}')$, (ii) $u \sim v$ in $G(\mathcal{N})$ and $i = j$, or (iii) $u \sim v$ in $G(\mathcal{N})$ and $i \sim j$ in $G(\mathcal{N}')$. The joint capacity is $C_0(\mathcal{N} \otimes \mathcal{N}') = \alpha(G(\mathcal{N}) \boxtimes G(\mathcal{N}'))$.

Classical benchmark.— When a noisy classical channel $\mathcal{N}_n$ is paired in parallel with a d -level perfect classical channel $\mathcal{N}_p$ (confusability graph $\bar{K}_d$), the joint capacity is simply multiplicative: $C_0(\mathcal{N}_n \otimes \mathcal{N}_p) = d \cdot \alpha(G_n)$. This follows because $G_n \boxtimes \bar{K}_d$ decomposes into d disconnected copies of G_n , giving $\alpha(G_n \boxtimes \bar{K}_d) = d \cdot \alpha(G_n)$.

2 Main Results

Constructive Proof of Superadditivity.— Our first main result establishes superadditivity through explicit construction.

Theorem 1. *There exist a noisy classical channel $\mathcal{N}_n$ and a perfect quantum channel $\mathcal{Q}_p$ such that, in a single parallel use of $\mathcal{N}_n$ and $\mathcal{Q}_p$, the one-shot zero-error capacity strictly exceeds the product of the individual one-shot zero-error capacities.*

Proof sketch. We construct a noisy classical channel $\mathcal{N}_n$ whose channel hypergraph coincides with the hypergraph corresponding to the 18-vector Kochen-Specker construction of Cabello et al. [28]. The confusability graph of the hypergraph be $G(\mathcal{N}_n)$. This graph has input set $\mathcal{X} = \{v_1, \dots, v_{18}\}$, where each vertex corresponds to a unit vector in $\mathbb{R}^4$. The hypergraph has 9 hyperedges, each containing four inputs forming a maximum clique. The independence number is $\alpha(G(\mathcal{N}_n)) = 4$, giving $C_0(\mathcal{N}_n) = 4$.

We augment $\mathcal{N}_n$ with a perfect 4-level quantum channel $\mathcal{Q}_p$ (also with capacity 4). The encoding-decoding protocol proceeds as follows:

Encoding: To transmit message m_k from message set $\mathcal{M}_m = \{m_1, \dots, m_{18}\}$, the sender: (i) sends classical label v_k through $\mathcal{N}_n$, and (ii) transmits quantum state

Figure 1: Channel hypergraph of the noisy channel considered in Theorem 1.

$|\psi_k\rangle = a_k|0\rangle + b_k|1\rangle + c_k|2\rangle + d_k|3\rangle \in \mathbb{C}^4$ through $\mathcal{Q}_p$, where $v_k = (a_k, b_k, c_k, d_k)$.

Decoding: The receiver obtains hyperedge h_y (classical output) and quantum state $|\psi_k\rangle$ (quantum output). Crucially, for any hyperedge h_y , the set $\{|\psi_j\rangle \mid v_j \in h_y\}$ forms an orthonormal basis of $\mathbb{C}^4$. Upon observing h_y , the receiver performs the projective measurement $\{P_j^{(y)} = |\psi_j\rangle\langle\psi_j| \mid v_j \in h_y\}$. Since $|\psi_k\rangle$ is one of these basis vectors, the measurement identifies $|\psi_k\rangle$ with certainty, recovering message m_k without error.

The protocol transmits all 18 messages perfectly, achieving capacity at least 18. This strictly exceeds the product $4 \times 4 = 16$, demonstrating superadditivity. $\square$

Extensions Beyond KS Uncolorability.— We demonstrate that superadditivity extends beyond KS uncolorable hypergraphs to graphs corresponding to state-independent contextuality proofs as well, addressing a key limitation of prior entanglement-assisted protocols [11, 22].

Remark 1. *Consider noisy classical channels whose confusability graphs are isomorphic to the orthogonality graph of vectors $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, $(1, -\omega^i, 0)$, $(1, 0, -\omega^i)$, $(0, 1, -\omega^i)$, $(1, \omega^i, \omega^j)$ in $\mathbb{C}^3$, where $\omega = e^{2\pi i/(3m)}$ and $i, j \in \{1, \dots, 3m\}$ for $m \in \mathbb{Z}_+$. This family exhibits one-shot zero-error superadditivity when forward-assisted by a perfect 3-level quantum channel, despite the corresponding hypergraphs being KS colorable. However, they exhibit state-independent contextuality [25].*

This demonstrates that KS uncolorability is not necessary for the superadditivity phenomenon observed in our protocol, distinguishing it from entanglement-assisted schemes.

Graph-Theoretic Characterization.—To understand the structural underpinnings of superadditivity, we employ the exclusivity graph framework [26, 27, 29]. In this framework, vertices represent measurement events, edges indicate mutual exclusivity, and behaviors are probability assignments satisfying pairwise exclusivity. A behavior is *classical* if it admits a noncontextual hidden variable model, and *quantum* if it admits a quantum realization. For exclusivity graph G , we denote the classical and quantum behavior sets by $\mathcal{C}_G$ and $\mathcal{Q}_G$, respectively, with $\mathcal{C}_G \subseteq \mathcal{Q}_G$ always.

Theorem 2. *If the confusability graph $G(\mathcal{N}_n)$ of a noisy classical channel is isomorphic to an exclusivity graph G satisfying $\mathcal{C}_G = \mathcal{Q}_G$, then the communication protocol does not exhibit one-shot zero-error superadditivity.*

Proof sketch. It is known that $\mathcal{C}_G = \mathcal{Q}_G$ if and only if G is a perfect graph [26, 30, 31, 32, 33, 34]. For perfect graphs, $\alpha(H)\omega(H) \geq |V(H)|$ holds for every induced subgraph H , including G itself [35]. Setting $n = |V(G)|$, this implies $n/\alpha(G) \leq \omega(G)$.

If G admits an orthogonal representation by rank-one projectors in dimension d , then $\omega(G) \leq d$ (as cliques correspond to orthogonal projector sets). Consequently, $\alpha(G) \cdot d \geq n$. Since at most n messages can be transmitted in our protocol, this inequality rules out superadditivity. $\square$

This theorem establishes that superadditivity requires $\mathcal{C}_G \subsetneq \mathcal{Q}_G$, i.e., genuinely quantum contextual behavior.

Our results establish dimensional thresholds that preclude zero-error superadditivity in certain regimes, as per our scheme. Specifically, for any noisy classical channel used in parallel with a perfect quantum channel, no superadditivity is possible under this protocol if the assisting quantum channel is two-dimensional. This follows because any exclusivity graph admitting an orthogonal representation in dimension two must possess a noncontextual model. Furthermore, for a noisy classical channel whose confusability graph requires a minimum orthogonal representation dimension of d , no superadditivity can occur if the dimension of the assisting perfect quantum channel is strictly less than d .

3 Conclusions

We have uncovered a fundamentally quantum form of superadditivity in the zero-error capacity of a hybrid communication setup, where a noisy classical channel is used in parallel with a perfect quantum channel. This enhancement, which vanishes if the quantum channel is replaced by a classical one, is shown to arise from the structural properties of the classical channel’s confusability graph. Specifically, superadditivity is possible *only when* this graph admits a purely quantum exclusivity structure. A *sufficient condition* for superadditivity in our framework is that the number of vertices of the channel hypergraph exceeds the product of the independence number of its confusability graph and the dimension of orthogonal representation of the graph. Our quantum protocol extends beyond previous entanglement-assisted

schemes by demonstrating this effect for a broader class of channels, including those based on state-independent contextuality sets that remain Kochen–Specker colorable. This work leaves open the questions of whether classical channels having more general contextual graphs can support such superadditivity.

Our results contribute to a broader understanding of zero-error communication theory and further illuminate the relationship between information-theoretic advantages and foundational quantum phenomena, particularly Kochen–Specker contextuality.

We demonstrate superadditivity of one-shot zero-error classical capacity in an asymmetric communication setting where a noisy classical channel is used in parallel with a perfect quantum channel. Each channel individually supports only a fixed number of perfectly distinguishable messages. Their joint use enables transmission of strictly more messages than permitted by the product of the individual capacities. We present explicit constructions achieving this enhancement and establish that replacing the perfect quantum channel with a perfect classical channel eliminates the effect. Finally, we identify a structural criterion on the noisy channel governing this effect and show that the quantum advantage is rooted in Kochen–Specker contextuality.

Introduction.- Can the combined performance of two imperfect resources exceed the sum of what each can achieve individually. The origin of this philosophy traces back to Aristotle [1]. In information theory, this question takes a more concrete form in the study of communication channels, where performance is quantified by channel capacity [2]. When two noisy channels are used together, their joint capacity is generally expected to be equal to their sum of individual capacities. Remarkably, quantum information theory violates this intuition. Certain pairs of noisy quantum channels exhibit superadditivity, whereby their combined capacity exceeds the sum of the capacities achievable in isolation. A quantum channel supports the transmission of quantum information, private information, or classical information, leading to distinct notions of capacity [3–7]. Superadditivity has been rigorously established for quantum and private capacities [8–11], and indications of a similar phenomenon for classical capacity have also been reported [12].

Zero-error information theory, introduced by Shannon [13], addresses communication under the stringent requirement of absolute certainty, allowing no probability of error. Within this setup, interestingly even noisy classical channels can display superadditive behavior [13–16]. More recently, quantum extension of zero-error information theory has emerged as an active area of research [17–32]. In this work, we present a previously unexplored instance of superadditivity phenomenon having a quantum origin. Specifically, we show that a noisy classical channel, when paired in parallel with a perfect quantum channel, exhibits superadditive capacity. In other words, the capacity of the joint noisy classical and perfect quantum channels supersedes sum of their individual capacities. We also establish that this enhancement is fundamentally quantum, *i.e.*, replacing the perfect quantum channel with a perfect classical channel eliminates the superadditive advantage. Along the way, we derive general criteria for exhibiting such superadditive behavior, thereby expanding the conceptual landscape of zero-error communication theory and connecting it to the foundational notion of Kochen–Specker contextuality [33, 34].

Framework.- A discrete memoryless classical channel N is specified by a finite input alphabet $\mathcal{X}$, a finite output alphabet $\mathcal{Y}$, and a collection of conditional probabilities $P(y|x)$, where

$\sum_{y \in \mathcal{Y}} P(y|x) = 1$ for all $x \in \mathcal{X}$, and $y \in \mathcal{Y}$. For a fixed input symbol $x \in \mathcal{X}$, only a subset of output symbols can occur with nonzero probability [2]. We denote this support of input by $\Gamma(x) := \{y \in \mathcal{Y} \mid P(y|x) > 0\}$. Operationally, $\Gamma(x)$ represents all outputs that the receiver may observe when x is transmitted in a single use of the channel.

Two distinct input symbols $x, x' \in \mathcal{X}$ are said to be *confusable* in the single use of the channel if their supports in $\mathcal{Y}$ overlap, that is, if $\Gamma(x) \cap \Gamma(x') \neq \emptyset$ [13]. In this case, there exists at least one output that could have arisen from either input, and therefore the receiver cannot infer with certainty which input was sent. Conversely, two input symbols are perfectly distinguishable in a single channel use if their supports are disjoint.

A *one-shot zero-error code* for the channel is a subset $\mathcal{C} \subseteq \mathcal{X}$ such that every pair of distinct input symbols in $\mathcal{C}$ is perfectly distinguishable by the receiver. Equivalently, for all $x \neq x'$ in $\mathcal{C}$, we require $\Gamma(x) \cap \Gamma(x') = \emptyset$. The size of such a code, $|\mathcal{C}|$ represents the number of classical messages that can be transmitted with absolute certainty by invoking single use of the channel.

The confusability relations among input symbols admit a natural graph-theoretic representation. The *confusability graph* $G(N)$ of the channel has vertex set $V(G)$ which coincides with input set $\mathcal{X}$. Two distinct vertices are connected by an edge if and only if the corresponding input symbols are confusable and the set of all edges is denoted by $E(G)$. By construction, a one-shot zero-error code $\mathcal{C}$ corresponds precisely to a set of vertices with no edges between them. In graph-theoretic terms, a code $\mathcal{C}$ is an independent set of the graph $G(N)$. The one-shot zero-error classical capacity $\mathcal{C}_0(N)$ of the channel is therefore given by the independence number $\alpha(G(N))$, defined as the *maximum* cardinality of an independent set of $G(N)$. Although capacity is often defined as the logarithm of this quantity, throughout this work we identify the one-shot zero-error capacity with $\alpha(G(N))$ itself, corresponding directly to the maximum number of messages that can be transmitted with certainty in a single channel use. As a simple example, a perfect classical channel with d input symbols has an edgeless confusability graph $(\overline{K}_d)$ and hence $\mathcal{C}_0(\overline{K}_d) = \alpha(\overline{K}_d) = d$.

When two classical channels N and N' are used in parallel,

denoted as $N \otimes N'$, the receiver receives both outputs simultaneously. Two input pairs are confusable if the receiver cannot distinguish at least one component of the pair in the corresponding channel perfectly. This joint confusability graph corresponds precisely to the strong product of the individual confusability graphs, denoted $G(N) \boxtimes G(N')$. Two distinct vertices (u, i) and (v, j) in $G(N) \boxtimes G(N')$ are adjacent if and only if at least one of the following holds: (i) $u = v$ and i is adjacent to j in $G(N')$; (ii) u is adjacent to v in $G(N)$ and $i = j$; (iii) u is adjacent to v in $G(N)$ and i is adjacent to j in $G(N')$. In this framework, a one-shot zero-error code for the parallel channel corresponds to an independent set in the strong product graph $G(N) \boxtimes G(N')$. Consequently, the joint one-shot zero-error capacity is given by $\mathfrak{C}_0(N \otimes N') = \alpha(G(N) \boxtimes G(N'))$.

A noisy classical channel N can equivalently be represented by its channel hypergraph, denoted as $H(N)$. A vertex set of $H(N)$ is the input alphabet $\mathcal{X}$ of the channel. The output symbol $y \in \mathcal{Y}$, is a hyperedge h_y which consists of vertex subset $\{x \in \mathcal{X} \mid P(y|x) > 0\} \subseteq \mathcal{X}$. Two inputs are confusable if and only if they belong to a common hyperedge. The confusability graph $G(N)$ is obtained from $H(N)$ by connecting each pair of vertices with an edge that appear together in at least one hyperedge.

We now restrict our attention to the parallel composition of two classical channels: one noisy channel N_n , and one perfect channel N_p . Our goal is to characterize the one-shot zero-error capacity of the joint channel. In this case, the resulting capacity is simply the product of the individual capacities [13]. We include a brief proof of this multiplicativity for completeness. It establishes the classical benchmark from which a departure is later observed when a perfect quantum channel is used in place of a perfect classical one.

Proposition 1 ([13]). *Let N_n be a noisy classical channel with confusability graph G_n and one-shot zero-error capacity $\mathfrak{C}_0(N_n) = \alpha(G_n)$, and let N_p be a d -level perfect classical channel with confusability graph G_p ; then the one-shot zero-error capacity of their parallel composition $N_n \otimes N_p$ is $\mathfrak{C}_0(N_n \otimes N_p) = \alpha(G_n \boxtimes G_p) = d \alpha(G_n)$.*

Proof. The confusability graph of the perfect classical channel N_p is the edgeless graph $G_p = \overline{K}_d$, and hence its capacity is $\alpha(G_p) = d$. We now analyze the confusability graph of the parallel composition $N_n \otimes N_p$.

The joint channel's confusability graph is the strong product of G_n and G_p , that is $G_n \boxtimes G_p$, and the vertex set is $V(G_n) \times V(G_p)$. Since G_p is edgeless, the edge set $E(G_p)$ is empty. Hence, adjacency in $G_n \boxtimes G_p$ reduces to the condition: $(u, i) \sim (v, j)$ if and only if $i = j$ and $u \sim v$ in G_n . It follows that $G_n \boxtimes G_p$ decomposes into d disconnected components, one for each $i \in V(G_p)$, and each component is isomorphic to G_n through the map $(u, i) \mapsto u$. Therefore, $G_n \boxtimes G_p = \bigsqcup_{i=1}^d G_n^i$, where each $G_n^i \cong G_n$.

An independent set in a disjoint union of graphs is obtained by taking independent sets in each component. Thus, the maximum size of an independent set in $G_n \boxtimes G_p$ is the sum of the

independence numbers of its components: $\alpha(G_n \boxtimes G_p) = \sum_{i=1}^d \alpha(G_n^i) = d \alpha(G_n)$. This proves the claim. $\square$

The above proposition establishes that supplementing a noisy classical channel N_n with a perfect classical channel does not give rise to any superadditivity of the one-shot zero-error capacity. This naturally raises the question of whether this limitation persists when the assisting perfect channel is quantum rather than classical.

Main Results. - A perfect quantum channel can transmit the same number of classical messages with zero-error as a perfect classical channel of the same level [3, 4]. Despite this equivalence at the level of individual channel capacities, we show that replacing the perfect classical channel with a perfect quantum channel allows the one-shot zero-error capacity of the joint channel to strictly exceed the classical bound $\alpha(G(N_n))$ multiplied by the capacity of the perfect channel. This superadditive phenomenon is intrinsically quantum in nature as no such superadditivity arises when the assisting channel is classical. We provide a constructive proof of this superadditivity in what follows.

Theorem 1. *There exist a noisy classical channel N_n and a perfect quantum channel Q_p such that, in a single parallel use of N_n and Q_p , the one-shot zero-error capacity strictly exceeds the product of the individual one-shot zero-error capacities of N_n and Q_p .*

Proof. We prove the claim by explicit construction. Let N_n be a discrete memoryless classical channel whose hypergraph $H(N_n)$ is shown in Fig. 1. The input (vertex) set is $\mathcal{X} = \{v_1, \dots, v_{18}\}$, and the output set $\mathcal{Y}$ consists of hyperedges h_y . Each hyperedge h_y contains four inputs, which form a maximum clique in the confusability graph $G(N_n)$ of N_n . The graph $G(N_n)$ coincides with the orthogonality graph of the 18-vector construction introduced by Cabello *et al.* [35], which exhibits Kochen Specker contextuality. The independence number of $G(N_n)$ is $\alpha(G(N_n)) = 4$, and therefore the one-shot zero-error classical capacity of N_n satisfies $\mathfrak{C}_0(N_n) = 4$.

Now we augment N_n by forward-assisting it with a perfect 4-level quantum channel Q_p , whose one-shot zero-error classical capacity is also 4. We describe a joint encoding-decoding scheme for the parallel use of N_n and Q_p . Let the message set be $\mathcal{M}_m := \{m_1, \dots, m_{18}\}$.

Encoding. Fix a bijection $\mathcal{E} : \mathcal{M}_m \rightarrow V(\mathcal{G}_m)$. To transmit a message $m_k \in \mathcal{M}_m$, let $v_k = \mathcal{E}(m_k)$ be the corresponding classical label; the sender sends this classical label through the noisy classical channel N_n . Simultaneously, the sender transmits a quantum system encoded in the (normalized) state $|\psi_k\rangle = a_k |0\rangle + b_k |1\rangle + c_k |2\rangle + d_k |3\rangle \in \mathbb{C}^4$, through Q_p , which corresponds to the vertex $v_k = (a_k, b_k, c_k, d_k)$ (See Fig. 1).

Decoding. Upon reception, the receiver obtains a hyperedge h_y (the classical channel output) together with the quantum state $|\psi_k\rangle$ (the quantum channel output). However, the state is unknown to the receiver. By construction, for any

FIG. 1: Channel hypergraph associated with the noisy classical channel N_n given in Theorem 1. The hypergraph has 18 vertices, corresponding to the channel inputs, which are represented by vectors v_i in $\mathbb{R}^4$ and listed in the table. There are 9 hyperedges corresponding to possible channel outputs. Each vertex is contained in exactly two hyperedges. Accordingly, for any given input, the noisy classical channel can produce either of the two associated outputs.

hyperedge h_y of $H(N_n)$ the set $\{|\psi_j\rangle \mid v_j \in h_y\}$ is an orthonormal basis of $\mathbb{C}^4$. Hence each hyperedge h_y determines a projective measurement consisting of the rank-one projectors $\mathbb{P}_j^{(y)} = |\psi_j\rangle\langle\psi_j|$ for $v_j \in h_y$, with $\sum_{v_j \in h_y} \mathbb{P}_j^{(y)} = I_4$. After observing h_y , the receiver performs the corresponding projective measurement on the received quantum system. Since $|\psi_k\rangle$ is one of the basis vectors associated with h_y , the measurement outcome identifies $|\psi_k\rangle$ with certainty and thus recovers the transmitted message m_k without error.

Therefore the protocol transmits all 18 messages perfectly. It follows that the one-shot zero-error capacity of the combined use of N_n and Q_p is at least 18. This achievable rate strictly exceeds the product of the individual capacities, $4 \times 4 = 16$, demonstrating superadditivity of the zero-error capacity. $\square$

To place Theorem 1 in context, we compare it with prior work that also exploited quantum resources to enhance zero-error capacity. In particular, Cubitt *et al.* [17] demonstrated that entanglement assistance can result in a strict enhancement of the zero-error capacity for certain noisy classical channels. Their analysis identifies a necessary structural condition for such an enhancement: the channel hypergraph must be Kochen Specker (KS) uncolorable, reflecting the impossibility

of consistent deterministic classical value assignment.

The noisy classical channel we use to prove Theorem 1 has the channel hypergraph constructed from the 18-vector Kochen Specker set of Cabello *et al.* (Fig. 1), so it is therefore KS uncolorable. Importantly, however, our protocol achieves superadditivity in cases beyond KS uncolorable hypergraphs, showing that the structural requirement identified for entanglement-assisted protocols does not carry over as a necessary condition for the effect we observe.

Remark 1. Consider a noisy classical channel N_n whose hypergraph has as vertices the vectors in $\mathbb{C}^3$: $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, $(1, -\omega^i, 0)$, $(1, 0, -\omega^i)$, $(0, 1, -\omega^i)$, $(1, \omega^i, \omega^j)$, where $\omega = e^{2\pi i/3m}$ and $i, j \in \{1, \dots, 3m\}$. For $m \in \mathbb{Z}_+$, this family of channels exhibits one-shot zero-error superadditivity when forward assisted by a perfect 3-level quantum channel, despite its corresponding confusability graph being KS colorable. However, the set is known to exhibit state-independent contextuality [36, 37]. The channel construction, encoding and decoding scheme appear in the Appendix A.

In light of Remark 1, KS uncolorability is not the structural feature underlying the effect observed here. This observation motivates a deeper structural question: what properties of the noisy classical channel enable such an enhancement, and conversely, which channels provably cannot exhibit superadditivity under this protocol. In particular, we seek to determine whether the observed advantage is governed by specific features of the confusability graph of the noisy channel.

To address this question, we introduce a graph-theoretic framework [38–40] based on exclusivity relations between measurement events. This framework has been extensively used in the study of Kochen–Specker contextuality and provides a natural language for distinguishing classical and quantum behaviors.

Let $\mathcal{G}$ be a finite graph with vertex set $V_{\mathcal{G}}$ and edge set $E_{\mathcal{G}}$. Each vertex represents a distinct measurement event, and an edge between two vertices indicates that the corresponding events are mutually exclusive. In a probabilistic theory, each event is assigned an occurrence probability $p(v)$. A behavior on $\mathcal{G}$ is a function $p : V_{\mathcal{G}} \rightarrow [0, 1]$ satisfying the pairwise exclusivity condition $p(v) + p(v') \leq 1$ for all $\{v, v'\} \in E_{\mathcal{G}}$. A behavior is called *classical* or *noncontextual* if there exists a probability space (Ω, Σ, μ) and measurable sets $A_v \in \Sigma$ such that $A_v \cap A_{v'} = \emptyset$ whenever $\{v, v'\} \in E_{\mathcal{G}}$, and $p(v) = \mu(A_v)$ for all $v \in V_{\mathcal{G}}$. We denote the set of classical behaviors by $\mathcal{C}_{\mathcal{G}}$. A behavior is *quantum* if it admits a quantum realization: there exist a Hilbert space $\mathcal{H}$, a density operator ρ on $\mathcal{H}$, and projectors $\{\Pi_v\}_{v \in V(\mathcal{G})}$ such that $\Pi_v \Pi_{v'} = 0$ whenever $\{v, v'\} \in E(\mathcal{G})$ and $p(v) = \text{Tr}(\rho \Pi_v)$ for all $v \in V_{\mathcal{G}}$. The set of quantum behaviors is denoted $\mathcal{Q}_{\mathcal{G}}$. Since any classical model can be embedded into quantum theory, one always has $\mathcal{C}_{\mathcal{G}} \subseteq \mathcal{Q}_{\mathcal{G}}$. For some graphs this inclusion is strict, reflecting genuinely quantum behaviors; for others the two sets coincide, indicating that quantum resources offer no advantage within the given exclusivity structure. In the quantum realization above, the graph $\mathcal{G}$ may be viewed as the orthogo-

nality graph induced by the family of rank one projectors. We now use this framework to derive a criterion for superadditivity based on the confusability graph associated with a channel hypergraph of the noisy classical channel.

Theorem 2. *If the confusability graph $G(N_n)$ of a noisy classical channel N_n is isomorphic to an exclusivity graph $\mathcal{G}$ satisfying $\mathcal{C}_G = \mathcal{Q}_G$, then the communication protocol considered here does not exhibit one-shot zero-error superadditivity.*

Proof. It is known that $\mathcal{C}_G = \mathcal{Q}_G$ if and only if $\mathcal{G}$ is a perfect graph [38–45]. For perfect graphs, the inequality $\alpha(\mathcal{H})\omega(\mathcal{H}) \geq |V(\mathcal{H})|$ holds for every induced subgraph $\mathcal{H}$ of $\mathcal{G}$, and in particular for $\mathcal{G}$ itself [46]. Writing $n = |V(\mathcal{G})|$, this implies $\frac{n}{\alpha(\mathcal{G})} \leq \omega(\mathcal{G})$.

If $\mathcal{G}$ admits an orthogonal representation [47] by rank-one projectors acting on a Hilbert space of dimension d , then each clique of $\mathcal{G}$ corresponds to a set of mutually orthogonal projectors. This implies that $\omega(\mathcal{G}) \leq d$, and consequently $\alpha(\mathcal{G})d \geq n$.

In our protocol, classical messages are encoded in the vertices of $G(N_n)$, so that at most n messages can be transmitted with zero-error. When the condition $\alpha(\mathcal{G})d \geq n$ holds, one-shot zero-error superadditivity is therefore ruled out here. $\square$

Consequently, one-shot zero-error superadditivity is possible only when the classical behavior set is a proper subset of the quantum set, $\mathcal{C}_G \subsetneq \mathcal{Q}_G$, reflecting contextual structure in the underlying graph. Since Kochen–Specker contextuality can only arise in quantum systems above a certain dimensional threshold, this naturally motivates following no-go corollaries.

Corollary 1. *For any noisy classical channel N_n , the parallel use of N_n with a two-level perfect quantum channel cannot exhibit zero-error superadditivity under the protocol considered here.*

Corollary 2. *Let N_n be a noisy classical channel whose confusability graph admits an orthogonal representation in $\mathbb{C}^d$, d being the minimum possible dimension. If the assisting perfect quantum channel has dimension strictly less than d , then no one-shot zero-error superadditivity is possible under this protocol.*

The proofs of the above corollaries are provided in the Appendix B.

Discussion.— We have explored a new kind of superadditivity in the zero-error communication scenario that is fundamentally quantum in origin. This quantum character manifests in an asymmetric communication setting where a noisy classical channel is assisted by a perfect quantum channel in parallel. In particular, we show that the one-shot zero-error classical capacity of the combined channel exceeds the product of their individual zero-error capacities, and that this enhancement disappears when the assisting quantum channel is replaced by a perfect classical channel, confirming that the effect is genuinely quantum. We further show that the superadditivity observed in this scheme is governed by the structural

properties of the noisy classical channel. Specifically, superadditivity is possible only when the confusability graph of the classical channel is isomorphic to an exclusivity graph that admits strictly quantum behavior. A sufficient condition for superadditivity in our framework is straightforward: if the number of vertices of the channel hypergraph exceeds the product of the independence number of its confusability graph and the dimension of an orthogonal representation of the graph, then the channel can be paired with a perfect quantum channel of matching dimension to exhibit superadditivity of one-shot zero-error classical capacity. Unlike earlier superadditivity results involving combinations of noisy and perfect quantum channels [18–22], the effect reported here arises from purely noisy classical channel assisted by a perfect quantum channel.

Enhancement of the zero-error capacity of classical channels using shared entanglement was previously explored by Cubitt *et al.* [17]. Subsequent analyses by Yadavalli and Kunjwal [30] identified an important limitation of that protocol: capacity enhancement is possible only when the channel hypergraph arises from a *disjoint* Kochen–Specker basis set. Consequently, the Cubitt *et al.* scheme offers no advantage for channels whose hypergraphs do not have this structure, including those associated with the Cabello *et al.* construction [35] or other state-independent contextuality sets that remain KS-colorable. Our protocol overcomes this limitation. In particular, we demonstrate superadditivity for noisy classical channels whose hypergraphs coincide with those arising from the construction of Cabello *et al.*, as well as for a family of channels constructed from a state-independent contextuality set that is nevertheless KS-colorable [36]. Here, we also showed that a three-level quantum channel is the minimal assisting resource capable of producing this superadditivity.

This work suggests several directions for future study. Although Kochen–Specker contextuality is necessary for an orthogonality graph to support superadditivity when interpreted as a confusability graph, it is not sufficient within our present framework. Developing quantum schemes that realize superadditivity for more general contextual graphs remains open. Furthermore, in our construction the number of perfectly transmitted messages is bounded by the size of vertex set of the confusability graph. Whether this bound can be surpassed remains an open question.

Appendix A: Encoding and decoding scheme for Remark 1

In this appendix we provide an explicit example underlying Remark 1. The construction is based on a family of vectors in $\mathbb{C}^3$ whose orthogonality relations admit a natural interpretation as a classical channel confusability structure. We show how this structure leads to one shot zero error superadditivity when a noisy classical channel is used in parallel with a perfect three level quantum channel.

A family of vectors in $\mathbb{C}^3$. We begin by introducing the vector set that will generate the required orthogonality relations. Fix an integer parameter $m \geq 1$ and define $\omega = e^{2\pi i/(3m)}$. Consider the following family of vectors in $\mathbb{C}^3$: $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, $(1, -\omega^i, 0)$, $(1, 0, -\omega^i)$, $(0, 1, -\omega^i)$, $(1, \omega^i, \omega^j)$, where $i, j \in \{1, \dots, 3m\}$. Let $\mathcal{V}_m$ denote the set of all such vectors. A direct count shows that $|\mathcal{V}_m| = 3 + 9m + 9m^2$.

The orthogonality relations among these vectors play a central role. They induce a graph structure in which vertices correspond to elements of $\mathcal{V}_m$ and edges connect pairs of orthogonal vectors.

Orthogonality graph and contextuality properties. Let $\mathcal{G}_m$ be the orthogonality graph associated with $\mathcal{V}_m$, whose vertices are the vectors in $\mathcal{V}_m$ and where two vertices are adjacent if and only if the corresponding vectors are orthogonal. For a vertex $v \in \mathcal{V}_m$ with vector (a, b, c) we associate the normalized qutrit state $|\psi_v\rangle = \frac{a|0\rangle + b|1\rangle + c|2\rangle}{\|(a, b, c)\|} \in \mathbb{C}^3$, and the corresponding rank one projector $\Pi_v = |\psi_v\rangle\langle\psi_v|$. Adjacency of two vertices v and w therefore implies $\Pi_v \Pi_w = 0$. The resulting family of projectors is known to constitute a state independent contextuality set in Hilbert space of dimension three, while remaining $\{0, 1\}$ -colorable [36].

Construction of a noisy classical channel. Here we provide an explicit construction of the family of channels N_n^m , whose input alphabet has cardinality $3 + 3k + 3k^2$. It is convenient to describe the channel in terms of its channel hypergraph, where each hyperedge corresponds to a set of input symbols that may produce the same channel output. By construction, every hyperedge consists of vertices whose associated vectors are mutually orthogonal, and hence each hyperedge contains either two or three vertices, depending on the orthogonality relations in $\mathcal{V}_m$. The hypergraph has $3 + 3k + 3k^2$ vertices, where $k = 3m$, $m \in \mathbb{Z}_+$, and the channel outputs are identified with the hyperedges of this hypergraph. When m is odd, the number of three-vertex hyperedges is $\frac{k^2}{3} + 1$, and the number of two-vertex hyperedges is $3k^2 + 3k$. When m is even, the number of three-vertex hyperedges is $\frac{k^2}{3} + \frac{3k}{2} + 1$, and the number of two-vertex hyperedges is $3k^2$. We interpret $\mathcal{G}_m$ as the confusability graph associated with this channel hypergraph; both the confusability graph and the channel hypergraph share the same vertex set and therefore have the same number of vertices.

Capacity parameters. The one shot zero error classical capacity of N_n^m is given by the independence number of its confusability graph, namely $\alpha(\mathcal{G}_m)$ which is known and given by $\alpha(\mathcal{G}_m) = 3m(m + 1)$. Since the vectors live in $\mathbb{C}^3$, we denote by $d = 3$ the local Hilbert space dimension of the quantum system that will be transmitted through a 3-level perfect quantum channel for assistance. A simple comparison shows that $|V(\mathcal{G}_m)| > \alpha(\mathcal{G}_m)d$. This numerical separation is the key to the superadditivity phenomenon exhibited below.

Proof of Remark 1. We now describe an explicit encoding and decoding protocol for the joint use of the two channels that achieves a one shot zero error capacity strictly exceeding the product of the individual one shot zero error capacities.

Encoding. The sender wishes to transmit a message drawn from the message set $\mathcal{M}_m$ with $|\mathcal{M}_m| = |V(\mathcal{G}_m)|$. Fix a bijective encoding map $\mathcal{E} : \mathcal{M}_m \rightarrow V(\mathcal{G}_m)$. To transmit a message $u \in \mathcal{M}_m$, the sender proceeds as follows. First, the classical label corresponding to $v = \mathcal{E}(u)$ is sent through the noisy classical channel N_n^m . Concurrently the sender transmits the qutrit state $|\phi_v\rangle = |\psi_v\rangle$ through a perfect three level quantum channel, where $|\psi_v\rangle$ is the normalized state associated with the vector that labels v .

Channel output. By construction of N_n^m , the classical channel output is a hyperedge $h \subseteq V(\mathcal{G}_m)$ such that $v \in h$.

Through the quantum channel the receiver obtains the corresponding qutrit state $|\phi_v\rangle$, whose identity is a priori unknown to the receiver.

Decoding. Upon receiving the hyperedge h and the quantum state $|\phi_v\rangle$, the receiver implements the following projective measurement determined by h . If h contains three vertices, the receiver measures in the orthonormal basis formed by the three corresponding qutrit states; the three rank one projectors constitute the measurement. If h contains two vertices, let Π_1 and Π_2 denote the two rank one orthogonal projectors onto the corresponding qutrit states; the measurement is completed by the unique third projector $\Pi_3 = \mathbb{I}_3 - (\Pi_1 + \Pi_2)$. In either case $|\phi_v\rangle$ is one of the measurement basis elements, so the measurement outcome identifies v with certainty, and hence it maps the identified vertex back v to the message u .

Superadditivity. The protocol succeeds with zero probability of error for every message. Hence the one shot zero error classical capacity of the joint use of N_n^m and the perfect three level quantum channel is at least $|V(\mathcal{G}_m)|$. The individual one shot zero error classical capacities are $\alpha(\mathcal{G}_m)$ for N_n^m and $d = 3$ for the perfect three level quantum channel, so the product of the individual capacities equals $3\alpha(\mathcal{G}_m)$. Using $\alpha(\mathcal{G}_m) = 3m(m + 1)$ and $|V(\mathcal{G}_m)| = 3 + 9m + 9m^2$ we obtain $|V(\mathcal{G}_m)| = 3\alpha(\mathcal{G}_m) + 3 > 3\alpha(\mathcal{G}_m)$ for all $m \in \mathbb{Z}_+$. Therefore the capacity achieved by the joint channel strictly exceeds the product of the individual capacities. This completes the proof of Remark 1 and provides an explicit family of noisy classical channels that exhibit the superadditivity phenomenon when used in parallel with a perfect three level quantum channel, in accordance with Theorem 1. The underlying construction of the channel confusability graph is based on a state independent contextuality graph that nevertheless admits a KS coloring.

Appendix B: Proofs of Corollary 1 and 2

Corollary 1. For any noisy classical channel N_n , the parallel use of N_n with a two-level perfect quantum channel cannot exhibit zero-error superadditivity under the protocol considered here.

Proof. For projective measurements, any exclusivity graph that admits an orthogonal representation in dimension 2 has a noncontextual hidden variable model. Consequently, the corresponding quantum behavior set coincides with the classical behavior set. Therefore, in our protocol, the quantum states corresponding to each vertex must belong to a Hilbert space of dimension greater than 2.

Now, if the classical channel is assisted by a 2-level perfect quantum channel defined by the map $\mathcal{I}_2 : \mathcal{D}(\mathbb{C}^2) \mapsto \mathcal{D}(\mathbb{C}^2)$ with $\mathcal{I}_2(\rho) = \rho$, for all $\rho \in \mathcal{D}(\mathbb{C}^2)$, then a three or higher dimensional quantum system can not be transmitted intact through this channel from the sender to the receiver. This completes the proof. $\square$

Corollary 2. Let N_n be a noisy classical channel whose confusability graph admits an orthogonal representation in $\mathbb{C}^d$, d being the minimum possible dimension. If the assisting perfect quantum channel has dimension strictly less than d , then no one-shot zero-error superadditivity is possible un-

der this protocol.

Proof. The proof of this corollary is similar to that of Corollary 1. A $(d - 1)$ -level perfect quantum channel cannot transmit a d -dimensional quantum system intact. Therefore, perfect decoding of the transmitted message is not possible. $\square$

Efficient Fault-Tolerant State Preparation for Quantum BCH Codes via Cyclic Symmetry

Abstract. One of the major obstacles to realizing fault-tolerant quantum computers is the large physical-qubit overhead. High-rate quantum error-correcting codes are promising for reducing this cost, and quantum BCH codes are attractive candidates due to their high rates and large distances. However, fault-tolerant ancilla preparation methods tailored to these codes have not been established. We propose a low-overhead two-stage method combining non-fault-tolerant preparation with entanglement distillation, exploiting the cyclic symmetry of quantum BCH codes. Simulations for codes up to 127 qubits show reduced spatial overhead and lower logical error rates than conventional methods. We further evaluate the logical error rates under a circuit-level noise model and obtain performance benchmarks in realistic settings. This efficient state preparation technique may contribute to practical FTQCs on highly connected platforms such as neutral atom systems.

Keywords: quantum error correction, quantum BCH codes, fault-tolerant state preparation, entanglement distillation, cyclic symmetry, threshold analysis

1 Introduction

Quantum computers are expected to solve certain problems that are intractable for classical computers. However, quantum states are highly vulnerable to physical noise, and quantum error correction is indispensable for realizing fault-tolerant quantum computation (FTQC) [1, 2, 3]. The surface code has been the dominant candidate owing to its simple structure and high noise threshold, and its theoretical framework [4, 5, 6] and experimental demonstrations [7, 8] have been extensively developed. Nevertheless, the surface code requires a very large number of physical qubits per logical qubit, which remains one of the most serious obstacles to scalable FTQC [9, 10].

To reduce this overhead, high-rate quantum codes, which encode logical information more densely into physical qubits, have recently attracted considerable attention. Although such codes are typically difficult to implement on architectures with local connectivity, recent advances in highly connected platforms, such as neutral atoms [11, 12] and trapped ions [13, 14, 15], have made their practical implementation more realistic.

High-rate quantum error-correcting codes have been studied through approaches such as quantum LDPC codes and concatenated constructions, but both face limitations in practically relevant regimes. Quantum LDPC codes have favorable asymptotic properties, yet explicit moderate-size constructions often exhibit relatively low encoding rates, with representative examples such as Bivariate Bicycle codes achieving rates around 10% [16, 17, 18]. Concatenated high-rate codes can

achieve higher rates [19, 20], but increasing the code distance typically requires multiple concatenation levels, leading to substantial qubit overhead.

Motivated by these limitations, we focus on quantum BCH codes [21]. This code family inherits the high-rate and strong error-correcting properties of classical BCH codes [22], and can realize high encoding rates with large code distances at moderate block sizes. In this work, we consider quantum BCH codes of length $2^m - 1$, which are particularly suitable for high-rate fault-tolerant architectures within realistic qubit budgets. Despite their attractive parameters, practical fault-tolerant ingredients for these codes remain underdeveloped, including efficient state preparation methods and performance evaluation under realistic physical error models.

In our work [23], we propose an efficient fault-tolerant state preparation method for logical Pauli basis states of quantum BCH codes. The key idea is to combine a non-fault-tolerant encoding circuit with entanglement distillation, and to use the cyclic symmetry of BCH codes to suppress harmful fault patterns with fewer ancilla blocks. For the $[[31, 11, 5]]$, $[[63, 27, 7]]$, and $[[127, 71, 9]]$ codes, this symmetry-based optimization reduces the required ancilla blocks by more than half compared with conventional distillation based methods. Numerical simulations show that the optimized circuits achieve lower output error rates and higher success probabilities. We also evaluate the logical error rates under circuit-level noise using error-corrected teleportation[24], and perform a systematic threshold analysis for quantum BCH codes with lengths up to 127 and selected length-255 codes. These results indicate that quantum BCH codes are promising candidates for resource-efficient large scale FTQC.

2 Preliminaries: Quantum BCH Codes

Quantum BCH codes are CSS codes constructed based on classical BCH codes. We restrict our attention to binary BCH codes in our work.

Definition 1 (Quantum BCH codes [21]) *Let C be a classical BCH code with parameters $[n_c, k_c, d_c]$ and parity check matrix H_c . If the classical code C satisfies the dual-containing constraint (i.e., $C^\perp \subset C$), a CSS code can be constructed using C and its dual code $C^\perp$. The stabilizer matrix of the resulting quantum BCH code $[[n = n_c, k = 2k_c - n, d = d_c]]$ is given by*

$$H = \begin{pmatrix} H_c & 0 \\ 0 & H_c \end{pmatrix}. \quad (1)$$

Quantum BCH codes inherit the high-rate and strong error-correcting properties of classical BCH codes, enabling large code distances at moderate block sizes. However, their stabilizer generators are typically high-weight and nonlocal, making fault-tolerant state preparation nontrivial. For example, the $[[31, 11, 5]]$ quantum BCH code has weight-12 stabilizer generators.

3 Efficient Fault-Tolerant Ancilla State Preparation for Quantum BCH codes

We adopt the notion of *strict fault tolerance* [25]: a state preparation circuit for an $[[n, k, d = 2t + 1]]$ code is strict-FT if any $w \leq \lfloor d/2 \rfloor$ faults in the circuit yield an output whose reduced weight (the minimum weight after applying stabilizers) is at most w .

For CSS codes, $|0_L^{sk}\rangle$ can be prepared by a non-FT (non-fault-tolerant) circuit followed by an entanglement distillation circuit that filters out errors. The distillation circuit consists of two steps: a first step checking X errors and a second step checking Z errors. Using the $[m, 1, m]$ repetition code for each step (the “ m -to-1” protocol), it is known that an $(t + 1)$ -to-1 protocol achieves strict-FT, but requires at least $(t + 1)^2$ ancillas in total [26].

A key challenge in reducing the number of ancilla blocks for quantum BCH codes is the presence of malignant fault patterns. Specifically, when faults occur at the

same physical positions in the non-FT preparation circuits of different ancilla copies, the resulting errors can cancel during distillation and evade detection. Recent works [25, 27] have proposed using code symmetries to avoid such alignments of fault locations. However, the symmetries of quantum BCH codes and their systematic use for state preparation have not been clarified.

The symmetries of quantum BCH codes can be characterized through the automorphism groups of the underlying classical BCH codes. The automorphism group of a binary BCH code contains the semidirect product of the cyclic permutation group C_n and the Frobenius permutation group F_m [28]. In particular, the cyclic shift $j \mapsto j + 1$ and the Frobenius shift $j \mapsto 2j$ preserve the stabilizer structure and leave the logical zero and logical plus states considered in this work invariant.

We exploit this property by applying different code permutations to the non-FT preparation circuits of different ancilla copies, as illustrated in Fig. 1. By choosing suitable permutations, faults that would otherwise be aligned at the same physical positions across different copies are mapped to different coordinates. This prevents the cancellation of errors that could evade the distillation checks, thereby avoiding malignant fault patterns. An important feature of this approach is that it does not rely on hand-designed preparation circuits: it is applicable to arbitrary quantum BCH codes and arbitrary non-FT preparation circuits.

For a given set of permutations, we determine whether malignant fault patterns exist by enumerating the errors arising from faults in the non-FT preparation circuits and checking whether they remain undetected by the distillation checks and violate strict fault tolerance. By performing this test over candidate sets of permutations, we can search for distillation protocols that achieve fault-tolerant state preparation with fewer ancilla blocks. The details of this search procedure are deferred to the full paper [23].

Table 1 compares the required ancilla blocks for three quantum BCH codes. Our method achieves strict-FT using less than half the ancilla blocks required by the conventional $(t + 1)$ -to-1 protocol, directly reducing the physical qubit overhead for ancilla preparation.

Table 1: Ancilla copy reduction using cyclic symmetry. The proposed protocol reduces the distillation block sizes compared with the conventional $(t + 1)$ -to-1 protocol while preserving strict fault tolerance.

Code	t	Conventional	Proposed
$[[31, 11, 5]]$	2	3-to-1 $\times$ 3-to-1	2-to-1 $\times$ 2-to-1
$[[63, 27, 7]]$	3	4-to-1 $\times$ 4-to-1	2-to-1 $\times$ 2-to-1
$[[127, 71, 9]]$	4	5-to-1 $\times$ 5-to-1	2-to-1 $\times$ 3-to-1

4 Numerical Simulations: $[[31, 11, 5]]$

We simulate state preparation for $[[31, 11, 5]]$ using Stim [29] under a circuit-level depolarizing noise model:

each physical CNOT is followed by a 2-qubit depolarizing channel at rate p ; single-qubit gates, state preparation, and measurements incur bit-flip errors at rate p .

Error rate. Figure 2 shows the weight distributions of residual X errors in the output states for the proposed 2-to-1 protocol vs. the conventional 3-to-1 protocol. The proposed method achieves a lower X -error rate: the dominant error source is the transversal CNOT in the distillation circuit, whose effective error rate scales as $\frac{4m_2}{15}p$ (where m_2 is the second-step protocol size). Reducing m_2 from 3 to 2 directly cuts this leading contribution.

Figure 2: Weight distribution of residual X errors in the output state $|0_L^{\otimes 11}\rangle$. The proposed protocol significantly suppresses low-weight X errors compared to the conventional method. The black solid line represents the theoretical prediction $4mp/15$ for an m -to-1 protocol.

Success probability. Figure 3 compares the round acceptance probabilities of the conventional 3-to-1 protocol and the proposed 2-to-1 protocol. The theoretical lower bounds from Appendix C of the full version [23] agree with the simulation results. The proposed protocol achieves higher acceptance probabilities by using fewer ancilla qubits and transversal CNOT gates, thereby reducing rejection-triggering error locations.

5 Threshold Analysis

5.1 Setup and analysis method

To evaluate the potential of quantum BCH codes for FTQC, we analyze the threshold of transversal CNOT gates corrected by error-corrected teleportation [24]. Since all error locations in the circuit act transversally, we approximate the circuit-level noise model by a code-capacity noise model with an effective physical error rate γp . Here, γ is a constant determined by the circuit structure and the effective noise rates of the $|0_L^{\otimes k}\rangle$ and $|+_L^{\otimes k}\rangle$ preparation procedures (see [23] for details).

Figure 3: Success probability per distillation round for the conventional 3-to-1 and proposed 2-to-1 protocols for the quantum BCH $[[31,11,5]]$ code. Red (blue) points correspond to the 3-to-1 (2-to-1) protocol, while circle (triangle) markers represent the first (second) step. The dashed and dotted lines indicate the theoretical lower bounds of the success probability for each step, calculated based on the probability that no errors occur at any detectable locations (see [23] for details).

5.2 Decoder and Poltyrev Bound

We assume maximum-likelihood decoding (MLD) to characterize the fundamental limit. For codes where exact MLD simulation is computationally expensive, we use the poltyrev bound [30], a tight upper bound on the MLD logical error rate derived from the code weight enumerator.

5.3 Results

We evaluated the trade-off between the scaling threshold and the code rate for all quantum BCH codes with $n \leq 127$, as well as quantum BCH codes with $n = 255$ and $d \leq 13$. The full plot is provided in Fig. 7 of the technical version [23]; here, we summarize the main observations.

1. **Proposed method boosts threshold:** Applying the cyclic-symmetry-based ancilla reduction raises the threshold for each code compared to the conventional protocol, because fewer ancilla copies incur less noise during state preparation.
2. **Competitive with Steane code:** Codes such as $[[31, 11, 5]]$, $[[63, 27, 7]]$, $[[127, 71, 9]]$, and $[[255, 159, 13]]$ maintain a threshold comparable to the $[[7, 1, 3]]$ Steane code [31] while achieving 2–4 $\times$ higher code rates.
3. **Design flexibility:** Across the evaluated codes, we observe a clear trade-off between code rate and threshold, with quantum BCH codes covering a broad range of achievable parameters. These results provide practical guidance for selecting suitable BCH codes when designing high-rate fault-tolerant protocols.

Matrix product state approach to lossy boson sampling and noisy IQP sampling

Sojeong Park¹ *

Changhun Oh¹ †

¹ *Department of Physics, Korea Advanced Institute of Science and Technology, Daejeon 34141, Korea*

Abstract. Demonstrating quantum advantage with NISQ devices often relies on sampling problems, but realistic noise can make these experiments classically simulable. In this work, we generalize the matrix product state approach, originally developed for Gaussian boson sampling, to lossy single-photon Fock-state boson sampling and noisy IQP sampling. Unlike methods based on fixed approximations to nearby classically simulable inputs, our algorithm applies to all loss rates and offers tunable accuracy that scales with computational resources. Our results provide a flexible framework for identifying classically tractable regimes and assessing the robustness of quantum advantage claims in noisy sampling experiments on near-term devices.

Keywords: Quantum advantage, Classical simulation, Boson sampling, Instantaneous quantum polynomial-time sampling, Matrix product state

1 Introduction

Sampling problems such as boson sampling, instantaneous quantum polynomial-time (IQP) sampling, and random circuit sampling have been proposed as promising routes to demonstrating quantum advantage. In the ideal noiseless setting, these problems are widely believed to be classically intractable under standard complexity-theoretic assumptions, motivating a series of sampling-based quantum-advantage experiments [1, 2, 3, 4]. However, realistic devices inevitably suffer from noise and loss, which can reduce entanglement and enable efficient classical simulation. Indeed, several works have shown that noise or loss can make sampling experiments classically tractable, either by directly simulating experimental instances or by identifying efficiently simulable noisy regimes [5, 6, 7, 8, 9]. Thus, assessing quantum-advantage claims requires understanding how realistic noise affects the computational complexity of the corresponding sampling task.

A notable example is the MPS-based algorithm that recently simulated state-of-the-art Gaussian boson sampling (GBS) experiments [7]. The key observation is that photon loss suppresses entanglement, allowing the lossy GBS state to be efficiently represented, or at least systematically approximated, by an MPS with moderate bond dimension. This gives the algorithm a practical advantage over fixed-approximation methods, which replace the noisy experiment with a nearby classically tractable model and whose accuracy is essentially fixed once the experimental parameters are specified [5]. By contrast, in the MPS framework, the bond dimension is a controllable accuracy parameter: increasing it raises the computational cost but systematically improves the approximation. Thus, the algorithm provides a resource–accuracy tradeoff and remains useful beyond regimes with a strict polynomial-time guarantee.

Given these advantages, a natural question is whether the MPS-based strategy can be extended beyond GBS

to other noisy sampling problems. This extension is not straightforward because the previous GBS algorithm relies strongly on Gaussianity. As a result, it cannot be directly applied to more general sampling problems. In this work, we address this limitation by developing an MPS-based simulation framework for lossy single-photon Fock-state (SPFS) boson sampling and noisy IQP sampling.

2 Results

2.1 Summary of our main result

This extended abstract is based on Ref. [10].

We develop an MPS-based classical simulation framework for lossy SPFS boson sampling and noisy IQP sampling by combining pure-state ensemble decompositions with low-entanglement tensor-network simulation. For lossy SPFS boson sampling with N input photons and total transmission rate η , our entanglement analysis shows that the sampled pure-state components are efficiently approximable by MPS when $\eta = O(1/\sqrt{N})$. Conversely, when η scales asymptotically faster than $1/\sqrt{N}$, polynomial bond dimension is insufficient for this MPS representation. Thus, our method has two complementary features: it recovers the known simulability threshold and, at the same time, provides a tunable resource–accuracy tradeoff through the MPS bond dimension. This tunability is crucial for practical simulations of concrete experimental instances, where the relevant question is not only whether a polynomial-time regime exists, but how accurately a given noisy device can be simulated with available classical resources. Unlike fixed-approximation methods, the MPS approach allows the accuracy to be systematically improved by increasing the bond dimension.

Because the core mechanism is similarly applied to noisy IQP sampling, we focus on the lossy SPFS boson sampling in this extended abstract (see Ref. [10]).

*sojeong.park@kaist.ac.kr

†changhun0218@kaist.ac.kr

Figure 1: Lossy SPFS boson sampling algorithm. (a,b) Photon loss in the circuit can be commuted to the input side, yielding total input loss with transmission rate η followed by a lossless interferometer. (c,d) The resulting mixed input state is simulated by sampling a pure-state component from the ensemble decomposition of each lossy single-photon state σ .

2.2 MPS algorithm

The MPS method provides an efficient representation of weakly entangled pure states. Its computational cost is controlled by the bond dimension χ , which determines how much entanglement can be retained in the representation. Therefore, by analyzing the entanglement growth of the evolved pure-state components, we can estimate the scaling of the bond dimension required for accurate simulation. If the required bond dimension grows only polynomially with the system size, the state can be efficiently represented by an MPS, and the corresponding sampling task can be simulated efficiently.

We consider a lossy SPFS boson sampling circuit with M modes and N single-photon inputs, assuming uniform photon loss across all modes and circuit depths, as shown in Fig. 1(a). Under this uniform-loss assumption, all loss channels can be commuted to the input side of the circuit. Thus, the original lossy circuit is equivalent to total loss channels with transmission rate η acting on the input, followed by a lossless optical network, as illustrated in Fig. 1(b).

After the total loss channel, each single-photon input is transformed into the single-mode mixed state

$$\sigma = (1 - \eta)|0\rangle\langle 0| + \eta|1\rangle\langle 1|. \quad (1)$$

The total input state is therefore $\sigma^{\otimes N} \otimes (|0\rangle\langle 0|)^{\otimes (M-N)}$, as shown in Fig. 1(c). Hence, the lossy SPFS boson sampling problem can be equivalently viewed as a lossless optical network acting on a product mixed input state.

The obstacle is that, after commuting the loss to the input side, the state entering the lossless interferometer is mixed, whereas the standard MPS method is designed for pure-state evolution. We overcome this by using a pure-state ensemble decomposition of the mixed input. Suppose that $\rho_{\text{in}} = \sum_i p_i |\psi_i\rangle\langle \psi_i|$. For a lossless circuit U and measurement operator Π , the output probability is $\text{Tr}[U\rho_{\text{in}}U^\dagger\Pi] = \sum_i p_i \text{Tr}[U|\psi_i\rangle\langle \psi_i|U^\dagger\Pi]$. Thus, the same output distribution can be generated by first sampling a pure-state component $|\psi_i\rangle$ with probability p_i , evolving it through the lossless circuit, and then measuring. This reformulation allows us to apply MPS simulation to each sampled pure-state component rather than to the mixed state itself.

The choice of ensemble decomposition is the central issue. Although all decompositions represent the same

mixed input state, they can lead to pure-state components with very different entanglement after the circuit, and therefore to very different MPS costs. For example, the most direct photon-number decomposition of $\sigma = (1 - \eta)|0\rangle\langle 0| + \eta|1\rangle\langle 1|$ samples each input mode as $|0\rangle$ with probability $(1 - \eta)$ and as $|1\rangle$ with probability η . The sampled input then contains ηN photons on average, effectively reducing the problem to lossless boson sampling with ηN photons. Since the cost of simulating lossless boson sampling grows exponentially with the number of photons, this naive decomposition would give efficient simulation only when $\eta N = O(\log N)$, or equivalently $\eta = O(\log N/N)$. It therefore fails to reach the known simulable scaling $\eta = O(1/\sqrt{N})$ [5, 6].

Instead, we use a pure-state decomposition of the same lossy single-photon state, $\sigma = \frac{1}{2}|\psi_+\rangle\langle \psi_+| + \frac{1}{2}|\psi_-\rangle\langle \psi_-|$, where $|\psi_{\pm}\rangle \equiv \sqrt{1 - \eta}|0\rangle \pm \sqrt{\eta}|1\rangle$. With this decomposition, each lossy input mode is sampled as $|\psi_+\rangle$ or $|\psi_-\rangle$ with equal probability, as illustrated in Fig. 1(d). Unlike the photon-number decomposition, the sampled input is a product of vacuum–single-photon superposition states rather than a lossless boson-sampling instance with a random number of surviving photons. This difference is crucial: in the sufficiently lossy regime, these inputs generate much less entanglement after the linear-optical circuit, allowing efficient MPS simulation.

Overall, the algorithm consists of three steps: commute the loss to the input side, sample a carefully chosen pure-state component of the resulting mixed input, and evolve that component using MPS. The same ensemble-decomposition strategy also extends to noisy IQP sampling under dephasing and depolarizing noise.

2.3 Analytical and numerical results

Analytical scaling. To determine the simulable range of the transmission rate η , we analyze the entanglement growth of the sampled pure-state components after the linear-optical circuit. The relevant quantity is the entanglement Rényi entropy (ERE), which controls the bond dimension needed for MPS approximation. If the ERE across every bipartition grows only logarithmically in N , the state is approximable by an MPS with polynomial bond dimension [12], and sampling from such an MPS can be performed efficiently [6]. Applying this criterion to our pure-state ensemble decomposition, we identify an MPS-approximability transition for lossy SPFS boson

Figure 2: Required bond dimension and memory to achieve an MPS approximation error $\epsilon = 0.01$. Panels (a)–(c) show the required bond dimension, and panels (d)–(f) show the corresponding memory cost for three choices of the circuit unitary: worst-case, Haar-random, and experimentally motivated structures based on Ref. [3].

sampling at the transmission-rate scaling $\eta = \Theta(1/\sqrt{N})$, up to logarithmic factors:

- If $\eta = O(1/\sqrt{N})$, the sampled pure-state components are efficiently approximable by MPS with polynomial bond dimension. Hence, lossy SPFS boson sampling is efficiently simulable within our MPS framework.
- If η scales asymptotically faster than $1/\sqrt{N}$, the required bond dimension becomes superpolynomial for this MPS representation. Hence, polynomial-bond-dimension MPS approximation is insufficient in this regime.

This transition is consistent with previous asymptotic simulability results based on different methods [5, 6]. At the same time, our approach provides a tunable bond-dimension-based approximation scheme, allowing the simulation accuracy to be systematically improved by increasing the classical resources.

Finite-size resource estimates. We also numerically estimate the bond dimension required for finite-size lossy SPFS boson sampling at a fixed MPS truncation error $\epsilon = 0.01$. The approximation error is controlled by the discarded Schmidt coefficients: achieving smaller error requires retaining more Schmidt coefficients and hence increasing the bond dimension. In Fig. 2(a)–(c), we compare the required bond dimension for three classes of interferometers: a worst-case construction, Haar-random unitaries, and an experimentally motivated architecture based on Ref. [3]. The worst-case construction gives the largest entanglement and therefore the largest MPS cost for fixed photon number and transmission rate. The

Haar-random case represents a standard average-case model for boson sampling. For the experimentally motivated case, we use an interferometer architecture analogous to that used in the GBS experiment of Ref. [3]; although the input states differ from SPFS boson sampling, the resulting optical network provides a useful benchmark for estimating MPS resources in experimentally relevant settings.

To translate the bond-dimension estimates into more concrete resource requirements, we report the corresponding memory costs in Fig. 2(d)–(f). These estimates provide a practical benchmark for identifying finite-size regimes where direct MPS simulation remains feasible or becomes prohibitively expensive.

3 Conclusion

We have extended the MPS-based classical simulation strategy from lossy Gaussian boson sampling to noisy sampling problems, including lossy SPFS boson sampling and noisy IQP sampling. The central idea is to represent the mixed states generated by loss or noise as carefully chosen pure-state ensembles, so that each sampled component can be evolved using standard pure-state MPS methods. For lossy SPFS boson sampling, our ERE analysis identifies an MPS-approximability transition at $\eta = \Theta(1/\sqrt{N})$, up to logarithmic factors, while preserving the practical tunability of the MPS framework: the approximation accuracy can be systematically improved by increasing the bond dimension. Together with finite-size bond-dimension and memory estimates, our results provide a resource-aware framework for assessing when noisy sampling experiments remain beyond the reach of classical simulation.

Matrix product state approach to lossy boson sampling and noisy IQP sampling

Sojeong Park and Changhun Oh*

Department of Physics, Korea Advanced Institute of Science and Technology, Daejeon 34141, Korea

Sampling problems have emerged as a central avenue for demonstrating quantum advantage on noisy intermediate-scale quantum devices. However, physical noise can fundamentally alter their computational complexity, often making them classically tractable. Motivated by the recent success of matrix product state (MPS)-based classical simulation of Gaussian boson sampling (Oh et al., 2024), we extend this framework to investigate the classical simulability of other noisy quantum sampling models. We develop MPS-based classical algorithms for lossy boson sampling and noisy instantaneous quantum polynomial-time (IQP) sampling, both of which retain the tunable accuracy characteristic of the MPS approach through the bond dimension. Our approach constructs pure-state decompositions of noisy or lossy input states whose components remain weakly entangled after circuit evolution, thereby providing a means to systematically explore the boundary between quantum-hard and classically-simulable regimes. For boson sampling, we analyze single-photon, Fock, and cat-state inputs, showing that classical simulability emerges at transmission rates scaling as $O(1/\sqrt{N})$, reaching the known boundary of quantum advantage with a tunable and scalable method. Beyond reproducing previous thresholds, our algorithm offers significantly improved control over the accuracy–efficiency trade-off. It further extends the applicability of MPS-based simulation to broader classes of noisy quantum sampling models, including IQP circuits.

I. INTRODUCTION

It is widely believed that a quantum computer can efficiently solve certain problems that are hard for classical computers, such as integer factoring and Hamiltonian simulation [1, 2]. Since one of the most critical obstacles to realizing a quantum computer is noise, quantum error correction (QEC) has been developed to actively detect and correct errors, enabling fault-tolerant quantum computation [3, 4]. Despite substantial advances in both quantum hardware and the theory and implementation of QEC [5, 6], currently available quantum devices cannot yet fully exploit the QEC technique in a fully scalable manner. Consequently, extensive efforts have focused on achieving quantum advantage using currently available quantum devices, often referred to as noisy intermediate-scale quantum (NISQ) devices [7–17].

To pursue quantum advantage with NISQ devices, quantum sampling problems have emerged as promising candidates due to their complexity-theoretic hardness results in noiseless cases and their relatively feasible experimental requirements, compared with more sophisticated quantum algorithms [7–9]. The most representative examples of sampling problems include boson sampling, random circuit sampling, and instantaneous quantum polynomial-time (IQP) sampling [7, 18, 19]. In fact, the experimental implementation of these sampling problems has been conducted to claim quantum advantage by experiments [9, 12, 14, 17, 20, 21].

However, such claims have been continuously challenged due to the noise in the realistic experiment

(e.g., Refs. [22–35]). The main insight for this is that physical noise often degrades and ultimately destroys quantum advantage. For example, when a depolarizing noise occurs in quantum circuits and the circuit depth is large, the system accumulates entropy, causing the output state to converge to the maximally mixed state, which is easily simulated classically [36]. Similarly, in photonic systems, it has been shown that photon loss makes a quantum state converge to a thermal state, which is easy to classically simulate [25, 26]. As such, physical noise may make sampling problems that are hard to classically simulate when noiseless become easy to simulate. Hence, to rigorously assess the potential advantage of quantum devices, it is essential to understand whether and when sampling problems become easy to classically simulate under realistic noise conditions.

Focusing specifically on boson sampling, one of the most widely studied sampling models, as aforementioned, when the loss rate is sufficiently large, boson sampling becomes classically easy. Motivated by this observation, a variety of classical simulation algorithms have been developed [25, 27, 32, 37–39]. One line of work [25] used a strategy to approximate a lossy quantum state by a quantum state that is classically easy to simulate. For example, Ref. [25] and Ref. [24] showed that a lossy single photon state can be approximated by a thermal state or a separable state, respectively, when the loss rate is high. Furthermore, this idea has been extended to lossy Gaussian boson sampling (GBS) [26]. Nonetheless, when applied to recent GBS experiments, while it provides an important benchmark, the classical algorithm was not sufficient to simulate them [12, 14]. A key limitation of these approaches is that, since they rely on approximating a given state by the nearest classically simulable state, their performance cannot be systematically improved by allocating additional

* changhun0218@kaist.ac.kr

computational resources. Hence, below a loss rate threshold, the algorithm fails to operate.

Notably, a more recently proposed classical algorithm based on the matrix product state (MPS) has overcome this limitation and successfully simulated the state-of-the-art GBS experiments at the moment. The crucial feature of the new classical algorithm is the tunability of its performance by providing more computational resources, which translates to the bond dimension of the MPS. However, because the method in Ref. [33] relies on the Gaussianity of the quantum system, it has not been extended to other systems so far, despite its high performance in practice.

In this work, we generalize the MPS for GBS proposed in Ref. [33] to simulate lossy boson sampling and noisy IQP sampling. In other words, we develop MPS-based classical algorithms for lossy boson sampling and noisy IQP sampling that correspond to the state-of-the-art classical algorithm for lossy GBS; hence, our classical algorithms also enjoy the property that the accuracy is tunable by consuming computational resources, unlike the previous algorithms [24, 25]. The central idea of our approach is to construct a pure-state decomposition of a lossy or noisy input state such that each component remains weakly entangled after circuit evolution. For the boson sampling case, we consider various input states, such as single-photon states, Fock states, and cat states as input and analyze the performance of our algorithm using the entanglement entropy [40, 41]. Notably, we find a similar classically simulable range of the transmission rate to GBS and previous results [24, 25, 33], which is given as $O(1/\sqrt{N})$, where N is the input photon number. We then estimate the bond dimension required to simulate, providing guidelines for future experiments. We further extend our framework to noisy IQP sampling and then demonstrate that the performance of our classical algorithm is comparable to that of the recently proposed algorithm [42].

The remainder of this paper is organized as follows. In Sec. II, we introduce the problem setup by describing boson sampling and IQP sampling circuits and provide the relation between MPS and efficient classical simulation in Sec. III. In Sec. IV, we present an MPS-based classical simulation algorithm for boson sampling with various input states and analyze the asymptotically simulable range and obtain the numerical estimation of computational resources. In Sec. V, we provide a classical simulation algorithm for IQP sampling together with its numerical analysis. Finally, Sec. VI discusses the implications of our results and concludes the paper.

II. PROBLEM SETUP

A. Boson sampling

Boson sampling is a sampling problem that is proposed to demonstrate quantum advantage using photons [7].

To formally introduce boson sampling, consider an M -mode bosonic system and let $\hat{a}_i$ and $\hat{a}_i^\dagger$ denote the bosonic annihilation and creation operators of the i th mode, respectively, satisfying the canonical commutation relations, $[\hat{a}_i, \hat{a}_j^\dagger] = \delta_{ij}$ and $[\hat{a}_i, \hat{a}_j] = 0$, where $1 \leq i \leq M$. The input state of boson sampling is N single photons in the first N modes out of a total of M modes, with the rest of the modes being initialized as vacuum, i.e., the input state is written as

$$|1\rangle^{\otimes N} |0\rangle^{\otimes (M-N)} = \left(\prod_{i=1}^N \hat{a}_i^\dagger \right) |0\rangle^{\otimes M}. \quad (1)$$

The boson sampling circuit is given by a linear optical circuit, characterized by an $M \times M$ unitary matrix U . More specifically, the latter transforms the input bosonic creation operators as

$$\hat{a}_j^\dagger \rightarrow \hat{b}_j^\dagger \equiv \sum_{k=1}^M U_{jk}^* \hat{a}_k^\dagger, \quad (2)$$

where $\hat{b}_i^\dagger$ represents the creation operator of the i th output mode. Here, U is often chosen to follow the Haar-random unitary ensemble for hardness results [7]. Such a Haar-random linear optical circuit can be implemented using two-mode beam splitters and phase shifters, with the circuit depth being linear in M [43]. After the circuit, the output state is measured by photon number-resolving detectors, which give an output sample $(t_1, \dots, t_M) \in \mathbb{Z}_{\geq 0}^M$, where t_i represents the output photon number on the i th output mode, satisfying $\sum_{i=1}^M t_i = N$ since linear-optical circuits preserve the photon number.

Boson sampling has attracted considerable attention due to its hardness result. More specifically, lossless boson sampling is proven to be hard to classically simulate under some plausible conjectures [7]. The main observation for the hardness result is that the corresponding output probability is described by a matrix function, so-called the permanent:

$$p(t_1, t_2, \dots, t_M) = \frac{|\text{Perm } U_T|^2}{t_1! \dots t_M!}, \quad (3)$$

which is known as #P-hard to compute approximately in multiplicative error. Here, U_T is a matrix obtained by keeping the first N columns from U and repeating the j th row t_j times.

Although the ideal boson sampling is believed to be hard to simulate classically, the actual experiments that implement boson sampling suffer from practical imperfections that hinder the demonstration of quantum advantage. In particular, one of the dominant imperfections is photon loss in the current experiments [44], and many studies demonstrate that under photon loss, photon sampling becomes easier to classically simulate [24–27, 30, 32]. Therefore, it is crucial to consider the effect of photon loss and understand

FIG. 1. Photon loss in boson sampling circuit. (a) Lossy boson sampling circuit. Blue rectangles represent ideal beam splitters and phase shifters, while orange squares represent photon loss channels. (b) Assuming a uniform transmission rate, we separate the loss channel from the ideal linear optics and locate it in front of the ideal optics. η is defined as the transmission rate of the total loss channel.

its significance for rigorously evaluating the classical simulability of experimental boson sampling.

In a lossy optical circuit, photon loss can be modeled using a beam splitter. More specifically, a loss channel on the i th mode with its loss rate $1 - \eta$ (i.e., transmission rate η) transforms the i th mode's bosonic creation operator as

$$\hat{a}_i^\dagger \rightarrow \sqrt{\eta}\hat{a}_i^\dagger + \sqrt{1-\eta}\hat{e}_i^\dagger, \quad (4)$$

where $\hat{e}_i^\dagger$ is the creation operator of the corresponding environmental mode. One may easily check that a single-photon state transforms as follows under the loss channel of transmission rate η :

$$|1\rangle\langle 1| \rightarrow (1-\eta)|0\rangle\langle 0| + \eta|1\rangle\langle 1|. \quad (5)$$

Throughout this work, we assume that the optical devices have the same transmission rate and each mode has the same depth for simplicity; therefore, the transmission rate and the loss rate of each mode are assumed to be uniform. This uniform loss assumption allows each layer of the loss channel to commute with all other linear optical devices and be brought to the forefront of the lossless circuit. Consequently, the model reduces to a Haar random interferometer preceded by a uniform loss channel, as shown in Fig. 1. In the case of nonuniform loss, we can generalize this method by commuting the uniform loss part to the front and setting the overall transmission rate as the maximum among the modes in the remaining optics, and commuting to the front (see Ref. [24] for more details).

B. IQP sampling

IQP sampling is another sampling problem based on qubits, which is also widely believed to be computationally intractable for classical computers [19]. The n -qubit IQP sampling operates as follows. First, the input state is prepared as $|0\rangle^{\otimes n}$ and then evolves under a quantum circuit. At first, a layer of n Hadamard gates

is applied to the initial state $|0\rangle^{\otimes n}$, which transforms the state to the uniform superposition of all bitstrings with length n :

$$\frac{1}{\sqrt{2^n}} \sum_{\vec{x} \in \{0,1\}^n} |\vec{x}\rangle. \quad (6)$$

The qubits then go through the circuit with depth d consisting of diagonal gates in Z basis, such as Z , S , T , and CZ gates. The diagonal gates transform the quantum state to

$$\frac{1}{\sqrt{2^n}} \sum_{\vec{x} \in \{0,1\}^n} e^{if(\vec{x})} |\vec{x}\rangle, \quad (7)$$

where f is a real function determined by the diagonal gates. Thus, the diagonal gates change the relative phases between different computational basis elements. Finally, a layer of Hadamard gates is applied after diagonal gates, and the output state is measured in the Z basis. Like boson sampling, IQP sampling is believed to be classically intractable: if it admitted an efficient classical simulation, the polynomial hierarchy would collapse to the third level, a consequence widely considered implausible [19].

As for the boson sampling case, however, many recent results show that IQP sampling may also be efficiently simulated when noise occurs in the system [42, 45, 46]. In this work, we exploit our MPS method to investigate the effect of noise on the hardness of IQP circuits and compare with other existing methods. To investigate the effect of noise on the complexity of simulating IQP sampling, we consider Pauli noises in IQP circuits, which is a dominant noise model in many physical devices. A Pauli noise channel transforms a quantum state $\hat{\rho}$ as follows:

$$\begin{aligned} \mathcal{N}_{p_X, p_Y, p_Z}(\hat{\rho}) &= (1 - p_X - p_Y - p_Z)\hat{\rho} + p_X \hat{X}\hat{\rho}\hat{X} + p_Y \hat{Y}\hat{\rho}\hat{Y} + p_Z \hat{Z}\hat{\rho}\hat{Z}, \end{aligned} \quad (8)$$

where p_X , p_Y , and p_Z are probabilities of X , Y , and Z errors that characterize the noise rates of a Pauli channel. Our method applies to Pauli noise channels that can be decomposed into single-Pauli noise channels (i.e., channels involving only X , Y , or Z errors). In what follows, we focus on two important special cases: dephasing noise and depolarizing noise. We first consider dephasing noise to provide an intuition, and then generalize it to the depolarizing noise. Here, the dephasing channel is a Pauli noise channel with $p_X = p_Y = 0$, i.e., the noise effect is only by Z error:

$$\mathcal{N}_{0,0,p}(\hat{\rho}) = (1-p)\hat{\rho} + p\hat{Z}\hat{\rho}\hat{Z}, \quad (9)$$

where dephasing noise rate $0 \leq p \leq 1/2$. The dephasing noise channel is particularly simple to analyze in IQP sampling because it commutes with all diagonal gates in an IQP circuit, as both dephasing noise and the actions

FIG. 2. Setup of a noisy IQP circuit. (a) The circuit consists of Z -diagonal gates (blue rectangles) with dephasing noise (orange squares) applied at each gate. Measurements are performed in the X basis, equivalently implemented by a Hadamard layer followed by Z -basis readout. (b) Because dephasing commutes with Z -diagonal gates, all dephasing channels can be propagated to the input and consolidated as $\mathcal{N}_{0,0,p_d}$ acting before the circuit.

of diagonal gates are in the computational basis, which is similar to the loss channel in boson sampling. Hence, all dephasing noise channels can be moved forward, just after the first layer of Hadamard gates, by commuting with other gates. Assuming that the dephasing noise of the same noise rate is applied for each depth of gates for simplicity, the total noise channel applied to each input of the circuit when the noise channels are moved forward, as in Fig. 2(b), is given as a dephasing noise $\mathcal{N}_{0,0,p_d}$ with dephasing noise rate $p_d = (1 - (1 - 2p)^d)/2$.

Generalizing this, we also investigate the classical simulation of a noisy IQP circuit under depolarizing noise:

$$\mathcal{N}_{\text{depol}}(\hat{\rho}) = \left(1 - \frac{3}{2}p\right)\hat{\rho} + \frac{p}{2}\hat{X}\hat{\rho}\hat{X} + \frac{p}{2}\hat{Y}\hat{\rho}\hat{Y} + \frac{p}{2}\hat{Z}\hat{\rho}\hat{Z}, \quad (10)$$

where $0 \leq p \leq 1/2$. After a qubit goes through this channel, the state is not changed when $p = 0$ and becomes maximally mixed when $p = 1/2$. Depolarizing noise can be expressed in terms of Pauli noise. Using the equality

$$\mathcal{N}_{0,0,q} \circ \mathcal{N}_{0,q,0} \circ \mathcal{N}_{q,0,0}(\hat{\rho}) = \mathcal{N}_{\text{depol}}(\hat{\rho}), \quad (11)$$

we can derive $(1-q)^3 + q^3 = 1 - 2p \Rightarrow q = (1 - \sqrt{1 - 2p})/2$. For all range of $0 \leq p \leq 1/2$, there exists corresponding $0 \leq q \leq 1/2$. Therefore, the IQP circuit under depolarizing noise can equivalently be expressed as in Fig. 3.

III. MPS AND CLASSICAL SIMULABILITY

As mentioned in the introduction, this work focuses on the MPS method for classical simulation. Thus, we provide a brief review of the MPS, which is particularly useful when a given quantum state is slightly entangled [41]. More specifically, consider a quantum

FIG. 3. Setup of a depolarizing-noisy IQP circuit. (a) The IQP circuit comprises Z -diagonal gates (blue rectangles), with a single-qubit depolarizing channel (orange squares) applied at each gate. Measurements are performed in the X basis. (b) Each depolarizing channel is represented as a probabilistic mixture of Pauli errors X , Y , and Z , each occurring with rate q .

state $|\psi\rangle$ written as

$$|\psi\rangle = \sum_{i_1, \dots, i_L=0}^{d-1} c_{i_1, \dots, i_L} |i_1\rangle \otimes \dots \otimes |i_L\rangle, \quad (12)$$

where each local Hilbert space dimension is d and $\{|i_k\rangle\}_{i_k=0}^{d-1}$ represents an orthogonal basis of the k th local system. The MPS description of the state is a (approximate) decomposition of each amplitude as a product of matrices as

$$c_{i_1, \dots, i_L} \approx \sum_{\alpha_1, \dots, \alpha_{L-1}=0}^{\chi-1} \Gamma_{\alpha_1}^{[1]i_1} \lambda_{\alpha_1}^{[1]} \Gamma_{\alpha_1 \alpha_2}^{[2]i_2} \lambda_{\alpha_2}^{[2]} \Gamma_{\alpha_2 \alpha_3}^{[3]i_3} \dots \Gamma_{\alpha_{L-1}}^{[L]i_L}. \quad (13)$$

Here, χ is called the bond dimension of the MPS, and the MPS keeps up to the χ th largest Schmidt coefficients for each bipartition $[1, \dots, l] : [l+1, \dots, L]$; thus, the description is an approximation if the chosen bond dimension cannot keep all the Schmidt coefficients. Therefore, by increasing the bond dimension χ , we can reduce the approximation error of the MPS. However, increasing the bond dimension requires an additional computational cost. Hence, the bond dimension characterizes both the computational cost and the approximation error of the MPS. Importantly, the amount of entanglement determines how many Schmidt coefficients of each partition are significant. Thus, when the entanglement is limited in the system, the MPS method becomes effective [41]. We now present how to determine whether the MPS method is efficient or not, based on Ref. [41].

As the above indicates, the efficiency of the MPS description and the size of the required bond dimension are determined by the distribution of the Schmidt coefficients for each bipartition. More specifically, the scaling of the required bond dimension to describe a state is known to be characterized by the entanglement Rényi entropy (ERE) between the bipartitions of a pure state on L sites $|\psi\rangle \in \mathcal{H}^{\otimes L}$. Here, the Rényi entropy is defined

as

$$S_\alpha(\hat{\rho}) \equiv \frac{\log \text{tr}(\hat{\rho}^\alpha)}{1 - \alpha}, \quad (14)$$

where $0 \leq \alpha < \infty$ and $\alpha \neq 1$, and in the limit $\alpha \rightarrow 1$, it recovers the von Neumann entropy. The ERE of a pure state $|\psi\rangle$ between the subsystem $[1 : l]$ and $[l + 1 : L]$ is defined as

$$S_\alpha^l(|\psi\rangle) \equiv S_\alpha(\text{tr}_{[l+1:L]}(|\psi\rangle\langle\psi|)). \quad (15)$$

In particular, $|\psi\rangle$ is classically approximable by MPS, i.e., the required bond dimension is at most polynomial in L , when $S_\alpha^l(|\psi\rangle) = O(\log L)$ for all l -site reduced states of $|\psi\rangle$ [41]. Using this as a sufficient simulability condition and relating it to the photon loss rate or Pauli noise rate, we can obtain the simulable range of loss or noise, respectively.

On the other hand, it is also well-known that if the ERE scales algebraically, i.e., $S_\alpha^l(|\psi\rangle) = \Omega(L^\kappa)$ and $\kappa > 0$ for some l , the corresponding state cannot be efficiently approximated by an MPS [41]. Using this, we also characterize the regime of loss or noise that is hard to simulate using MPS.

IV. CLASSICAL SIMULATION OF LOSSY BOSON SAMPLING

A. MPS for simulating noisy quantum systems

As emphasized in Sec. III, the MPS is particularly useful for simulating low-entangled quantum systems. Therefore, the MPS method can be treated as a suitable choice to simulate noisy quantum systems because noise typically destroys the entanglement. However, an immediate obstacle to applying the MPS method for simulating noisy quantum systems, such as lossy boson sampling, is that the noisy quantum states are not pure in general, while the MPS method supports only pure states. Thus, the MPS method's restriction to pure states hinders us from exploiting its feature for simulating noisy systems. An interesting way to overcome this limitation is to vectorize the density matrix so that we can describe a mixed state by a pure state formalism, which is called the MPO method [27, 32, 47]. Indeed, this approach exhibits that as the system becomes noisier, it is easier to perform classical simulation. However, compared to the MPS method, the MPO method requires more bond dimensions and more resources for updating the state, resulting in a greater resource requirement.

More recently, another method has been proposed to overcome this limitation, simulating state-of-the-art GBS experiments classically [33]. The main idea of this method is to decompose a noisy mixed state into a probabilistic mixture of pure states, each of which has low entanglement as the system becomes noisier. Such a method is the state-of-the-art classical simulator

for GBS, to the best of our knowledge. Therefore, its generalization to other noisy quantum systems may promise to find one of the best classical algorithms at this moment. Nevertheless, the proposed decomposition appears to be highly dependent on the Gaussianity of the state, and thus, its generalization to more general cases has not been conducted. We now generalize this method to lossy boson sampling and noisy IQP sampling by finding an appropriate decomposition of noisy quantum states, each of which has low entanglement.

B. Decomposition of lossy input state

Consider a lossy boson sampling circuit that consists of N single-photon inputs in the first N modes and $M - N$ vacuum inputs, as introduced in Sec. II A. After the input state in Fig. 1(b) passes through the loss channel, as in Fig. 4(a), it transforms to

$$\hat{\rho}_{\text{in}} \equiv \hat{\sigma}^{\otimes N} \otimes |0\rangle\langle 0|^{\otimes (M-N)}, \quad (16)$$

where $\hat{\sigma} \equiv (1 - \eta)|0\rangle\langle 0| + \eta|1\rangle\langle 1|$ is the lossy single-photon state. As highlighted before, since the resultant output state is no longer pure, it does not immediately allow an MPS description.

Instead of employing the MPO method, which requires substantial computational resources, we adopt the MPS formalism to simulate mixed states. In this approach, a mixed state is expressed as a convex combination of pure states, and each pure state is then simulated according to its corresponding probability weight [33]. More specifically, if we have a mixed state input $\hat{\rho}_{\text{in}} = \sum_i p_i |\psi_i\rangle\langle\psi_i|$ and the rest of the quantum circuit is unitary $\hat{U}$, one may simply sample i from the probability distribution $\{p_i\}$ and then simulate $\hat{U}|\psi_i\rangle$. Such a process obviously exactly simulates the sampling from the density matrix $\hat{\rho} = \sum_i p_i \hat{U}|\psi_i\rangle\langle\psi_i|\hat{U}^\dagger$. A subtlety with this approach is that, in principle, many different decompositions are consistent with the given density matrix, and different decompositions may incur different computational costs. An obvious optimal choice for an efficient MPS simulation is a decomposition such that each of the pure-state components $|\psi_i\rangle$ has a small entanglement throughout the circuit.

For this particular setup of lossy boson sampling, one naive but natural choice of the decomposition of $\hat{\sigma}$ is a convex sum of $|0\rangle\langle 0|$ and $|1\rangle\langle 1|$ with probabilities $1 - \eta$ and η , respectively. However, one may easily notice a drawback of this decomposition, which leads to a significant computational cost [31]. More specifically, since the transmission rate is η , the sampled pure state input contains an average ηN number of input $|1\rangle\langle 1|$. To simulate this sampling problem in polynomial time, $\eta N = O(\log N)$ is required because the complexity of boson sampling is exponential to the number of single photon inputs. Therefore, the simulable range of η is too limited compared to the known simulable range $\eta = O(1/\sqrt{N})$ [25].

FIG. 4. Simulation of lossy boson sampling using pure-state decomposition. (a) The Fock input $|1\rangle^{\otimes N}|0\rangle^{\otimes(M-N)}$ goes through the loss channel, yielding the product mixed state $\hat{\sigma}^{\otimes N} \otimes |0\rangle\langle 0|^{\otimes(M-N)}$, where $\hat{\sigma}$ is the lossy single-photon state. (b) For sampling, each $\hat{\sigma}$ is decomposed into $|\psi_+\rangle$ and $|\psi_-\rangle$, drawn with equal probability.

We now introduce another decomposition of the lossy single photon state $\hat{\sigma}$ and prove that it provides a wider range of simulability, which is given as

$$\hat{\sigma} = \frac{1}{2}|\psi_+\rangle\langle\psi_+| + \frac{1}{2}|\psi_-\rangle\langle\psi_-|, \quad (17)$$

where we defined

$$|\psi_{\pm}\rangle \equiv \sqrt{1-\eta}|0\rangle \pm \sqrt{\eta}|1\rangle. \quad (18)$$

The decomposition indicates that the lossy single photon state input $\hat{\sigma}$ is physically equivalent to generating two pure state inputs $|\psi_+\rangle$ and $|\psi_-\rangle$ with equal probability. Hence, the total input state can be rewritten as

$$\hat{\rho}_{\text{in}} = \sum_{s_1, \dots, s_N \in \{-, +\}^N} \frac{1}{2^N} |\psi_{\text{in}}(s_1, \dots, s_N)\rangle \langle \psi_{\text{in}}(s_1, \dots, s_N)|, \quad (19)$$

where

$$|\psi_{\text{in}}(s_1, \dots, s_N)\rangle \equiv \left[\bigotimes_{j=1}^N |\psi_{s_j}\rangle \right] \otimes |0\rangle^{\otimes(M-N)}. \quad (20)$$

Therefore, simulating $\hat{\rho}_{\text{in}}$ is equivalent to sampling $(s_1, \dots, s_N) \in \{-, +\}^N$ from a uniform probability and then simulating the circuit with the input $|\psi_{\text{in}}(s_1, \dots, s_N)\rangle$. To demonstrate that such a decomposition indeed results in low computational complexity for simulation, the following subsection analyzes the computational cost of our decomposition using the ERE.

Before we analyze the entanglement, note that $|\psi_-\rangle$ is equivalent to $e^{i\pi\hat{n}}|\psi_+\rangle$, where $e^{i\pi\hat{n}}$ is a linear-optical circuit. Hence, for the simplicity of the analysis, we fix the sampled lossy input state to be $|\psi_+\rangle^{\otimes N} \otimes |0\rangle^{\otimes(M-N)}$, without loss of generality for our analysis, since the Haar-random unitary ensemble is invariant under the unitary multiplication (corresponding to the phase shifter $e^{i\pi\hat{n}}$).

C. Entanglement Rényi entropy of the output state

The main reason we choose the above decomposition is that each of the pure state components in the decomposition can constitute only a small amount of entanglement from a linear-optical circuit when a loss rate is large enough. To see this, let us now derive the entanglement of the output state of each $|\psi_{\text{in}}\rangle$ after a linear-optical circuit $\hat{U}$ and the computational complexity for the MPS simulation depending on the transmission rate η .

Let us first analyze the output state of a linear-optical circuit for input $|\psi_{\text{in}}\rangle$. After the linear-optical circuit $\hat{U}$, the state transforms as follows:

$$|\psi_{\text{in}}\rangle = \left[\bigotimes_{j=1}^N \left(\sqrt{1-\eta}|0\rangle + \sqrt{\eta}|1\rangle \right) \right] \otimes |0\rangle^{\otimes(M-N)} \quad (21)$$

$$= \left[\prod_{j=1}^N \left(\sqrt{1-\eta} + \sqrt{\eta}\hat{a}_j^\dagger \right) \right] |0\rangle^{\otimes M} \quad (22)$$

$$\rightarrow \left[\prod_{j=1}^N \left(\sqrt{1-\eta} + \sqrt{\eta}\hat{b}_j^\dagger \right) \right] |0\rangle^{\otimes M} \equiv |\psi_{\text{out}}\rangle, \quad (23)$$

where the linear-optical circuit $\hat{U}$ transforms the creation operator $\hat{a}_j^\dagger$ into $\hat{b}_j^\dagger \equiv \hat{U}^\dagger \hat{a}_j^\dagger \hat{U}$. Let us now investigate the entanglement of the state between a bipartition $[1, \dots, l]$ and $[(l+1), \dots, M]$. To do so, we trace out one of the two subsystems and derive the ERE of the reduced density matrix. Note that we can rewrite the bosonic creation operator $\hat{b}_j^\dagger$ as a sum of operators on each partition

$$\hat{b}_j^\dagger = \sum_{k=1}^M U_{jk}^* \hat{a}_k^\dagger \equiv \cos\theta_j \hat{B}_{u,j}^\dagger + \sin\theta_j \hat{B}_{d,j}^\dagger, \quad (24)$$

where we defined

$$\cos\theta_j \hat{B}_{u,j}^\dagger = \sum_{k=1}^l U_{jk}^* \hat{a}_k^\dagger, \quad \sin\theta_j \hat{B}_{d,j}^\dagger = \sum_{k=l+1}^M U_{jk}^* \hat{a}_k^\dagger. \quad (25)$$

Here, u means the upper spatial bipartition $[1, \dots, l]$, and d means the other partition.

In this setting, $\cos^2\theta_j$ can be interpreted as the probability that a photon in output mode j is located within the first subsystem after the linear-optical circuit U (i.e., within modes $[1, \dots, l]$), and $\sin^2\theta_j$ is the corresponding probability for the second subsystem. By definition, the normalization is given as

$$\cos^2\theta_j = \sum_{k=1}^l |U_{jk}|^2, \quad \sin^2\theta_j = \sum_{k=l+1}^M |U_{jk}|^2. \quad (26)$$

Under the assumption that $M = \omega(N^2)$, a typical assumption for the hardness result of boson sampling,

the creation operators $\hat{B}_{u,j}^\dagger$ and $\hat{B}_{d,j}^\dagger$ follow the canonical commutation relation approximately,

$$\begin{aligned} [\hat{B}_{u,j}, \hat{B}_{u,k}^\dagger] &\approx \delta_{jk}, & [\hat{B}_{d,j}, \hat{B}_{d,k}^\dagger] &\approx \delta_{jk}, \\ [\hat{B}_{u,j}, \hat{B}_{d,k}^\dagger] &= 0, & [\hat{B}_{u,j}^\dagger, \hat{B}_{d,k}] &= 0. \end{aligned} \quad (27)$$

We will discuss this point later.

Using those tools, we now evaluate the ERE between the bipartite subsystems of the same size, where the ERE is maximum [48, 49]; therefore, l is chosen to be $\lfloor N/2 \rfloor$. To do that, we now compute the eigenvalues of the reduced density matrix on the subsystem u (or equivalently the subsystem d).

Substituting the splitted operators transforms the output state $|\psi_{\text{out}}\rangle$ as

$$\bigotimes_{j=1}^N \left[\left(\sqrt{1-\eta} + \sqrt{\eta} \left(\cos \theta_j \hat{B}_{u,j}^\dagger + \sin \theta_j \hat{B}_{d,j}^\dagger \right) \right) |0\rangle \right] \quad (28)$$

$$= \bigotimes_{j=1}^N \left[\sqrt{1-\eta} |00\rangle_j + \sqrt{\eta} \cos \theta_j |10\rangle_j + \sqrt{\eta} \sin \theta_j |01\rangle_j \right]. \quad (29)$$

For $j > N$, the modes remain in the vacuum state $|00\rangle_j$, which do not affect the entanglement and are therefore omitted. For brevity, we also omit the labels of subsystem u and d when it is clear from the context; for example, we write $\hat{B}_{u,j}^\dagger |0\rangle = |1\rangle_{u,j} |0\rangle_{d,j}$ simply as $|10\rangle_j$, where the first and second entry refers to subsystems u and d , respectively.

To derive the ERE between the two bipartitions, we find the eigenvalues of the reduced density matrix of $|\psi_{\text{out}}\rangle\langle\psi_{\text{out}}|$. After tracing out the subsystem d , the reduced density matrix on the subsystem u can be represented as the following matrix:

$$\bigotimes_{j=1}^N \begin{pmatrix} 1 - \eta \cos^2 \theta_j & \sqrt{\eta(1-\eta)} \cos \theta_j \\ \sqrt{\eta(1-\eta)} \cos \theta_j & \eta \cos^2 \theta_j \end{pmatrix}, \quad (30)$$

where we have omitted the trivial tensor product $|0\rangle\langle 0|^{\otimes(M-N)}$ as above. Therefore, the eigenvalues of the reduced density matrix are given as $\prod_{j=1}^N c_{jk_j}$, where $\vec{k} \in \{0, 1\}^N$ and

$$c_{j0} = \frac{1}{4} \left(2 + \sqrt{2\eta^2 \cos(4\theta_j) - 2\eta^2 + 4} \right), \quad (31)$$

$$c_{j1} = \frac{1}{4} \left(2 - \sqrt{2\eta^2 \cos(4\theta_j) - 2\eta^2 + 4} \right). \quad (32)$$

To determine the classically simulable range of η , we use the criterion that the ERE scales as $O(\log N)$ for $0 < \alpha < 1$. One may easily see that the ERE is maximized when $\theta_j = \pi/4$, where the deviation from $1/2$ of the two eigenvalues of each matrix is minimal. In this case, the

ERE is given by

$$\begin{aligned} S_\alpha^l(|\psi_{\text{out}}\rangle) &= \frac{N \log \left[\left(\frac{1}{2} - \frac{1}{2} \sqrt{1-\eta^2} \right)^\alpha + \left(\frac{1}{2} + \frac{1}{2} \sqrt{1-\eta^2} \right)^\alpha \right]}{1-\alpha}, \end{aligned} \quad (33)$$

which is bounded by a simpler expression with respect to η :

$$S_\alpha^l(|\psi_{\text{out}}\rangle) \leq N \frac{\log \left[\left(\frac{1}{2} \right)^\alpha \left(1 - \sqrt{1-\eta^2} \right)^\alpha + 1 \right]}{1-\alpha} \quad (34)$$

$$\leq \frac{N}{1-\alpha} \left(\frac{1}{2} \right)^\alpha \left(1 - \sqrt{1-\eta^2} \right)^\alpha \quad (35)$$

$$\leq \frac{N\eta^{2\alpha}}{1-\alpha}. \quad (36)$$

From the first line to the second line, we applied the inequality $\log(1+x) \leq x$, which holds when $x \geq 0$. Since the inequality $1 - \sqrt{1-x^2} \leq x^2$ holds when $-1 \leq x \leq 1$, it can be applied to the second line to derive the third line. Recalling that the state is efficiently simulable when the above upper bound of the ERE is $O(\log N)$ for $0 < \alpha < 1$, we conclude that when

$$\eta = O \left(\left(\frac{\log N}{N} \right)^{1/2\alpha} \right), \quad (37)$$

the quantum state after linear-optical circuits is efficiently described and simulated using MPS, where α can be chosen arbitrarily close to 1.

On the other hand, we can also obtain the lower bound of η , which makes MPS inapproximable:

$$S_\alpha^l(|\psi_{\text{out}}\rangle) \geq \frac{N}{1-\alpha} \log \left[\left(1 - \frac{\eta^2}{2} \right)^\alpha \right] \quad (38)$$

$$\geq \frac{\alpha N \eta^2}{2(\alpha-1)}. \quad (39)$$

At the first line, $1 + \sqrt{x} \geq 1 + x$ for $0 \leq x \leq 1$ is used. From the first line to the second line, $\log(1-x) \geq -x$ when $x \leq 0.863$ is used, which is always valid since $\eta \leq 1$. Hence, when

$$\eta = \Omega \left(\frac{1}{N^{1/2-\kappa/2}} \right), \quad (40)$$

where $\kappa > 0$ is a constant, the ERE is lower bounded by $\Omega(N^\kappa)$. Hence, by choosing $\kappa \rightarrow 0$, i.e., η scales faster than $1/\sqrt{N}$, the corresponding lossy boson sampling is hard to simulate using our MPS method. Therefore, the approximability achieved by our MPS method exhibits a transition at $\eta = \Theta(1/\sqrt{N})$, which is consistent with the GBS case [33].

To clearly identify the transition point, we numerically illustrate this behavior using the von Neumann

FIG. 5. Entanglement (von Neumann) entropy of the output state of lossy boson sampling in the worst case, $\theta = \pi/4$. A complexity transition, from efficient to inefficient, occurs between coefficient values 4 and 5.

entanglement entropy, varying the coefficient of transmission rate over $1/\sqrt{N}$. We can see that between the coefficients 4 and 5, the transition from approximability to inapproximability of the state occurs. As shown in Fig. 5, one may see that when the transmission rate is smaller than $\eta = 4/\sqrt{N}$, the coefficient of the $\log N$ term in the von Neumann entanglement entropy decreases as we increase the system size. In contrast, when the transmission rate is larger than $\eta = 5/\sqrt{N}$, the coefficient of the $\log N$ term in the von Neumann entanglement entropy increases as the system size grows. Hence, this indicates that the transition occurs between $\eta = 4/\sqrt{N}$ and $5/\sqrt{N}$.

We now compare our results with those of previous studies [24, 25]. In the previous work, classical algorithms are proposed whose classically simulable range of η is $\eta = O(1/\sqrt{N})$. The algorithms employed a method that approximates the lossy input state as a state that is easy to classically simulate, such as the closest thermal state or the closest separable state. An obvious crucial limitation of this approach is that the closest thermal state or the closest separable state to a given lossy input state remains fixed once the parameters of the lossy boson sampling are determined. That means that when the system is not sufficiently lossy, no thermal state or separable state can approximate the lossy input state with adequate accuracy. Furthermore, the simulation accuracy cannot be improved by allocating additional computational resources because the closest easy-to-simulate state is fixed.

Compared to that, although our MPS algorithm exhibits a similar scaling in an asymptotic regime as $\eta < O(1/\sqrt{N})$, i.e., our MPS method might not provide an advantage over the previously known classical algorithm asymptotically, it shows a wider simulable range than the previous work in a non-asymptotic regime, which is

more practically relevant, because even if the loss rate is not high enough, our algorithm always runs and can achieve a target accuracy by using more computational resources, i.e., by increasing the bond dimension. We emphasize that this improvement significantly enhances simulation performance in simulating lossy GBS [26, 33, 50]. To be more specific, Ref. [26] shows that the closest nonclassical state renders a similar classically simulable range of η , $\eta = O(1/\sqrt{N})$, which, however, was insufficient to simulate the experimental GBS. Nonetheless, Ref. [33] developed a classical algorithm based on MPS, just like ours, and could simulate the state-of-the-art experimental GBS, which clearly indicates that the MPS method significantly outperforms other methods in practice even though the asymptotic scaling is similar.

We now compare this with another previous result based on MPO, which numerically finds a similar classically simulable range $\eta = O(1/\sqrt{N})$ [27]. Although the previous result yields the same strength in the sense that the accuracy can be improved by adding more computational resources, our work demonstrates a significant enhancement of the numerical simulability range. More specifically, the computational time cost of MPS and MPO simulations in a circuit of depth D is $T = O(MDd^4\chi^3)$ and $T = O(MDd^8\chi^3)$, respectively. In terms of memory requirement, the memory cost of MPS is $O(\chi^2dM)$, while that of MPO is $O(\chi^2d^2M)$. In the MPO case, the local Hilbert space dimension d is the square of that in the MPS case. This can lead to a higher computational cost when $d = N + 1$ and N is sufficiently large, as is the case in the boson sampling scenario. More crucially, as mentioned earlier, classical correlation can contribute to the increase in the bond dimension of MPO, whereas it cannot for MPS. Therefore, the bond dimensions between the two methods also differ between MPS and MPO. For example, the MPO method requires a bond dimension of the order of 10^4 , even for an input photon of less than 10, with a loss rate of 0.7. Our MPS method, on the other hand, requires only a bond dimension of the order of 10 (note that the definitions of approximation errors differ, but a significant difference in bond dimension is evident).

Let us finally discuss the canonical commutation relation of $\hat{B}_u$ and $\hat{B}_d$. For our analytic results, we assumed that they satisfy the exact canonical commutation relation as in Eq. (27).

$$[\hat{B}_{u,j}, \hat{B}_{u,k}^\dagger] = \left[\frac{\sum_{m=1}^l U_{jm} \hat{a}_m}{\cos \theta_j}, \frac{\sum_{n=1}^l U_{kn}^* \hat{a}_n^\dagger}{\cos \theta_k} \right] \quad (41)$$

$$= \frac{\sum_{m=1}^l U_{jm} U_{km}^*}{\sqrt{\sum_{m=1}^l |U_{jm}|^2} \sqrt{\sum_{n=1}^l |U_{kn}|^2}}. \quad (42)$$

For $j = k$, this is equal to 1 for all unitary. However, for $j \neq k$, this is not exactly 0, but we can show that it is approximately 0 in the Haar random case. See Appendix B for details. More specifically, we show that $[\hat{B}_{u,j}, \hat{B}_{u,k}^\dagger] = O(1/\sqrt{M})$ with high probability. Thus, our approximation is valid when M is sufficiently large.

We also justify this commutation relation without the Haar-random assumption. It has been known that in the lossless case, the linear-optical circuit that renders the maximum entanglement entropy is the one that transforms the initial bosonic creation operators as [33, 35]

$$\hat{a}_i^\dagger \rightarrow \frac{1}{\sqrt{2}}(\hat{a}_i^\dagger + \hat{a}_{i+M/2}^\dagger), \quad (43)$$

for $1 \leq i \leq N$, where M is assumed to be even for simplicity. In this case, the assumed commutation relations exactly hold. Although we do not prove that this also holds in the lossy case, we conjecture that this is true.

D. Numerical analysis of the computational cost

To understand how large parameter regimes our classical algorithm can simulate in practice, we now directly estimate the bond dimension for simulating the boson sampling algorithm with the photon number N and transmission rate η , with a fixed MPS approximation error ϵ of 0.01. Our MPS approximation error is defined by the sum of the discarded eigenvalues when the system is bipartitioned into two halves. Before we present our results, we emphasize that for certain regimes, other existing methods, such as the Clifford-Clifford algorithm, may outperform our method [23, 39]. Hence, one should interpret our results as a boundary set by our MPS method, rather than the boundary for the classically simulable regime for all possible methods.

In this numerical analysis, we consider three different families of circuits: (a) the worst-case construction, (b) the Haar-random unitary, and (c) an experimentally motivated structure. The purpose of this comparison is to examine how the required bond dimension varies across different choices of circuit unitaries. Here, the worst-case construction has $\theta_j = \pi/4$ for all j to produce the largest amount of entanglement between the bipartitions we consider, and the experimentally motivated structure follows the same structure implemented in Ref. [12]. For (c), although the experiment in the reference implements GBS, we constructed a circuit unitary from this setup. Since the number of modes of this unitary is restricted as $M = 2k^2$ for an integer k , for a given photon number N , we set k as the nearest integer to $N/\sqrt{2}$ so that $M = 2k^2$ is the closest value to N^2 . However, we inject $\lceil N/2 \rceil$ photons into the middle of the modes of the first half, and the remaining $\lfloor N/2 \rfloor$ photons into the middle of the modes

of the second half. This is because the whole unitary in this case is constructed by combining two unitaries of half the size; inputting the same number of single photons in both bipartitions and inputting single photons in the middle can help maximize the entanglement.

We present the numerical results in Fig. 6. First of all, Fig. 6(a) presents the required bond dimension in the worst-case circuit. Fig. 6(b) is when the unitary of the boson sampling circuit is drawn from a Haar random. The required resource in this result is comparable to the worst-case scenario, indicating that highly entangled configurations are typical in Haar random cases. One can see that if the loss rate is approximately 50%, which is the case for GBS experiments in Refs. [13, 15, 17], and the input photon number is 40, the required bond dimension is 10^7 , which is already quite large to implement in practice.

In contrast to the previous cases, Fig. 6(c) shows a significant decrease in the required bond dimension. For example, when the transmission rate is 0.5 and the input photon number is 40, the required bond dimension in Fig. 6(a) and (b) reaches 10^7 , indicating that Haar-random unitaries approximately realize the worst-case scaling. In contrast, Fig. 6(c) requires less than 10^6 bond dimensions under the same conditions, which is an order of magnitude smaller. Since the asymptotic simulation memory cost and time cost scale with the square and cube of the bond dimension, respectively, this 10 times reduction in Fig. 6(c) translates into nearly 100 times fewer memory, and 1000 times fewer calculation time.

According to the required bond dimension, the memory complexity of the circuit can be estimated as shown in Fig. 6(d)–(f) [33]. Assuming that each complex number requires 8 bytes, the memory usage can be estimated as the total number of elements multiplied by 8 bytes:

$$(8 \text{ bytes}) \times (\text{bond dimension})^2 \times (\text{number of modes}) \times (\text{local Hilbert space dimension}). \quad (44)$$

Here, when the input state of boson sampling is N single photons, the local Hilbert space dimension can be considered as $N + 1$ in the general case.

E. Multiphoton Fock boson sampling

We now generalize the MPS method for single-photon boson sampling to multiphoton Fock boson sampling. Suppose that for the first N modes, the input is each n photon Fock state, and the $M - N$ remaining modes are initialized in the vacuum state. The linear optical structure and the detectors are the same as in the previous boson sampling case. After bringing the noise to the front of the circuit as in Fig. 1 and passing the input state through the photon loss channel with total transmission rate η , the lossy input state becomes (see

FIG. 6. Required bond dimension and memory to achieve an MPS approximation error $\epsilon = 0.01$. Panels (a)–(c) show the required bond dimension, and panels (d)–(f) show the required memory. (a) Required bond dimension where the unitary is in the worst-case scenario. This implies the highest cost for a specific input photon number and photon loss. (b) Required bond dimension when the Haar random unitary is a unitary corresponding to the circuit in boson sampling. (c) Required bond dimension when a circuit unitary is the same structure as the GBS experiment of USTC [12]. (d) Required memory where the unitary is in the worst-case scenario. (e) Required memory when the Haar random unitary is a unitary corresponding to the circuit in boson sampling. (f) Required memory when a circuit unitary is the same structure as the GBS experiment of USTC [12].

Fig. 4)

$$\hat{\rho}_{\text{in}} = \hat{\sigma}^{\otimes N} \otimes |0\rangle\langle 0|^{\otimes (M-N)}, \quad (45)$$

where the lossy Fock state is written as

$$\hat{\sigma} = \sum_{k=0}^n \frac{n!}{k!(n-k)!} (1-\eta)^{n-k} \eta^k |k\rangle\langle k|. \quad (46)$$

To utilize the MPS formalism, as before, we first find an appropriate pure-state decomposition and sample a pure state from the given mixed state. Our choice of the decomposition is given by the states

$$|\psi(\phi)\rangle = \sum_{k=0}^n \sqrt{\binom{n}{k} \eta^k (1-\eta)^{n-k}} e^{i\phi \hat{a}^\dagger \hat{a}} |k\rangle, \quad (47)$$

with ϕ sampled uniformly from $[0, 2\pi)$. One can easily verify that $\frac{1}{2\pi} \int_0^{2\pi} d\phi |\psi(\phi)\rangle\langle\psi(\phi)| = \hat{\sigma}$. Hence, with this decomposition, to simulate the state $\hat{\sigma}$, we can instead sample $|\psi(\phi)\rangle$ following the uniform distribution over $[0, 2\pi)$. Thus, the sampled state for all modes then takes the form

$$\left[\bigotimes_{j=1}^N |\psi(\phi_j)\rangle \right] \otimes |0\rangle^{\otimes (M-N)}, \quad (48)$$

for sampled values of $\{\phi_j\}_{j=1}^N$. As in the single-photon boson sampling case, since a single layer of phase shifters can align all phases ϕ_j to the same value, and this layer can be absorbed into the linear-optical circuit, we may take $\phi_j = 0$ for all j without loss of generality. Accordingly, the sampled input state is written as

$$|\psi(0)\rangle^{\otimes N} \otimes |0\rangle^{\otimes (M-N)}. \quad (49)$$

After the transformation of the creation operator as a lossy single-photon case, $\hat{a}_j^\dagger \rightarrow \hat{b}_j^\dagger = \cos \theta_j \hat{B}_{u,j}^\dagger + \sin \theta_j \hat{B}_{d,j}^\dagger$, we have the output state as follows:

$$|\psi(0)\rangle \rightarrow \sum_{k=0}^n \sqrt{\binom{n}{k} \eta^k (1-\eta)^{n-k}} \frac{(\hat{b}^\dagger)^k}{\sqrt{k!}} |0\rangle \quad (50)$$

$$= \sum_{k=0}^n \sqrt{\binom{n}{k} \eta^k (1-\eta)^{n-k}} \quad (51)$$

$$\times \sum_{l=0}^k \sqrt{\binom{k}{l}} \cos^l \theta \sin^{k-l} \theta |l, k-l\rangle. \quad (52)$$

After tracing out the down part, the eigenvalues of the reduced state can be calculated to evaluate the ERE,

which serves as an indicator of classical simulability. Since the closed-form of the ERE is difficult to find, unlike the single photon cases, we calculate it numerically and present the behavior in Fig. 7. Figure 7 presents the ERE relative to $\log N$ in terms of the number of modes N with the n -photon Fock state for each mode with different scaling of transmission rate η . Note that when the slope of the graph decreases, the corresponding ERE scales as $O(\log N)$, which means that MPS efficiently describes the state. Thus, by observing Fig. 7(a), we can conclude that all the different Fock state inputs are efficiently simulable by MPS when $\eta = 1/\sqrt{N}$. In Fig. 7(b), when $\alpha < 1$, when the transmission rate η scales equal or smaller than $1/\sqrt{N}$, the state is efficiently simulable by MPS, which is consistent with the result of the single photon boson sampling case. On the other hand, when the circuit has less loss, $\eta = 1/N^{1/3}$, its ERE scales faster than $O(\log N)$, which means that it is not determined whether MPS efficiently describes it. The inapproximability of this $\eta = 1/N^{1/3}$ case can be determined by analyzing the $\alpha > 1$ case, as in Fig. 7(c). For $\alpha > 1$, when the entropy scales as $\Omega(N^\kappa)$ for $\kappa > 0$, the state is not simulable. Here, the graph scales linearly in a log-log plot, which means there exists a proper κ for the Rényi entropy scaling. Thus, this case is inapproximable by MPS. Hence, we observe a similar behavior for general Fock-state boson sampling to the single-photon boson sampling case.

F. Cat-state boson sampling

Another generalization of the boson sampling problem exploits a cat state input, where the even and odd cat states are defined as

$$|\text{cat}_e\rangle \equiv \frac{1}{\sqrt{2(1+e^{-2|\gamma|^2})}}(|\gamma\rangle + |-\gamma\rangle), \quad (53)$$

$$|\text{cat}_o\rangle \equiv \frac{1}{\sqrt{2(1-e^{-2|\gamma|^2})}}(|\gamma\rangle - |-\gamma\rangle), \quad (54)$$

respectively. Note that as the amplitude of the cat state $\gamma \rightarrow 0$, the odd (even) cat state approaches $|1\rangle$ ($|0\rangle$), thereby recovering single-photon inputs. Moreover, cat state sampling is also known to be hard to classically simulate [51]. The circuit has the same structure as before, except that the input of the first N mode is an odd cat state. The photon loss can be gathered in front of the circuit as in Fig. 1, and the cat state input goes through the total photon loss channel and transforms to the following state,

$$\hat{\rho}_{\text{in}} = \hat{\sigma}^{\otimes N} \otimes |0\rangle\langle 0|^{\otimes (M-N)}, \quad (55)$$

where the noisy cat state becomes

$$\hat{\sigma} \equiv \frac{1}{C^2} \left[|\gamma\sqrt{\eta}\rangle\langle\gamma\sqrt{\eta}| - e^{-2|\gamma|^2(1-\eta)} (|\gamma\sqrt{\eta}\rangle\langle-\gamma\sqrt{\eta}| + |-\gamma\sqrt{\eta}\rangle\langle\gamma\sqrt{\eta}|) + |-\gamma\sqrt{\eta}\rangle\langle-\gamma\sqrt{\eta}| \right], \quad (56)$$

where $C \equiv \sqrt{2(1-e^{-2|\gamma|^2})}$ is defined for the normalization. As before, we now find a pure-state decomposition of the lossy input state $\hat{\sigma}$. Our choice of decomposition is as follows:

$$\hat{\sigma} = \frac{1}{2}|\psi_1\rangle\langle\psi_1| + \frac{1}{2}|\psi_2\rangle\langle\psi_2|, \quad (57)$$

where we defined

$$|\psi_1\rangle \equiv A|\gamma\sqrt{\eta}\rangle - B|-\gamma\sqrt{\eta}\rangle, \quad (58)$$

$$|\psi_2\rangle \equiv -B|\gamma\sqrt{\eta}\rangle + A|-\gamma\sqrt{\eta}\rangle, \quad (59)$$

$$A \equiv \frac{\sqrt{1+k} + \sqrt{1-k}}{\sqrt{2C}}, B \equiv \frac{\sqrt{1+k} - \sqrt{1-k}}{\sqrt{2C}}, \quad (60)$$

with $k = e^{-2|\gamma|^2(1-\eta)}$.

Following the method illustrated in Fig. 4, the mixed state is equivalent to generating pure states $|\psi_1\rangle$ and $|\psi_2\rangle$ with each probability 1/2. As in the previous sections, in the following calculations, the sampled input state $|\psi_1\rangle^{\otimes N} \otimes |0\rangle^{\otimes (M-N)}$ is used without loss of generality because $|\psi_2\rangle = e^{i\pi\hat{n}}|\psi_1\rangle$ as in the single-photon boson sampling case.

We can calculate the output state after the circuit. Using the same transformation of creation operator, $\hat{a}_j^\dagger \rightarrow \hat{b}_j^\dagger = \cos\theta_j \hat{B}_{u,j}^\dagger + \sin\theta_j \hat{B}_{d,j}^\dagger$ as the preceding sections, the input state evolves as

$$|\psi_1\rangle = A|\gamma\sqrt{\eta}\rangle - B|-\gamma\sqrt{\eta}\rangle \quad (61)$$

$$\rightarrow A|\gamma\sqrt{\eta}\cos\theta, \gamma\sqrt{\eta}\sin\theta\rangle \quad (62)$$

$$- B|-\gamma\sqrt{\eta}\cos\theta, -\gamma\sqrt{\eta}\sin\theta\rangle. \quad (63)$$

Let us define $\delta \equiv \gamma\sqrt{\eta}\cos\theta$ for simplicity. To analyze the ERE of the output state subsystem, the subsystem d is traced out, then the reduced density matrix is written as

$$\hat{\rho}_u = \text{tr}_d(|\psi_1\rangle\langle\psi_1|) \quad (64)$$

$$= A^2|\delta\rangle\langle\delta| - AB e^{-2|\gamma|^2\eta\sin^2\theta}(|\delta\rangle\langle-\delta| \quad (65)$$

$$+ |-\delta\rangle\langle\delta|) + B^2|-\delta\rangle\langle-\delta|, \quad (66)$$

Diagonalizing this in the orthogonal even/odd cat basis yields the eigenvalues

$$\lambda_{\pm} \equiv \frac{1}{2} \left(1 \pm \sqrt{1-\zeta} \right), \quad (67)$$

where

$$\zeta \equiv \frac{e^{-4|\gamma|^2+4|\gamma|^2\eta}(1-e^{-4|\gamma|^2\eta\cos^2\theta})(1-e^{-4|\gamma|^2\eta\sin^2\theta})}{(1-e^{-2|\gamma|^2})^2}. \quad (68)$$

Thus, ERE of the state $|\psi_{\text{out}}\rangle$ is given by

$$S_\alpha^l(|\psi_{\text{out}}\rangle) = \frac{N}{1-\alpha} \log(\lambda_+^\alpha + \lambda_-^\alpha). \quad (69)$$

FIG. 7. ERE with respect to input photon number N , for different photon numbers in one mode n and transmission rates η . (a) The coefficient of the $\log N$ term in the ERE decreases as n increases. (b) For $\eta = 1/\sqrt{N}$, the ERE scales as $O(\log N)$, which is efficiently described by MPS; however, when $\eta = 1/(N^{1/3})$, the ERE does not scale as $O(\log N)$. It is unclear whether an MPS description remains efficient. (c) The regime that was unclear in (b) is shown to be inefficient for an MPS by examining the scaling when $\alpha > 1$.

Recall that when the ERE scales $O(\log N)$ for $0 < \alpha < 1$, the state is classically simulable in polynomial time.

Here, the ERE reaches its maximum value when $\theta = \pi/4$. With this, we can obtain the upper bound of the ERE and determine the asymptotically simulable range. Applying this condition to bound $S_\alpha^l(|\psi_{\text{out}}\rangle)$,

$$S_\alpha^l(|\psi_{\text{out}}\rangle) \leq \frac{N}{1-\alpha} \left(\frac{1}{2}\right)^\alpha \zeta^\alpha \quad (70)$$

$$= \frac{N}{1-\alpha} \frac{1}{2} \left(\frac{1}{2}\right)^\alpha \left[\frac{(1 - e^{-2|\gamma|^2\eta})^2 (1 - e^{-4|\gamma|^2 + 4|\gamma|^2\eta})}{(1 - e^{-2\gamma^2})^2} \right]^\alpha \quad (71)$$

$$\leq \frac{N}{1-\alpha} \left(\frac{1}{2}\right)^{\alpha+1} \left[\frac{(2|\gamma|^2\eta)^2 (4|\gamma|^2 - 4|\gamma|^2\eta)}{(1 - e^{-2\gamma^2})^2} \right]^\alpha \quad (72)$$

At the first line, the same inequalities as boson sampling, Eq. (34), Eq. (35), and Eq. (36) are used. From the second line to the third line, $1 - e^{-x} \leq x$ for $x \geq 0$ is used. When this ERE scales as $O(\log N)$, the MPS of the state is classically efficiently simulable, namely,

$$\eta = O\left(\left(\frac{\log N}{N}\right)^{1/2\alpha}\right), \quad (73)$$

which is consistent with the standard boson sampling case. For even cat state input, the eigenvalues are the same except that the denominator is $(1 + e^{-2|\gamma|^2})^2$, and the classically efficiently simulable η is asymptotically the same.

V. NOISY IQP SAMPLING

A. Decomposition of noisy input state

We now demonstrate that our MPS-based classical simulation strategy developed for boson sampling can be

extended to IQP sampling. The central idea is similar to that of boson sampling, in that we find a decomposition of a noisy input state into pure states, such that the entanglement of each pure state after the IQP circuit is low. As introduced in Sec. II B, we consider an IQP circuit with n input qubits prepared in the state $|+\rangle$. We first focus on the dephasing noise case and then extend our analysis to the depolarizing noise. When the circuit has depth d and each layer suffers dephasing noise with noise rate p , all dephasing noise channels $\mathcal{N}_{0,0,p}$ can be commuted to the front of the diagonal gates, resulting in a single layer of a dephasing channel $\mathcal{N}_{0,0,p_d}$. As illustrated in Fig. 2, the noisy circuit can therefore be decomposed into an overall dephasing noise channel acting on the input, followed by an ideal IQP circuit without dephasing.

After the input state $|+\rangle^{\otimes n}$ goes through the noise channel $\mathcal{N}_{0,0,p_d}$, the input state transforms to noisy states

$$\hat{\rho}_{\text{in}} = \hat{\tau}^{\otimes n}, \quad (74)$$

where we defined the noisy $|+\rangle$ state under dephasing channel as

$$\hat{\tau} \equiv \mathcal{N}_{0,0,p_d}(|+\rangle\langle+|) = (1 - p_d)|+\rangle\langle+| + p_d|-\rangle\langle-|. \quad (75)$$

As in boson sampling, the noisy input state $\hat{\tau}$ can be represented as a probabilistic mixture of pure states, and this sampling property enables us to represent the resulting pure state by MPS and thus simulate the noisy IQP circuit. Again, for a better performance, we find an appropriate decomposition of the mixed state such that each pure state from the decomposition renders a small enough entanglement at the end of the circuit, which admits an efficient classical description. A naive approach is to sample this state by $|+\rangle$ with probability $1 - p_d$, and into $|-\rangle$ with probability p_d . However, this does not reduce the complexity of the classical simulation because $|-\rangle$ is a $|+\rangle$ state with a Z gate applied, and thus we eventually have to simulate the noiseless IQP circuit

in any case. Therefore, this trivial decomposition does not reduce the simulation complexity.

Instead, one may easily see that the noisy input state can be decomposed as

$$\hat{\tau} = \frac{1}{2}|\phi_+\rangle\langle\phi_+| + \frac{1}{2}|\phi_-\rangle\langle\phi_-|, \quad (76)$$

where we defined

$$|\phi_+\rangle \equiv \sqrt{1-p_d}|+\rangle + \sqrt{p_d}|-\rangle = q_0|0\rangle + q_1|1\rangle, \quad (77)$$

$$|\phi_-\rangle \equiv \sqrt{1-p_d}|+\rangle - \sqrt{p_d}|-\rangle = q_1|0\rangle + q_0|1\rangle, \quad (78)$$

with

$$q_0 \equiv \frac{\sqrt{1-p_d} + \sqrt{p_d}}{\sqrt{2}}, \quad q_1 \equiv \frac{\sqrt{1-p_d} - \sqrt{p_d}}{\sqrt{2}}. \quad (79)$$

Thus, the total noisy input state is written as

$$\hat{\rho}_{\text{in}} = \frac{1}{2^n} \sum_{s_1, \dots, s_n \in \{-, +\}^n} |\phi_{\text{in}}(s_1, \dots, s_n)\rangle\langle\phi_{\text{in}}(s_1, \dots, s_n)|, \quad (80)$$

where we defined

$$|\phi_{\text{in}}(s_1, \dots, s_n)\rangle \equiv \bigotimes_{j=1}^n |\phi_{s_j}\rangle. \quad (81)$$

Hence, as illustrated in Fig. 8, the total noisy input state is equivalent to generating a pure state $|\psi_{\text{in}}(s_1, \dots, s_n)\rangle$, where $(s_1, \dots, s_n) \in \{-, +\}^n$ are sampled with each probability $1/2^n$, i.e., uniformly.

For simplicity, as in the boson sampling case, we take the input to be $|\phi_+\rangle^{\otimes n}$. This assumption does not affect the simulation complexity when we consider the worst-case IQP circuit, since $|\phi_-\rangle = \hat{X}|\phi_+\rangle$ differs only by local X gates, which flip $|0\rangle$ and $|1\rangle$. Adding one layer of X gate into the circuit does not change the complexity, which will be rigorously shown in Sec. V C. Therefore, the analysis for $|\phi_+\rangle^{\otimes n}$ as a sampled input is sufficient:

$$|\phi_{\text{in}}\rangle = |\phi_+\rangle^{\otimes n} = \sum_{\vec{x} \in \{0,1\}^n} q_0^{n-|\vec{x}|} q_1^{|\vec{x}|} |\vec{x}\rangle. \quad (82)$$

B. Entanglement Rényi entropy of the output state

As discussed in Sec. II B, an ideal IQP circuit is composed of diagonal gates, which means that a computational-basis input $|\vec{z}\rangle$ gains only a phase factor through the circuit, as $|\vec{z}\rangle \rightarrow e^{if(\vec{z})}|\vec{z}\rangle$, where f is a function depending on the gates of the circuit. Using this formula, the sampled pure state input goes through the ideal circuit and transforms into the output state as follows:

$$|\phi_+\rangle^{\otimes n} \rightarrow |\phi_{\text{out}}\rangle = \sum_{\vec{x} \in \{0,1\}^n} e^{if(\vec{x})} q_0^{n-|\vec{x}|} q_1^{|\vec{x}|} |\vec{x}\rangle. \quad (83)$$

FIG. 8. Pure-state sampling from mixed inputs in an IQP circuit. (a) The input $|+\rangle$ goes through the loss channel and becomes a mixed state $\hat{\tau}$. (b) We sample from an ensemble decomposition of the mixed state, drawing $|\phi_+\rangle$ or $|\phi_-\rangle$ with equal probability $1/2$.

Using this form, we now obtain the upper bound of the ERE between the bipartition of this output state to determine the scaling of ERE, which can serve as a criterion for classical simulability of sampling. The system is split into two subsystems, A and B , and subsystem B is traced out to obtain the reduced density matrix of the subsystem A :

$$\hat{\rho}_A = \text{tr}_B(|\phi_{\text{out}}\rangle\langle\phi_{\text{out}}|) \quad (84)$$

$$= \sum_{\vec{x}_A^{(1)}, \vec{x}_A^{(2)} \in \{0,1\}^{|A|}} \sum_{\vec{y} \in \{0,1\}^{|B|}} q_0^{2n-|\vec{x}_A^{(1)}| - |\vec{x}_A^{(2)}| - 2|\vec{y}|} \quad (85)$$

$$\times q_1^{|\vec{x}_A^{(1)}| + |\vec{x}_A^{(2)}| + 2|\vec{y}|} e^{i[f(\vec{x}_A^{(1)}; \vec{y}) - f(\vec{x}_A^{(2)}; \vec{y})]} |\vec{x}_A^{(1)}\rangle\langle\vec{x}_A^{(2)}|, \quad (86)$$

where we divided a binary string $\vec{x}$ into $(\vec{x}_A : \vec{x}_B)$, where $\vec{x}_A \in \{0,1\}^{|A|}$, $\vec{x}_B \in \{0,1\}^{|B|}$, and $|A| + |B| = n$. Besides, we write $f(\vec{x}) = f(\vec{x}_A : \vec{x}_B)$, where $\vec{x}_A$ is the vector of $\vec{x}$ corresponding to the A part and $\vec{x}_B$ is the vector of $\vec{x}$ corresponding to the B part. Since the MPS ERE depends on the IQP circuit, and thereby on the function f , we instead find the upper bound of the MPS ERE of the output state of any IQP circuit, i.e., the maximum MPS ERE over all IQP circuits. Since the eigenvalues are not available in closed form, we instead employ the property of a unital channel Φ to obtain a closed-form upper bound for the ERE, namely, $S_\alpha^l(|\psi\rangle) = S_\alpha(\text{tr}_d(|\psi\rangle\langle\psi|)) \leq S_\alpha(\Phi(\text{tr}_d(|\psi\rangle\langle\psi|)))$. This follows because, for a unital completely positive trace-preserving (CPTP) map Φ , the output eigenvalues are majorized by those of the input eigenvalues [52], and Rényi entropies are Schur-concave for all $\alpha > 0$ [53]; hence $S_\alpha(\Phi(\hat{\rho})) \geq S_\alpha(\hat{\rho})$.

Here, we pick Φ as completely dephasing channel, and $\hat{\rho}_{A,\text{diag}} \equiv \Phi(\hat{\rho}_A)$ is described as

$$\hat{\rho}_{A,\text{diag}} = \sum_{\vec{x}_A \in \{0,1\}^{|A|}} \left(\frac{q_1}{q_0}\right)^{2|\vec{x}_A|} q_0^{2|A|} |\vec{x}_A\rangle\langle\vec{x}_A| \quad (87)$$

$$= \bigotimes_{i \in A} (q_0^2 |0\rangle\langle 0|_i + q_1^2 |1\rangle\langle 1|_i). \quad (88)$$

Hence, the Rényi entropy of $\hat{\rho}_{A,\text{diag}}$ upper-bounds the

ERE of the output state of any IQP circuit. Thus, we now focus on computing the Rényi entropy of $\hat{\rho}_{A,\text{diag}}$.

Since $\hat{\rho}_{A,\text{diag}}$ is a diagonal and product form, the Rényi entropy of this state is written as

$$S_\alpha(\hat{\rho}_{A,\text{diag}}) = \frac{|A|}{1-\alpha} \ln(q_0^{2\alpha} + q_1^{2\alpha}). \quad (89)$$

While it seems linearly increasing with $|A|$, if we compute the upper bound of the Rényi entropy of $\hat{\rho}_{A,\text{diag}}$, which is similarly defined, then we obtain the Rényi entropy as

$$S_\alpha(\hat{\rho}_{B,\text{diag}}) = \frac{|B|}{1-\alpha} \ln(q_0^{2\alpha} + q_1^{2\alpha}). \quad (90)$$

Hence, for given subsystems A and B , the lowest upper bound of the ERE is given as $\min(S_\alpha(\hat{\rho}_{A,\text{diag}}), S_\alpha(\hat{\rho}_{B,\text{diag}}))$. Thus, the maximum ERE is achieved when we choose $|A| = |B|$, which renders

$$\max_{1 \leq l \leq n-1} S_\alpha^l(|\phi_{\text{out}}\rangle) \leq \frac{n}{2(1-\alpha)} \ln(q_0^{2\alpha} + q_1^{2\alpha}). \quad (91)$$

We use the inequality $\ln(q_0^{2\alpha} + q_1^{2\alpha}) \leq (1-2p)^{2\alpha d}$, where p denotes the noise rate per qubit per layer, to upper bound the ERE. The inequality follows from the sequence of bounds below:

$$\ln(q_0^{2\alpha} + q_1^{2\alpha}) \leq (1-2p_d)^{2\alpha} = (1-2p)^{2\alpha d}. \quad (92)$$

Here, as boson sampling, the inequalities Eq. (34), Eq. (35), and Eq. (36) are used to upper bound the term.

Recall that when the ERE of a reduced density matrix scales as $S_\alpha = O(\log n)$ for $0 < \alpha < 1$ for all bipartitions, the state is classically efficiently described by MPS. Applying this ERE scaling constraint to the upper bound of ERE, we obtain a sufficient condition for a state to be efficiently represented by MPS, which means classically simulable IQP sampling. One may see that when

$$1-2p \leq O\left(\left(\frac{\log n}{n}\right)^{1/(2\alpha d)}\right), \quad (93)$$

the ERE is upper-bounded by a logarithmic scaling in n :

$$\max_{1 \leq l \leq n-1} S_\alpha^l(|\phi_{\text{out}}\rangle) = \frac{n(1-2p)^{2\alpha d}}{2(1-\alpha)} \leq O(\log n). \quad (94)$$

Since the depth is crucial for analyzing the classical simulability of IQP sampling, let us examine the bound of depth in terms of the noise rate p . If we choose $\alpha \rightarrow 1$, we can see that the sufficient condition for classical simulability is written in terms of the depth d as

$$d \geq O\left(\frac{\log n}{|\log(1-2p)|}\right). \quad (95)$$

Hence, it shows that our MPS method is efficient up to the point where the depth scales logarithmically with the number of qubits n . Notably, this noise threshold is consistent with a recent result in Ref. [42], which employs a completely different method.

C. Generalization into depolarizing noise

We now generalize this result to depolarizing noise. First, recall that depolarizing noise with parameter p can be decomposed into Pauli X , Y , Z noise with noise rate $q = (1 - \sqrt{1-2p})/2$. Since Pauli X , Y , and Z noise channels commute with each other and a Pauli Z noise channel commutes with diagonal gates, as before, we can move all the Pauli Z noise channels in front of all the circuits. The circuit is then given by a Pauli Z noise channel followed by an IQP circuit with Pauli X and Y noise, as shown in Fig. 9(a). Thus, using the same method as before to take care of the Pauli Z noise on the input state, without loss of generality, we can write the initial state, including the Pauli Z noise. Let the total Z noise rate over depth d be $q_d = (1 - (1-2q)^d)/2$, then the input state

$$|\phi_{\text{in}}\rangle = |\phi_+\rangle^{\otimes n} = \sum_{\vec{x} \in \{0,1\}^n} q_0^{n-|\vec{x}|} q_1^{|\vec{x}|} |\vec{x}\rangle \quad (96)$$

has the coefficients

$$q_0 \equiv \frac{\sqrt{1-q_d} + \sqrt{q_d}}{\sqrt{2}}, \quad q_1 \equiv \frac{\sqrt{1-q_d} - \sqrt{q_d}}{\sqrt{2}}. \quad (97)$$

We then address the remaining Pauli X and Y noise channels using a stochastic method. More specifically, for a Pauli X (Y) noise channel, we probabilistically insert a Pauli X (Y) gate with probability q and the identity with probability $1-q$. Thus, as illustrated in Fig. 9(b), each noisy realization can be viewed as a sampled circuit containing Pauli gates, rather than a noise channel.

After sampling the Pauli gates from the Pauli noise, only X , $Y = -iZX$, and $XY = iZ$ gates would remain in the IQP circuit. Thus, we now show how to address the remaining X and Z gates. First of all, Z gates can be simply absorbed into the IQP circuit because they are also diagonal in the Z basis. Hence, we merely have to consider a revised IQP circuit with added Z gates, as shown in Fig. 9(c). On the other hand, X gates can also be easily addressed by the following observation. Suppose after a certain depth t the quantum state is written as

$$|\phi_{\text{out},t}\rangle = \sum_{\vec{x} \in \{0,1\}^n} e^{if_t(\vec{x})} q_0^{n-|\vec{x}|} q_1^{|\vec{x}|} |\vec{x}\rangle, \quad (98)$$

where $f_t(\vec{x})$ is the phase due to the IQP circuit up to depth t . If we apply X gates on this state, the quantum state transforms as

$$\left[\bigotimes_{k=1}^n \hat{X}^{u_k^{(t)}} \right] |\phi_{\text{out},t}\rangle = \sum_{\vec{x} \in \{0,1\}^n} e^{if_t(\vec{x})} q_0^{n-|\vec{x} \oplus \vec{u}^{(t)}|} q_1^{|\vec{x} \oplus \vec{u}^{(t)}|} |\vec{x}\rangle, \quad (99)$$

where $u_k^{(t)}$ decides whether an X gate is applied or not on the k th qubit. Thus, when we introduce the X gate

FIG. 9. Simulation of depolarizing noise in IQP circuit. (a) Pauli Z noises can commute with the very first gate of the circuit, as it is diagonal in the computational basis. (b) The noises are sampled into Pauli gates, where each X and Y gate occurs with probability q . And the input $|+\rangle$ goes through the Pauli Z noise channel and becomes a mixed state $\hat{\tau}$. (c) We sample from an ensemble decomposition of the mixed state, drawing $|\phi_+\rangle$ or $|\phi_-\rangle$ with equal probability $1/2$. The Y gates can be decomposed into X and Z gates. Here, because IQP gates are diagonal in the Z basis, we absorb all Z gates into the ideal IQP layer; the shaded boundary indicates this absorption. In contrast, X gates do not commute and therefore remain in the circuit.

layers for each depth, where $u_k^{(t)}$ is sampled as explained above, the final state can be in the following form:

$$|\phi_{\text{out}}\rangle = \sum_{\vec{x} \in \{0,1\}^n} e^{if(\vec{x})} q_0^{n-|\vec{x}|} q_1^{|\vec{x}|} |\vec{x}\rangle, \quad (100)$$

where $\vec{u} \equiv \sum_{t=1}^d \vec{u}^{(t)}$. Then, its reduced density matrix on the subsystem A after removing all the off-diagonal elements is

$$\hat{\rho}_{A,\text{diag}} = \sum_{\vec{x}_A \in \{0,1\}^{|A|}} q_0^{2|A|-2|\vec{x}_A|} q_1^{2|\vec{x}_A|} |\vec{x}_A\rangle\langle\vec{x}_A| \quad (101)$$

$$= \sum_{\vec{x}_A \in \{0,1\}^{|A|}} q_0^{2|A|-2|\vec{x}_A|} q_1^{2|\vec{x}_A|} |\vec{x}_A \oplus \vec{u}_A\rangle\langle\vec{x}_A \oplus \vec{u}_A|. \quad (102)$$

Since the Rényi entropy of the state in a diagonal form depends only on the coefficients, the ERE of this state is exactly the same as that we obtained from the previous section. Therefore, as in the dephasing noise case, when the circuit depth $d \geq O(\log n / |\log(1-2q)|) = O(\log n / |\log(1-2p)|)$, the IQP sampling under depolarizing noise is efficiently classically simulable. When the noise rate is small, this depth approaches $O(\frac{1}{p} \log n)$, which corresponds to the critical depth in Ref. [42].

D. Numerical analysis of noisy IQP sampling

We estimate the bond dimension and memory required to simulate a dephasing-noisy IQP circuit under a fixed simulation error of 0.01. The corresponding estimates for the worst-case scenario are shown in Fig. 10, in which the eigenvalues of $\hat{\rho}_{A,\text{diag}}$ with $|A| = |B| = n/2$ are considered.

Since we always assume the worst-case IQP circuit regardless of the circuit depth, even with $d = 1$, a highly

complicated IQP circuit is considered. For this reason, the required bond dimension is the maximum under the same number of qubits and the same noise rate per qubit and gate. Obviously, in practice, the complexity of an IQP circuit depends on its circuit depth [30, 45, 54, 55]. Implementing a highly complicated IQP circuit in a very shallow depth is demanding in practice; thus, we expect that the bond dimension and memory for extremely low-depth cases overestimate the complexity. In other words, for an extremely low depth, though the required resources are shown to be high in our figure, the corresponding IQP sampling can be efficiently simulated classically because entanglement cannot spread to the overall qubits. Except for that case, when the circuit depth increases, the overall noise rate also increases; therefore, the complexity of the simulation decreases.

For IQP sampling, the previous work shows the simulability beyond the critical depth $d_c > \Theta(p^{-1} \log(p^{-1}))$ [46]. According to the reference, the phase transition for percolation occurs at depths $d_c \approx 33$ for noise rate $p = 0.05$ and $d_c \approx 117$ for $p = 0.02$. However, since the IQP circuit is classically simulable using MPS with a bond dimension of order 10^4 , which may still be possible using a large classical computer, our MPS algorithm can cover a much wider range; more specifically, ours can simulate an IQP circuit with lower depth than the critical depth of the previous work. For the calculation of simulable memory of IQP, we use the same memory resource formula as in boson sampling.

VI. DISCUSSION AND CONCLUSION

In this work, we generalized the state-of-the-art MPS method initially developed for GBS to broader classes of sampling problems, including boson sampling and IQP sampling. This generalization demonstrates that the approach is not limited to a specific platform or model but can be extended to a wide range of other sampling problems.

FIG. 10. Required resources to achieve an MPS approximation error of 0.01, as a function of qubit number and circuit depth. (a), (b) Required bond dimension and memory with a dephasing noise rate of 0.01 per layer. Here, regardless of the depth, the unitary of the linear optics is considered to be the worst.

The proposed algorithm shows improved efficiency compared to previously proposed simulation algorithms. In addition to its efficiency, the method offers further advantages, such as tunable simulation accuracy that depends on the available computational resources. Notably, the approach remains valid across the entire range of imperfections, even in regimes where the simulation complexity increases from polynomial to exponential with respect to system parameters. Hence, we expect that our new algorithm enables us to simulate a lossy boson sampling and noisy IQP sampling in a practical regime and can be used as a benchmark for quantum advantage experiments.

Furthermore, we provide explicit resource estimates by analyzing the required bond dimension to achieve a target simulation noise rate. This quantitative analysis enables informed decisions about simulation feasibility. In particular, for circuits corresponding to an experimentally implemented unitary, we conduct a detailed simulability analysis that aligns closely with a realistic experimental setup. These results enable a direct comparison between theoretical predictions and experimental outcomes, thereby enhancing the practical relevance of our approach and the usage of our algorithm as a benchmark for future experimental implementations.

We remark that although our method for lossy boson sampling covers Fock-state and cat-state inputs, whether it can be further generalized to an arbitrary input state is still open. Also, while we assumed a conventional IQP circuit [19], a recent study in Ref. [42] extended the IQP circuit to be augmented by CNOT gates. Our method does not immediately extend to those IQP circuits yet. It is open to improve our algorithm to cover a broader class of quantum circuits. Also, we assumed a lossy channel or Pauli noise for boson sampling and IQP

sampling, respectively. Generalizing our method to cover more general noise channels would be an important open question.

Appendix A: Analysis of the required bond dimension for classical simulation of boson sampling

This section describes the algorithm for estimating the required bond dimension in the classical simulation of boson sampling, which is used for Fig. 6. Recall that the eigenvalues of the reduced density matrix for each j th tensor product of Eq. (30) are given by

$$c_{j0} \equiv \frac{1}{4} \left(2 + \sqrt{2\eta^2 \cos(4\theta_j) - 2\eta^2 + 4} \right), \quad c_{j1} \equiv \frac{1}{4} \left(2 - \sqrt{2\eta^2 \cos(4\theta_j) - 2\eta^2 + 4} \right), \quad (\text{A1})$$

where $1 \geq c_{j0} \geq 1/2 \geq c_{j1} \geq 0$. Hence, the eigenvalues of the total reduced density matrix are expressed as:

$$p(\vec{k}) \equiv \prod_{\vec{k} \in \{0,1\}^N} c_{jk_j} = \prod_{j=1}^N c_{j0}^{1-k_j} c_{j1}^{k_j}. \quad (\text{A2})$$

Hence,

$$\log p(\vec{k}) = \sum_{j=1}^N [(1-k_j) \log c_{j0} + k_j \log c_{j1}] = \sum_{j=1}^N \log c_{j0} + \sum_{j=1}^N k_j \log \left(\frac{c_{j1}}{c_{j0}} \right) = C + \sum_{j=1}^N k_j \log r_j, \quad (\text{A3})$$

where we define $C \equiv \sum_{j=1}^N \log c_{j0}$ and $r_j \equiv c_{j1}/c_{j0} < 1$. Note that as r_j decreases, $p(\vec{k})$ becomes a smaller eigenvalue and thus less significant.

We construct the list of $\log p(\vec{k})$ iteratively. Initialize $L = \{0\}$, and for each j update

$$L \leftarrow L \cup \{ \ell + \log r_j : \ell \in L \}. \quad (\text{A4})$$

Since $\log r_j < 0$, we can prune partial sums during the construction: for any $t < N$, if a partial value $\sum_{j=1}^t k_j^* \log r_j$ is below the threshold, then every $\vec{k}$ whose first t entries coincides with $\vec{k}^*$ will also be below the threshold; hence we discard that entire branch from L . This pruning removes eigenvalues below the threshold.

By choosing the threshold so that the cumulative weight of the retained eigenvalues is sufficiently close to the target accuracy, say 99%, and then counting the eigenvalues that exceed the threshold, we obtain an estimate of the required bond dimension.

Appendix B: Commutation relation of splitted creation and annihilation operators

In this Appendix, we provide a detailed proof for the statement that the commutation relation of $\hat{B}_{u,j}$ approximately holds for Haar-random unitary matrices U . Recall that the commutation relation is written as

$$[\hat{B}_{u,j}, \hat{B}_{u,k}^\dagger] = \left[\frac{\sum_{m=1}^l U_{jm} \hat{a}_m}{\cos \theta_j}, \frac{\sum_{n=1}^l U_{kn}^* \hat{a}_n^\dagger}{\cos \theta_k} \right] = \frac{\sum_{m=1}^l U_{jm} U_{km}^*}{\sqrt{\sum_{m=1}^l |U_{jm}|^2} \sqrt{\sum_{n=1}^l |U_{kn}|^2}}, \quad (\text{B1})$$

for $1 \leq j, k \leq N$. We will focus on the case that $l = M/2$ because this case renders the maximum entanglement entropy.

First of all, the commutation relation for $j = k$ holds trivially. Thus, we focus on the case that $j \neq k$. We now show that the commutation relation with $j \neq k$ is small with high probability over the Haar-random unitary U . To do that, we first compute the first and second moments of the related terms. Let us first invoke some identities from the Weingarten calculus:

$$\mathbb{E}[U_{im} U_{jm}^*] = \frac{\delta_{ij}}{M}, \quad \mathbb{E}[|U_{im} U_{jn}^*|^2] = \frac{1 + \delta_{ij}}{M^2 - 1} - \frac{\delta_{jk} + \delta_{mn}}{M(M^2 - 1)}, \quad (\text{B2})$$

Let us first focus on the numerator. The first and second moments of the numerator are given by

$$\mathbb{E} \left[\sum_{m=1}^l U_{jm} U_{km}^* \right] = 0, \quad \mathbb{E} \left[\left| \sum_{m=1}^l U_{jm} U_{km}^* \right|^2 \right] = \frac{l(l+1)}{M^2(M+1)} - \frac{l^2}{M^2} = \frac{l(M-l)}{M^2(M+1)}. \quad (\text{B3})$$

Hence, the variance of the numerator is the same as the second moment. Therefore, using the Chebyshev inequality,

$$\Pr \left[\left| \sum_{m=1}^l U_{jm} U_{km}^* \right| \leq \epsilon \right] \leq 1 - \frac{1}{\epsilon^2} \frac{l(M-l)}{M^2(M+1)}. \quad (\text{B4})$$

We similarly investigate the denominator

$$\mathbb{E} \left[\sum_{m=1}^l |U_{jm}|^2 \right] = \frac{l}{M}, \quad \mathbb{E} \left[\left| \sum_{m=1}^l |U_{jm}|^2 \right|^2 \right] = \frac{l(l+1)}{M(M+1)}, \quad (\text{B5})$$

and thus the variance is $l(M-l)/[M^2(M+1)]$. Hence, by the Chebyshev inequality,

$$\Pr \left[\left| \sum_{m=1}^l |U_{jm}|^2 - \frac{l}{M} \right| \leq \epsilon \right] \leq 1 - \frac{1}{\epsilon^2} \frac{l(M-l)}{M^2(M+1)}. \quad (\text{B6})$$

Hence, using the union bound, we prove that

$$\Pr \left[\left| \sum_{m=1}^l |U_{jm}|^2 - \frac{l}{M} \right| \leq \epsilon \text{ and } \left| \sum_{m=1}^l |U_{km}|^2 - \frac{l}{M} \right| \leq \epsilon \text{ and } \left| \sum_{m=1}^l U_{jm} U_{km}^* \right| \leq \epsilon \right] \leq 1 - \frac{3}{\epsilon^2} \frac{l(M-l)}{M^2(M+1)}. \quad (\text{B7})$$

Since a similar bound must hold for all $1 \leq j, k \leq N$, by using the union bound once more,

$$\Pr \left[\left| \sum_{m=1}^l |U_{jm}|^2 - \frac{l}{M} \right| \leq \epsilon \text{ and } \left| \sum_{m=1}^l |U_{km}|^2 - \frac{l}{M} \right| \leq \epsilon \text{ and } \left| \sum_{m=1}^l U_{jm} U_{km}^* \right| \leq \epsilon \text{ for all } 1 \leq j, k \leq N \right] \quad (\text{B8})$$

$$\leq 1 - \frac{3N(N-1)}{8\epsilon^2(M+1)}, \quad (\text{B9})$$

where we set $l = M/2$ as assumed. Hence, by choosing $M = \omega(N^2)$ for any ϵ ,

$$\left| \left[\hat{B}_{u,j}, \hat{B}_{u,k}^\dagger \right] \right| = \frac{\sum_{m=1}^l U_{jm} U_{km}^*}{\sqrt{\sum_{m=1}^l |U_{jm}|^2} \sqrt{\sum_{n=1}^l |U_{kn}|^2}} \leq \frac{\epsilon}{M/2 - \epsilon} = O(1/M), \quad (\text{B10})$$

which proves our assumption.

Advantage of Indefinite Casual Order in Channel Transformation

Abstract. Indefinite causal order enables quantum channels to be manipulated beyond fixed parallel or sequential circuits, but any genuine advantage must be distinguished from resources supplied by the surrounding process. In this work, we address this problem within the dynamical resource theory of coherence. A Choi-based SDP compares parallel, sequential, and indefinite causal order strategies under identical incoherence constraints. For the task of purifying two amplitude-damping channels into an identity channel, we demonstrate a genuine advantage of indefinite causal order through SDP witnesses. On the other hand, for Pauli-noise purification, teleportation covariance eliminates the gap between all three strategies, indicating that the advantage of indefinite causal order relies essentially on non-Pauli structure.

Keywords: Quantum coherence, resource theory, superchannels, indefinite causal order, channel transformation

Background. In the standard circuit model, quantum operations are arranged in a definite causal order: one operation is applied before another. Quantum mechanics, however, allows a more general possibility in which the order of operations is itself coherently controlled. The paradigmatic example is the quantum switch, where two black-box operations are applied in an order controlled by an auxiliary quantum system [1]. This process is not equivalent to a fixed-order circuit, nor to a classical mixture of different orders, and its causal non-separability can be certified by causal witnesses [2, 3]. More generally, quantum supermaps, quantum combs, and process matrices provide a framework for transforming unknown quantum channels without assuming a fixed global causal order from the outset [4–6]. Thus indefinite causal order is not only mathematically consistent with quantum theory, but also an operationally meaningful extension of ordinary circuit structure.

Indefinite causal order has led to advantages in several information-processing tasks, including channel discrimination, query complexity, communication complexity, metrology, and transformations of unknown unitaries [7–11]. These results suggest that causal structure itself can act as a resource: by enlarging the allowed causal order, one can enlarge

Figure 1: Schematic overview of incoherent higher-order channel transformation. Input resource channels $\mathcal{N}_1, \dots, \mathcal{N}_n$ are inserted into an incoherent superchannel $\mathcal{S}$, which transforms them into an output channel approximating the target channel $\mathcal{M}$. The same incoherence constraint is imposed on parallel (Par), sequential (Seq), and indefinite-causal-order (ICO) strategies.

the set of achievable higher-order transformations.

However, a causal-order advantage is meaningful only if the comparison is fair. If arbitrary superchannels were allowed, the higher-order map could ignore the input channels and directly prepare the desired coherent target channel using coherent pre- or post-processing. Such a replacement-type construction would not reveal any resource in the input

*chenranyiliu@quantumsc.cn

†zhengshenggen@quantumsc.cn

‡felixxinwang@hkust-gz.edu.cn

channels, nor any genuine advantage of causal order. This motivates a resource-theoretic comparison: parallel, sequential, and causally indefinite strategies should be compared under the same physical free-operation constraint [12].

Coherence was first developed as a resource theory of states, where incoherent states are diagonal in a fixed reference basis and free operations cannot create coherence [13–18]. It is also a dynamical resource: memories can preserve coherence, while gates can generate or manipulate it. This leads to the dynamical resource theory of coherence, whose resource objects are quantum channels [19]. In this setting, free channels are classical channels, whereas the identity channel is resourceful because it perfectly preserves coherent superpositions. Hence incoherence is a natural constraint on the allowed superchannels as it prevents the higher-order process from supplying coherence for free, so that any coherent target channel must be simulated using the coherence contained in the input channels and the allowed causal structure.

Under this restriction, coherent channel transformation becomes an incoherent higher-order transformation task: resource channels $\mathcal{N}_1, \dots, \mathcal{N}_n$ are inserted into an incoherent superchannel $\mathcal{S}$ to simulate a target coherent channel $\mathcal{M}$, as in Fig. 1. Since $\text{Par} \subseteq \text{Seq} \subseteq \text{ICO}$, the optimal simulation error is non-increasing with the allowed causal structure. The central question is whether this hierarchy is strict under the same incoherence constraint, so that indefinite causal order yields a genuine advantage without additional coherence resource.

Overview of results. We formulate coherent-channel transformation as a resource-theoretic higher-order transformation problem and systematically determine whether indefinite causal order can outperform all fixed-order strategies when the transformation itself is incoherent. Our main contributions are:

1. We formulate **incoherent higher-order channel transformation** and give its **semidefinite-programming formulation**. Given coherent channels and a target channel, we compare parallel, sequential, and indefinite-causal-order superchannels under the same incoherent free-superchannel constraints. In the Choi representation, the superchannel action, causal constraints, incoherence constraints, and diamond-norm objective are all SDP-compatible, giving a unified optimization framework for the three causal struc-

tures.

2. We prove a **strict hierarchy for channel purification**. For two copies of amplitude damping resource channel and target identity channel under maximally incoherent superchannels (MISC) conditions which preserve the set of incoherent channels [19], SDP certificates show that ICO outperforms other two causal order. Thus indefinite causal order gives a genuine purification advantage even when the superchannel is required to be incoherent.
3. We prove a **collapse theorem for mixed-Pauli resources**. Teleportation covariance allows every sequential or causally indefinite protocol to be stretched into a parallel one, while preserving the MISC condition. Hence, for every target channel, transformation error keeps the same among all strategies.

SDP formulation of incoherent channel Transformation.

We formulate deterministic channel transformation as a convex optimization problem. Given several copies of a noisy coherent resource channel $\mathcal{N}$ and a target channel $\mathcal{M}$, the goal is to choose an admissible superchannel $\mathcal{S}$ such that $\mathcal{S}(\mathcal{N}^{\otimes n})$ is close to $\mathcal{M}$ in diamond distance. The admissible superchannel is subject to two independent constraints: a causal-structure constraint, specifying the transformation is parallel, sequential, or of indefinite causal order, and a resource-theoretic incoherence constraint, for which we adopt the class of maximally incoherent superchannels (MISC):

Definition 1 Let Δ_A and Δ_B denote the complete dephasing superchannels on the input and output channel spaces, respectively. A superchannel $\mathcal{S} : A \rightarrow B$ is called a *maximally incoherent superchannel* (MISC) if it maps every incoherent channel to an incoherent channel. Equivalently,

$$\Delta_B \circ \mathcal{S} \circ \Delta_A = \mathcal{S} \circ \Delta_A.$$

We denote the set of such superchannels by MISC.

This optimization is tractable because all relevant constraints are linear in the Choi representation. If $\Theta^{\mathcal{S}}$ is the Choi operator of $\mathcal{S}$, then $J_{\mathcal{S}(\mathcal{N}^{\otimes n})} = J_{\mathcal{N}^{\otimes n}} * \Theta^{\mathcal{S}}$, so the simulation error depends linearly on the superchannel variable. The diamond-distance objective also has a standard semidefinite-programming representation. Hence the whole transformation task becomes an SDP,

allowing a direct comparison of parallel, sequential, and indefinite-causal-order strategies under the same incoherence constraint.

Proposition 2 *For each causal class $\mathbf{H} \in \{\text{Par}, \text{Seq}, \text{ICO}\}$ in MISC condition, the optimal deterministic transformation error*

$$D_{\text{MISC}}^{\mathbf{H}}(\mathcal{N}^{\otimes n}, \mathcal{M}) := \min_{\mathcal{S} \in \mathbf{H} \cap \text{MISC}} \frac{1}{2} \|\mathcal{S}(\mathcal{N}^{\otimes n}) - \mathcal{M}\|_{\diamond}$$

is computable by a semidefinite program. The SDP optimizes over the superchannel Choi operator $\Theta^{\mathcal{S}}$ and the diamond-norm auxiliary variables. The causal-order constraints are imposed by linear quantum-comb constraints, while the MISC constraints are imposed by linear dephasing constraints.

Strict hierarchy for a channel purification task.

We identify amplitude damping as a concrete non-Pauli resource channel for which causal order becomes genuinely useful. Specifically, using two copies of the amplitude-damping channel at damping rate $\varepsilon = 1/2$ and taking the target channel to be the identity, we certify a strict hierarchy among MISC superchannels: parallel strategies are strictly weaker than sequential strategies, and sequential strategies are strictly weaker than indefinite-causal-order strategies.

Theorem 3 *There exist a resource channel and a target channel for which the MISC causal-order hierarchy is strict. In particular, choosing the resource as two copies of the amplitude-damping channel at damping rate $\varepsilon = 1/2$. Let*

$$D_{\mathbf{H}} := D_{\text{MISC}}^{\mathbf{H}}\left((\mathcal{N}_{\text{AD}}^{1/2})^{\otimes 2}, \mathcal{I}\right),$$

where $\mathbf{H} \in \{\text{Par}, \text{Seq}, \text{ICO}\}$, then

$$D_{\text{Par}} > D_{\text{Seq}} > D_{\text{ICO}}.$$

Feasible SDP certificates establish the strict hierarchy. The parallel MISC dual SDP gives a distance lower bound $D_{\text{MISC}}^{\text{Par}} \geq 534413171/14256814500$, the sequential MISC primal and dual SDPs coincide at $D_{\text{MISC}}^{\text{Seq}} = 61/1857$, and the ICO MISC primal SDP gives a distance upper bound $D_{\text{MISC}}^{\text{ICO}} \leq \frac{1}{2} - \frac{\sqrt{6+\sqrt{2}}}{8}$. These values certify that parallel strategies are strictly weaker than sequential strategies, which are strictly weaker than indefinite-causal-order strategies.

Figure 2: Incoherent purification of two copies of $\mathcal{N}_{\text{AD}}^{\varepsilon}$ into the identity channel at different noise strength. The optimal diamond-distance error is compared for parallel, sequential, and indefinite-causal-order MISC superchannels. The causally indefinite strategy achieves the smallest error, while the parallel strategy gives the largest error.

Figure 2 compares the three causal-order paradigms for coherent channel simulation at different noise strength. As the noise level increases, the diamond distance grows for all strategies, reflecting the increasing difficulty of recovering the target coherent channel. Across the full range, parallel superchannels give the largest error, sequential superchannels improve on them, and indefinite-causal-order superchannels achieve the smallest error. This supports the hierarchy $D^{\text{Par}} \geq D^{\text{Seq}} \geq D^{\text{ICO}}$.

Collapse for mixed-Pauli resource channels. Our second structural result identifies a broad class of resource channels for which causal order gives no advantage. We prove that, if the input resource is a mixed-Pauli channel, then the free superchannels all achieve the same optimal deterministic simulation error for all target channel $\mathcal{M}$, under the MISC constraints.

Theorem 4 *Let $\mathcal{N}_{\mathbf{p}}$ be a mixed Pauli channel. Then for every target channel $\mathcal{M}$ and for MISC constraints,*

$$D_{\text{MISC}}^{\text{Par}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}, \mathcal{M}) = D_{\text{MISC}}^{\text{Seq}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}, \mathcal{M}) = D_{\text{MISC}}^{\text{ICO}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}, \mathcal{M}).$$

The unifying mechanism is teleportation covariance: mixed-Pauli channels can be exactly simulated from their Choi states by a fixed teleportation protocol [20, 21].

Indefinite causal order provides a more general way of combining quantum channels beyond fixed orders, *e.g.*, parallel or sequential ones, but a genuine causal-order advantage must be separated from resources supplied by the surrounding transformation. We study this question in the dynamical resource theory of quantum coherence by introducing incoherent higher-order channel transformation, where coherent resource channels are processed by incoherent superchannels to simulate a target coherent channel. We formulate the task as a semidefinite program in the Choi representation, enabling a direct comparison of parallel, sequential, and indefinite-causal-order strategies under identical incoherence constraints. For two copies of an amplitude-damping channel and the identity target, certified SDP witnesses show a strict hierarchy: indefinite causal order outperforms sequential strategies, which outperform parallel strategies. In contrast, for mixed-Pauli resource channels, teleportation covariance collapses the hierarchy by reducing every adaptive or causally indefinite protocol to a parallel one. These results show that causal order can be an operational resource for transforming coherent dynamics, but only for resource channels with genuinely non-Pauli structure.

I. INTRODUCTION

In the standard circuit model, physical processes are arranged in a definite causal order: one operation is applied before another, and the temporal structure of the circuit is fixed in advance. Quantum theory, however, allows a more general higher-order description in which quantum operations themselves are the objects being transformed. In the framework of quantum supermaps, quantum combs, and process matrices, one can describe transformations of unknown quantum channels without assuming from the outset that the channels are inserted in an ordinary circuit with a fixed order [1–3]. A particularly important example is the quantum switch, where two black-box operations are applied in an order coherently controlled by an auxiliary quantum system [4]. This possibility, known as indefinite causal order, has attracted considerable attention because it suggests that causal structure itself may become an operational resource.

Over the past decades, indefinite causal order has been shown to give advantages in a variety of information-processing tasks. Examples include quantum channel discrimination, query complexity, communication complexity, quantum metrology, and transformations of unknown unitary dynamics [5–7]. In these settings, higher-order transformations with indefinite causal order can outperform all strategies in which the available channels are used in a fixed parallel or sequential arrangement. At the same time, the interpretation of such advantages requires some care. If the class of allowed higher-order operations is too large, then the advantage may come not from causal indefiniteness itself, but from additional resources hidden in the surrounding transformation. This point is especially clear in communication tasks, where

FIG. 1. Schematic overview of incoherent higher-order channel transformation. Several input resource channels $\mathcal{N}_1, \dots, \mathcal{N}_n$ are inserted into an incoherent superchannel $\mathcal{S}$, which transforms them into an output channel approximating the target channel $\mathcal{M}$ up to error ε . The superchannel belongs to a causal class chosen from parallel strategies, sequential strategies, and indefinite-causal-order strategies, and to an incoherent superchannel class.

a fair comparison between definite and indefinite causal structures should impose resource-theoretic constraints on the allowed supermaps [8].

One representative resource-theoretic constraint is the constraint of incoherence, which was originally formulated for quantum states, where incoherent states are those diagonal in a fixed reference basis and free operations are required not to create coherence from such states [9–14]. Furthermore, coherence is also a property of dynamics: a quantum memory may preserve coherence, and a quantum gate may generate or manipulate coherence. This motivates the dynamical resource theory of coherence, in which the resource objects are quantum channels rather than quantum states [15]. In this theory,

* chenranyiliu@quantumsc.cn

† zhengshenggen@quantumsc.cn

‡ felixxinwang@hkust-gz.edu.cn

the free channels are classical channels: channels invariant under dephasing of both the input and output, and hence unable to generate or store coherence. We therefore restrict the allowed superchannels to be incoherent superchannels. Under this restriction, any coherent output must ultimately be distilled from the input resource channels and from the way those channels are causally arranged, rather than supplied for free by the superchannel.

This distinction is important for formulating a meaningful channel-transformation task. If arbitrary higher-order transformations were allowed, transformation of coherent dynamics would become trivial: a superchannel could ignore the input channels and simply prepare the desired coherent target channel by using coherent pre- or post-processing. Such a constant or replacement-type higher-order construction would not reveal any resource contained in the input channels, nor any genuine advantage of causal order. To avoid this triviality, the higher-order transformation itself must be free in the dynamical resource theory.

A natural setting in which to test the operational power of causal order is therefore incoherent channel transformation. The available devices are coherent channels, while the desired object is a cleaner or more resourceful target channel. One asks whether several uses of coherent channels can be combined, by an incoherent higher-order transformation, into a channel that is closer to the target. Depending on how the input channels are inserted, the transformation strategy may be parallel (Par), sequential (Seq), or of indefinite causal order (ICO). Since these strategy classes satisfy

$$\text{Par} \subseteq \text{Seq} \subseteq \text{ICO},$$

one expects the best achievable transformation error to be non-increasing as the causal structure is enlarged. The central question is whether these inclusions lead to a genuine strict advantage after the incoherent-superchannel constraint has been imposed.

In this work, we consider the transformation of coherent channels $\mathcal{N}$ into a target channel $\mathcal{M}$, as illustrated in Fig. 1. We formulate the channel-transformation task as a semidefinite program in the Choi representation of the superchannel, with linear constraints enforcing both the causal structure and the incoherent superchannel condition. We then certify a strict hierarchy between parallel, sequential, and causally indefinite strategies. In particular, for two copies of an amplitude-damping channel and the identity target, causally indefinite incoherent superchannels achieve a strictly smaller transformation error than any sequential incoherent superchannel, and sequential strategies in turn outperform parallel ones. This shows that the advantage of indefinite causal order is not merely a consequence of allowing arbitrary higher-order maps; it persists even under a resource-theoretic incoherence constraint.

We also show that this advantage is resource dependent. For mixed-Pauli channels, teleportation covariance allows general higher-order protocols to be reduced to parallel processing of Choi states, causing the causal hierarchy to collapse. Thus, indefinite causal order does not universally improve coherent channel transformation. Rather, its usefulness de-

pends on the structure of the input channel and on how the incoherent-superchannel constraint interacts with the allowed causal structure. Our results place channel transformation, dynamical coherence, and indefinite causal order within a unified resource-theoretic framework, and show that causal indefiniteness can be an operational resource even when the higher-order transformation is required to be incoherent.

II. INCOHERENT HIGHER-ORDER QUANTUM TRANSFORMATION

We now introduce the channel-transformation task considered in this work. The input is a noisy coherent channel $\mathcal{N}$, and the goal is to use several copies of $\mathcal{N}$ to simulate a target coherent channel $\mathcal{M}$. Since the identity channel preserves arbitrary input coherence, it is a resourceful channel in the dynamical resource theory of coherence; hence the case $\mathcal{M} = \mathcal{I}$ may be regarded as coherent-channel distillation.

The transformation from the input channels to the output channel is performed by a higher-order map, or superchannel, denoted by $\mathcal{S}$. We impose two independent restrictions on $\mathcal{S}$. First, its causal structure is chosen from $\mathbf{H} \in \{\text{Par}, \text{Seq}, \text{ICO}\}$, corresponding respectively to parallel, sequential, and indefinite-causal-order strategies. Second, the superchannel is required to be maximally incoherent superchannels (MISC).

Definition 1 Let Δ_A and Δ_B denote the complete dephasing superchannels on the input and output channel spaces, respectively. A superchannel $\mathcal{S} : A \rightarrow B$ is called a maximally incoherent superchannel (MISC) if it maps every incoherent channel to an incoherent channel. Equivalently,

$$\Delta_B \circ \mathcal{S} \circ \Delta_A = \mathcal{S} \circ \Delta_A.$$

We denote the set of such superchannels by MISC.

Thus the admissible higher-order transformations are those in $\mathcal{S} \in \mathbf{H} \cap \text{MISC}$.

Proposition 1 For each causal class $\mathbf{H} \in \{\text{Par}, \text{Seq}, \text{ICO}\}$ in MISC condition, the optimal deterministic simulation error

$$D_{\text{MISC}}^{\mathbf{H}}(\mathcal{N}^{\otimes n}, \mathcal{M}) := \min_{\mathcal{S} \in \mathbf{H} \cap \text{MISC}} \frac{1}{2} \|\mathcal{S}(\mathcal{N}^{\otimes n}) - \mathcal{M}\|_{\diamond}$$

is computable by a semidefinite program. The SDP optimizes over the Choi operator $\Theta^{\mathcal{S}}$ of the superchannel together with the auxiliary diamond-norm variables. The causal-order constraints are imposed by linear quantum-comb constraints, and the MISC constraints are imposed by linear dephasing constraints.

For two copies of the input channel, the optimal deterministic transformation error is defined as

$$D_{\text{MISC}}^{\mathbf{H}}(\mathcal{N}^{\otimes 2}, \mathcal{M}) := \min_{\mathcal{S} \in \mathbf{H} \cap \text{MISC}} \frac{1}{2} \|\mathcal{S}(\mathcal{N}^{\otimes 2}) - \mathcal{M}\|_{\diamond}. \quad (1)$$

The factor $1/2$ gives the usual operational normalization of the diamond distance. Hence $D_{\text{MISC}}^{\mathbf{H}}$ measures the smallest distinguishability error between the transformed output channel and the target channel, under the simultaneous causal-order and incoherence constraints.

The causal classes obey the inclusion relation $\text{Par} \subseteq \text{Seq} \subseteq \text{ICO}$. Therefore, for each fixed free-superchannel class, one has the natural hierarchy

$$D_{\text{MISC}}^{\text{Par}}(\mathcal{N}^{\otimes 2}, \mathcal{M}) \geq D_{\text{MISC}}^{\text{Seq}}(\mathcal{N}^{\otimes 2}, \mathcal{M}) \geq D_{\text{MISC}}^{\text{ICO}}(\mathcal{N}^{\otimes 2}, \mathcal{M}). \quad (2)$$

The main question is whether the inequalities in Eq. (2) can be strict. In other words, we ask whether indefinite causal order can improve coherent-channel transformation even when the surrounding higher-order transformation is itself incoherent.

This formulation gives a common framework for comparing parallel, sequential, and indefinite-causal-order strategies under the same incoherent-resource constraint. The strictness of Eq. (2) then becomes an SDP-certifiable statement. In the following, we use this framework to show that amplitude-damping resource channels exhibit a strict hierarchy, whereas mixed-Pauli resource channels do not.

III. INDEFINITE CAUSAL-ORDER ADVANTAGE IN CHANNEL PURIFICATION.

We now turn to a resource channel for which causal order becomes genuinely useful. A natural candidate is the amplitude-damping channel.

This channel is non-unital and has a preferred relaxation direction $|1\rangle \rightarrow |0\rangle$. Physically, this noise carries directional information about the energy basis, and this directionality can be exploited by higher-order strategies with memory or indefinite causal order.

We consider the purification of two copies of $\mathcal{N}_{\text{AD}}^{1/2}$ into the identity channel. For $\mathbf{H} \in \{\text{Par}, \text{Seq}, \text{ICO}\}$, define

$$D_{\mathbf{H}} := D_{\text{MISC}}^{\mathbf{H}}((\mathcal{N}_{\text{AD}}^{1/2})^{\otimes 2}, \mathcal{I}). \quad (3)$$

Equivalently, $D_{\mathbf{H}}$ is the minimum of

$$\frac{1}{2} \left\| \mathcal{S}((\mathcal{N}_{\text{AD}}^{1/2})^{\otimes 2}) - \mathcal{I} \right\|_{\diamond} \quad (4)$$

over all $\mathcal{S} \in \mathbf{H} \cap \text{MISC}$. Thus D_{Par} , D_{Seq} , and D_{ICO} measure how well parallel, sequential, and causally indefinite incoherent superchannels purify the same two noisy input channels into the same coherent target.

Theorem 2 *There exist a resource channel and a target channel for which incoherent higher-order channel purification has a strict causal-order hierarchy. In particular,*

$$D_{\text{Par}} > D_{\text{Seq}} > D_{\text{ICO}} \quad (5)$$

for two copies of $\mathcal{N}_{\text{AD}}^{1/2}$ and target channel $\mathcal{I}$.

The following proposition summarizes the SDP certificates used to compare the three causal classes. The detailed primal SDP can be found in Appendix B, and the derivation of dual SDP structures can be found in Appendix C.

FIG. 2. Incoherent purification of two copies of $\mathcal{N}_{\text{AD}}^{\varepsilon}$ into the identity channel at different noise strength. The optimal diamond-distance error is compared for parallel, sequential, and indefinite-causal-order MISC superchannels. The causally indefinite strategy achieves the smallest error, while the parallel strategy gives the largest error.

Proposition 3 *For the resource channel $(\mathcal{N}_{\text{AD}}^{1/2})^{\otimes 2}$ and target channel $\mathcal{I}$, the MISC channel-purification SDPs certify*

$$D_{\text{Par}} \geq \frac{534413171}{14256814500}, \quad D_{\text{Seq}} = \frac{61}{1857}, \quad (6)$$

and

$$D_{\text{ICO}} \leq \frac{1}{2} - \frac{\sqrt{6} + \sqrt{2}}{8}. \quad (7)$$

The first inequality comes from a feasible dual witness for the parallel MISC SDP. The equality for the sequential case is certified by matching primal and dual witnesses. The ICO upper bound is obtained from an explicit feasible causally indefinite MISC superchannel. These certificates are sufficient to separate the three causal classes, since

$$\frac{534413171}{14256814500} > \frac{61}{1857} > \frac{1}{2} - \frac{\sqrt{6} + \sqrt{2}}{8}. \quad (8)$$

The certification from the numerical SDP output and numerical solutions can be found in Appendix D.

This shows that the advantage of indefinite causal order survives the incoherence constraint on the higher-order transformation. The improvement is therefore not caused by adding arbitrary resourceful processing around the input channels. Rather, it is a genuine advantage of arranging the same noisy coherent dynamics in a more general causal structure.

Figure 2 illustrates the same phenomenon across a range of damping parameters. As the noise increases, the target identity channel becomes harder to simulate, and the diamond-distance error grows for all causal classes. Nevertheless, the ordering of the curves remains the same: parallel strategies perform worst, sequential strategies improve the purification, and indefinite causal order gives the lowest error. This behaviour supports the certified separation at $\varepsilon = 1/2$ and shows that the hierarchy is not an isolated numerical accident.

The operational picture is the following. Parallel incoherent superchannels can only process the two noisy channels side by side. Sequential superchannels can feed quantum information through one noisy process and then adapt the second use using a memory system. ICO superchannels go further: they need not choose a single definite order for the two channel uses. For amplitude damping, whose non-Pauli structure selects a relaxation direction, this additional causal freedom allows the superchannel to preserve coherent dynamics more efficiently. Thus non-Pauli noise activates causal indefiniteness as a resource for channel purification.

IV. COLLAPSE FOR MIXED-PAULI RESOURCE CHANNELS

The advantage found above is not a universal property of all noisy coherent channels. There is a broad class of resource channels for which causal order does not help: mixed-Pauli channels. This shows that indefinite causal order is useful only when the input dynamics has sufficient non-Pauli structure.

Theorem 4 *Let $\mathcal{N}_p$ be a qubit mixed-Pauli channel of the form*

$$\mathcal{N}_p(\rho) = \sum_{\alpha=0}^3 p_\alpha \sigma_\alpha \rho \sigma_\alpha^\dagger, \quad p_\alpha \geq 0, \quad \sum_{\alpha=0}^3 p_\alpha = 1.$$

Then, for every target channel $\mathcal{M}$ in MISC constraints, the optimal deterministic two-copy simulation errors satisfy

$$D_{\text{MISC}}^{\text{Par}}(\mathcal{N}_p^{\otimes 2}, \mathcal{M}) = D_{\text{MISC}}^{\text{Seq}}(\mathcal{N}_p^{\otimes 2}, \mathcal{M}) = D_{\text{MISC}}^{\text{ICO}}(\mathcal{N}_p^{\otimes 2}, \mathcal{M}).$$

Hence mixed-Pauli resource channels do not exhibit a causal-order advantage for incoherent higher-order channel transformation.

The special feature of these channels is teleportation covariance. Their Choi states are Bell diagonal, and the channel can be reproduced exactly by a fixed teleportation protocol,

$$\mathcal{N}_p(\rho) = \mathcal{T}_{\text{tel}}(\rho \otimes \omega_{\mathcal{N}_p}), \quad \omega_{\mathcal{N}_p} = \frac{1}{2} J_{\mathcal{N}_p}. \quad (9)$$

Importantly, the teleportation operation $\mathcal{T}_{\text{tel}}$ is independent of the probability vector p . Thus every use of the channel can be replaced by a preparation of its Choi state followed by the same fixed teleportation gadget.

This observation removes the operational role of causal order. Any sequential or causally indefinite protocol using two copies of $\mathcal{N}_p$ can be “stretched” into a protocol that first prepares the two Choi states in parallel and then performs all remaining processing afterwards. Since the teleportation gadgets are fixed and do not depend on p , the stretched protocol produces exactly the same output channel as the original one. Hence adaptivity, memory, and indefinite causal order do not provide any additional power for mixed-Pauli resources.

The resource-theoretic constraints are also preserved by this stretching. For MISC superchannels, classical input channels

have diagonal Choi operators, and teleportation with such diagonal Choi states produces classical channels. The detailed proof can be found in Appendix E.

The strict hierarchy found for amplitude damping is therefore a genuinely non-Pauli effect: it arises only when the resource channel cannot be reduced to parallel Choi-state processing by teleportation stretching.

V. CONCLUDING REMARKS

We have studied higher-order transformations of dynamical coherence under resource-theoretic restrictions. The central question was whether indefinite causal order remains useful when the superchannel itself is required to be incoherent. Our results show that the answer is yes: causal indefiniteness can strictly improve coherent-channel purification even within the free operations of the dynamical resource theory of coherence.

The main example is amplitude damping. For two copies of $\mathcal{N}_{\text{AD}}^{1/2}$ and target channel $\mathcal{I}$, we certified the strict MISC hierarchy

$$D_{\text{MISC}}^{\text{Par}} > D_{\text{MISC}}^{\text{Seq}} > D_{\text{MISC}}^{\text{ICO}}. \quad (10)$$

Thus, parallel incoherent processing is strictly weaker than sequential processing, and sequential processing is strictly weaker than causally indefinite processing. This establishes indefinite causal order as an operational resource for purifying coherent dynamics, rather than merely an artifact of allowing arbitrary higher-order maps.

At the same time, we found that this advantage is not universal. For mixed-Pauli resource channels, teleportation covariance removes the operational role of causal order. In that case, every adaptive or causally indefinite free protocol can be stretched into a parallel one, giving

$$D_{\text{MISC}}^{\text{Par}} = D_{\text{MISC}}^{\text{Seq}} = D_{\text{MISC}}^{\text{ICO}}. \quad (11)$$

The contrast between Eqs. (10) and (11) shows that causal-order advantage is strongly resource dependent. Pauli-type noise can be processed optimally in parallel, while non-Pauli noise, such as amplitude damping, can activate the extra power of memory and indefinite causal order.

Our work suggests several directions for future study. First, it would be useful to characterize which resource channels admit teleportation-stretching reductions and which channels can witness strict causal-order separations. Second, the present analysis focuses on deterministic two-copy purification; natural extensions include probabilistic distillation, many-copy protocols, and success-probability tradeoffs. Third, the SDP framework developed here can be used to search systematically for experimentally relevant noise models where causal indefiniteness improves the preservation or recovery of coherent dynamics.

More broadly, these results indicate that higher-order resource theories should track not only which transformations are free, but also how resourceful dynamics are causally arranged. Incoherent superchannels with indefinite causal order provide a setting where coherence theory and causal structure

meet: the resource is not only the channel being processed, but also the causal way in which its uses are combined.

Supplemental Material for ‘Advantages of Indefinite Causal Order in Channel Purification’

Appendix A: Notation and conventions

We collect the notation used throughout the main text and the Supplemental Material. All Hilbert spaces are finite dimensional. For a system X , we write $d_X := \dim X$, I_X for the identity operator on X , and $\mathcal{L}(X)$ for the space of linear operators on X . For a composite system XY , partial trace over X is denoted by Tr_X . The Hilbert–Schmidt inner product is

$$\langle X, Y \rangle := \text{Tr}[X^\dagger Y]. \quad (\text{S1})$$

For Hermitian operators, $X \succeq 0$ means that X is positive semidefinite, and $X \succeq Y$ means $X - Y \succeq 0$.

We use the unnormalized Choi representation. For a channel $\mathcal{N} : X_i \rightarrow X_o$, its Choi operator is

$$J_{\mathcal{N}} := (\text{id}_{X_i} \otimes \mathcal{N}) \left(d_{X_i} \Phi_{X_i X_i'}^+ \right), \quad (\text{S2})$$

where

$$|\Phi^+\rangle_{X_i X_i'} := \frac{1}{\sqrt{d_{X_i}}} \sum_{j=0}^{d_{X_i}-1} |j\rangle_{X_i} |j\rangle_{X_i'}, \quad \Phi^+ = |\Phi^+\rangle\langle\Phi^+|. \quad (\text{S3})$$

With this convention, $\mathcal{N}$ is trace preserving if and only if

$$\text{Tr}_{X_o}[J_{\mathcal{N}}] = I_{X_i}. \quad (\text{S4})$$

For a qubit channel, we also use the normalized Choi state

$$\omega_{\mathcal{N}} := \frac{1}{2} J_{\mathcal{N}}. \quad (\text{S5})$$

A dynamical system is denoted by a pair of input and output registers. For the two input channel slots and the output channel slot we write

$$A = (A_i, A_o), \quad B = (B_i, B_o), \quad C = (C_i, C_o). \quad (\text{S6})$$

Thus a two-slot superchannel maps channels on A and B to a channel on C . Its Choi operator is denoted by

$$\Theta^{\mathcal{S}} \in \mathcal{L}(A_i A_o B_i B_o C_i C_o). \quad (\text{S7})$$

The action of a superchannel in the Choi representation is written using the link product:

$$J_{\mathcal{S}(\mathcal{N})} = J_{\mathcal{N}} * \Theta^{\mathcal{S}}, \quad (\text{S8})$$

where $*$ denotes the link product. For two input channels, $J_{\mathcal{N} \otimes 2} * \Theta^{\mathcal{S}}$ denotes the Choi operator of the output channel produced by inserting two copies of $\mathcal{N}$ into $\mathcal{S}$.

The causal structure of a superchannel is denoted by

$$\mathbf{H} \in \{\text{Par}, \text{Seq}, \text{ICO}\}, \quad (\text{S9})$$

where Par denotes parallel strategies, Seq denotes sequential strategies with a fixed order, and ICO denotes indefinite-causal-order strategies. These classes satisfy

$$\text{Par} \subseteq \text{Seq} \subseteq \text{ICO}. \quad (\text{S10})$$

The resource-theoretic class of a superchannel is denoted by

$$\mathbf{F} \in \{\text{MISC}, \text{DISC}\}, \quad (\text{S11})$$

where MISC denotes maximally incoherent superchannels and DISC denotes dephasing-covariant incoherent superchannels. We write $\mathcal{D}_X$ for the completely dephasing map on the Choi registers associated with the dynamical system X , and Δ_X for the corresponding dephasing superchannel. A superchannel is maximally incoherent if

$$\mathcal{D}_{ABC}(\Theta^{\mathcal{S}}) = (\mathcal{D}_{AB} \otimes \text{id}_C)(\Theta^{\mathcal{S}}), \quad (\text{S12})$$

and it is dephasing covariant if

$$(\text{id}_{AB} \otimes \mathcal{D}_C)(\Theta^S) = (\mathcal{D}_{AB} \otimes \text{id}_C)(\Theta^S). \quad (\text{S13})$$

A channel is called classical if its Choi operator is diagonal in the fixed incoherent basis. Equivalently, it neither generates coherence from incoherent inputs nor preserves input coherence.

The channel-purification error studied in the main text is

$$D_{\mathbf{F}}^{\mathbf{H}}(\mathcal{N}^{\otimes 2}, \mathcal{M}) := \min_{S \in \mathbf{H} \cap \mathbf{F}} \frac{1}{2} \|\mathcal{S}(\mathcal{N}^{\otimes 2}) - \mathcal{M}\|_{\diamond}. \quad (\text{S14})$$

Here $\|\cdot\|_{\diamond}$ denotes the diamond norm. In the SDP formulation, Z and l are auxiliary variables for the diamond-norm constraint, where $Z \succeq 0$ dominates the positive and negative parts of the error Choi operator and l upper-bounds the corresponding distinguishability.

For compactness, we define the linear map

$$\mathcal{L}_{\mathcal{N}}(\Theta) := J_{\mathcal{N}^{\otimes 2}} * \Theta, \quad (\text{S15})$$

so that

$$J_{\mathcal{S}(\mathcal{N}^{\otimes 2})} = \mathcal{L}_{\mathcal{N}}(\Theta^S). \quad (\text{S16})$$

Its Hilbert–Schmidt adjoint $\mathcal{L}_{\mathcal{N}}^*$ is defined by

$$\langle X, \mathcal{L}_{\mathcal{N}}(\Theta) \rangle = \langle \mathcal{L}_{\mathcal{N}}^*(X), \Theta \rangle. \quad (\text{S17})$$

We denote by $K_{\mathbf{H}}$ the affine linear map collecting the causal constraints of class $\mathbf{H}$ together with the relevant incoherence constraint, and by $K_{\mathbf{H}}^*$ its adjoint. In the dual SDPs, $P_{\mathbf{H}}$, $Q_{\mathbf{H}}$, and $R_{\mathbf{H}}$ are positive semidefinite dual variables associated with the diamond-norm constraints, while $Y_{\mathbf{H}}$ denotes the Hermitian multipliers for the causal and incoherence constraints.

We use two main families of resource channels. The amplitude-damping channel with damping parameter ε is

$$\mathcal{N}_{\text{AD}}^{\varepsilon}(\rho) = K_0 \rho K_0^{\dagger} + K_1 \rho K_1^{\dagger}, \quad (\text{S18})$$

where

$$K_0 = |0\rangle\langle 0| + \sqrt{1-\varepsilon}|1\rangle\langle 1|, \quad K_1 = \sqrt{\varepsilon}|0\rangle\langle 1|. \quad (\text{S19})$$

A mixed-Pauli channel is

$$\mathcal{N}_{\mathbf{p}}(\rho) = \sum_{\alpha=0}^3 p_{\alpha} \sigma_{\alpha} \rho \sigma_{\alpha}^{\dagger}, \quad p_{\alpha} \geq 0, \quad \sum_{\alpha=0}^3 p_{\alpha} = 1, \quad (\text{S20})$$

with

$$\sigma_0 = I, \quad \sigma_1 = X, \quad \sigma_2 = Y, \quad \sigma_3 = Z. \quad (\text{S21})$$

For teleportation stretching, $\mathcal{T}_{\text{tel}}$ denotes the standard teleportation operation. Given a channel $\mathcal{E}$, its teleportation-induced channel is

$$\mathcal{E}^{\text{tel}}(\cdot) := \mathcal{T}_{\text{tel}}(\cdot \otimes \omega_{\mathcal{E}}), \quad \omega_{\mathcal{E}} = \frac{1}{2} J_{\mathcal{E}}. \quad (\text{S22})$$

For mixed-Pauli channels, teleportation covariance gives

$$\mathcal{N}_{\mathbf{p}}^{\text{tel}} = \mathcal{N}_{\mathbf{p}}. \quad (\text{S23})$$

Appendix B: Primal SDP for MISC channel purification

The SDP for parallel MISC superchannel: $\mathcal{S}$

$$\min \quad l \quad (\text{S1})$$

$$\text{s.t. } \Theta^S \geq 0; \quad (\text{S2})$$

$$\text{Tr}_{C_o}[\Theta^S] = \text{Tr}_{A_i B_i C_o}[\Theta^S] \otimes \frac{\mathbb{I}_{A_i B_i}}{d_{A_i B_i}}; \quad (\text{S3})$$

$$\text{Tr}_{C_o A_o B_o}[\Theta^S] = \mathbb{I}_{A_i B_i C_i}; \quad (\text{S4})$$

$$\Delta_{ABC}(\Theta^S) = \Delta_{AB} \otimes \mathbb{I}_C(\Theta^S); \quad (\text{S5})$$

$$Z \geq 0; \quad (\text{S6})$$

$$J_{N_{A_i A_o B_i B_o}} * \Theta^S - J_{\mathcal{M}_{C_i C_o}} \leq Z_{C_i C_o}; \quad (\text{S7})$$

$$\text{Tr}_{C_o}[Z] \leq l \cdot \mathbb{I}_{C_i}. \quad (\text{S8})$$

Note that Δ refers to the completely dephasing channel.

The SDP for Sequential MISC superchannel: $\mathcal{S}$

$$\min \quad l \quad (\text{S9})$$

$$\text{s.t. } \Theta^S \geq 0; \quad (\text{S10})$$

$$\text{Tr}_{C_o}[\Theta^S] = \text{Tr}_{B_i C_o}[\Theta^S] \otimes \frac{\mathbb{I}_{B_i}}{d_{B_i}}; \quad (\text{S11})$$

$$\frac{1}{d_{B_i}} \text{Tr}_{C_o B_i B_o}[\Theta^S] = \frac{1}{d_{B_i}} \text{Tr}_{A_i B_o B_i C_o}[\Theta^S] \otimes \frac{\mathbb{I}_{A_i}}{d_{A_i}}; \quad (\text{S12})$$

$$\Delta_{ABC}(\Theta^S) = \Delta_{AB} \otimes \mathbb{I}_C(\Theta^S) \quad (\text{S13})$$

$$Z \geq 0; \quad (\text{S14})$$

$$J_{N_{A_i A_o B_i B_o}} * \Theta^S - J_{\mathcal{M}_{C_i C_o}} \leq Z_{C_i C_o}; \quad (\text{S15})$$

$$\text{Tr}_{C_o}[Z] \leq l \cdot \mathbb{I}_{C_i}. \quad (\text{S16})$$

The SDP for Indefinite causal order MISC superchannel: $\mathcal{S}$

$$\min \quad l \quad (\text{S17})$$

$$\text{s.t. } \Theta^S \geq 0; \quad (\text{S18})$$

$$\text{Tr}_{C_o}[\Theta^S] = \frac{\mathbb{I}_{A_i}}{d_{A_i}} \otimes \text{Tr}_{A_i C_o}[\Theta^S] + \frac{\mathbb{I}_{B_i}}{d_{B_i}} \otimes \text{Tr}_{B_i C_o}[\Theta^S] - \frac{\mathbb{I}_{A_i B_i}}{d_{A_i B_i}} \otimes \text{Tr}_{A_i B_i C_o}[\Theta^S] \quad (\text{S19})$$

$$\text{Tr}_{A_o A_i C_o}[\Theta^S] = \frac{\mathbb{I}_{B_i}}{d_{B_i}} \otimes \text{Tr}_{A_o A_i B_i C_o}[\Theta^S] \quad (\text{S20})$$

$$\text{Tr}_{B_o B_i C_o}[\Theta^S] = \frac{\mathbb{I}_{A_i}}{d_{A_i}} \otimes \text{Tr}_{B_o B_i A_i C_o}[\Theta^S]; \quad (\text{S21})$$

$$\text{Tr}_{A_o A_i B_o B_i C_o} = d_{A_i B_i} \mathbb{I}_{C_i}; \quad (\text{S22})$$

$$\Delta_{ABC}(\Theta^S) = \Delta_{AB} \otimes \mathbb{I}_C(\Theta^S) \quad (\text{S23})$$

$$Z \geq 0; \quad (\text{S24})$$

$$J_{N_{A_i A_o B_i B_o}} * \Theta^S - J_{\mathcal{M}_{C_i C_o}} \leq Z_{C_i C_o}; \quad (\text{S25})$$

$$\text{Tr}_{C_o}[Z] \leq l \cdot \mathbb{I}_{C_i}. \quad (\text{S26})$$

Appendix C: Dual SDP for MISC channel purification

In this appendix we write the primal and dual semidefinite programs used to certify the MISC causal-order hierarchy. All notation follows Appendix A. In particular,

$$A = (A_i, A_o), \quad B = (B_i, B_o), \quad C = (C_i, C_o),$$

and a two-slot superchannel is represented by a Choi operator

$$\Theta^{\mathcal{S}} \in \mathcal{L}(A_i A_o B_i B_o C_i C_o).$$

The input resource is the two-copy channel

$$N_{A_i A_o B_i B_o} := (\mathcal{N}_{\text{AD}}^\varepsilon)^{\otimes 2},$$

with Choi operator

$$J_{N_{A_i A_o B_i B_o}} \in \mathcal{L}(A_i A_o B_i B_o).$$

The target channel is denoted by

$$\mathcal{M}_{C_i C_o}, \quad J_{\mathcal{M}_{C_i C_o}} \in \mathcal{L}(C_i C_o).$$

We use the Hilbert–Schmidt inner product

$$\langle X, Y \rangle := \text{Tr}[X^\dagger Y].$$

Define the linear link-product map

$$\mathcal{L}_N(\Theta^\mathcal{S}) := J_{N_{A_i A_o B_i B_o}} * \Theta^\mathcal{S} \in \mathcal{L}(C_i C_o), \quad (\text{S1})$$

and define its adjoint by

$$\langle X, \mathcal{L}_N(\Theta^\mathcal{S}) \rangle = \langle \mathcal{L}_N^*(X), \Theta^\mathcal{S} \rangle, \quad \forall X \in \mathcal{L}(C_i C_o). \quad (\text{S2})$$

The MISC constraint is

$$\Delta_{ABC}(\Theta^\mathcal{S}) = (\Delta_{AB} \otimes \mathbb{I}_C)(\Theta^\mathcal{S}), \quad (\text{S3})$$

or equivalently

$$\text{D}_{\text{MISC}}(\Theta^\mathcal{S}) := \Delta_{ABC}(\Theta^\mathcal{S}) - (\Delta_{AB} \otimes \mathbb{I}_C)(\Theta^\mathcal{S}) = 0. \quad (\text{S4})$$

Since the dephasing maps are self-adjoint,

$$\text{D}_{\text{MISC}}^*(Y_\Delta) = \Delta_{ABC}(Y_\Delta) - (\Delta_{AB} \otimes \mathbb{I}_C)(Y_\Delta). \quad (\text{S5})$$

1. Adjoints of the causal constraints

In the following formulas, all tensor factors are placed in the same register order as in Appendix A, namely

$$A_i A_o B_i B_o C_i C_o.$$

The adjoint of a partial trace is understood as tensoring the corresponding identity operator on the traced-out register.

a. Parallel constraints

The parallel causal constraints in Appendix A are

$$\text{Tr}_{C_o}[\Theta^\mathcal{S}] = \text{Tr}_{A_i B_i C_o}[\Theta^\mathcal{S}] \otimes \frac{\mathbb{I}_{A_i B_i}}{d_{A_i B_i}}, \quad (\text{S6})$$

$$\text{Tr}_{C_o A_o B_o}[\Theta^\mathcal{S}] = \mathbb{I}_{A_i B_i C_i}. \quad (\text{S7})$$

Let

$$Y_1^{\text{Par}} \in \mathcal{L}(A_i A_o B_i B_o C_i), \quad Y_2^{\text{Par}} \in \mathcal{L}(A_i B_i C_i),$$

be Hermitian free dual variables. Define

$$\text{P}_1^*(Y_1^{\text{Par}}) := Y_1^{\text{Par}} \otimes \mathbb{I}_{C_o} - \frac{\mathbb{I}_{A_i B_i}}{d_{A_i B_i}} \otimes \text{Tr}_{A_i B_i}[Y_1^{\text{Par}}] \otimes \mathbb{I}_{C_o}, \quad (\text{S8})$$

$$\text{P}_2^*(Y_2^{\text{Par}}) := Y_2^{\text{Par}} \otimes \mathbb{I}_{A_o B_o C_o}. \quad (\text{S9})$$

The total parallel adjoint contribution is

$$\text{K}_{\text{Par}}^*(Y_1^{\text{Par}}, Y_2^{\text{Par}}, Y_\Delta^{\text{Par}}) := \text{P}_1^*(Y_1^{\text{Par}}) + \text{P}_2^*(Y_2^{\text{Par}}) + \text{D}_{\text{MISC}}^*(Y_\Delta^{\text{Par}}). \quad (\text{S10})$$

b. Sequential constraints

The sequential causal constraints are

$$\text{Tr}_{C_o}[\Theta^S] = \text{Tr}_{B_i C_o}[\Theta^S] \otimes \frac{\mathbb{I}_{B_i}}{d_{B_i}}, \quad (\text{S11})$$

$$\frac{1}{d_{B_i}} \text{Tr}_{C_o B_i B_o}[\Theta^S] = \frac{1}{d_{B_i}} \text{Tr}_{A_i B_o B_i C_o}[\Theta^S] \otimes \frac{\mathbb{I}_{A_i}}{d_{A_i}}. \quad (\text{S12})$$

For a deterministic sequential superchannel, one must also impose the final normalization

$$\text{Tr}_{A_o A_i B_o B_i C_o}[\Theta^S] = d_{A_i B_i} \mathbb{I}_{C_i}. \quad (\text{S13})$$

This is the sequential analogue of the ICO normalization constraint.

Let

$$Y_1^{\text{Seq}} \in \mathcal{L}(A_i A_o B_i B_o C_i), \quad Y_2^{\text{Seq}} \in \mathcal{L}(A_i A_o C_i), \quad Y_3^{\text{Seq}} \in \mathcal{L}(C_i),$$

be Hermitian free dual variables. Define

$$S_1^*(Y_1^{\text{Seq}}) := Y_1^{\text{Seq}} \otimes \mathbb{I}_{C_o} - \frac{\mathbb{I}_{B_i}}{d_{B_i}} \otimes \text{Tr}_{B_i}[Y_1^{\text{Seq}}] \otimes \mathbb{I}_{C_o}, \quad (\text{S14})$$

$$S_2^*(Y_2^{\text{Seq}}) := \frac{1}{d_{B_i}} \left[Y_2^{\text{Seq}} \otimes \mathbb{I}_{B_i B_o C_o} - \frac{\mathbb{I}_{A_i}}{d_{A_i}} \otimes \text{Tr}_{A_i}[Y_2^{\text{Seq}}] \otimes \mathbb{I}_{B_i B_o C_o} \right], \quad (\text{S15})$$

$$S_3^*(Y_3^{\text{Seq}}) := Y_3^{\text{Seq}} \otimes \mathbb{I}_{A_i A_o B_i B_o C_o}. \quad (\text{S16})$$

The total sequential adjoint contribution is

$$K_{\text{Seq}}^*(Y_1^{\text{Seq}}, Y_2^{\text{Seq}}, Y_3^{\text{Seq}}, Y_{\Delta}^{\text{Seq}}) := S_1^*(Y_1^{\text{Seq}}) + S_2^*(Y_2^{\text{Seq}}) + S_3^*(Y_3^{\text{Seq}}) + D_{\text{MISC}}^*(Y_{\Delta}^{\text{Seq}}). \quad (\text{S17})$$

c. Indefinite-causal-order constraints

The ICO causal constraints in Appendix A are

$$\text{Tr}_{C_o}[\Theta^S] = \frac{\mathbb{I}_{A_i}}{d_{A_i}} \otimes \text{Tr}_{A_i C_o}[\Theta^S] + \frac{\mathbb{I}_{B_i}}{d_{B_i}} \otimes \text{Tr}_{B_i C_o}[\Theta^S] - \frac{\mathbb{I}_{A_i B_i}}{d_{A_i B_i}} \otimes \text{Tr}_{A_i B_i C_o}[\Theta^S], \quad (\text{S18})$$

$$\text{Tr}_{A_o A_i C_o}[\Theta^S] = \frac{\mathbb{I}_{B_i}}{d_{B_i}} \otimes \text{Tr}_{A_o A_i B_i C_o}[\Theta^S], \quad (\text{S19})$$

$$\text{Tr}_{B_o B_i C_o}[\Theta^S] = \frac{\mathbb{I}_{A_i}}{d_{A_i}} \otimes \text{Tr}_{B_o B_i A_i C_o}[\Theta^S], \quad (\text{S20})$$

$$\text{Tr}_{A_o A_i B_o B_i C_o}[\Theta^S] = d_{A_i B_i} \mathbb{I}_{C_i}. \quad (\text{S21})$$

Let

$$Y_1^{\text{ICO}} \in \mathcal{L}(A_i A_o B_i B_o C_i),$$

$$Y_2^{\text{ICO}} \in \mathcal{L}(B_i B_o C_i), \quad Y_3^{\text{ICO}} \in \mathcal{L}(A_i A_o C_i), \quad Y_4^{\text{ICO}} \in \mathcal{L}(C_i),$$

be Hermitian free dual variables. Define

$$\begin{aligned} I_1^*(Y_1^{\text{ICO}}) &:= Y_1^{\text{ICO}} \otimes \mathbb{I}_{C_o} - \frac{\mathbb{I}_{A_i}}{d_{A_i}} \otimes \text{Tr}_{A_i}[Y_1^{\text{ICO}}] \otimes \mathbb{I}_{C_o} \\ &\quad - \frac{\mathbb{I}_{B_i}}{d_{B_i}} \otimes \text{Tr}_{B_i}[Y_1^{\text{ICO}}] \otimes \mathbb{I}_{C_o} + \frac{\mathbb{I}_{A_i B_i}}{d_{A_i B_i}} \otimes \text{Tr}_{A_i B_i}[Y_1^{\text{ICO}}] \otimes \mathbb{I}_{C_o}, \end{aligned} \quad (\text{S22})$$

$$I_2^*(Y_2^{\text{ICO}}) := Y_2^{\text{ICO}} \otimes \mathbb{I}_{A_i A_o C_o} - \frac{\mathbb{I}_{B_i}}{d_{B_i}} \otimes \text{Tr}_{B_i}[Y_2^{\text{ICO}}] \otimes \mathbb{I}_{A_i A_o C_o}, \quad (\text{S23})$$

$$l_3^*(Y_3^{\text{ICO}}) := Y_3^{\text{ICO}} \otimes \mathbb{I}_{B_i B_o C_o} - \frac{\mathbb{I}_{A_i}}{d_{A_i}} \otimes \text{Tr}_{A_i}[Y_3^{\text{ICO}}] \otimes \mathbb{I}_{B_i B_o C_o}, \quad (\text{S24})$$

$$l_4^*(Y_4^{\text{ICO}}) := Y_4^{\text{ICO}} \otimes \mathbb{I}_{A_i A_o B_i B_o C_o}. \quad (\text{S25})$$

The total ICO adjoint contribution is

$$\begin{aligned} & \mathsf{K}_{\text{ICO}}^*(Y_1^{\text{ICO}}, Y_2^{\text{ICO}}, Y_3^{\text{ICO}}, Y_4^{\text{ICO}}, Y_{\Delta}^{\text{ICO}}) \\ & := l_1^*(Y_1^{\text{ICO}}) + l_2^*(Y_2^{\text{ICO}}) + l_3^*(Y_3^{\text{ICO}}) + l_4^*(Y_4^{\text{ICO}}) + \mathsf{D}_{\text{MISC}}^*(Y_{\Delta}^{\text{ICO}}). \end{aligned} \quad (\text{S26})$$

2. Exact dual SDP

We now write the dual SDPs corresponding to the one-sided Watrous diamond-distance formulation used in the primal SDP. In this convention, the diamond-norm part of the primal is

$$Z \succeq 0, \quad (\text{S27})$$

$$Z \succeq \mathcal{L}_N(\Theta^{\mathcal{S}}) - J_{\mathcal{M}_{C_i C_o}}, \quad (\text{S28})$$

$$\text{Tr}_{C_o}[Z] \preceq l \mathbb{I}_{C_i}, \quad (\text{S29})$$

and the primal objective is $\min l$. Thus l directly upper-bounds the normalized channel distance

$$\frac{1}{2} \|\mathcal{S}(N^{\otimes 2}) - \mathcal{M}\|_{\diamond}.$$

For the derivation, let $P_{\mathbf{H}} \succeq 0$ be the dual variable associated with

$$Z - \mathcal{L}_N(\Theta^{\mathcal{S}}) + J_{\mathcal{M}_{C_i C_o}} \succeq 0,$$

and let $R_{\mathbf{H}} \succeq 0$ be the dual variable associated with

$$l \mathbb{I}_{C_i} - \text{Tr}_{C_o}[Z] \succeq 0.$$

The Lagrangian minimization over l , $Z \succeq 0$, and $\Theta^{\mathcal{S}} \succeq 0$ gives the dual constraints

$$\text{Tr}[R_{\mathbf{H}}] = 1, \quad P_{\mathbf{H}} \preceq R_{\mathbf{H}} \otimes \mathbb{I}_{C_o},$$

and

$$\mathcal{L}_N^*(P_{\mathbf{H}}) - \mathsf{K}_{\mathbf{H}}^*(Y_{\mathbf{H}}) \succeq 0.$$

The constant contribution from the diamond-distance term is

$$-\langle P_{\mathbf{H}}, J_{\mathcal{M}_{C_i C_o}} \rangle.$$

The dual of the exact parallel MISC primal SDP is

$$\begin{aligned} d_{\text{Par}}^* &= \max \quad \langle Y_2^{\text{Par}}, \mathbb{I}_{A_i B_i C_i} \rangle - \langle P_{\text{Par}}, J_{\mathcal{M}_{C_i C_o}} \rangle \\ \text{s.t.} \quad & P_{\text{Par}} \succeq 0, \quad R_{\text{Par}} \succeq 0, \\ & \text{Tr}[R_{\text{Par}}] = 1, \\ & P_{\text{Par}} \preceq R_{\text{Par}} \otimes \mathbb{I}_{C_o}, \\ & \mathcal{L}_N^*(P_{\text{Par}}) - \mathsf{K}_{\text{Par}}^*(Y_1^{\text{Par}}, Y_2^{\text{Par}}, Y_{\Delta}^{\text{Par}}) \succeq 0. \end{aligned} \quad (\text{S30})$$

The variables

$$Y_1^{\text{Par}}, \quad Y_2^{\text{Par}}, \quad Y_{\Delta}^{\text{Par}}$$

are Hermitian and unconstrained.

The dual of the exact sequential MISC primal SDP is

$$\begin{aligned}
d_{\text{Seq}}^* = \max \quad & d_{A_i B_i} \langle Y_3^{\text{Seq}}, \mathbb{I}_{C_i} \rangle - \langle P_{\text{Seq}}, J_{\mathcal{M}_{C_i C_o}} \rangle \\
\text{s.t.} \quad & P_{\text{Seq}} \succeq 0, \quad R_{\text{Seq}} \succeq 0, \\
& \text{Tr}[R_{\text{Seq}}] = 1, \\
& P_{\text{Seq}} \preceq R_{\text{Seq}} \otimes \mathbb{I}_{C_o}, \\
& \mathcal{L}_N^*(P_{\text{Seq}}) - \mathcal{K}_{\text{Seq}}^*(Y_1^{\text{Seq}}, Y_2^{\text{Seq}}, Y_3^{\text{Seq}}, Y_{\Delta}^{\text{Seq}}) \succeq 0.
\end{aligned} \tag{S31}$$

The variables

$$Y_1^{\text{Seq}}, \quad Y_2^{\text{Seq}}, \quad Y_3^{\text{Seq}}, \quad Y_{\Delta}^{\text{Seq}}$$

are Hermitian and unconstrained.

The dual of the exact ICO MISC primal SDP is

$$\begin{aligned}
d_{\text{ICO}}^* = \max \quad & d_{A_i B_i} \langle Y_4^{\text{ICO}}, \mathbb{I}_{C_i} \rangle - \langle P_{\text{ICO}}, J_{\mathcal{M}_{C_i C_o}} \rangle \\
\text{s.t.} \quad & P_{\text{ICO}} \succeq 0, \quad R_{\text{ICO}} \succeq 0, \\
& \text{Tr}[R_{\text{ICO}}] = 1, \\
& P_{\text{ICO}} \preceq R_{\text{ICO}} \otimes \mathbb{I}_{C_o}, \\
& \mathcal{L}_N^*(P_{\text{ICO}}) - \mathcal{K}_{\text{ICO}}^*(Y_1^{\text{ICO}}, Y_2^{\text{ICO}}, Y_3^{\text{ICO}}, Y_4^{\text{ICO}}, Y_{\Delta}^{\text{ICO}}) \succeq 0.
\end{aligned} \tag{S32}$$

The variables

$$Y_1^{\text{ICO}}, \quad Y_2^{\text{ICO}}, \quad Y_3^{\text{ICO}}, \quad Y_4^{\text{ICO}}, \quad Y_{\Delta}^{\text{ICO}}$$

are Hermitian and unconstrained.

Appendix D: Algebraic dual witness at $\varepsilon_0 = 1/2$

1. Certification from numerical SDP output

Fix $\varepsilon_0 \in (0, 1)$. A numerical certificate becomes a rigorous proof of the strict MISC hierarchy if the following steps are performed. We use the one-sided Watrous diamond-distance SDP convention, in which the primal objective is $\min l$, and l directly upper-bounds the normalized distance

$$\frac{1}{2} \|\mathcal{S}(N^{\otimes 2}) - \mathcal{M}\|_{\diamond}.$$

1. Solve the primal SDPs for $H = \text{Seq, ICO}$, and solve the one-sided dual SDPs for $H = \text{Par, Seq}$.
2. Hermitian-symmetrize every numerical matrix:

$$X \mapsto \frac{X + X^{\dagger}}{2}.$$

3. Project the primal Choi operators onto the exact causal and MISC affine spaces:

$$\Theta_{\text{Seq}}^S \in \text{Seq} \cap \text{MISC}, \quad \Theta_{\text{ICO}}^S \in \text{ICO} \cap \text{MISC}.$$

After projection, verify the affine equalities exactly, or enclose the residuals in rational intervals containing zero.

4. Project or normalize the one-sided dual variables so that

$$\text{Tr}[R_H] = 1, \quad P_H \preceq R_H \otimes I_{C_o},$$

for $H = \text{Par, Seq}$. Equivalently, certify

$$R_H \otimes I_{C_o} - P_H \succeq 0.$$

5. Replace floating-point entries by rational entries, or enclose them in rational intervals with outward rounding.
6. Certify every primal positivity constraint:

$$\Theta_H^S \succeq 0, \quad Z_H \succeq 0,$$

and

$$Z_H \succeq \mathcal{L}_N(\Theta_H^S) - J_{\mathcal{M}_{C_i C_o}},$$

together with

$$\text{Tr}_{C_o}[Z_H] \preceq l_H I_{C_i}.$$

Here $H = \text{Seq}, \text{ICO}$. Since the one-sided Watrous SDP is being used, no constraint of the form $Z_H \succeq J_{\mathcal{M}} - \mathcal{L}_N(\Theta_H^S)$ is required.

7. Certify every dual positivity constraint:

$$P_H \succeq 0, \quad R_H \succeq 0, \quad R_H \otimes I_{C_o} - P_H \succeq 0,$$

and

$$\mathcal{L}_N^*(P_H) - \mathcal{K}_H^*(Y_H) \succeq 0,$$

for $H = \text{Par}, \text{Seq}$.

8. Compute interval-certified objective values

$$L_{\text{Par}, \text{MISC}}, \quad U_{\text{Seq}, \text{MISC}}, \quad L_{\text{Seq}, \text{MISC}}, \quad U_{\text{ICO}, \text{MISC}}.$$

In the one-sided convention, the primal upper bounds are

$$U_{H, \text{MISC}} = l_H, \quad H = \text{Seq}, \text{ICO}.$$

The dual lower bounds are computed from the corresponding one-sided dual objectives.

9. Verify the strict interval inequalities

$$L_{\text{Par}, \text{MISC}} > U_{\text{Seq}, \text{MISC}}, \quad L_{\text{Seq}, \text{MISC}} > U_{\text{ICO}, \text{MISC}}.$$

If all steps succeed, then the strict MISC hierarchy is rigorously certified at ε_0 .

2. Exact algebraic dual witness for the parallel MISC SDP at $\varepsilon_0 = 1/2$

Consider the parallel MISC channel-simulation SDP at

$$\varepsilon_0 = \frac{1}{2}, \quad \text{input resource } \left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \quad \text{target channel } \mathcal{I}.$$

As in Appendix B, write

$$\mathcal{L}_{\mathcal{N}}(\Theta^S) := J_{\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}} * \Theta^S.$$

We use the one-sided dual formulation for the parallel MISC SDP. The dual variables are

$$(P_{\text{Par}}, R_{\text{Par}}, Y_{\text{Par}}), \quad Y_{\text{Par}} = (Y_1^{\text{Par}}, Y_{\text{red}}^{\text{Par}}, Y_2^{\text{Par}}, Y_{\Delta}^{\text{Par}}).$$

The matrix $P_{\text{Par}} \in \mathcal{L}(C_i C_o)$ is written in the basis

$$\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}_{C_i C_o},$$

and $R_{\text{Par}} \in \mathcal{L}(C_i)$ is written in the basis

$$\{|0\rangle, |1\rangle\}_{C_i}.$$

The register order for the full parallel slack is

$$A_i B_i A_o B_o C_i C_o.$$

The matrix $Y_1^{\text{Par}} \in \mathcal{L}(A_i B_i A_o B_o C_i)$ is written in the basis

$$\{|a_i b_i a_o b_o c_i\rangle : a_i, b_i, a_o, b_o, c_i \in \{0, 1\}\},$$

the matrix $Y_2^{\text{Par}} \in \mathcal{L}(A_o B_o C_i)$ is written in the basis

$$\{|a_o b_o c_i\rangle : a_o, b_o, c_i \in \{0, 1\}\},$$

and $Y_{\Delta}^{\text{Par}} \in \mathcal{L}(A_i B_i A_o B_o C_i C_o)$ is written in the basis

$$\{|a_i b_i a_o b_o c_i c_o\rangle : a_i, b_i, a_o, b_o, c_i, c_o \in \{0, 1\}\}.$$

All omitted entries are zero.

The one-sided parallel adjoint is

$$\begin{aligned} K_{\text{Par}}^*(Y_{\text{Par}}) &:= (Y_1^{\text{Par}} - D_{A_o B_o}(Y_1^{\text{Par}})) \otimes I_{C_o} + \frac{1}{4} I_{A_i B_i A_o B_o} \otimes Y_{\text{red}}^{\text{Par}} \otimes I_{C_o} \\ &\quad + I_{A_i B_i} \otimes Y_2^{\text{Par}} \otimes I_{C_o} + D_{\text{MISC}}^*(Y_{\Delta}^{\text{Par}}), \end{aligned}$$

where

$$D_{A_o B_o}(X) := \text{Tr}_{A_o B_o}(X) \otimes \frac{I_{A_o B_o}}{4},$$

with the registers reordered back to $A_i B_i A_o B_o C_i$, and

$$D_{\text{MISC}}^* = \Delta_{A_i B_i A_o B_o C_i C_o} - \Delta_{A_i B_i A_o B_o} \otimes \text{id}_{C_i C_o}.$$

Set

$$R_{\text{Par}} = \frac{1}{2} I_{C_i}.$$

Define

$$P_{\text{Par}} = \begin{pmatrix} \frac{1}{4} & 0 & 0 & -\frac{249}{1000} \\ 0 & \frac{4}{9} & 0 & 0 \\ 0 & 0 & \frac{4}{9} & 0 \\ -\frac{249}{1000} & 0 & 0 & \frac{1}{4} \end{pmatrix}.$$

Set

$$Y_{\text{red}}^{\text{Par}} = \begin{pmatrix} \frac{3}{226} & 0 \\ 0 & \frac{3}{226} \end{pmatrix}.$$

Set

$$Y_2^{\text{Par}} = \text{diag}\left(\frac{13}{690}, \frac{13}{690}, -\frac{5}{954}, -\frac{5}{954}, -\frac{5}{954}, -\frac{5}{954}, -\frac{1}{529}, -\frac{1}{529}\right).$$

The diagonal of Y_1^{Par} is

$$\begin{aligned} \text{diag}(Y_1^{\text{Par}}) = & \left(-\frac{1}{443}, -\frac{1}{443}, \frac{1}{535}, \frac{1}{535}, \frac{1}{535}, \frac{1}{535}, -\frac{1}{675}, -\frac{1}{675}, \right. \\ & \frac{3}{400}, \frac{3}{400}, -\frac{1}{507}, -\frac{1}{507}, \frac{1}{535}, \frac{1}{535}, -\frac{1}{675}, -\frac{1}{675}, \\ & \frac{3}{400}, \frac{3}{400}, \frac{1}{535}, \frac{1}{535}, -\frac{1}{507}, -\frac{1}{507}, -\frac{1}{675}, -\frac{1}{675}, \\ & \left. \frac{39}{968}, \frac{39}{968}, -\frac{16}{943}, -\frac{16}{943}, -\frac{16}{943}, -\frac{16}{943}, -\frac{4}{629}, -\frac{4}{629} \right). \end{aligned}$$

The nonzero upper-triangular off-diagonal entries of Y_1^{Par} are

$$\begin{aligned}
(Y_1^{\text{Par}})_{1,11} &= \frac{8}{567}, & (Y_1^{\text{Par}})_{1,21} &= \frac{8}{567}, & (Y_1^{\text{Par}})_{1,31} &= \frac{9}{902}, \\
(Y_1^{\text{Par}})_{2,12} &= \frac{8}{567}, & (Y_1^{\text{Par}})_{2,22} &= \frac{8}{567}, & (Y_1^{\text{Par}})_{2,32} &= \frac{9}{902}, \\
(Y_1^{\text{Par}})_{9,29} &= \frac{40}{339}, & (Y_1^{\text{Par}})_{10,30} &= \frac{40}{339}, \\
(Y_1^{\text{Par}})_{11,21} &= -\frac{2}{205}, & (Y_1^{\text{Par}})_{11,31} &= -\frac{1}{145}, \\
(Y_1^{\text{Par}})_{12,22} &= -\frac{2}{205}, & (Y_1^{\text{Par}})_{12,32} &= -\frac{1}{145}, \\
(Y_1^{\text{Par}})_{17,27} &= \frac{40}{339}, & (Y_1^{\text{Par}})_{18,28} &= \frac{40}{339}, \\
(Y_1^{\text{Par}})_{21,31} &= -\frac{1}{145}, & (Y_1^{\text{Par}})_{22,32} &= -\frac{1}{145}.
\end{aligned} \tag{S1}$$

The remaining entries are fixed by Hermiticity, and all other off-diagonal entries are zero.

Finally, Y_{Δ}^{Par} is the real symmetric 64×64 matrix whose only nonzero upper-triangular entries are

$$\begin{aligned}
(Y_{\Delta}^{\text{Par}})_{1,4} &= \frac{26}{713}, \\
(Y_{\Delta}^{\text{Par}})_{17,20} &= \frac{116}{741}, \\
(Y_{\Delta}^{\text{Par}})_{33,36} &= \frac{116}{741}, \\
(Y_{\Delta}^{\text{Par}})_{49,52} &= \frac{31}{498}, \\
(Y_{\Delta}^{\text{Par}})_{53,56} &= \frac{81}{904}, \\
(Y_{\Delta}^{\text{Par}})_{57,60} &= \frac{81}{904}.
\end{aligned} \tag{S2}$$

All other entries are zero apart from symmetry.

Then

$$(P_{\text{Par}}, R_{\text{Par}}, Y_{\text{Par}})$$

is an exact feasible point of the one-sided parallel MISC dual SDP. Namely,

$$P_{\text{Par}} \succeq 0, \quad R_{\text{Par}} \succeq 0, \tag{S3}$$

$$\text{Tr } R_{\text{Par}} = 1, \tag{S4}$$

$$P_{\text{Par}} \preceq R_{\text{Par}} \otimes I_{C_o}, \tag{S5}$$

$$\mathcal{L}_{\mathcal{N}}^*(P_{\text{Par}}) - K_{\text{Par}}^*(Y_{\text{Par}}) \succeq \frac{1}{100000} I \succeq 0. \tag{S6}$$

Moreover, the exact dual objective value is

$$L_{\text{MISC}}^{\text{Par}} = \frac{534413171}{14256814500}. \tag{S7}$$

Proof We verify all one-sided parallel MISC dual constraints by exact fractional calculation.

The one-sided dual constraints are

$$P_{\text{Par}} \succeq 0, \tag{S8}$$

$$R_{\text{Par}} \succeq 0, \tag{S9}$$

$$\text{Tr } R_{\text{Par}} = 1, \tag{S10}$$

$$P_{\text{Par}} \preceq R_{\text{Par}} \otimes I_{C_o}, \tag{S11}$$

$$\mathcal{L}_{\mathcal{N}}^*(P_{\text{Par}}) - K_{\text{Par}}^*(Y_{\text{Par}}) \succeq 0. \tag{S12}$$

There is no separate positivity constraint on $Y_1^{\text{Par}}, Y_{red}^{\text{Par}}, Y_2^{\text{Par}}, Y_{\Delta}^{\text{Par}}$; they are unrestricted dual variables and are checked only through the slack constraint.

First,

$$R_{\text{Par}} = \frac{1}{2}I_{C_i}. \quad (\text{S13})$$

Hence

$$\text{spec}(R_{\text{Par}}) = \left\{ \frac{1}{2}, \frac{1}{2} \right\}, \quad \lambda_{\min}(R_{\text{Par}}) = \frac{1}{2} > 0. \quad (\text{S14})$$

Therefore $R_{\text{Par}} \succ 0$. Moreover,

$$\text{Tr } R_{\text{Par}} = \text{Tr} \left(\frac{1}{2}I_{C_i} \right) = \frac{1}{2} + \frac{1}{2} = 1. \quad (\text{S15})$$

Thus (S9) and (S10) hold exactly.

Next, write P_{Par} as

$$P_{\text{Par}} = \begin{pmatrix} \frac{1}{4} & 0 & 0 & -\frac{249}{1000} \\ 0 & \frac{4}{9} & 0 & 0 \\ 0 & 0 & \frac{4}{9} & 0 \\ -\frac{249}{1000} & 0 & 0 & \frac{1}{4} \end{pmatrix}. \quad (\text{S16})$$

The nontrivial 2×2 block is

$$\begin{pmatrix} \frac{1}{4} & -\frac{249}{1000} \\ -\frac{249}{1000} & \frac{1}{4} \end{pmatrix}. \quad (\text{S17})$$

Its two eigenvalues are

$$\frac{1}{4} - \frac{249}{1000} = \frac{250}{1000} - \frac{249}{1000} = \frac{1}{1000}, \quad (\text{S18})$$

$$\frac{1}{4} + \frac{249}{1000} = \frac{250}{1000} + \frac{249}{1000} = \frac{499}{1000}. \quad (\text{S19})$$

The remaining two eigenvalues are both $4/9$. Therefore

$$\text{spec}(P_{\text{Par}}) = \left\{ \frac{1}{1000}, \frac{499}{1000}, \frac{4}{9}, \frac{4}{9} \right\}, \quad \lambda_{\min}(P_{\text{Par}}) = \frac{1}{1000} > 0. \quad (\text{S20})$$

Thus $P_{\text{Par}} \succ 0$, proving (S8).

We now verify the compact one-sided constraint. Since

$$R_{\text{Par}} \otimes I_{C_o} = \frac{1}{2}I_{C_i C_o}, \quad (\text{S21})$$

we have

$$R_{\text{Par}} \otimes I_{C_o} - P_{\text{Par}} = \begin{pmatrix} \frac{1}{4} & 0 & 0 & \frac{249}{1000} \\ 0 & \frac{1}{18} & 0 & 0 \\ 0 & 0 & \frac{1}{18} & 0 \\ \frac{249}{1000} & 0 & 0 & \frac{1}{4} \end{pmatrix}. \quad (\text{S22})$$

Indeed,

$$\frac{1}{2} - \frac{1}{4} = \frac{1}{4}, \quad \frac{1}{2} - \frac{4}{9} = \frac{9}{18} - \frac{8}{18} = \frac{1}{18}. \quad (\text{S23})$$

The nontrivial 2×2 block of $R_{\text{Par}} \otimes I_{C_o} - P_{\text{Par}}$ is

$$\begin{pmatrix} \frac{1}{4} & \frac{249}{1000} \\ \frac{249}{1000} & \frac{1}{4} \end{pmatrix}, \quad (\text{S24})$$

whose eigenvalues are

$$\frac{1}{4} - \frac{249}{1000} = \frac{1}{1000}, \quad (\text{S25})$$

$$\frac{1}{4} + \frac{249}{1000} = \frac{499}{1000}. \quad (\text{S26})$$

The remaining two eigenvalues are both $1/18$. Hence

$$\text{spec}(R_{\text{Par}} \otimes I_{C_o} - P_{\text{Par}}) = \left\{ \frac{1}{1000}, \frac{499}{1000}, \frac{1}{18}, \frac{1}{18} \right\}, \quad \lambda_{\min}(R_{\text{Par}} \otimes I_{C_o} - P_{\text{Par}}) = \frac{1}{1000} > 0. \quad (\text{S27})$$

Therefore

$$R_{\text{Par}} \otimes I_{C_o} - P_{\text{Par}} \succ 0, \quad (\text{S28})$$

or equivalently

$$P_{\text{Par}} \prec R_{\text{Par}} \otimes I_{C_o}. \quad (\text{S29})$$

This proves (S11) strictly.

It remains to verify the full dual slack constraint. Define

$$S_{\text{Par}} := \mathcal{L}_{\mathcal{N}}^*(P_{\text{Par}}) - K_{\text{Par}}^*(Y_{\text{Par}}). \quad (\text{S30})$$

Using the one-sided parallel adjoint,

$$\begin{aligned} K_{\text{Par}}^*(Y_{\text{Par}}) &= (Y_1^{\text{Par}} - D_{A_o B_o}(Y_1^{\text{Par}})) \otimes I_{C_o} + \frac{1}{4} I_{A_i B_i A_o B_o} \otimes Y_{\text{red}}^{\text{Par}} \otimes I_{C_o} \\ &\quad + I_{A_i B_i} \otimes Y_2^{\text{Par}} \otimes I_{C_o} + D_{\text{MISC}}^*(Y_{\Delta}^{\text{Par}}). \end{aligned} \quad (\text{S31})$$

Substituting the displayed fractional entries of $P_{\text{Par}}, Y_1^{\text{Par}}, Y_{\text{red}}^{\text{Par}}, Y_2^{\text{Par}}, Y_{\Delta}^{\text{Par}}$ gives a 64×64 Hermitian matrix S_{Par} with entries in

$$\mathbb{K} = \mathbb{Q}(\sqrt{2}). \quad (\text{S32})$$

The exact blockwise calculation gives

$$S_{\text{Par}} - \frac{1}{100000} I_{64} \succeq 0. \quad (\text{S33})$$

Equivalently,

$$S_{\text{Par}} = \mathcal{L}_{\mathcal{N}}^*(P_{\text{Par}}) - K_{\text{Par}}^*(Y_{\text{Par}}) \succeq \frac{1}{100000} I_{64}. \quad (\text{S34})$$

In particular,

$$\lambda_{\min}(S_{\text{Par}}) \geq \frac{1}{100000} > 0. \quad (\text{S35})$$

Hence

$$\mathcal{L}_{\mathcal{N}}^*(P_{\text{Par}}) - K_{\text{Par}}^*(Y_{\text{Par}}) \succ 0, \quad (\text{S36})$$

which proves the slack constraint (S12) strictly.

For completeness, we spell out how the exact positivity check is certified. After a simultaneous permutation of the computational basis, the nonzero graph of S_{Par} decomposes into blocks of sizes

$$8, 4, 4, 4, 4, 2, 2, 2, 2, 2, \quad (\text{S37})$$

together with scalar blocks. For every such block B , exact Sylvester tests over $\mathbb{Q}(\sqrt{2})$ are applied to

$$B - \frac{1}{100000} I. \quad (\text{S38})$$

All leading principal minors are nonnegative elements of $\mathbb{Q}(\sqrt{2})$. Therefore every block satisfies

$$B \succeq \frac{1}{100000} I, \quad (\text{S39})$$

and hence the direct sum satisfies

$$S_{\text{Par}} \succeq \frac{1}{100000} I_{64}. \quad (\text{S40})$$

Thus all SDP constraints are satisfied with exact fractional margins

$$\lambda_{\min}(R_{\text{Par}}) = \frac{1}{2}, \quad \lambda_{\min}(P_{\text{Par}}) = \frac{1}{1000}, \quad \lambda_{\min}(R_{\text{Par}} \otimes I_{C_o} - P_{\text{Par}}) = \frac{1}{1000}, \quad (\text{S41})$$

and

$$\lambda_{\min}(\mathcal{L}_{\mathcal{N}}^*(P_{\text{Par}}) - K_{\text{Par}}^*(Y_{\text{Par}})) \geq \frac{1}{100000}. \quad (\text{S42})$$

Finally, we compute the objective using only fractions. First,

$$\text{Tr}(Y_{\text{red}}^{\text{Par}}) = \frac{3}{226} + \frac{3}{226} = \frac{6}{226} = \frac{3}{113}. \quad (\text{S43})$$

Next,

$$\begin{aligned} \text{Tr}(Y_2^{\text{Par}}) &= 2 \cdot \frac{13}{690} + 4 \cdot \left(-\frac{5}{954}\right) + 2 \cdot \left(-\frac{1}{529}\right) \\ &= \frac{13}{345} - \frac{10}{477} - \frac{2}{529} \\ &= \frac{16321}{1261665}. \end{aligned} \quad (\text{S44})$$

The target term is

$$\langle P_{\text{Par}}, J_{\mathcal{I}} \rangle = \frac{1}{500}. \quad (\text{S45})$$

Therefore

$$\begin{aligned} L_{\text{MISC}}^{\text{Par}} &= \text{Tr}(Y_{\text{red}}^{\text{Par}}) + \text{Tr}(Y_2^{\text{Par}}) - \langle P_{\text{Par}}, J_{\mathcal{I}} \rangle \\ &= \frac{3}{113} + \frac{16321}{1261665} - \frac{1}{500} \\ &= \frac{534413171}{14256814500}. \end{aligned} \quad (\text{S46})$$

■

3. Exact algebraic primal witness for the sequential MISC SDP at $\varepsilon_0 = 1/2$

Consider the sequential MISC channel-simulation primal SDP at

$$\varepsilon_0 = \frac{1}{2}, \quad \text{input resource } \left(\mathcal{N}_{\text{AD}}^{1/2}\right)^{\otimes 2}, \quad \text{target channel } \mathcal{I}.$$

As in Appendix B, write

$$\mathcal{L}_{\mathcal{N}}(\Theta^S) := J_{\left(\mathcal{N}_{\text{AD}}^{1/2}\right)^{\otimes 2}} * \Theta^S.$$

We use the one-sided Watrous primal formulation

$$\min \quad l$$

$$\begin{aligned}
\text{s.t. } & \Theta^S \succeq 0, \\
& \Theta^S \in \text{Seq} \cap \text{MISC}, \\
& Z \succeq 0, \\
& \mathcal{L}_{\mathcal{N}}(\Theta^S) - J_{\mathcal{I}} \preceq Z, \\
& \text{Tr}_{C_o} Z \preceq lI_{C_i}.
\end{aligned} \tag{S47}$$

The SDP constraints are written in the register order

$$A_i A_o B_i B_o C_i C_o.$$

For compactness, define an algebraic matrix $\tilde{\Theta}_{\text{Seq}}$ in the reordered computational basis

$$A_o A_i B_o B_i C_i C_o.$$

Let Π_{Seq} be the permutation unitary satisfying

$$\Pi_{\text{Seq}}|a_o, a_i, b_o, b_i, c_i, c_o\rangle = |a_i, a_o, b_i, b_o, c_i, c_o\rangle.$$

Then the sequential Choi operator in the Appendix B register order is

$$\Theta_{\text{Seq}} = \Pi_{\text{Seq}} \tilde{\Theta}_{\text{Seq}} \Pi_{\text{Seq}}^\dagger.$$

We use one-based indices for $\tilde{\Theta}_{\text{Seq}}$:

$$r = 1 + 32a_o + 16a_i + 8b_o + 4b_i + 2c_i + c_o.$$

Define

$$\delta_{\text{Seq}} := \frac{122}{1857}.$$

Let

$$g = \frac{47}{151}, \quad n = \frac{24}{121}, \quad e = \frac{5}{58}, \quad c = \frac{24}{113}.$$

Define

$$h := \sqrt{2ng} = \sqrt{\frac{2256}{18271}},$$

$$a := 1 - g - 2n = \frac{5336}{18271},$$

$$b := \frac{1 - \delta_{\text{Seq}} - c}{\sqrt{2}} - \frac{h}{2} - \frac{n}{2} = \frac{151487\sqrt{2}}{419682} - \frac{1}{2}\sqrt{\frac{2256}{18271}} - \frac{12}{121},$$

$$d := g - \frac{e}{\sqrt{2}} = \frac{47}{151} - \frac{5\sqrt{2}}{116},$$

$$f := 2n - \sqrt{2}e = \frac{48}{121} - \frac{5\sqrt{2}}{58}.$$

Set also

$$i := 2n = \frac{48}{121}, \quad j := \frac{e}{\sqrt{2}} = \frac{5\sqrt{2}}{116},$$

$$\kappa := -e = -\frac{5}{58}, \quad \lambda := \sqrt{2}e = \frac{5\sqrt{2}}{58},$$

$$m := \frac{1}{4} - \frac{n}{2} = \frac{73}{484}, \quad o := \frac{n}{2} = \frac{12}{121}.$$

Then

$$h^2 = gi, \quad \kappa^2 = j\lambda, \quad d = g - j, \quad f = i - \lambda, \quad o = \frac{n}{2}.$$

All unlisted entries of $\tilde{\Theta}_{\text{Seq}}$ are zero. Its nonzero blocks are as follows:

$$\tilde{\Theta}_{\text{Seq}}[1, 16, 64] = \tilde{\Theta}_{\text{Seq}}[4, 13, 61] = B_3, \quad B_3 := \begin{pmatrix} a & b & c \\ b & d & e \\ c & e & f \end{pmatrix}.$$

The scalar diagonal entries

$$(\tilde{\Theta}_{\text{Seq}})_{5,5} = (\tilde{\Theta}_{\text{Seq}})_{6,6} = (\tilde{\Theta}_{\text{Seq}})_{7,7} = (\tilde{\Theta}_{\text{Seq}})_{8,8} = \frac{a}{2}$$

are nonzero. The rank-one radical blocks are

$$\tilde{\Theta}_{\text{Seq}}[9, 60] = \tilde{\Theta}_{\text{Seq}}[12, 57] = \begin{pmatrix} g & h \\ h & i \end{pmatrix}, \quad h^2 = gi,$$

and

$$\tilde{\Theta}_{\text{Seq}}[14, 62] = \tilde{\Theta}_{\text{Seq}}[15, 63] = \begin{pmatrix} j & \kappa \\ \kappa & \lambda \end{pmatrix}, \quad \kappa^2 = j\lambda.$$

Moreover,

$$(\tilde{\Theta}_{\text{Seq}})_{r,r} = m, \quad r = 17, 18, \dots, 32.$$

The final rank-one blocks are

$$\tilde{\Theta}_{\text{Seq}}[33, 48] = \tilde{\Theta}_{\text{Seq}}[36, 45] = \begin{pmatrix} n & n \\ n & n \end{pmatrix}.$$

The remaining nonzero diagonal entries are

$$(\tilde{\Theta}_{\text{Seq}})_{37,37} = (\tilde{\Theta}_{\text{Seq}})_{38,38} = (\tilde{\Theta}_{\text{Seq}})_{39,39} = (\tilde{\Theta}_{\text{Seq}})_{40,40} = o,$$

and

$$(\tilde{\Theta}_{\text{Seq}})_{41,41} = (\tilde{\Theta}_{\text{Seq}})_{44,44} = n.$$

Now define the one-sided diamond variable

$$Z_{\text{Seq}} = \frac{\delta_{\text{Seq}}}{2} \begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \end{pmatrix} = \frac{61}{1857} \begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \end{pmatrix},$$

and

$$l_{\text{Seq}} = \frac{\delta_{\text{Seq}}}{2} = \frac{61}{1857}.$$

Then

$$(\Theta_{\text{Seq}}, Z_{\text{Seq}}, l_{\text{Seq}})$$

is feasible for the one-sided sequential MISC primal SDP. In particular,

$$\Theta_{\text{Seq}} \succeq 0, \quad Z_{\text{Seq}} \succeq 0, \quad (\text{S48})$$

$$\text{Tr}_{C_o}[\Theta_{\text{Seq}}] = \text{Tr}_{B_i C_o}[\Theta_{\text{Seq}}] \otimes \frac{I_{B_i}}{2}, \quad (\text{S49})$$

$$\frac{1}{2} \text{Tr}_{C_o B_i B_o}[\Theta_{\text{Seq}}] = \frac{1}{2} \text{Tr}_{A_i B_o B_i C_o}[\Theta_{\text{Seq}}] \otimes \frac{I_{A_i}}{2}, \quad (\text{S50})$$

$$\text{Tr}_{A_o A_i B_o B_i C_o}[\Theta_{\text{Seq}}] = 4I_{C_i}, \quad (\text{S51})$$

$$\Delta_{ABC}(\Theta_{\text{Seq}}) = (\Delta_{AB} \otimes \text{id}_C)(\Theta_{\text{Seq}}), \quad (\text{S52})$$

$$\mathcal{L}_{\mathcal{N}}(\Theta_{\text{Seq}}) - J_{\mathcal{I}} \preceq Z_{\text{Seq}}, \quad (\text{S53})$$

$$\text{Tr}_{C_o}[Z_{\text{Seq}}] = l_{\text{Seq}} I_{C_i}. \quad (\text{S54})$$

Hence the achieved primal objective value is

$$U_{\text{MISC}}^{\text{Seq}} = l_{\text{Seq}} = \frac{61}{1857}.$$

Therefore

$$D_{\text{MISC}}^{\text{Seq}} \left(\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \mathcal{I} \right) \leq \frac{61}{1857}.$$

Proof We verify the SDP constraints directly.

First, we prove positivity of Θ_{Seq} . Since

$$\Theta_{\text{Seq}} = \Pi_{\text{Seq}} \tilde{\Theta}_{\text{Seq}} \Pi_{\text{Seq}}^{\dagger},$$

it is enough to prove

$$\tilde{\Theta}_{\text{Seq}} \succeq 0.$$

The matrix $\tilde{\Theta}_{\text{Seq}}$ is block diagonal with respect to the blocks displayed above. The blocks

$$\begin{pmatrix} g & h \\ h & i \end{pmatrix}$$

are positive semidefinite because

$$g = \frac{47}{151} > 0, \quad i = \frac{48}{121} > 0, \quad h^2 = gi.$$

Equivalently,

$$\begin{pmatrix} g & h \\ h & i \end{pmatrix} = \begin{pmatrix} \sqrt{g} \\ \sqrt{i} \end{pmatrix} \begin{pmatrix} \sqrt{g} & \sqrt{i} \end{pmatrix} \succeq 0.$$

Similarly,

$$\begin{pmatrix} j & \kappa \\ \kappa & \lambda \end{pmatrix} \succeq 0$$

because

$$j = \frac{5\sqrt{2}}{116} > 0, \quad \lambda = \frac{5\sqrt{2}}{58} > 0, \quad \kappa^2 = j\lambda.$$

The blocks

$$\begin{pmatrix} n & n \\ n & n \end{pmatrix}$$

have eigenvalues 0 and $2n$, and

$$2n = \frac{48}{121} > 0.$$

All scalar diagonal blocks are nonnegative because

$$a = \frac{5336}{18271} > 0, \quad m = \frac{73}{484} > 0, \quad n = \frac{24}{121} > 0, \quad o = \frac{12}{121} > 0.$$

It remains to check the 3×3 block B_3 . Since B_3 is real symmetric, Sylvester's criterion applies. The first leading principal minor is

$$\Delta_1 = a = \frac{5336}{18271} > 0.$$

For the second leading principal minor,

$$\Delta_2 = \det \begin{pmatrix} a & b \\ b & d \end{pmatrix} = ad - b^2.$$

Exact algebraic simplification gives

$$\Delta_2 > \frac{1}{60} > 0.$$

For the determinant of B_3 , exact algebraic simplification gives

$$\Delta_3 := \det B_3 > \frac{1}{30000000000} > 0.$$

The inequalities are exact inequalities in the real algebraic field

$$\mathbb{K} = \mathbb{Q}(\sqrt{2}, \sqrt{18271}, \sqrt{36542}).$$

Thus

$$B_3 \succ 0.$$

Therefore every block of $\tilde{\Theta}_{\text{Seq}}$ is positive semidefinite, so

$$\Theta_{\text{Seq}} \succeq 0.$$

Next, Z_{Seq} is positive semidefinite because

$$Z_{\text{Seq}} = \delta_{\text{Seq}} |\Phi^-\rangle \langle \Phi^-|, \quad |\Phi^-\rangle = \frac{|00\rangle - |11\rangle}{\sqrt{2}},$$

and

$$\delta_{\text{Seq}} = \frac{122}{1857} > 0.$$

Thus

$$Z_{\text{Seq}} \succeq 0.$$

We now verify the sequential comb constraints. Direct partial tracing of the above block ansatz reduces (S49)–(S51) to the scalar identities

$$d - g + j = 0, \quad e + \kappa = 0, \quad n - 2o = 0,$$

$$f - i + \lambda = 0,$$

$$2a + d + g + j - 8m = 0,$$

$$f + i + \lambda - 3n - 2o = 0,$$

and

$$2a + d + f + g + i + j + \lambda + 8m + 3n + 2o - 4 = 0.$$

The first four identities follow immediately from

$$d = g - j, \quad \kappa = -e, \quad o = \frac{n}{2}, \quad f = i - \lambda.$$

For the fifth identity, using $a = 1 - g - 2n$, $d = g - j$, and $m = 1/4 - n/2$, we get

$$\begin{aligned} 2a + d + g + j - 8m &= 2(1 - g - 2n) + (g - j) + g + j - 8\left(\frac{1}{4} - \frac{n}{2}\right) \\ &= 2 - 2g - 4n + 2g - 2 + 4n \\ &= 0. \end{aligned}$$

For the sixth identity, using $i = 2n$, $f = i - \lambda$, and $o = n/2$,

$$\begin{aligned} f + i + \lambda - 3n - 2o &= (i - \lambda) + i + \lambda - 3n - 2\left(\frac{n}{2}\right) \\ &= 2i - 4n \\ &= 4n - 4n \\ &= 0. \end{aligned}$$

For the final identity,

$$\begin{aligned} 2a + d + f + g + i + j + \lambda + 8m + 3n + 2o - 4 &= 2(1 - g - 2n) + (g - j) + (i - \lambda) + g + i + j + \lambda + 8\left(\frac{1}{4} - \frac{n}{2}\right) + 3n + n - 4 \\ &= 2 - 2g - 4n + 2g + 2i + 2 - 4n + 4n - 4 \\ &= 2i - 4n \\ &= 4n - 4n \\ &= 0. \end{aligned}$$

Hence the sequential comb constraints hold exactly.

The MISC affine constraint also holds exactly. By construction, every off-diagonal entry of Θ_{Seq} that changes the $C_i C_o$ register also changes at least one register in AB . Therefore dephasing the AB -registers already removes every off-diagonal element that would be removed by dephasing all ABC -registers. Hence

$$\Delta_{ABC}(\Theta_{\text{Seq}}) = (\Delta_{AB} \otimes \text{id}_C)(\Theta_{\text{Seq}}).$$

It remains to verify the one-sided diamond-norm constraints. At $\varepsilon_0 = 1/2$, the amplitude-damping Choi operator is

$$J_{\mathcal{N}_{\text{AD}}^{1/2}} = \begin{pmatrix} 1 & 0 & 0 & \frac{1}{\sqrt{2}} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{2} & 0 \\ \frac{1}{\sqrt{2}} & 0 & 0 & \frac{1}{2} \end{pmatrix}.$$

A direct exact contraction gives

$$\mathcal{L}_{\mathcal{N}}(\Theta_{\text{Seq}}) = \begin{pmatrix} 1 & 0 & 0 & 1 - \delta_{\text{Seq}} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 - \delta_{\text{Seq}} & 0 & 0 & 1 \end{pmatrix}.$$

Since

$$J_{\mathcal{I}} = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix},$$

we have

$$\mathcal{L}_{\mathcal{N}}(\Theta_{\text{Seq}}) - J_{\mathcal{I}} = -\delta_{\text{Seq}} (|00\rangle\langle 11| + |11\rangle\langle 00|).$$

Therefore

$$\begin{aligned} Z_{\text{Seq}} - (\mathcal{L}_{\mathcal{N}}(\Theta_{\text{Seq}}) - J_{\mathcal{I}}) &= \frac{\delta_{\text{Seq}}}{2} \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix} \\ &= \delta_{\text{Seq}} |\Phi^+\rangle\langle \Phi^+| \succeq 0, \end{aligned}$$

where

$$|\Phi^+\rangle = \frac{|00\rangle + |11\rangle}{\sqrt{2}}.$$

Thus

$$\mathcal{L}_{\mathcal{N}}(\Theta_{\text{Seq}}) - J_{\mathcal{I}} \preceq Z_{\text{Seq}}.$$

Finally,

$$\text{Tr}_{C_o}[Z_{\text{Seq}}] = \frac{\delta_{\text{Seq}}}{2} I_{C_i} = \frac{61}{1857} I_{C_i} = l_{\text{Seq}} I_{C_i}.$$

Hence

$$\text{Tr}_{C_o}[Z_{\text{Seq}}] \preceq l_{\text{Seq}} I_{C_i}.$$

All one-sided sequential MISC primal constraints are therefore satisfied exactly, and the achieved objective value is

$$l_{\text{Seq}} = \frac{61}{1857}.$$

Thus

$$D_{\text{MISC}}^{\text{Seq}} \left(\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \mathcal{I} \right) \leq \frac{61}{1857}.$$

■

4. Exact algebraic dual witness for the sequential MISC SDP at $\varepsilon_0 = 1/2$

Consider the sequential MISC channel-simulation SDP at

$$\varepsilon_0 = \frac{1}{2}, \quad \text{input resource } \left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \quad \text{target channel } \mathcal{I}.$$

As in Appendix B, write

$$\mathcal{L}_{\mathcal{N}}(\Theta^S) := J_{\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}} * \Theta^S.$$

We use the one-sided Watrous dual formulation from Appendix C. Thus the sequential dual variables are

$$(P_{\text{Seq}}, R_{\text{Seq}}, Y_{\text{Seq}}), \quad Y_{\text{Seq}} = \left(Y_1^{\text{Seq}}, Y_2^{\text{Seq}}, Y_3^{\text{Seq}}, Y_{\Delta}^{\text{Seq}} \right),$$

and the constraints are

$$P_{\text{Seq}} \succeq 0, \quad R_{\text{Seq}} \succeq 0, \quad (\text{S55})$$

$$\text{Tr } R_{\text{Seq}} = 1, \quad (\text{S56})$$

$$P_{\text{Seq}} \preceq R_{\text{Seq}} \otimes I_{C_o}, \quad (\text{S57})$$

$$\mathcal{L}_{\mathcal{N}}^*(P_{\text{Seq}}) - K_{\text{Seq}}^*(Y_{\text{Seq}}) \succeq 0. \quad (\text{S58})$$

The matrix $P_{\text{Seq}} \in \mathbb{L}(C_i C_o)$ is written in the basis

$$\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}_{C_i C_o}.$$

Let

$$\alpha := \frac{10027}{49758}, \quad \beta := \frac{1}{4} - \alpha = \frac{4825}{99516}.$$

Set

$$R_{\text{Seq}} = \frac{1}{2} I_{C_i}.$$

Let

$$|\Phi^\pm\rangle = \frac{1}{\sqrt{2}} (|00\rangle \pm |11\rangle).$$

Define

$$P_{\text{Seq}} := \frac{1}{2} |\Phi^-\rangle\langle\Phi^-| + 2\alpha (|01\rangle\langle 01| + |10\rangle\langle 10|).$$

Equivalently,

$$P_{\text{Seq}} = \begin{pmatrix} \frac{1}{4} & 0 & 0 & -\frac{1}{4} \\ 0 & \frac{10027}{24879} & 0 & 0 \\ 0 & 0 & \frac{10027}{24879} & 0 \\ -\frac{1}{4} & 0 & 0 & \frac{1}{4} \end{pmatrix}.$$

This is the one-sided lift of the old two-sided pair:

$$P_{\text{Seq}} = P_{\text{Seq}}^{(2)} - Q_{\text{Seq}}^{(2)} + \frac{1}{4} I_{C_i C_o} = 2P_{\text{Seq}}^{(2)},$$

where

$$P_{\text{Seq}}^{(2)} = \frac{1}{4} |\Phi^-\rangle\langle\Phi^-| + \alpha (|01\rangle\langle 01| + |10\rangle\langle 10|),$$

and

$$Q_{\text{Seq}}^{(2)} = \frac{1}{4} |\Phi^+\rangle\langle\Phi^+| + \beta (|01\rangle\langle 01| + |10\rangle\langle 10|).$$

The matrix $Q_{\text{Seq}}^{(2)}$ is not a one-sided dual variable; it is used only to display how the one-sided witness is obtained from the older two-sided certificate.

Now take the old algebraic sequential multipliers

$$Y_{\text{Seq}}^{(2)} = (Y_1^{(2)}, Y_2^{(2)}, Y_3^{(2)}, Y_\Delta^{(2)})$$

from the reduced algebraic sequential certificate, namely

$$Y_\Delta^{(2)} = 0, \quad Y_3^{(2)} = -\frac{1735}{7428} I_{C_i}.$$

The matrices $Y_1^{(2)}$ and $Y_2^{(2)}$ are exactly the reduced matrices displayed in the old sequential certificate:

$$Y_1^{(2)} = \tilde{Y}_1^{(2)} \otimes I_{C_i}, \quad Y_2^{(2)} = \tilde{Y}_2^{(2)} \otimes I_{C_i}.$$

Here

$$\tilde{Y}_2^{(2)} = \begin{pmatrix} -a & 0 & 0 & -b \\ 0 & a & 0 & 0 \\ 0 & 0 & r & 0 \\ -b & 0 & 0 & -r \end{pmatrix},$$

where

$$a = \frac{1735}{14856}, \quad b = \sqrt{2}a, \quad r = \frac{420}{14789}.$$

The nonzero entries of $\tilde{Y}_1^{(2)}$ are

$$\begin{aligned} (\tilde{Y}_1^{(2)})_{1,1} &= -a, & (\tilde{Y}_1^{(2)})_{1,4} &= -\sqrt{2}a, & (\tilde{Y}_1^{(2)})_{1,13} &= -\frac{a}{\sqrt{2}}, & (\tilde{Y}_1^{(2)})_{1,16} &= -a, \\ (\tilde{Y}_1^{(2)})_{2,2} &= a, & (\tilde{Y}_1^{(2)})_{2,14} &= \frac{a}{\sqrt{2}}, \\ (\tilde{Y}_1^{(2)})_{3,3} &= \frac{980}{57641}, & (\tilde{Y}_1^{(2)})_{3,15} &= \frac{893}{74280}, \\ (\tilde{Y}_1^{(2)})_{4,1} &= -\sqrt{2}a, & (\tilde{Y}_1^{(2)})_{4,4} &= -\frac{980}{57641}, & (\tilde{Y}_1^{(2)})_{4,13} &= -\frac{5141}{38426}, & (\tilde{Y}_1^{(2)})_{4,16} &= -\frac{893}{74280}, \\ (\tilde{Y}_1^{(2)})_{9,9} &= -\frac{\sqrt{2}}{32}, & (\tilde{Y}_1^{(2)})_{9,12} &= \frac{224}{9805}, \\ (\tilde{Y}_1^{(2)})_{10,10} &= \frac{\sqrt{2}}{32}, & (\tilde{Y}_1^{(2)})_{11,11} &= \frac{\sqrt{2}}{32}, \\ (\tilde{Y}_1^{(2)})_{12,9} &= \frac{224}{9805}, & (\tilde{Y}_1^{(2)})_{12,12} &= -\frac{\sqrt{2}}{32}, \\ (\tilde{Y}_1^{(2)})_{13,1} &= -\frac{a}{\sqrt{2}}, & (\tilde{Y}_1^{(2)})_{13,4} &= -\frac{5141}{38426}, & (\tilde{Y}_1^{(2)})_{13,13} &= -\frac{1431}{21404}, & (\tilde{Y}_1^{(2)})_{13,16} &= -\frac{8853}{93580}, \\ (\tilde{Y}_1^{(2)})_{14,2} &= \frac{a}{\sqrt{2}}, & (\tilde{Y}_1^{(2)})_{14,14} &= \frac{1431}{21404}, \\ (\tilde{Y}_1^{(2)})_{15,3} &= \frac{893}{74280}, & (\tilde{Y}_1^{(2)})_{15,15} &= -\frac{481}{84403}, \\ (\tilde{Y}_1^{(2)})_{16,1} &= -a, & (\tilde{Y}_1^{(2)})_{16,4} &= -\frac{893}{74280}, & (\tilde{Y}_1^{(2)})_{16,13} &= -\frac{8853}{93580}, & (\tilde{Y}_1^{(2)})_{16,16} &= \frac{481}{84403}. \end{aligned} \tag{S59}$$

All omitted entries are zero, apart from Hermitian symmetry.

To pass from the old two-sided certificate to the one-sided certificate, add the exact normalization multiplier

$$\hat{Y}_{\text{Seq}} = (\hat{Y}_1, \hat{Y}_2, \hat{Y}_3, \hat{Y}_\Delta)$$

defined by the identity

$$K_{\text{Seq}}^*(\hat{Y}_{\text{Seq}}) = \mathcal{L}_{\mathcal{N}}^* \left(\frac{1}{4} I_{C_i C_o} \right),$$

and normalized so that its affine contribution is

$$G_{\text{Seq}}(\hat{Y}_{\text{Seq}}) = \left\langle \frac{1}{4} I_{C_i C_o}, J_{\mathcal{I}} \right\rangle = \frac{1}{2}.$$

Here $G_{\text{Seq}}(Y_{\text{Seq}})$ denotes the affine constant term in the one-sided sequential dual objective. Equation (D 4) is the adjoint form of the deterministic trace-preservation identity

$$\text{Tr}_{C_o}[\mathcal{L}_{\mathcal{N}}(\Theta^S)] = I_{C_i}$$

for every sequential comb Θ^S after insertion of two trace-preserving channels $\mathcal{N}$. Therefore it is an exact consequence of the sequential comb equalities in Appendix B.

Finally define the one-sided sequential multiplier by

$$Y_{\text{Seq}} := Y_{\text{Seq}}^{(2)} + \widehat{Y}_{\text{Seq}}.$$

Then

$$(P_{\text{Seq}}, R_{\text{Seq}}, Y_{\text{Seq}})$$

is an exact feasible point of the one-sided sequential MISC dual SDP. More precisely,

$$P_{\text{Seq}} \succeq 0, \quad R_{\text{Seq}} \succeq 0, \quad (\text{S60})$$

$$\text{Tr } R_{\text{Seq}} = 1, \quad (\text{S61})$$

$$P_{\text{Seq}} \preceq R_{\text{Seq}} \otimes I_{C_o}, \quad (\text{S62})$$

$$\mathcal{L}_{\mathcal{N}}^*(P_{\text{Seq}}) - K_{\text{Seq}}^*(Y_{\text{Seq}}) \succeq \frac{1}{32}I \succeq 0. \quad (\text{S63})$$

Moreover, the exact one-sided dual objective value is

$$L_{\text{MISC}}^{\text{Seq}} = \frac{61}{1857}. \quad (\text{S64})$$

Thus

$$D_{\text{MISC}}^{\text{Seq}} \left(\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \mathcal{I} \right) \geq \frac{61}{1857}. \quad (\text{S65})$$

Proof We verify all one-sided dual constraints exactly.

First,

$$R_{\text{Seq}} = \frac{1}{2}I_{C_i},$$

so

$$\text{spec}(R_{\text{Seq}}) = \left\{ \frac{1}{2}, \frac{1}{2} \right\}, \quad R_{\text{Seq}} \succeq 0, \quad \text{Tr } R_{\text{Seq}} = 1.$$

Next, since

$$P_{\text{Seq}} = \frac{1}{2}|\Phi^-\rangle\langle\Phi^-| + 2\alpha(|01\rangle\langle 01| + |10\rangle\langle 10|),$$

we have

$$\text{spec}(P_{\text{Seq}}) = \left\{ \frac{1}{2}, 0, 2\alpha, 2\alpha \right\} = \left\{ \frac{1}{2}, 0, \frac{10027}{24879}, \frac{10027}{24879} \right\}.$$

Therefore

$$P_{\text{Seq}} \succeq 0.$$

Moreover,

$$R_{\text{Seq}} \otimes I_{C_o} = \frac{1}{2}I_{C_i C_o}.$$

Hence

$$R_{\text{Seq}} \otimes I_{C_o} - P_{\text{Seq}}$$

has spectrum

$$\left\{ 0, \frac{1}{2}, \frac{1}{2} - 2\alpha, \frac{1}{2} - 2\alpha \right\}.$$

Using

$$\frac{1}{2} - 2\alpha = \frac{1}{2} - \frac{10027}{24879} = \frac{24879 - 20054}{49758} = \frac{4825}{49758} > 0,$$

we obtain

$$R_{\text{Seq}} \otimes I_{C_o} - P_{\text{Seq}} \succeq 0.$$

Thus

$$P_{\text{Seq}} \preceq R_{\text{Seq}} \otimes I_{C_o}.$$

It remains to prove the slack constraint. By construction,

$$P_{\text{Seq}} = P_{\text{Seq}}^{(2)} - Q_{\text{Seq}}^{(2)} + \frac{1}{4}I_{C_i C_o}.$$

Therefore

$$\begin{aligned} & \mathcal{L}_{\mathcal{N}}^*(P_{\text{Seq}}) - K_{\text{Seq}}^*(Y_{\text{Seq}}) \\ &= \mathcal{L}_{\mathcal{N}}^*\left(P_{\text{Seq}}^{(2)} - Q_{\text{Seq}}^{(2)} + \frac{1}{4}I_{C_i C_o}\right) - K_{\text{Seq}}^*\left(Y_{\text{Seq}}^{(2)} + \hat{Y}_{\text{Seq}}\right) \\ &= \left[\mathcal{L}_{\mathcal{N}}^*\left(P_{\text{Seq}}^{(2)} - Q_{\text{Seq}}^{(2)}\right) - K_{\text{Seq}}^*(Y_{\text{Seq}}^{(2)})\right] + \left[\mathcal{L}_{\mathcal{N}}^*\left(\frac{1}{4}I_{C_i C_o}\right) - K_{\text{Seq}}^*(\hat{Y}_{\text{Seq}})\right]. \end{aligned} \quad (\text{S66})$$

The second bracket is zero by (D4). Hence

$$\mathcal{L}_{\mathcal{N}}^*(P_{\text{Seq}}) - K_{\text{Seq}}^*(Y_{\text{Seq}}) = \mathcal{L}_{\mathcal{N}}^*\left(P_{\text{Seq}}^{(2)} - Q_{\text{Seq}}^{(2)}\right) - K_{\text{Seq}}^*(Y_{\text{Seq}}^{(2)}).$$

The old reduced algebraic slack calculation gives the exact blockwise lower bound

$$\mathcal{L}_{\mathcal{N}}^*\left(P_{\text{Seq}}^{(2)} - Q_{\text{Seq}}^{(2)}\right) - K_{\text{Seq}}^*(Y_{\text{Seq}}^{(2)}) \succeq \frac{1}{32}I.$$

Indeed, after a simultaneous permutation of the computational basis, the nonzero graph decomposes into blocks with supports

$$\begin{aligned} & \{1, 4, 13, 16, 49, 52, 61, 64\}, \\ & \{2, 14, 50, 62\}, \quad \{3, 15, 51, 63\}, \quad \{9, 12, 57, 60\}, \quad \{33, 36, 45, 48\}, \\ & \{5, 53\}, \quad \{6, 54\}, \quad \{7, 55\}, \quad \{8, 56\}, \\ & \{10, 58\}, \quad \{11, 59\}, \quad \{34, 46\}, \quad \{35, 47\}, \quad \{41, 44\}. \end{aligned}$$

Exact LDL^T decomposition over

$$\mathbb{K} = \mathbb{Q}(\sqrt{2})$$

gives the certified block lower bounds

block support	certified lower bound
$\{1, 4, 13, 16, 49, 52, 61, 64\}$	$\frac{1}{16}$
$\{2, 14, 50, 62\}, \{3, 15, 51, 63\}$	$\frac{1}{6}$
$\{9, 12, 57, 60\}$	$\frac{1}{20}$
$\{33, 36, 45, 48\}$	$\frac{1}{32}$
all listed 2×2 blocks	$\frac{1}{16}$
all scalar blocks	$\frac{1}{8}$.

The smallest certified lower bound is $1/32$. Therefore

$$\mathcal{L}_{\mathcal{N}}^*(P_{\text{Seq}}) - K_{\text{Seq}}^*(Y_{\text{Seq}}) \succeq \frac{1}{32}I \succeq 0.$$

This proves the one-sided slack constraint.

Finally, we compute the objective. The one-sided sequential objective is

$$G_{\text{Seq}}(Y_{\text{Seq}}) - \langle P_{\text{Seq}}, J_{\mathcal{I}} \rangle.$$

Because

$$P_{\text{Seq}} = \frac{1}{2}|\Phi^-\rangle\langle\Phi^-| + 2\alpha(|01\rangle\langle 01| + |10\rangle\langle 10|)$$

and

$$J_{\mathcal{I}} = 2|\Phi^+\rangle\langle\Phi^+|,$$

we have

$$\langle P_{\text{Seq}}, J_{\mathcal{I}} \rangle = 0.$$

Furthermore,

$$G_{\text{Seq}}(Y_{\text{Seq}}) = G_{\text{Seq}}(Y_{\text{Seq}}^{(2)}) + G_{\text{Seq}}(\hat{Y}_{\text{Seq}}).$$

The old reduced algebraic certificate gives

$$G_{\text{Seq}}(Y_{\text{Seq}}^{(2)}) = -\frac{1735}{3714},$$

while the normalization multiplier satisfies

$$G_{\text{Seq}}(\hat{Y}_{\text{Seq}}) = \frac{1}{2}.$$

Hence

$$\begin{aligned} L_{\text{MISC}}^{\text{Seq}} &= G_{\text{Seq}}(Y_{\text{Seq}}) - \langle P_{\text{Seq}}, J_{\mathcal{I}} \rangle \\ &= -\frac{1735}{3714} + \frac{1}{2} - 0 \\ &= -\frac{1735}{3714} + \frac{1857}{3714} \\ &= \frac{122}{3714} = \frac{61}{1857}. \end{aligned}$$

Therefore the exact one-sided dual feasible point certifies

$$D_{\text{MISC}}^{\text{Seq}} \left(\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \mathcal{I} \right) \geq \frac{61}{1857}.$$

■

5. Exact algebraic primal ICO MISC witness at $\varepsilon_0 = 1/2$

The primal variables are

$$\Theta_{\text{ICO}}^S, \quad Z_{\text{ICO}}, \quad l_{\text{ICO}}.$$

In the one-sided Watrous formulation used in Appendix B–C, the primal objective value is

$$U_{\text{MISC}}^{\text{ICO}} = l_{\text{ICO}}.$$

The matrix Θ_{ICO}^S is written in the computational basis ordered as

$$A_o A_i B_o B_i C_i C_o.$$

Equivalently, the basis vectors are

$$|a_o, a_i, b_o, b_i, c_i, c_o\rangle, \quad a_o, a_i, b_o, b_i, c_i, c_o \in \{0, 1\}.$$

We use one-based indices

$$r = 1 + 32a_o + 16a_i + 8b_o + 4b_i + 2c_i + c_o. \quad (\text{S67})$$

All omitted entries of Θ_{ICO}^S are zero, and the matrix is Hermitian.

Define

$$a := \frac{3 - \sqrt{3}}{6}, \quad b := \frac{3 + \sqrt{3}}{6}, \quad g := \frac{b}{2} = \frac{3 + \sqrt{3}}{12}, \quad (\text{S68})$$

$$c := \frac{21 - 5\sqrt{3}}{120}, \quad d := \frac{9 - 5\sqrt{3}}{120}, \quad e := \frac{1}{10}, \quad f := \frac{1}{5}, \quad (\text{S69})$$

$$h := \frac{\sqrt{6}}{6}, \quad \lambda := 1 - \frac{\sqrt{6} + \sqrt{2}}{4}. \quad (\text{S70})$$

Then

$$a > 0, \quad b > 0, \quad c > 0, \quad d > 0, \quad e > 0, \quad f > 0, \quad g > 0,$$

and

$$ab = h^2, \quad a + b = 1.$$

The nonzero diagonal entries of Θ_{ICO}^S are

$$\begin{aligned} (\Theta_{\text{ICO}}^S)_{1,1} &= (\Theta_{\text{ICO}}^S)_{4,4} = a, \\ (\Theta_{\text{ICO}}^S)_{61,61} &= (\Theta_{\text{ICO}}^S)_{64,64} = b, \\ (\Theta_{\text{ICO}}^S)_{5,5} &= (\Theta_{\text{ICO}}^S)_{6,6} = (\Theta_{\text{ICO}}^S)_{7,7} = (\Theta_{\text{ICO}}^S)_{8,8} = c, \\ (\Theta_{\text{ICO}}^S)_{17,17} &= (\Theta_{\text{ICO}}^S)_{18,18} = (\Theta_{\text{ICO}}^S)_{19,19} = (\Theta_{\text{ICO}}^S)_{20,20} = c, \\ (\Theta_{\text{ICO}}^S)_{21,21} &= (\Theta_{\text{ICO}}^S)_{22,22} = (\Theta_{\text{ICO}}^S)_{23,23} = (\Theta_{\text{ICO}}^S)_{24,24} = e, \\ (\Theta_{\text{ICO}}^S)_{25,25} &= (\Theta_{\text{ICO}}^S)_{26,26} = (\Theta_{\text{ICO}}^S)_{27,27} = (\Theta_{\text{ICO}}^S)_{28,28} = f, \\ (\Theta_{\text{ICO}}^S)_{37,37} &= (\Theta_{\text{ICO}}^S)_{38,38} = (\Theta_{\text{ICO}}^S)_{39,39} = (\Theta_{\text{ICO}}^S)_{40,40} = f, \\ (\Theta_{\text{ICO}}^S)_{29,29} &= (\Theta_{\text{ICO}}^S)_{30,30} = (\Theta_{\text{ICO}}^S)_{31,31} = (\Theta_{\text{ICO}}^S)_{32,32} = d, \\ (\Theta_{\text{ICO}}^S)_{53,53} &= (\Theta_{\text{ICO}}^S)_{54,54} = (\Theta_{\text{ICO}}^S)_{55,55} = (\Theta_{\text{ICO}}^S)_{56,56} = d, \\ (\Theta_{\text{ICO}}^S)_{9,9} &= (\Theta_{\text{ICO}}^S)_{12,12} = (\Theta_{\text{ICO}}^S)_{33,33} = (\Theta_{\text{ICO}}^S)_{36,36} = g, \\ (\Theta_{\text{ICO}}^S)_{45,45} &= (\Theta_{\text{ICO}}^S)_{48,48} = (\Theta_{\text{ICO}}^S)_{57,57} = (\Theta_{\text{ICO}}^S)_{60,60} = g. \end{aligned} \quad (\text{S71})$$

The nonzero off-diagonal entries are

$$\begin{aligned} (\Theta_{\text{ICO}}^S)_{1,64} &= (\Theta_{\text{ICO}}^S)_{64,1} = h, \\ (\Theta_{\text{ICO}}^S)_{4,61} &= (\Theta_{\text{ICO}}^S)_{61,4} = h, \\ (\Theta_{\text{ICO}}^S)_{9,60} &= (\Theta_{\text{ICO}}^S)_{60,9} = g, \\ (\Theta_{\text{ICO}}^S)_{12,57} &= (\Theta_{\text{ICO}}^S)_{57,12} = g, \\ (\Theta_{\text{ICO}}^S)_{33,48} &= (\Theta_{\text{ICO}}^S)_{48,33} = g, \\ (\Theta_{\text{ICO}}^S)_{36,45} &= (\Theta_{\text{ICO}}^S)_{45,36} = g. \end{aligned} \quad (\text{S72})$$

In the basis

$$\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}_{C_i C_o},$$

define the corrected one-sided diamond variable

$$Z_{\text{ICO}} = \frac{\lambda}{2} \begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \end{pmatrix}, \quad l_{\text{ICO}} = \frac{\lambda}{2}. \quad (\text{S73})$$

Equivalently,

$$Z_{\text{ICO}} = \lambda |\Phi^-\rangle\langle\Phi^-|, \quad |\Phi^-\rangle = \frac{|00\rangle - |11\rangle}{\sqrt{2}}.$$

Then

$$(\Theta_{\text{ICO}}^S, Z_{\text{ICO}}, l_{\text{ICO}})$$

is an exact feasible point of the one-sided ICO MISC primal SDP. Namely,

$$\Theta_{\text{ICO}}^S \succeq 0, \quad Z_{\text{ICO}} \succeq 0,$$

it satisfies the ICO comb constraints

$$\text{Tr}_{C_o}[\Theta_{\text{ICO}}^S] = \frac{I_{A_i}}{d_{A_i}} \otimes \text{Tr}_{A_i C_o}[\Theta_{\text{ICO}}^S] + \frac{I_{B_i}}{d_{B_i}} \otimes \text{Tr}_{B_i C_o}[\Theta_{\text{ICO}}^S] - \frac{I_{A_i B_i}}{d_{A_i B_i}} \otimes \text{Tr}_{A_i B_i C_o}[\Theta_{\text{ICO}}^S], \quad (\text{S74})$$

$$\text{Tr}_{A_o A_i C_o}[\Theta_{\text{ICO}}^S] = \frac{I_{B_i}}{d_{B_i}} \otimes \text{Tr}_{A_o A_i B_i C_o}[\Theta_{\text{ICO}}^S], \quad (\text{S75})$$

$$\text{Tr}_{B_o B_i C_o}[\Theta_{\text{ICO}}^S] = \frac{I_{A_i}}{d_{A_i}} \otimes \text{Tr}_{B_o B_i A_i C_o}[\Theta_{\text{ICO}}^S], \quad (\text{S76})$$

$$\text{Tr}_{A_o A_i B_o B_i C_o}[\Theta_{\text{ICO}}^S] = d_{A_i B_i} I_{C_i}, \quad (\text{S77})$$

the MISC affine constraint

$$\Delta_{ABC}(\Theta_{\text{ICO}}^S) = (\Delta_{AB} \otimes \text{id}_C)(\Theta_{\text{ICO}}^S), \quad (\text{S78})$$

and the one-sided diamond-norm primal constraints

$$Z_{\text{ICO}} \succeq \mathcal{L}_{\mathcal{N}}(\Theta_{\text{ICO}}^S) - J_{\mathcal{I}}, \quad (\text{S79})$$

$$\text{Tr}_{C_o}[Z_{\text{ICO}}] = l_{\text{ICO}} I_{C_i}. \quad (\text{S80})$$

Consequently,

$$D_{\text{MISC}}^{\text{ICO}} \left(\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \mathcal{I} \right) \leq U_{\text{MISC}}^{\text{ICO,alg}} = l_{\text{ICO}} = \frac{1}{2} - \frac{\sqrt{6} + \sqrt{2}}{8}. \quad (\text{S81})$$

Proof We verify each one-sided primal SDP constraint directly.

First, we prove positivity. After grouping basis vectors according to the off-diagonal entries in Eq. (S72), the matrix Θ_{ICO}^S decomposes into scalar blocks and nontrivial 2×2 blocks.

The first type of nontrivial block is

$$\begin{pmatrix} a & h \\ h & b \end{pmatrix}.$$

Since

$$a = \frac{3 - \sqrt{3}}{6} > 0, \quad b = \frac{3 + \sqrt{3}}{6} > 0,$$

and

$$ab = \frac{(3 - \sqrt{3})(3 + \sqrt{3})}{36} = \frac{9 - 3}{36} = \frac{1}{6} = h^2,$$

this block is positive semidefinite with determinant zero.

The second type of nontrivial block is

$$\begin{pmatrix} g & g \\ g & g \end{pmatrix}.$$

Its eigenvalues are 0 and $2g$. Since

$$2g = \frac{3 + \sqrt{3}}{6} = b > 0,$$

this block is positive semidefinite.

All remaining blocks are one-dimensional scalar blocks equal to one of c, d, e, f . These are positive because

$$c = \frac{21 - 5\sqrt{3}}{120} > 0, \quad d = \frac{9 - 5\sqrt{3}}{120} > 0, \quad e = \frac{1}{10} > 0, \quad f = \frac{1}{5} > 0.$$

For $d > 0$, note that

$$9 > 5\sqrt{3} \iff 81 > 75.$$

Hence

$$\Theta_{\text{ICO}}^S \succeq 0.$$

Next,

$$\lambda = 1 - \frac{\sqrt{6} + \sqrt{2}}{4} > 0,$$

because

$$\sqrt{6} + \sqrt{2} < 4 \iff 8 + 4\sqrt{3} < 16 \iff \sqrt{3} < 2.$$

Therefore

$$Z_{\text{ICO}} = \lambda |\Phi^- \rangle \langle \Phi^-| \succeq 0.$$

Second, we verify the ICO comb constraints. Direct partial tracing of the entries in Eqs. (S71) and (S72) reduces the four ICO comb equations to the following scalar identities:

$$a + b = 1, \quad 2g = b, \quad c - d = e, \quad c + d = \frac{a}{2}, \quad e = \frac{1}{10}, \quad f = \frac{1}{5}.$$

These identities hold exactly:

$$a + b = \frac{3 - \sqrt{3}}{6} + \frac{3 + \sqrt{3}}{6} = 1,$$

$$2g = 2 \cdot \frac{3 + \sqrt{3}}{12} = \frac{3 + \sqrt{3}}{6} = b,$$

$$c - d = \frac{21 - 5\sqrt{3}}{120} - \frac{9 - 5\sqrt{3}}{120} = \frac{12}{120} = \frac{1}{10} = e,$$

and

$$c + d = \frac{30 - 10\sqrt{3}}{120} = \frac{3 - \sqrt{3}}{12} = \frac{a}{2}.$$

Hence Eqs. (S74)–(S77) hold exactly.

Third, we verify the MISC affine constraint. Every nonzero off-diagonal entry in Eq. (S72) connects two basis vectors with different AB -register values. Therefore these entries are removed by $\Delta_{AB} \otimes \text{id}_C$, and they are also removed by Δ_{ABC} . The diagonal entries are preserved by both maps. Hence

$$\Delta_{ABC}(\Theta_{\text{ICO}}^S) = (\Delta_{AB} \otimes \text{id}_C)(\Theta_{\text{ICO}}^S)$$

exactly.

Fourth, we verify the link product and the one-sided diamond-norm inequality. At $\varepsilon_0 = 1/2$, the amplitude-damping Choi operator is

$$J_{\mathcal{N}_{\text{AD}}^{1/2}} = \begin{pmatrix} 1 & 0 & 0 & \frac{1}{\sqrt{2}} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{2} & 0 \\ \frac{1}{\sqrt{2}} & 0 & 0 & \frac{1}{2} \end{pmatrix}.$$

A direct contraction of

$$J_{(\mathcal{N}_{\text{AD}}^{1/2})^{\otimes 2}}$$

with Θ_{ICO}^S gives

$$\mathcal{L}_{\mathcal{N}}(\Theta_{\text{ICO}}^S) = \begin{pmatrix} 1 & 0 & 0 & \mu \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \mu & 0 & 0 & 1 \end{pmatrix}, \quad \mu = \frac{\sqrt{6} + \sqrt{2}}{4}. \quad (\text{S82})$$

Since

$$J_{\mathcal{I}} = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix},$$

and

$$\lambda = 1 - \mu,$$

we obtain

$$\mathcal{L}_{\mathcal{N}}(\Theta_{\text{ICO}}^S) - J_{\mathcal{I}} = -\lambda(|00\rangle\langle 11| + |11\rangle\langle 00|).$$

Therefore

$$\begin{aligned} Z_{\text{ICO}} - (\mathcal{L}_{\mathcal{N}}(\Theta_{\text{ICO}}^S) - J_{\mathcal{I}}) &= \frac{\lambda}{2} \begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 1 \end{pmatrix} + \lambda \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \\ &= \frac{\lambda}{2} \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix} \\ &= \lambda |\Phi^+\rangle\langle \Phi^+| \succeq 0. \end{aligned}$$

Thus

$$Z_{\text{ICO}} \succeq \mathcal{L}_{\mathcal{N}}(\Theta_{\text{ICO}}^S) - J_{\mathcal{I}}.$$

Finally,

$$\text{Tr}_{C_o}[Z_{\text{ICO}}] = \frac{\lambda}{2} I_{C_i} = l_{\text{ICO}} I_{C_i}.$$

Hence all one-sided diamond-norm primal constraints are satisfied exactly.

Combining positivity, the ICO comb constraints, the MISC affine constraint, and the one-sided diamond-norm constraints proves that

$$(\Theta_{\text{ICO}}^S, Z_{\text{ICO}}, l_{\text{ICO}})$$

is feasible for the ICO MISC primal SDP. Since this SDP is a minimization problem, every feasible primal point gives an upper bound on the optimum. Therefore

$$D_{\text{MISC}}^{\text{ICO}} \left(\left(\mathcal{N}_{\text{AD}}^{1/2} \right)^{\otimes 2}, \mathcal{I} \right) \leq l_{\text{ICO}}.$$

Substituting

$$l_{\text{ICO}} = \frac{\lambda}{2} = \frac{1}{2} - \frac{\sqrt{6} + \sqrt{2}}{8}$$

gives

$$U_{\text{MISC}}^{\text{ICO,alg}} = l_{\text{ICO}} = \frac{1}{2} - \frac{\sqrt{6} + \sqrt{2}}{8}.$$

This proves the claim. ■

Appendix E: Teleportation stretching for mixed-Pauli channels

We now prove the collapse statement used in the main text. A qubit mixed-Pauli channel has the form

$$\mathcal{N}_{\mathbf{p}}(\rho) = \sum_{\alpha=0}^3 p_{\alpha} \sigma_{\alpha} \rho \sigma_{\alpha}^{\dagger}, \quad p_{\alpha} \geq 0, \quad \sum_{\alpha=0}^3 p_{\alpha} = 1. \quad (\text{S1})$$

Let

$$\omega_{\mathcal{N}_{\mathbf{p}}} = \frac{1}{2} J_{\mathcal{N}_{\mathbf{p}}}$$

be the normalized Choi state. Since this Choi state is Bell diagonal, the standard teleportation protocol simulates the channel exactly.

Lemma 1 *For every mixed-Pauli channel $\mathcal{N}_{\mathbf{p}}$, there exists a fixed teleportation operation $\mathcal{T}_{\text{tel}}$, independent of $\mathbf{p}$, such that*

$$\mathcal{N}_{\mathbf{p}}(\rho) = \mathcal{T}_{\text{tel}}(\rho \otimes \omega_{\mathcal{N}_{\mathbf{p}}}) \quad (\text{S2})$$

for every input state ρ .

Proof Define

$$|\Phi_{\alpha}\rangle = (I \otimes \sigma_{\alpha})|\Phi^{+}\rangle.$$

The Choi state of $\mathcal{N}_{\mathbf{p}}$ is

$$\omega_{\mathcal{N}_{\mathbf{p}}} = \sum_{\alpha=0}^3 p_{\alpha} |\Phi_{\alpha}\rangle \langle \Phi_{\alpha}|. \quad (\text{S3})$$

Teleportation through $|\Phi_{\alpha}\rangle$ implements the Pauli channel $\rho \mapsto \sigma_{\alpha} \rho \sigma_{\alpha}^{\dagger}$. By linearity, teleportation through $\omega_{\mathcal{N}_{\mathbf{p}}}$ implements $\mathcal{N}_{\mathbf{p}}$. ■

For an arbitrary qubit channel $\mathcal{E}$, define its teleportation-induced channel by

$$\mathcal{E}^{\text{tel}}(\cdot) := \mathcal{T}_{\text{tel}}(\cdot \otimes \omega_{\mathcal{E}}), \quad \omega_{\mathcal{E}} = \frac{1}{2} J_{\mathcal{E}}. \quad (\text{S4})$$

Lemma 2 If $\mathcal{C}$ is a classical channel, then $\mathcal{C}^{\text{tel}}$ is also a classical channel.

Proof If $\mathcal{C}$ is classical, then $J_{\mathcal{C}}$ is diagonal in the incoherent basis. Consequently $\omega_{\mathcal{C}}$ is a convex combination of computational-basis projectors. In the standard teleportation circuit, Bell measurement followed by Pauli correction maps diagonal input data to diagonal output data and kills off-diagonal matrix units. Hence

$$\mathcal{D} \circ \mathcal{C}^{\text{tel}} = \mathcal{C}^{\text{tel}} = \mathcal{C}^{\text{tel}} \circ \mathcal{D},$$

so $\mathcal{C}^{\text{tel}}$ neither generates nor preserves coherence. ■

Lemma 3 Let $\mathcal{S} \in \text{ICO} \cap \text{MISC}$ be a deterministic two-slot MISC superchannel. Then there exists a parallel MISC superchannel $\mathcal{P}_{\mathcal{S}} \in \text{Par} \cap \text{MISC}$ such that, for every mixed-Pauli channel $\mathcal{N}_{\mathbf{p}}$,

$$\mathcal{P}_{\mathcal{S}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}) = \mathcal{S}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}). \quad (\text{S5})$$

Proof For arbitrary channels $\mathcal{E}_A, \mathcal{E}_B$, define

$$\mathcal{P}_{\mathcal{S}}(\mathcal{E}_A \otimes \mathcal{E}_B) := \mathcal{S}(\mathcal{E}_A^{\text{tel}} \otimes \mathcal{E}_B^{\text{tel}}). \quad (\text{S6})$$

Operationally, $\mathcal{P}_{\mathcal{S}}$ first uses $\mathcal{E}_A$ and $\mathcal{E}_B$ in parallel to prepare their Choi states, and then applies fixed teleportation gadgets before feeding the resulting channels into $\mathcal{S}$. Therefore $\mathcal{P}_{\mathcal{S}} \in \text{Par}$.

If $\mathcal{C}_A, \mathcal{C}_B$ are classical, then $\mathcal{C}_A^{\text{tel}}, \mathcal{C}_B^{\text{tel}}$ are classical by Lemma 2. Since $\mathcal{S} \in \text{MISC}$, the output

$$\mathcal{S}(\mathcal{C}_A^{\text{tel}} \otimes \mathcal{C}_B^{\text{tel}})$$

is classical. Hence $\mathcal{P}_{\mathcal{S}} \in \text{MISC}$. Finally, Lemma 1 gives $\mathcal{N}_{\mathbf{p}}^{\text{tel}} = \mathcal{N}_{\mathbf{p}}$, and therefore Eq. (S5) holds. ■

For DISC one additionally needs compatibility with dephasing.

Lemma 4 For every qubit channel $\mathcal{E}$,

$$(\Delta(\mathcal{E}))^{\text{tel}} = \Delta(\mathcal{E}^{\text{tel}}), \quad (\text{S7})$$

where Δ denotes the dephasing superchannel induced by $\mathcal{D}$.

Proof The teleportation-induced Choi state is Bell diagonal:

$$\omega_{\mathcal{E}^{\text{tel}}} = \sum_{a,b} q_{ab}(\mathcal{E}) \Phi_{ab}, \quad q_{ab}(\mathcal{E}) = \text{Tr}[\Phi_{ab} \omega_{\mathcal{E}}].$$

Since

$$\mathcal{D}(\Phi_{ab}) = \frac{1}{2} \sum_{j=0}^1 |j\rangle\langle j| \otimes |j \oplus a\rangle\langle j \oplus a|$$

is independent of b , dephasing before teleportation and dephasing after teleportation give the same Bell-diagonal mixture. Multiplying by the Choi normalization gives Eq. (S7). ■

Lemma 5 Let $\mathcal{S} \in \text{ICO} \cap \text{DISC}$ be a deterministic two-slot DISC superchannel. Then there exists a parallel DISC superchannel $\mathcal{P}_{\mathcal{S}} \in \text{Par} \cap \text{DISC}$ such that, for every mixed-Pauli channel $\mathcal{N}_{\mathbf{p}}$,

$$\mathcal{P}_{\mathcal{S}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}) = \mathcal{S}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}). \quad (\text{S8})$$

Proof Define $\mathcal{P}_{\mathcal{S}}$ as in Eq. (S6). The construction is parallel. To show that it is DISC, use Lemma 4 and the dephasing covariance of $\mathcal{S}$:

$$\Delta_C \circ \mathcal{S} = \mathcal{S} \circ \Delta_{AB}.$$

Then, for all $\mathcal{E}_A, \mathcal{E}_B$,

$$\Delta_C \mathcal{P}_{\mathcal{S}}(\mathcal{E}_A \otimes \mathcal{E}_B) = \Delta_C \mathcal{S}(\mathcal{E}_A^{\text{tel}} \otimes \mathcal{E}_B^{\text{tel}}) \quad (\text{S9})$$

$$= \mathcal{S} \Delta_{AB}(\mathcal{E}_A^{\text{tel}} \otimes \mathcal{E}_B^{\text{tel}}) \quad (\text{S10})$$

$$= \mathcal{S}((\Delta_A \mathcal{E}_A)^{\text{tel}} \otimes (\Delta_B \mathcal{E}_B)^{\text{tel}}) \quad (\text{S11})$$

$$= \mathcal{P}_{\mathcal{S}} \Delta_{AB}(\mathcal{E}_A \otimes \mathcal{E}_B). \quad (\text{S12})$$

Thus $\mathcal{P}_{\mathcal{S}} \in \text{DISC}$. The equality of the action on $\mathcal{N}_{\mathbf{p}}^{\otimes 2}$ follows from $\mathcal{N}_{\mathbf{p}}^{\text{tel}} = \mathcal{N}_{\mathbf{p}}$. ■

Theorem S5 *Let $\mathcal{N}_{\mathbf{p}}$ be a mixed-Pauli channel. Then, for every target channel $\mathcal{M}$ and for both $\mathbf{F} \in \{\text{MISC}, \text{DISC}\}$,*

$$D_{\mathbf{F}}^{\text{Par}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}, \mathcal{M}) = D_{\mathbf{F}}^{\text{Seq}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}, \mathcal{M}) = D_{\mathbf{F}}^{\text{ICO}}(\mathcal{N}_{\mathbf{p}}^{\otimes 2}, \mathcal{M}). \quad (\text{S13})$$

Proof The inclusions $\text{Par} \subseteq \text{Seq} \subseteq \text{ICO}$ imply

$$D_{\mathbf{F}}^{\text{Par}} \geq D_{\mathbf{F}}^{\text{Seq}} \geq D_{\mathbf{F}}^{\text{ICO}}.$$

Conversely, choose an ϵ -optimal $S_{\epsilon} \in \text{ICO} \cap \mathbf{F}$. By Lemma 3 for $\mathbf{F} = \text{MISC}$, or Lemma 5 for $\mathbf{F} = \text{DISC}$, there exists $\mathcal{P}_{S_{\epsilon}} \in \text{Par} \cap \mathbf{F}$ with the same action on $\mathcal{N}_{\mathbf{p}}^{\otimes 2}$. Hence

$$D_{\mathbf{F}}^{\text{Par}} \leq D_{\mathbf{F}}^{\text{ICO}} + \epsilon.$$

Taking $\epsilon \rightarrow 0$ proves the reverse inequality and hence Eq. (S13). ■

Efficient Machine Learning Models for Phase Space Functions

Abstract. A fundamental challenge in continuous-variable quantum state tomography is inferring a continuous phase-space function from sparse, pointwise measurement data. In this paper, we develop two complementary methods for learning Wigner functions directly as continuous functions of phase-space coordinates. The first leverages machine learning theory to provide provable guarantees on measurement complexity for states with sparse Fock-space or coherent-state support, including binomial code states and cat states. For such states, the measurement complexity scales logarithmically with the Hilbert space cutoff. The second employs a deep neural network surrogate to represent Wigner functions, designed for states beyond the sparse-support regime. Numerical results show that this neural-network model efficiently reconstructs practical GKP states, outperforms maximum-likelihood estimation in the tested settings, and is more robust than regression-based models against statistical and experimental noise. Using circuit-QED experimental data, we further show that Wigner functions learned from sparse noisy measurements can reveal the most probable quantum error in the experiment, whereas conventional estimation methods can only resolve random noise.

Keywords: Quantum State Learning, Continuous Variable Systems, Wigner Function Tomography

1 Introduction

Characterization of continuous-variable (CV) quantum states has long been a challenging problem. In recent years, experimental advances have enabled the measurement of Wigner functions and other quasi-probability distributions, allowing point-wise estimation of their values in phase space. This capability is now routine in platforms such as superconducting circuit quantum electrodynamics (QED) [1] and ion traps [2, 3].

Despite these progresses, a reliable reconstruction of the Wigner function over the entire phase space remains difficult as the photon number increases—even for a single-mode state. A central obstacle in Wigner tomography is that measurements performed at only finitely many phase-space points cannot directly determine a continuous phase-space function. Consequently, reliable reconstructions typically require measurements on increasingly dense phase-space grids, leading to rapidly increasing experimental and computational costs.

In this work, we introduce two efficient machine learning models to reconstruct the entire phase space from point-wise measurement data. The first is a linear regression model with rigorous generalization bounds, suitable for states sparsely supported on some basis. The second is a deep neural network model that is robust to practical noise for more general states.

2 Main Results

2.1 Regression model

We first introduce the framework of the regression model, inspired by classical surrogate methods [4, 5, 6], which involves three steps: data collection, feature mapping, and model training.

Data collection.— The first step is to obtain accurate values of the Wigner function on a set of phase-space

points. As

$$W_\rho(\alpha) = \frac{1}{\pi} \text{Tr}(\rho D(-\alpha)(-1)^{\hat{n}} D(\alpha)), \quad (1)$$

the value of the Wigner function at α can be measured by performing a displacement operation $D(-\alpha)$ and then detecting the resulting photon parity $(-1)^{\hat{n}}$, where $\hat{n} = \hat{a}^\dagger \hat{a}$ is the photon number operator. The dataset

$$\mathcal{T} := \{(\alpha_i, y_i)\}_{i=1}^{\mathcal{N}} \quad (2)$$

consists of the statistical estimates y_i of $W(\alpha_i)$ at $\mathcal{N}$ distinct phase-space points $\{\alpha_i\}_{i=1}^{\mathcal{N}}$, where each α_i is sampled from a distribution $\mathbb{D}$, e.g., a uniform distribution over a specified phase-space region.

Feature mapping.— A feature mapping consists of selecting an appropriate set of linearly independent functions $\Phi_\omega(\cdot) : \alpha \in \mathbb{C} \mapsto \Phi_\omega(\alpha) \in \mathbb{R}$ using prior assumptions on the target state. The resulting feature space is spanned by $\{\Phi_\omega(\cdot)\}_{\omega=1}^{d_f}$, where d_f is the dimension of the feature space. The feature map Φ is the collection of these basis functions, defined as

$$\alpha \mapsto \Phi(\alpha) := (\Phi_1(\alpha), \Phi_2(\alpha), \dots, \Phi_{d_f}(\alpha))^T \in \mathbb{R}^{d_f}. \quad (3)$$

The surrogate of the Wigner function associated with the feature map Φ is a linear function of the form

$$\widehat{W}_\eta(\alpha) := \langle \eta, \Phi(\alpha) \rangle, \quad (4)$$

where $\eta := (\eta_1, \eta_2, \dots, \eta_{d_f})$ denotes the trainable parameters of the regression model $\widehat{W}_\eta$, and $\langle \cdot, \cdot \rangle$ denotes the inner product. Without confusion, $\widehat{W}$ tacitly implies $\widehat{W}_\eta$ with some suitable feature map Φ .

Model training.— In this step, the parameters η are learned using the dataset $\mathcal{T}$. Define the empirical error, i.e., the average prediction error over the training data

points in $\mathcal{T}$ as

$$\widehat{R}_{\mathcal{T}}(\widehat{W}_{\boldsymbol{\eta}}) := \frac{1}{N} \sum_{i=1}^N |\widehat{W}_{\boldsymbol{\eta}}(\alpha_i) - y_i|^2, \quad (5)$$

then the optimal $\boldsymbol{\eta}$ is obtained by solving the Lasso optimization:

$$\min_{\boldsymbol{\eta}} \widehat{R}_{\mathcal{T}}(\widehat{W}_{\boldsymbol{\eta}}) \quad \text{subject to} \quad \|\boldsymbol{\eta}\|_1 \leq t. \quad (6)$$

where $\|\boldsymbol{\eta}\|_1 = \sum_{i=1}^{d_f} |\eta_i|$. The ℓ_1 -regularization hyperparameter t serves two purposes. First, it determines the hypothesis class $\{\widehat{W}_{\boldsymbol{\eta}} : \|\boldsymbol{\eta}\|_1 \leq t\}$, i.e., the space of functions in which the Lasso optimization algorithm searches. Second, it controls the sparsity of the linear regression model in the feature space. In other words, if t is small, then the solution to Eq. (6) contains more zero entries.

Finally, the performance of the model is evaluated by the generalization error, a.k.a., the expected squared error:

$$R(\widehat{W}) := \mathbb{E}_{\alpha \sim \mathbb{D}} |\widehat{W}(\alpha) - W(\alpha)|^2. \quad (7)$$

The main task then is to determine the training data complexity $\mathcal{N}$, i.e., the number of different pointwise measurement settings in phase space, for the regression model to achieve a low generalization error. Note that this is not yet the total number of quantum states needed (sample complexity). Without additional assumptions on the target state, the training data required to reconstruct the entire phase space scales as $O(d^2)$ following an information-theoretic argument, where d denotes the truncated dimension from an infinite dimensional Hilbert space.

Here, we leverage the sparse nature of Lasso regression to achieve improved training data complexity for two broad classes of single-mode CV states. The first class comprises states sparse in the Fock support presented in Theorem 1, with binomial code states serving as the canonical example. The second class consists of states sparse in coherent-state support presented in Theorem 2, exemplified by cat states. The corresponding feature map involves the generalized Laguerre polynomials and the Gabor frame, respectively.

Theorem 1 *For any $\epsilon, \delta > 0$, suppose that the state ρ satisfies $\sum_{n,m=0}^d \mathbb{1}\{\rho_{mn} \neq 0\} \leq s^2$ and every training data pair in $\mathcal{T}$ satisfies $|W(\alpha_i) - y_i| \leq \sqrt{\epsilon/4}$. Let $\widehat{W}$ be the regression model with optimal parameters obtained by solving Eq. (6). If the training error in Eq. (5) satisfies $\widehat{R}_{\mathcal{T}}(\widehat{W}) \leq \epsilon/2$, then a training data of size*

$$\mathcal{N} = O\left(\frac{s^4}{\epsilon^2} \log \frac{d}{\delta}\right)$$

suffices to achieve $R(\widehat{W}) \leq \epsilon$ for any distribution $\mathbb{D}$ with probability at least $1 - \delta$.

Theorem 2 *Let the target state be $|\psi\rangle = \sum_{i=1}^s a_i |\alpha_i\rangle$ with the condition $|\alpha_j - \alpha_\ell| \geq \Delta_\alpha$ for all $j, \ell \in [s]$ and $j \neq \ell$. Then, set $\kappa = 1 - (s-1)e^{-\frac{1}{2}\Delta_\alpha^2}$ and let $\widehat{W}$ be the surrogate*

obtained by solving Eq. (6). For any $\epsilon, \delta > 0$, assume every training data pair in $\mathcal{T}$ satisfies $|W(\alpha_i) - y_i| \leq \sqrt{\epsilon/4}$, then a training data of size

$$\mathcal{N} = O\left(\frac{s^4}{\epsilon^2 \kappa^4} \log \frac{R}{\delta}\right)$$

suffices to achieve $R(\widehat{W}) \leq \epsilon$ for any distribution $\mathbb{D}$ with probability at least $1 - \delta$.

In both settings, when the sparsity is constant, meaning $s = O(1)$ (also $\kappa = O(1)$), then the training data complexity scales as $O(\log d)$ (note $R = O(\sqrt{d})$), indicating highly efficient learning.

2.2 DNN model

The regression model is efficient when a sparse feature representation is known. When such prior knowledge is unavailable, we present a deep neural network (DNN) surrogate, inspired by Refs. [7, 8], to reconstruct Wigner functions from sparse grid measurements, following the three steps below.

Data collection.— We assume that $W(\alpha)$ is supported on a finite phase-space region $\Omega \subset \mathbb{R}^2$ and collect estimates y_α on a coarse uniform grid Γ . Low- and medium-resolution training pairs are generated by interpolation-based downsampling, e.g., from a 23×23 grid to 8×8 – 14×14 inputs and 15×15 – 23×23 targets.

Feature mapping.— Instead of using analytical features as in the regression models, the DNN learns features automatically. Inspired by neural implicit representations [9, 10], we use an encoder-decoder architecture: a convolutional encoder extracts multi-scale features from coarse Wigner data, and a multilayer-perceptron decoder predicts $\widehat{W}_{\boldsymbol{\eta}}(\alpha)$ from local features and coordinates, giving a continuous Wigner-function surrogate.

Model training.— The model is trained self-supervisedly, with labels generated from the measured data rather than external high-resolution ground truth. The parameters $\boldsymbol{\eta}$ are optimized by minimizing the mean squared error to medium-resolution values y_α . Once trained, the network can predict a finer grid, e.g., an 81×81 Wigner function from a 23×23 input. This DNN formalism complements Theorem 1 and Theorem 2 by trading sparse-support guarantees for flexibility and robustness to practical noise.

2.3 Numerical examples

We numerically test the two learning models on a broad set of CV states. Due to the space limit, Fig. 1 highlights two canonical bosonic code states, viz., simulated binomial code states [11] for the regression model, and both simulated GKP states [12] and experimental GKP states from circuit-QED quantum error correction [1] for the DNN model. The figure of merit is the overlap between the ground truth $W(\alpha)$ and the reconstructed model $\widehat{W}(\alpha)$. In the reference paper below, we also explored cat states, finite-shot measurement noise, states generated by random displacement and SNAP circuits, and additional experimental circuit-QED data.

Figure 1: Selected numerical demonstrations on learning the Wigner function of bosonic code states with regression models and DNN models. **a,b.** Regression reconstruction of the binomial code state $|\bar{1}\rangle_b := 2^{-N/2} \sum_{p=\text{odd}}^{[0, N+1]} \sqrt{\binom{N+1}{p}} |p(S+1)\rangle$ for various combinations of (N, S) , with fidelity above 0.99 compared with conventional Wigner tomography. In each figure, the left panel shows a representative reconstruction and the right panel the corresponding training data complexity; **a** uses $(N, S) = (3, 11)$ and **b** uses $(N, S) = (11, 3)$ for the representative visualizations. Black crosses mark the training points. **c.** DNN reconstruction of approximate GKP states with $\psi_0(x) \propto \sum_{s=-s_{\max}}^{s_{\max}} e^{-2\pi\sigma^2 s^2} e^{-(x-2s\sqrt{\pi})^2/(2\sigma^2)}$; the left panel shows a magnified view of the fine phase-space structure. **d.** Identification of the dominant error subspace in experimental GKP data. From left to right, the panels show the Wigner function of the normalized projector $(|E_0\rangle\langle E_0| + |E_1\rangle\langle E_1|)/2$ inferred from sparse 27×27 measurements, full 81×81 measurements, and DNN-predicted 81×81 data trained only on the sparse grid. The rightmost panel shows the normalized photon-addition reference $\hat{a}^\dagger(|\bar{0}\rangle + |\bar{1}\rangle)(\langle\bar{0}| + \langle\bar{1}|)\hat{a}$, indicating that the DNN reconstruction reveals a heating-like error pattern from sparse noisy measurements. See the reference paper below for more details.

For the regression model, the main benchmark is the binomial code family, which is sparse in the Fock basis, matching the setting of Theorem 1. We sample phase-space coordinates uniformly at random, fit the Laguerre-feature Lasso model, and evaluate the reconstruction on a dense Wigner grid. As shown in Fig. 1a,b, the number of sampled points required to reach fidelity above 0.99 is much smaller than the $d^2 - 1$ scaling of information-complete Wigner tomography [13, 14]. We also test Gabor-frame regression on cat states and states generated by random displacement and SNAP circuits, where the method performs well for coherent-state sparse structure but degrades as the phase-space pattern becomes more complex.

For the DNN model, the first benchmark is practical GKP states (finite squeezing), which do not have the simple sparse support assumed by the regression theorems. Figure 1c shows that the DNN reconstructs noiseless and photon-loss GKP Wigner functions with fidelity above 0.99 from sparse coarse-grid measurements. The lossy case needs fewer points because loss smooths fine interference structures.

We then use experimental circuit-QED GKP data [1] as the main test of the DNN model under realistic noise. The recorded Wigner function is available on an 81×81 grid, but the DNN is trained using only the sparse 27×27 subgrid and predicts the full 81×81 phase-space map. From the reconstructed Wigner functions of the experi-

mental $\rho_{\bar{0}}$ and $\rho_{\bar{1}}$ states, we reconstruct density matrices and diagonalize their mixture $\rho_{\text{mix}} = (\rho_{\bar{0}} + \rho_{\bar{1}})/2$. The two leading eigenvectors define the experimental logical subspace, while the next two define the dominant error subspace. As shown in Fig. 1d, the error-subspace Wigner function inferred from the DNN prediction has a much clearer resemblance to the photon-addition reference $\hat{a}^\dagger(|\bar{0}\rangle + |\bar{1}\rangle)(\langle\bar{0}| + \langle\bar{1}|)\hat{a}$ than the direct reconstructions from sparse or full experimental grids.

3 Conclusion

We introduce two models for reconstructing Wigner functions from sparse pointwise measurements: a sparse regression model and a DNN model. The two approaches are both data-driven, but differ slightly in their learning formalisms. The first approach is theoretically motivated. Given measurement data on a set of points $\{\alpha_i\}$ randomly sampled from an arbitrary distribution $\mathbb{D}$, the learning model aims to minimize the expected prediction error of the Wigner function values $W(\alpha)$ when α is drawn from the same distribution $\mathbb{D}$. This formalism casts Wigner function learning as a PAC learning problem, for which we prove our main results in Theorem 1 and Theorem 2. The second is experimentally motivated. Given measurement data on a coarse-grained grid, the learning model targets predicting Wigner function values on a fine-grained grid at arbitrary resolution

beyond those encountered during training. This setting is closer to practical Wigner tomography experiments, in which measurements are typically performed over a grid of points within a region of phase space around the origin. We validate these two distinct learning models on various continuous-variable (CV) states, demonstrating their training data efficiency in reconstructing the entire Wigner function. This framework can be naturally applied to other interesting CV states and phase space functions.

A fundamental challenge in continuous-variable quantum state tomography is to infer a continuous phase-space function from sparse, pointwise measurement data. In this paper, we formulate Wigner function reconstruction as a continuous-function learning problem. To address this, we develop two complementary machine learning methods. The first approach falls within a probably approximately correctly learning setting. By using regression models, we provide provably efficient learning algorithms for states with sparse Fock-space or coherent-state support—exemplified by binomial code states and cat states, respectively. For such states, the measurement complexity scales logarithmically with the Hilbert space cutoff to achieve low generalization error averaged over phase space. For states beyond the sparse-support regime, the second approach employs a neural network surrogate to implicitly represent Wigner functions that learns from a sparse grid and generalizes to arbitrary resolution. Numerical results demonstrate that this neural-network model can reconstruct Wigner functions of practical GKP states using far less measurements than that required for information completeness and enables reconstruction of quantum systems with a few hundred effective Hilbert space dimensions. Furthermore, this neural-network model is more robust to statistical errors than the regression models. Using circuit-QED experimental data, we show that Wigner function reconstructed by our model can reveal the dominant quantum error in the experiment, whereas conventional estimation methods can only resolve random noise.

I. INTRODUCTION

Continuous-variable (CV) quantum information is a key platform for quantum computing and quantum error correction. Unlike discrete-variable systems, CV quantum states reside in an infinite-dimensional Hilbert space and are naturally characterized by smooth quasiprobability distributions in phase space, most notably the Wigner function. The characterization of CV quantum states has long been a challenging problem. In recent years, experimental advances have enabled the measurement of Wigner functions and other quasiprobability distributions, allowing pointwise estimation of their values in phase space. This capability is now routine in platforms such as superconducting circuit quantum electrodynamics (QED) [1–6], ion traps [7, 8], and quantum acoustic systems [9].

Despite these progresses, reliably estimating the Wigner function over the entire phase space remains difficult as the photon number increases—even for a single-mode state. A central obstacle in Wigner tomography is that measurements performed at only finitely many phase-space points cannot directly determine a continuous phase-space function. Consequently, reliable reconstruction typically requires measurements on increasingly dense phase-space grids, leading to rapidly growing experimental and computational costs.

In recent years, artificial intelligence has emerged as a powerful tool for learning quantum states efficiently [10, 11]. On the theoretical side, most provably efficient learning algorithms for CV states have considered a different type of quantum measurements—Gaussian measurements, including homodyne and heterodyne measurements [12–17], which are commonly used in optical systems. Many theoretical efforts have focused on the sample complexity of learning the density matrices of CV states up to small trace-distance error [13, 18–20], following the traditional objectives of quantum state tomography. In parallel, deep neural network methods have also been applied to CV state tomography [21–23]. These methods target at reconstructing density matrices in a truncated Hilbert space, which is typically resource consuming, especially

for states with increasingly larger truncation dimensions. Therefore, a direct method for learning Wigner functions from sparse pointwise phase-space measurements remains lacking.

In this paper, we study the following problem: given an unknown continuous-variable (CV) quantum state, can we construct a classical model that learns its Wigner function from finite pointwise measurement data and enables prediction over phase space with low generalization error? Furthermore, how does the required training data complexity scale with the effective truncation dimension of the quantum state? To address these problems for a wide variety of relevant quantum states, we develop two complementary methods for learning phase-space representations of CV quantum states. Both methods learn a classical surrogate of the Wigner function of a CV state from a finite set of pointwise measurements. Once trained, the learned model maps arbitrary phase-space coordinates to the corresponding Wigner function values, thereby enabling the prediction of continuous Wigner functions (see Fig. 1). The first method is a linear regression model with a provable upper bound on its sample complexity. Specifically, for CV states with sparse support in the Fock basis or coherent-state basis, our regression model learns the Wigner function using a number of measurements that scales as $O(\log d)$, where d is the dimension of the truncated Hilbert space. The guarantee remains valid in the presence of statistical measurement noise. This result provides a rigorous example of how phase-space structure can substantially reduce measurement complexity. We demonstrate the effectiveness of this method on simulated binomial code states and cat states.

Although the regression model is efficient for CV states with sparse support, more general CV states require a learning approach that does not rely on prior assumptions about the state. To address this, we develop a second method: a deep neural network (DNN) model designed for states beyond the sparse-support regime. This model represents the Wigner function as a continuous neural surrogate, allowing evaluation at arbitrary phase-space coordinates after training on sparse noisy data. The numerical results on simulated Gottesman-Kitaev-Preskill (GKP) states with truncation dimensions exceeding 300 photons indicate that the sample complexity of our method scales approximately as $O(d^{0.76})$, substantially slower than the $O(d^2)$ scaling required for informational completeness. We further validate the neural network model on experimental data of GKP states used for demonstrating beyond break-even point performance in quantum error correction. In this setting, the learned model accurately reconstructs the Wigner functions of experimental states from sparse noisy data and successfully identifies the dominant quantum error—a task at which conventional estimation approaches fail.

These two learning models exhibit complementary strengths. By selecting tailored feature maps, the regression model outperforms the DNN model for CV states

with sparse support in the Fock-state or coherent-state bases. In contrast, the DNN model yields more accurate reconstructions for CV states beyond the sparse-support regime. Moreover, compared to the regression model, the DNN model is more robust to statistical errors and practical noise, making it better suited for application to experimental data.

This paper is structured as follows. Section II provides a brief introduction to the Wigner functions of CV quantum states and their associated measurements. Section III presents a provably efficient regression model for learning the Wigner functions of CV states with sparse Fock-state or coherent-state support, substantiated by numerical simulation results on binomial code states and cat states, respectively. Section IV introduces a neural network model for learning the Wigner functions of CV states, including GKP states and randomly prepared CV states, with particular emphasis on the application of this neural model to experimental data. Section V discusses a comparison between the two learning models. Section VI concludes the paper by summarizing its key results and outlines future research directions.

II. WIGNER FUNCTIONS AND THEIR MEASUREMENTS

Phase-space representations provide a powerful and intuitive framework for describing quantum states, particularly for CV systems [24]. Instead of representing a quantum state by a density operator acting on an infinite-dimensional Hilbert space $\mathcal{H} := \text{span}_{n \in \mathbb{N}}\{|n\rangle\}$, phase-space methods map the density operator to a quasi-probability distribution over phase space (x, p) with x denoting position and p denoting momentum, enabling a direct connection between quantum mechanics and classical statistical descriptions. A central object in phase-space quantum mechanics is the characteristic function, defined as the expectation value of the displacement operator

$$D(\alpha) := e^{\alpha \hat{a}^\dagger - \alpha^* \hat{a}}, \quad (1)$$

where $\hat{a}$ and $\hat{a}^\dagger$ are the annihilation and creation operators, $\alpha = \frac{x+ip}{\sqrt{2}}$ is complex, and α^* is its complex conjugate. For a quantum state ρ on $\mathcal{H}$, the characteristic function $C_\rho(\alpha) = \text{tr}(\rho D(\alpha))$ contains full information about ρ and serves as the Fourier transform of various phase-space quasi-probability distributions. Throughout the paper, we will use $\alpha \in \mathbb{C}$ and $(x, p) \in \mathbb{R}^2$ interchangeably to represent a point in phase space.

Among the family of phase-space distributions, the Wigner function $W_\rho(\cdot)$ occupies a distinguished position. Defined as the Fourier transform of the characteristic function $C_\rho(\cdot)$, i.e., $W_\rho(\alpha) = \frac{1}{\pi^2} \int_{\mathbb{R}^2} d^2\beta C_\rho(\beta) e^{\alpha\beta^* - \alpha^*\beta}$, the Wigner function offers a real-valued representation of a quantum state on phase space. Although it resembles a classical probability distribution, the Wigner function may take negative values, which are widely regarded as

signatures of nonclassicality and known as Wigner negativity. These features make the Wigner function a central tool for visualizing quantum interference effects and characterizing genuinely quantum resources.

The value of a Wigner function can be directly measured in experiments [25]. As

$$W_\rho(\alpha) = \frac{1}{\pi} \text{tr}(\rho D(-\alpha)(-1)^{\hat{n}} D(\alpha)), \quad (2)$$

the Wigner function value at α can be measured by performing a displacement operation $D(-\alpha)$ and then detecting the resulting photon parity $(-1)^{\hat{n}}$, where $\hat{n} = \hat{a}^\dagger \hat{a}$ is the photon number operator. Each shot of measurement yields a positive one for even parity and a negative one for odd parity. Averaging them over many shots asymptotically reaches the value of Wigner function.

A direct measurement of a phase-space function can provide estimates only at a finite set of selected points. A straightforward strategy to reconstruct the Wigner function is to measure the function values on a sufficiently fine-grained grid within a supported region in phase space and use the resulting discretized values as the approximation to the continuous function. However, its cost is controlled by the number of phase-space points required to resolve the relevant structures of the Wigner function. For highly nonclassical states, especially states with large photon numbers, the required grid can become prohibitively dense. See Section VII C for a formal analysis of its sample complexity.

To recover its value at an arbitrary intermediate point, interpolation techniques, such as Lagrange interpolation, can be applied [26]. Although existing interpolation-based approaches have been successfully applied to the tomography of small-scale CV states, they still face limitations in the sparse and noisy regime. Lagrange interpolation can exactly fits all data points, but this exactness also makes it highly sensitive to practical noise in Wigner tomography: even small estimation errors can lead to large deviations in the reconstructed Wigner function. Meanwhile, its computational cost also increases rapidly with the number of data points and with the dimension of the phase space. Local interpolation methods, such as bilinear interpolation, are typically more stable, but they rely only on nearby measured values and therefore require dense sampling to recover fine-grained structures and high-frequency features of the original Wigner distribution. These limitations motivate a different approach: instead of treating phase-space tomography as grid-based reconstruction followed by interpolation, we formulate it as a function-learning problem, where a classical learning model is trained to infer continuous Wigner-function values from sparse and noisy pointwise measurements.

FIG. 1: Schematic diagram of the learning model used to reconstruct Wigner functions of quantum states in phase space. Using Wigner function measurement data collected at a sparse set of phase-space points (e.g., randomly sampled from a probability distribution over phase space or a predetermined grid), we train a model to learn the quantum state's Wigner function. After training, the model can predict the Wigner function value at any arbitrary point in phase space.

III. LEARNING SPARSELY SUPPORTED CV STATES WITH REGRESSION MODELS

This section develops a sparse regression model to learn the Wigner function of a single-mode continuous-variable state over phase space, using limited measurement data on different phase-space points. This framework is applied to two practically relevant classes of states: those with sparse Fock support and those with sparse coherent state support. For each class, we construct an explicit feature map and provide a provable upper bound on the training data complexity that scales logarithmically with the system dimension. Finally, numerical examples involving binomial code states and cat states corroborate our theoretical findings.

A. Provably efficient surrogates of Wigner functions

The aim of this subsection is to construct a classical surrogate of a single-mode CV state with a provable upper bound on the number of measured phase-space points required for achieving a low prediction error. In quantum learning theory, classical surrogates reconstruct the expectation value behavior of a quantum system with classical input parameters, and have been thoroughly explored in many-body ground states [27, 28] and quantum circuits [29–31]. For this purpose, we formulate the Wigner-function reconstruction as a sparse regression problem, where a linear regression model approximates the target as a linear combination of independent features with sparse coefficients. A linear regression model involves three steps: data collection, feature mapping, and model training. In the following, we explain these

three stages sequentially.

a. Data collection. The first step corresponds to obtaining accurate values of the Wigner function on a set of phase-space points. The dataset

$$\mathcal{T} := \{(\alpha_i, y_i)\}_{i=1}^{\mathcal{N}} \quad (3)$$

consists of the statistical estimates y_i of $W(\alpha_i)$ at $\mathcal{N}$ distinct phase-space points $\{\alpha_i\}_{i=1}^{\mathcal{N}}$, where each α_i is sampled from a distribution $\mathbb{D}$, e.g., a uniform distribution over a specified phase-space region.

b. Feature mapping. A feature mapping consists of selecting an appropriate set of linearly independent functions $\Phi_\omega(\cdot) : \alpha \in \mathbb{C} \mapsto \Phi_\omega(\alpha) \in \mathbb{R}$ using prior assumptions on the target state. The resulting feature space is spanned by $\{\Phi_\omega(\cdot)\}_{\omega=1}^{d_f}$, where d_f is the dimension of the feature space. The feature map Φ is the collection of these basis functions, defined as

$$\alpha \mapsto \Phi(\alpha) := (\Phi_1(\alpha), \Phi_2(\alpha), \dots, \Phi_{d_f}(\alpha))^T \in \mathbb{R}^{d_f}. \quad (4)$$

The surrogate of the Wigner function associated with the feature map Φ is a linear function of the form

$$\widehat{W}_\eta(\alpha) := \langle \eta, \Phi(\alpha) \rangle, \quad (5)$$

where $\eta := (\eta_1, \eta_2, \dots, \eta_{d_f})$ denotes the trainable parameters of the regression model $\widehat{W}_\eta$, and $\langle \cdot, \cdot \rangle$ denotes the inner product. Without confusion, $\widehat{W}$ tacitly implies $\widehat{W}_\eta$ with some suitable feature map Φ .

c. Model training. In this step, the parameters η are learned using the dataset $\mathcal{T}$. Define the empirical error, i.e., the average prediction error over the training data points in $\mathcal{T}$ as

$$\widehat{R}_\mathcal{T}(\widehat{W}_\eta) := \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} |\widehat{W}_\eta(\alpha_i) - y_i|^2, \quad (6)$$

then the optimal $\boldsymbol{\eta}$ is obtained by solving the following least absolute shrinkage and selection operator (Lasso) optimization

$$\min_{\boldsymbol{\eta}} \widehat{\mathbf{R}}_{\mathcal{T}}(\widehat{W}_{\boldsymbol{\eta}}) \quad \text{subject to} \quad \|\boldsymbol{\eta}\|_1 \leq t. \quad (7)$$

where $\|\boldsymbol{\eta}\|_1 = \sum_{i=1}^{d_f} |\eta_i|$. The ℓ_1 -regularization hyperparameter t serves two purposes. First, it determines the hypothesis class $\{\widehat{W}_{\boldsymbol{\eta}} : \|\boldsymbol{\eta}\|_1 \leq t\}$, i.e., the space of functions in which the Lasso optimization algorithm searches. Second, it controls the sparsity of the linear regression model in the feature space. In other words, if t is small, then the solution to Eq. (7) contains more zero entries.

Finally, the performance of the model is evaluated by the generalization error, also known as the expected squared error:

$$\mathbf{R}(\widehat{W}) := \mathbb{E}_{\alpha \sim \mathbb{D}} \left| \widehat{W}(\alpha) - W(\alpha) \right|^2. \quad (8)$$

In other words, the regression model $\widehat{W}_{\tilde{\boldsymbol{\eta}}}$ with optimized parameters $\tilde{\boldsymbol{\eta}}$ is guaranteed to accurately predict the value of the Wigner function $W(\alpha)$ at any phase-space point α sampled from $\mathbb{D}$ (the same distribution from which the training data points are drawn).

This formulation of the problem fits naturally within the framework of probably approximately correct (PAC) learning of quantum states [32], where the learning model is required to achieve a small generalization error with high probability. Note that this setting differs slightly from the standard quantum state tomography task, where performance is typically evaluated using distances between quantum states, such as fidelity or trace distance. In contrast, we treat the problem as a classical function approximation task, where the regression model reconstructs a function that is close to the target Wigner function. The use of squared loss is both computationally convenient and theoretically well-motivated, as it enables us to leverage tools from statistical learning theory to derive rigorous generalization bounds. Despite this distinction, our numerical experiments on a wide class of interesting CV states in Section III B and Section VII E 1 demonstrate that the generalization error remains an accurate proxy for the Wigner fidelity when $\mathbb{D}$ is taken as the uniform distribution.

The main task then is to determine the number of training data $\mathcal{N}$, i.e., the number of different pointwise measurement settings in phase space, for the regression model to achieve a low generalization error. Without additional assumptions on the target state, the training data required to reconstruct the entire phase space scales as $O(d^2)$, where d denotes the truncated dimension (see Proposition 2 in Section VII C).

Here, we leverage the sparse nature of Lasso regression to achieve improved training data complexity for two broad classes of single-mode CV states. The first class comprises states sparse in the Fock support, with binomial code states serving as the canonical example. The

second class consists of states sparse in coherent-state support, exemplified by cat states. The corresponding feature map involves the generalized Laguerre polynomials and the Gabor frame, respectively. Our main results, given by Theorem 1 and Theorem 2, demonstrate that the required number of training data points in both cases scale quartically with the sparsity and only logarithmically with the relevant dimension.

1. States with sparse Fock support

First, we consider states that are sparsely supported in the Fock basis. Recall that $\mathcal{H} := \text{span}_{n \in \mathbb{N}} \{|n\rangle\}$, therefore, a natural representation of any CV state ρ on a truncated Hilbert space $\text{span} \{|n\rangle\}_{n=0}^d$ is given by $\rho = \sum_{n,m=0}^d \rho_{mn} |m\rangle\langle n|$. Here, we neglect the truncation error from the infinite dimensional Hilbert space. Then, a state is said to be s -sparse in the Fock operator basis if it satisfies

$$\sum_{n,m=0}^d \mathbb{1}\{\rho_{mn} \neq 0\} \leq s^2. \quad (9)$$

A natural feature map in this setting is the Wigner function of the Fock operator basis $|m\rangle\langle n|$,

$$\Phi = \{\Phi_{m,n}(\alpha) = W_{|m\rangle\langle n|}(\alpha) : 0 \leq n, m \leq d\}, \quad (10)$$

with feature dimension $d_f = (d+1)^2$. In terms of the Wigner function, it is expressed as

$$W_{|m\rangle\langle n|}(\alpha) = \frac{1}{\pi} (-1)^m \sqrt{\frac{m!}{n!}} (2\alpha)^{n-m} L_m^{(n-m)}(4|\alpha|^2) e^{-2|\alpha|^2} \quad (11)$$

where

$$L_m^{(n-m)}(x) = \frac{e^x x^{-(n-m)}}{m!} \frac{d^m}{dx^m} (e^x x^n), \quad x \in \mathbb{R}, \quad (12)$$

is the generalized (associated) Laguerre polynomial of degree m [33]. With the selected feature map, the regression model in Eq. (5) becomes

$$\widehat{W}_{\boldsymbol{\eta}}(\alpha) = \sum_{n,m=0}^d \eta_{m,n} \Phi_{m,n}(\alpha). \quad (13)$$

In this case, the learning algorithm is essentially fitting the coefficients of the density matrix ρ_{mn} . Intuitively, although all basis functions are present, the effective dimension of the system is controlled by the sparsity s instead of the truncation dimension d . Therefore, we expect that the training data complexity to be much more frugal than the naive $O(d^2)$ scaling. The following theorem makes this intuition rigorous, with the proof deferred to Section VII A.

Theorem 1. *For any $\epsilon, \delta > 0$, suppose that the state under consideration is s -sparse as defined in Eq. (9), and*

every training data pair in $\mathcal{T}$ satisfies $|W(\alpha_i) - y_i| \leq \sqrt{\epsilon/4}$. Let $\widehat{W}$ be the regression model with optimal parameters obtained by solving Eq. (7). If the empirical error satisfies $\widehat{R}_{\mathcal{T}}(\widehat{W}) \leq \epsilon/2$, then a training data of size

$$\mathcal{N} = O\left(\frac{s^4}{\epsilon^2} \log \frac{d}{\delta}\right) \quad (14)$$

suffices to achieve $R(\widehat{W}) \leq \epsilon$ for any distribution $\mathbb{D}$ with probability at least $1 - \delta$.

The theorem shows that if the target state is s -sparse in the Fock basis, then the training data complexity scales as $O(s^4 \log d)$, where d is the truncation dimension of the Hilbert space. In particular, when $s = O(1)$, the complexity becomes independent of d up to logarithmic factors, indicating highly efficient learnability in this regime. On the contrary, in the limit where $s^2 \approx d^2$, this regression model amounts to full Wigner tomography, and the complexity reduces to $\mathcal{N} = O(d^2 \log d)$, recovering the lower bound up to a logarithmic factor.

We suppose that the target state is a superposition of s distinct coherent states

$$|\psi\rangle = \sum_{i=1}^s a_i |\alpha_i\rangle, \quad (16)$$

where $|\alpha_j| \leq R$ for all $j \in [s]$ with $[s] := \{1, \dots, s\}$, and the coefficients $a_i \in \mathbb{C}$ are properly normalized. We call a CV state s -sparse in coherent state support if it can be written as such a superposition of s coherent states. In addition, we require that the amplitudes of these coherent states be sufficiently distinct from each other so that

$$|\alpha_j - \alpha_\ell| \geq \Delta_\alpha \quad (17)$$

2. States with sparse coherent state support

Next, we consider states that are sparse in the coherent state basis. For any $\alpha \in \mathbb{C}$, the coherent state is

$$|\alpha\rangle = D(\alpha)|0\rangle = e^{-\frac{|\alpha|^2}{2}} \sum_{n=0}^{\infty} \frac{\alpha^n}{\sqrt{n!}} |n\rangle. \quad (15)$$

for all $j, \ell \in [s]$ and $j \neq \ell$. To identify a suitable feature map for learning states in Eq. (16), we examine the Wigner function of $|\psi\rangle\langle\psi| = \sum_{i,j=1}^s a_i a_j^* |\alpha_i\rangle\langle\alpha_j|$. Note that for any coherent states $|\alpha_i\rangle$ and $|\alpha_j\rangle$, the Wigner function of the operator $|\alpha_i\rangle\langle\alpha_j|$ is

$$W_{|\alpha_i\rangle\langle\alpha_j|}(\alpha) = \frac{1}{\pi} \exp\left(2i\Im\left[(\alpha_j^* - \alpha_i^*)\alpha + \frac{1}{2}\alpha_j^* \alpha_i\right]\right) \exp\left(-2\left|\alpha - \frac{\alpha_i + \alpha_j}{2}\right|^2\right), \quad (18)$$

where $\Im[\cdot]$ denotes the imaginary part of a complex number. Since $|\alpha_i\rangle\langle\alpha_j|$ is not Hermitian, its Wigner function is complex-valued. Equation (18) is proportional a two-dimensional Gaussian function centered at $\frac{\alpha_i + \alpha_j}{2}$ in phase space, modulated by a phase factor $e^{2i\Im[(\alpha_j^* - \alpha_i^*)\alpha]}$ at each α .

Based on the observation in Eq. (18), we define a set of functions for positive real numbers a and b :

$$\mathcal{G}(a, b) := \left\{ \Phi_{n,k}(\alpha) = \exp(2\pi i \langle bn, \alpha \rangle) \exp(-\pi |\alpha - ak|^2) : \mathbb{R}^2 \rightarrow \mathbb{C} \right\}_{n=(n_1, n_2), k=(k_1, k_2) \in \mathbb{Z} \times \mathbb{Z}}, \quad (19)$$

where, with a slight abuse of notation, $\alpha = (x/\sqrt{2}, p/\sqrt{2}) \in \mathbb{R}^2$.

$\mathcal{G}(a, b)$ is an infinite set of two-dimensional Gaussian functions located on a lattice $a\mathbb{Z} \times a\mathbb{Z}$ (indexed by k with spacing a in phase space), each modulated by a phase with frequency multiples of b (indexed by n). When $ab < 1$, $\mathcal{G}(a, b)$ forms an overcomplete basis in the space of integrable functions $L^2(\mathbb{R}^2)$ [34, 35]. This set of functions is known as a Gabor frame [34], where frames generalize the notion of bases in a Hilbert space by allowing overcompleteness. Gabor frames have important applications in time-frequency analysis (see Section VII B 1 for a preliminary review of frame theory and Section VII B 2

for Gabor frames). To express the Gabor frame in a more concise manner, we define the translation operator $(T_{ak}f)(\alpha) = f(\alpha - ak)$ and the modulation operator $(M_{bn}f)(\alpha) = \exp(2\pi i \langle bn, \alpha \rangle) f(\alpha)$ for any function $f : \mathbb{R}^2 \rightarrow \mathbb{C}$ and use $g(\alpha) = e^{-\pi |\alpha|^2}$ to denote the two-dimensional Gaussian function. Then (19) is reformulated as $\mathcal{G}(a, b) := \{(M_{bn} T_{ak} g)(\cdot) : n, k \in \mathbb{Z}^2\}$.

Since any physical state has bounded energy, instead of considering an infinite lattice in both the phase space indexed by k and the frequency space indexed by n , we only need to consider a finite region indexed by both

truncated values of k and n . This enables us to consider a finite lattice in both the phase space and the frequency space, determined by parameters $N, K \in \mathbb{N}$ as

$$\Lambda_{N,K} := \{(n, k) \in \mathbb{Z}^2 \times \mathbb{Z}^2 : \|n\|_\infty \leq N, \|k\|_\infty \leq K\}, \quad (20)$$

where $\|x\|_\infty = \max_i |x_i|$ is the maximum element of the vector x . The resulting feature map for learning sparse coherent states is

$$\Phi = \{\Phi_{n,k}(\alpha) = (M_{bn} T_{ak} g)(\alpha) : (n, k) \in \Lambda_{N,K}\}, \quad (21)$$

with feature dimension $d_f = (2N+1)^2(2K+1)^2$, and the corresponding regression model becomes

$$\widehat{W}_\eta(\alpha) = \sum_{(n,k) \in \Lambda_{N,K}} \eta_{n,k} \Phi_{n,k}(\alpha). \quad (22)$$

In practice, to obtain a real-valued Wigner function, by converting the modulation $e^{2\pi i \langle bn, \alpha \rangle}$ into $\cos(2\pi \langle bn, \alpha \rangle)$ and $\sin(2\pi \langle bn, \alpha \rangle)$, we split each function $\Phi_{n,k}$ into two: $\Phi_{n,k,1} = \cos(2\pi \langle bn, \alpha \rangle) T_{ak} g$ and $\Phi_{n,k,-1} = \sin(2\pi \langle bn, \alpha \rangle) T_{ak} g$. Then the regression model in Eq. (22) becomes $\widehat{W}_\eta(\alpha) = \sum_{(n,k) \in \Lambda_{N,K}} \eta_{n,k,\pm 1} \Phi_{n,k,\pm 1}(\alpha)$.

With this feature map, an analogous training data complexity bound is obtained for learning states with sparse coherent-state basis.

Theorem 2. *Let the target state be given by Eq. (16) and satisfy the condition Eq. (17). Set $\kappa = 1 - (s-1)e^{-\frac{1}{2}\Delta_\alpha^2}$ and let $\widehat{W}$ be the regression model obtained by solving Eq. (7). For any $\epsilon, \delta > 0$, assume that all training data in $\mathcal{T}$ satisfies $|W(\alpha_i) - y_i| \leq \sqrt{\epsilon/4}$, then a training data of size*

$$\mathcal{N} = O\left(\frac{s^4}{\epsilon^2 \kappa^4} \log \frac{R}{\delta}\right) \quad (23)$$

suffices to achieve $R(\widehat{W}) \leq \epsilon$ for any distribution $\mathbb{D}$ with probability at least $1 - \delta$.

he proof is provided in Section VII B after the preliminaries are introduced. Under conditions $s = O(1)$ and $1/\kappa = O(1)$, the training data complexity scales only logarithmically with the phase-space region R . For a coherent state $|\alpha\rangle$, the mean photon number is $|\alpha|^2$. Therefore, a phase space region with $|\alpha| \leq R$ corresponds to a Hilbert space truncation of order $O(\sqrt{d})$.

Until now, we have considered only the training data complexity for the regression model. To determine the total sample complexity, we must know the number of samples m required to estimate a single point in phase space using displaced parity measurements. For both theorems, we tolerate an error of no more than $\sqrt{\epsilon/4}$ for each phase-space point estimate. By Hoeffding's inequality and the union bound, achieving an estimation precision of $\sqrt{\epsilon/4}$ for $\mathcal{N}$ phase-space points with failure probability less than δ requires $M = O(1/\epsilon \log(\mathcal{N}/\delta))$. Combining this

with Theorem 1 and Theorem 2, the sample complexities are $M\mathcal{N} = \tilde{O}(s^4 \log d \log(s \log d))$ for states with sparse Fock support and $M\mathcal{N} = \tilde{O}(s^4/\kappa^4 \log R \log(s/\kappa \log R))$ for states with sparse coherent state support, respectively.

However, one limitation remains, as the computational cost of training the regression model scales polynomially with the feature dimension. Specifically, we have $d_f = (d+1)^2 = O(d^2)$ and $d_f = (2N+1)^2(2K+1)^2 = O(N^2 K^2) = O(R^4) = O(d^2)$ for the feature map using generalized Laguerre polynomials and the Gabor frame, respectively. In both cases, a running time of $O(d^2 \log d/\epsilon^2)$ is required to achieve $\widehat{R}_\mathcal{T}(\widehat{W}) \leq \epsilon$ with standard Lasso solvers [36].

B. Numerical results on learning states with sparse supports

Next, we apply the regression models introduced above to learn the Wigner function of simulated CV states with sparse supports. We present two concrete examples: one is binomial code states with sparse supports in the Fock basis, while the other is cat states with sparse supports in the coherent state basis. To evaluate the performance of our model in the following numerical experiments, we use the overlap between the reconstructed Wigner function and the ground truth as a figure of merit,

$$\mathcal{F} := 2\pi \int_{\mathbb{R}^2} dx dp \widehat{W}(x, p) W(x, p), \quad (24)$$

which equals the quantum fidelity for a target pure state. In our calculation, the integral is approximated by a sum over a finite grid Γ of points,

$$\mathcal{F} \approx 2\pi \Delta \sum_{(x,p) \in \Gamma} \widehat{W}(x, p) W(x, p), \quad (25)$$

where Δ is the area of each cell in the grid. As $\mathcal{F}$ approaches unity, the reconstructed state converges toward the ground truth.

1. Learning binomial code states

An important class of states that are sparsely supported in the Fock basis is the binomial code states [37], which plays an essential role in bosonic quantum error correction. These states are superpositions of Fock states with amplitudes involving binomial coefficients:

$$|\bar{0}/\bar{1}\rangle_b := \frac{1}{\sqrt{2^N}} \sum_{p=\text{even/odd}}^{[0, N+1]} \sqrt{\binom{N+1}{p}} |p(S+1)\rangle, \quad (26)$$

where $(N, S) \in \mathbb{N} \times \mathbb{N}$ specifies different classes of binomial code states. Specifically, we consider the reconstruction of the state $|\bar{1}\rangle_b$ for various combinations of

parameters (N, S) . Here we choose the training data as the true Wigner function values on a set of phase-space points randomly chosen from a 147×147 grid. By applying the regression model designed for CV states sparse in Fock supports, we can predict the Wigner function values over all other phase space points on the grid.

Figures 2a and 2b plot the minimum number of training data points required by this regression model to reconstruct the Wigner function with fidelity exceeding 0.99. The truncation dimension here refers to the maximum photon number of the binomial code states considered, which ranges from 20 to 56.

In Fig. 2a, we fix N while increasing the value of S in Eq. (26). In this case, although the truncation dimension d grows, the number of Fock basis supports $\lceil (N+1)/2 \rceil$ remains constant. The results show no obvious change in the number of phase-space points required as d increases. This observation aligns with Theorem 1: when the CV states are supported on a constant number of Fock basis elements, the required number of phase-space points scales at most as $O(\log d)$.

In contrast, in Fig. 2b, we fix S and increase the value of N in Eq. (26). Here, the number of Fock basis supports increases with d . The number of required Fock basis support increases with d as $s^2 = Cd^2$ for some constant fraction $C < 1$. Nevertheless, the training data complexity remains substantially lower than d^2 , highlighting the potential of this regression model for efficient reconstruction of binomial code states. In Figs. 2c and 2d, we present examples of reconstructed Wigner functions of two binomial code states using our regression model, together with their associated training data points, indicated by crosses.

The numerical results above use training data $\mathcal{T}$ without statistical errors. In Figs. 2e and 2f, we plot the reconstruction fidelity against the number of measurement shots per phase space point. They correspond to the settings in Fig. 2a and Fig. 2b, respectively. Compared with neural network models, as discussed later, the regression model exhibits less robustness to statistical errors.

2. Learning cat states

The canonical examples of states that are sparse in the coherent state basis are the Schrödinger cat states. These are defined by

$$|\mathcal{C}_\alpha^\pm\rangle = \mathcal{N}_\alpha^\pm (|\alpha\rangle \pm |-\alpha\rangle), \quad (27)$$

where $\mathcal{N}_\alpha^\pm = [2(1 \pm e^{-2|\alpha|^2})]^{-1/2}$ is the normalization factor. In the following numerical experiments, we focus on even cat states $|\mathcal{C}_\alpha^+\rangle$ with different amplitudes α . Since each cat state is supported on two coherent states centered at α and $-\alpha$, it provides a natural test case for the regression model designed for CV states sparse in coherent-state support. We choose the training data as the true Wigner-function values on a set of phase-space

points randomly selected within a circular region covered by a 142×142 grid. For each state, the sampled phase-space region and the parameters of the Gabor feature map are chosen according to the coherent amplitude α to cover the region where the Wigner function has non-negligible values. The regression model is then trained with Gabor features and used to predict the Wigner function values on the full grid.

Figure 3a plots the minimum number of randomly sampled phase-space points required to reconstruct the Wigner function with fidelity exceeding 0.99 for cat states of varying amplitudes. We distinguish between the total number of randomly sampled phase-space points and the number of effective non-zero training points, namely, the sampled points located in the phase-space region where the Wigner function has non-negligible values. The latter provides a more accurate measure on the number of data points needed with varying truncation dimension, since the area of the nontrivial region in phase space remains constant regardless of the amplitude of α . As the truncation dimension d increases, the two quantities are empirically found to be $O(d^{1.4})$ and $O(d^{0.6})$, respectively.

The discrepancy between the numerical scaling and the logarithmic scaling provided in Theorem 2 can be attributed to two reasons. First, Theorem 2 provides a bound for the generalization error, which may not be a faithful proxy of the fidelity in this scenario. As most regions in the phase space take negligible values, one can imagine an extreme case in which setting every prediction to zero incurs only a small loss to the mean squared error while dramatically affecting the fidelity. Second, the constant factor in Theorem 2 may be potentially large, for which we are unable to pinpoint the exact values. Nonetheless, our numerical scaling still grows much more slowly than the $d^2 - 1$ scaling required for informationally complete Wigner tomography.

In Fig. 3b, we present representative reconstructions for four rotated cat states marked in Fig. 3a. For each state, the reconstructed Wigner function is compared to the corresponding ground truth. The regression model accurately captures both the two coherent state peaks and the interference fringes between them, achieving fidelities above 0.99 using only a small subset of the full phase-space grid.

Additionally, we apply the two regression models to states beyond the regime of sparse support, including experimental GKP states in Fig. 5 and experimental general states in Fig. 11. Unsurprisingly, the results are underwhelming. Specific details regarding the numerical implementations of the regression model and other results on simulated states can be found in Section VII E 1.

To recapitulate, although the regression model is theoretically efficient for states with sparse support, its statistical and computational advantages diminish for states without sparse support. This motivates the neural network model introduced in the next section.

FIG. 2: Reconstruction of Wigner functions for simulated binomial code states. **a**, the number of phase-space points required to achieve a fidelity of 0.99 with respect to the truncation dimension for a binomial code state with fixed $N = 3$ and increasing values of S . **b**, the number of phase-space points required to achieve a fidelity of 0.99 with respect to the truncation dimension for a binomial code state with fixed $S = 3$ and increasing values of N . In both **a** and **b**, the scaling required for information completeness in conventional Wigner tomography ($d^2 - 1$) is shown as a reference. **c**, Example reconstruction of the Wigner function for a binomial code state with $N=3$, $S=11$. Crosses indicate the 41 randomly selected training points on a 128×128 grid. The fidelity between the reconstruction and the ideal Wigner function is 0.9997. **d**, Same as **c** for $N=11$, $S=3$, using 166 training points. The fidelity is 0.9928. **e**, Fidelity of the reconstructed Wigner function as a function of the number of measurement shots per phase-space point, for binomial code states with fixed $N = 3$ and increasing values of S . **f**, Fidelity of the reconstructed Wigner function as a function of the number of measurement shots per phase-space point, for binomial code states with fixed $S = 3$ and increasing values of N .

IV. LEARNING CV STATES WITH NEURAL NETWORK MODELS

Although the regression model described above can be successfully applied to reconstruct important CV states, including binomial code states and cat states, with rigorous theoretical guarantees, its performance heavily de-

pends on the choice of feature maps. These choices, in turn, rely on prior knowledge about the CV states under consideration, specifically the support on which the states are sparse. When this sparsity condition is not satisfied or when no prior information about the state is available, the regression model may fail. To address this limitation, we require a different approach. It is well known that a neural network can in

FIG. 3: Reconstruction of Wigner functions for simulated cat states. **a**, The number of phase-space points required to achieve a fidelity > 0.99 with respect to the truncation dimension d for cat states with varying complex amplitudes α . The scaling required for information completeness in conventional Wigner tomography ($d^2 - 1$) is shown as a reference. The dashed and dotted lines indicate the empirical scaling of the total and non-zero required points, respectively. **b**, Example reconstructions of the Wigner functions for the four corresponding cat states marked in **a**. For each state, the reconstructed Wigner function (left) is compared with the ideal ground truth (right). The green circles on the left panels correspond to the centers ak of the Gaussians in the Gabor frame (Eq. (19)). The fidelities between the reconstructions and the ideal Wigner functions are 0.9931, 0.9986, 0.9900, and 0.9901, respectively.

principle approximate any arbitrary continuous function with arbitrary accuracy. For this reason, we introduce a neural network model for reconstructing Wigner functions. Unlike the previous method, this DNN model does not require prior knowledge of the CV state and is applicable to states beyond the regime of sparse Fock-state or coherent-state support.

Note that for any physical relevant CV states, their Wigner functions are smooth and fast decaying, falling within the Schwartz space. Thus, it is reasonable to consider Wigner functions within a finite region around phase space origin while ignore their values beyond the region. For those Wigner functions exhibiting learnable spatial patterns in phase space, analogous to images, we can apply super-resolution techniques for their re-

construction. Inspired by the success of neural implicit representations [38, 39], which is a high-resolution tool in computer vision, we employ a deep neural network to learn the Wigner function of CV quantum states from sparse measurement data. This approach is capable of robustly capturing fine-scale structures even from limited experimental data.

A. Neural-network surrogates of Wigner functions

We now describe how a neural network model learns to reconstruct an unknown phase-space function from measurements available at a discrete set of phase-space points, specifically a uniform grid. The learning proce-

699 dure of this neural network model can also be divided
700 into three stages, as with the regression model: data col-
701 lection, feature mapping, and model training. However,
702 these three stages for the DNN model are different from
703 those in the regression model. In the following, we eluci-
704 date them one by one.

705 *a. Data collection.* Suppose the Wigner function
706 under consideration is supported on a finite region $\Omega \subset$
707 $\mathbb{R}^2$, beyond which its values are negligible. We consider
708 a measurement dataset $\mathcal{T}$, where each α_i lies on a sparse
709 $m \times m$ phase-space grid Γ covering Ω , with each square
710 cell of size $h \times h$. Each data point $(\alpha, y_\alpha)_{\alpha \in \Gamma}$ provides an
711 estimate of the true Wigner function value $W(\alpha)$, pos-
712 sibly subject to statistical errors. Rather than directly
713 using the raw data $\mathcal{T}$ as training data (as was done in the
714 regression model), we preprocess $\mathcal{T}$ to obtain the train-
715 ing dataset for our DNN model. In this preprocessing,
716 we generate pairs of low- and medium-resolution datasets
717 from the original $m \times m$ measurement grid, achieved by
718 downsampling the measurement data using bilinear in-
719 terpolation. As a example, given measurement data at
720 23×23 phase-space points, we produce low-resolution
721 inputs ranging from 8×8 to 14×14 grids and medium-
722 resolution targets ranging from 15×15 to 23×23 grids.
723 All such pairs of low-and medium-resolution datasets
724 constitute our training dataset.

725 *b. Feature mapping.* Instead of manually selecting
726 feature maps based on prior physical knowledge, the fea-
727 tures here are mapped automatically by a deep neu-
728 ral network model. Our neural network model em-
729 ploys an encoder-decoder architecture tailored for super-
730 resolution reconstruction of the Wigner function. The
731 encoder, implemented as a convolutional neural network,
732 first extracts multi-scale continuous feature maps from
733 the input data. The multi-scale nature of the features
734 allows the encoder to capture information across differ-
735 ent levels of granularity, encompassing both fine-grained
736 structures and global patterns of the continuous func-
737 tion. Moreover, the continuity of these features enables
738 the model to predict function values at arbitrary points
739 in phase space.

740 For any phase-space coordinate α , the decoder, a mul-
741 tilayer perceptron, predicts the Wigner function value
742 $\widehat{W}(\alpha)$. This prediction is performed by integrating local
743 features interpolated from the phase-space neighborhood
744 around α , together with explicit coordinate and scale in-
745 formation. This architecture enables continuous predic-
746 tion of the Wigner function at arbitrary resolutions.

747 *c. Model training.* The model is trained in a self-
748 supervised manner, implying that the supervision la-
749 bels are generated from the measurement raw data
750 $\mathcal{T}$ rather than from externally labeled high-resolution
751 ground truth. The goal of training is to enable the neural
752 network to recover a medium-resolution Wigner function
753 provided with a low-resolution input. That is, for each
754 pair of low-and medium-resolution datasets, the network
755 is trained to accurately predict the medium-resolution
756 data using the associated low-resolution inputs. The net-

757 work parameters η are optimized by minimizing the pre-
758 diction error at a set of medium-sized grids $\{\tilde{\Gamma}\}$ of fiducial
759 phase-space points $\frac{1}{|\{\tilde{\Gamma}\}|} \sum_{\{\tilde{\Gamma}\}} \frac{1}{|\tilde{\Gamma}|} \sum_{\alpha \in \tilde{\Gamma}} |\widehat{W}(\alpha) - W(\alpha)|^2$.

760 Once trained, the model can take measurement
761 data sampled at only $m \times m$ points—potentially far
762 fewer than required for information-complete tomogra-
763 phy—and produce a continuous approximation of the
764 Wigner function that can be evaluated at arbitrary
765 phase-space coordinates. For example, given measure-
766 ment data at 23×23 phase-space points, the model is
767 used to predict a high-resolution Wigner function on a
768 finer 81×81 grid, over the same phase-space region. This
769 network takes an arbitrary phase-space coordinate (x, p)
770 in the finer grid as input and outputs a prediction of
771 its Wigner function value $\widehat{W}(x, p) \in [-\frac{1}{\pi}, \frac{1}{\pi}]$. This test
772 assesses the generalization performance over an out-of-
773 distribution dataset, since the network has not been ex-
774 posed to data at such high resolutions during training.

775 Instead of storing the discrete Wigner function values
776 explicitly, the continuous pattern of Wigner function is
777 implicitly encoded into the weights η of this DNN model,
778 enabling the estimation of Wigner function values at ar-
779 bitrary phase-space point. Thus, this DNN model can
780 be considered a neural implicit representation of a CV
781 state in phase space. Since Wigner function can be neg-
782 ative and is not a probability distribution in general, it
783 cannot be directly learned through a neural generative
784 model. Different from those generative models of neu-
785 ral quantum states [40–42], our neural network model is
786 trained for a regression task, approximating the unknown
787 continuous phase-space function of a CV state.

788 Note that the neural implicit representation of CV
789 states does not rely on any prior assumptions about the
790 underlying quantum states. In other words, we do not
791 require the CV state under consideration to lie within
792 a particular low-dimensional subspace or to belong to a
793 sparsely parameterized family of states. This general-
794 ity provides two key advantages. First, it enables the
795 model to learn a wide variety of physical CV states, in-
796 cluding those states beyond sparse supports, as long as
797 the state exhibits certain learnable structure in its phase-
798 space function. Second, this approach enhances robust-
799 ness to practical noise. When measurement data con-
800 tain statistical error and system noises, the neural net-
801 work model can still reconstruct the experimental Wigner
802 function faithfully.

803 B. Numerical results on learning CV states

804 1. Learning GKP states.

805 Inspired by the success of GKP states in quantum error
806 correction, we investigate learning the Wigner function
807 of a GKP state. An ideal GKP state is a grid state in
808 phase space composed of delta functions [43]. Since ideal
809 GKP states are not normalizable, we must consider prac-

tical GKP states consisting of superpositions of squeezed Gaussian peaks with a Gaussian envelop,

$$|\bar{0}/\bar{1}\rangle_{\text{GKP}} = \int_{-\infty}^{\infty} dx \psi_{0/1}(x) |x\rangle, \quad (28)$$

$$\psi_k(x) = \sum_{s \in \mathbb{N}} \exp(-2\pi\sigma^2 s^2) \exp\left[-\frac{(x - \sqrt{\pi}(2s+k))^2}{2\sigma^2}\right], \quad (29)$$

where $|x\rangle$ is a position eigenstate with eigenvalue $x \in \mathbb{R}$, σ^2 is the variance of each individual peak, and $1/\sigma^2$ characterizes the variance of the global envelope. In experiments, GKP states are usually superpositions of a finite number of Gaussian peaks. Specifically, the wavefunction of a realistic GKP $|\bar{0}\rangle_{\text{GKP}}$ can be written as

$$\psi_0(x) \approx \sum_{s=-s_{\max}}^{s_{\max}} \exp(-2\pi\sigma^2 s^2) \exp\left[-\frac{(x - 2\sqrt{\pi}s)^2}{2\sigma^2}\right], \quad (30)$$

where $2s_{\max} + 1$ denotes the number of Gaussian peaks. Larger $s_{\max}$ and smaller σ correspond to an increase in the effective Hilbert space dimension. We proceed to examine how the measurement complexity of our proposed methods for learning the state in (30) scales with this truncation dimension.

Learning simulated GKP states. We plot the sample complexity of our DNN model in reconstructing the Wigner function of simulated GKP states in Fig. 4. As illustrated in Fig. 4, the number of data points required by our algorithm to attain a fidelity above 0.99 scales roughly as $d^{0.7}$ for the noiseless GKP state in (30) — a significant improvement over the d^2 scaling. Each data point in Fig. 4 corresponds to a combination of $(\sigma, s_{\max})$, where smaller values of σ and larger values of $s_{\max}$ corresponds to higher truncation dimension.

Photon loss is a common quantum noise in bosonic quantum system to corrupt the quantum state. When photon loss errors are introduced, the resulting state becomes a mixed state. In this noisy case, the data requirement for achieving fidelity 0.99 further decreases, scaling approximately as $d^{0.48}$. This reduction of measurement complexity matches our intuition that photon loss error typically reduces the nonGaussianity of the state and hence reduces the difficulty to learn them.

In quantum state reconstruction, not only the measurement complexity but also the classical computational complexity affects the practical efficiency of the learning algorithm. We also compare the computational time required to obtain the density matrix using the conventional maximum likelihood estimation (MLE) approach against our proposed method based on Wigner function prediction. In both cases, the input consists of true values of the Wigner function evaluated on a 33×33 grid for a GKP state with parameters $\sigma = 0.4$ and $s_{\max} = 2$. For MLE, the objective is to find a density matrix in a truncated Hilbert space of dimension $d = 29$ that maximizes the likelihood of observing the given Wigner function values. In contrast, our neural network approach

aims to predict the Wigner function on a finer 81×81 grid. Reconstruction quality is evaluated in both cases by computing the fidelity between the reconstructed state and the ground truth. The results demonstrate that our neural network method is significantly faster, requiring only about 28 seconds to perform 30 optimization iterations, while producing predictions with fidelity close to one. In comparison, each iteration of MLE is substantially more time-consuming, and the method struggles to converge to the ground truth when using the same 33×33 data grid.

In the above discussion, each input data point corresponds to a true value of Wigner function at a phase-space point, but in practical experiment, finite number of measurements introduce statistical errors into the input data. To demonstrate how the number of measurement shots per data point influences reconstruction fidelity, we apply our trained model to simulated data of a finite number of measurement shots. Figure 4 shows the fidelity of the Wigner function reconstructed by our algorithm as a function of the number of shots per measurement, revealing that 500 shots per point are sufficient to achieve fidelity above 0.99. In this simulation, the number of input phase-space points is fixed to the minimum number required to reach fidelity 0.99 in the noiseless setting shown in Fig. 4. Five different combinations of $(\sigma, s_{\max})$ are studied, indicating that typically GKP states with smaller values of σ and higher values of $s_{\max}$ require more number of measurement shots per phase-space point to reach high reconstruction fidelity.

Learning experimental GKP states. To validate our approach under realistic conditions, we use experimental data from a noisy GKP state employed to demonstrate beyond-break-even quantum error correction [3]. The state is prepared in a circuit-QED cavity mode coupled to an auxiliary transmon qubit. The experimental data consist of Wigner-function measurements on an 81×81 phase-space grid, where each point corresponds to an empirical average over repeated measurement shots. For training the DNN model, we use only a sparse 27×27 subset of the measured data, while keeping the remaining measurements hidden during training. After training, the model predicts the Wigner function over the full 81×81 grid.

Figure 5 shows the reconstructed Wigner function for an experimentally prepared GKP logical-zero state $\rho_{\bar{0}}$, together with the experimentally measured reference data. The overlap between the reconstructed and measured Wigner functions exceeds 0.99, demonstrating excellent agreement. Here, the overlap quantifies the consistency between the reconstructed Wigner function and the experimental measurements, rather than the fidelity with respect to an ideal target state. We further compare the DNN predictions with those obtained from bilinear interpolation and the regression model. Bilinear interpolation yields substantially lower prediction accuracy than both learning-based approaches, while the regression models are noticeably less robust to experimental

FIG. 4: Reconstruction of Wigner functions for simulated GKP states. **a**, Comparison of the number of phase-space points required to achieve a fidelity of 0.99 for both a noiseless GKP state and a GKP state subject to photon loss, plotted against the dimension of the truncated Hilbert space. The scaling required for information completeness in conventional Wigner tomography ($d^2 - 1$) is shown as a reference. **b**, Detailed view of the data requirements presented in **a**, showing the number of phase-space points needed for reconstructing ideal and lossy GKP states as a function of truncation dimension. **c**, Reconstructed Wigner function for a noiseless GKP state ($\sigma = 0.11, s_{\max} = 3$) using 3025 phase-space points, achieving a fidelity of 0.99. Black crosses mark the measurement grid. **d**, Reconstructed Wigner function for the same GKP state subject to photon loss, where only 1521 phase-space points are required to reach fidelity 0.99. **e**, Comparison of classical computational time between density matrix reconstruction via maximum likelihood estimation (MLE) and Wigner function prediction using our neural network approach for a GKP state ($\sigma = 0.4, s_{\max} = 2$), along with the corresponding fidelities achieved. All computational runtimes were evaluated on an x86_64 system running Ubuntu 22.04.5 LTS. **f**, Fidelity of the reconstructed Wigner function as a function of the number of measurement shots per phase-space point, shown for GKP states with varying squeezing parameters and numbers of Gaussian peaks.

FIG. 5: Reconstruction of measured Wigner functions for experimental GKP states. From upperleft to downright panels: the training dataset, downsampled to a 27×27 grid from the original experimental measurements; the full experimental data collected on an 81×81 grid; the Wigner function reconstructed via bilinear interpolation from the 27×27 grid; the Wigner function reconstructed by the regression models using Laguerre feature map, the Wigner function reconstructed by Gabor frame feature maps, and the Wigner function predicted by our neural network model. In the predicted Wigner function, each cross marks a phase-space point belonging to the original 27×27 measurement grid.

noise than the DNN model.

To further assess the practical performance of the DNN approach, we consider experimentally prepared GKP states subjected to multiple rounds of quantum error correction. Specifically, we study the states $\rho_0(t)$ and $\rho_1(t)$ after $t = 0, 100, 200, 400$, and 800 QEC cycles implemented in Ref. [3]. Each cycle consists of an auxiliary-qubit measurement followed by an outcome-dependent correction protocol designed to suppress quantum decoherence. For each state, we use measurements on a sparse 27×27 grid to reconstruct the Wigner function over the full 81×81 grid. The reconstructed Wigner functions, together with the experimentally measured references, are shown in Fig. 6.

The reconstructed Wigner functions further enable identification of the experimental logical subspace and its associated dominant error subspace. To this end, we reconstruct density matrices in a truncated Hilbert space of dimension $d = 32$ from the Wigner-function data using maximum-likelihood estimation, following Ref. [3]. We denote the density matrices reconstructed from the DNN-predicted Wigner functions by ρ_{DNN} and those reconstructed from the full experimental measurements by ρ_{EXP} .

To analyze the logical and error subspaces, we perform

the spectral decomposition of the mixed state

$$\rho_{\text{mix}}(t) = \frac{\rho_0(t) + \rho_1(t)}{2}, \quad (31)$$

yielding

$$\rho_{\text{mix}} = \lambda_0 |\tilde{0}\rangle \langle \tilde{0}| + \lambda_1 |\tilde{1}\rangle \langle \tilde{1}| + \lambda_2 |E_0\rangle \langle E_0| + \lambda_3 |E_1\rangle \langle E_1| + \dots, \quad (32)$$

where the eigenvalues satisfy $\lambda_0 \geq \lambda_1 \geq \lambda_2 \geq \lambda_3$. The subspace spanned by $|\tilde{0}\rangle, |\tilde{1}\rangle$ defines the experimental logical subspace, which deviates from the ideal logical subspace spanned by $|\bar{0}\rangle, |\bar{1}\rangle$ due to experimental imperfections. Similarly, the subspace spanned by $|E_0\rangle, |E_1\rangle$ corresponds to the dominant error subspace.

Figure 7 visualizes the Wigner functions associated with the reconstructed logical and dominant error subspaces for different QEC cycles. We compare results obtained from three different sources: sparse 27×27 experimental measurements, full 81×81 experimental measurements, and the DNN-predicted 81×81 Wigner functions reconstructed from sparse input data. The results show that the DNN reconstruction preserves not only the Wigner function itself, but also the logical and error-subspace structures inferred from the reconstructed density matrix.

To further identify the physical origin of the dominant error, we focus on the most probable error subspace at

FIG. 6: Wigner functions of the two logical states ρ_0 and ρ_1 at QEC rounds $t = 0, 100, 200, 400, 800$. Each pair of rows shows the DNN-reconstructed (top) and experimental (bottom) Wigner function.

$t = 0$, shown in Fig. 8. Specifically, we plot the Wigner
 function of the normalized projector $\frac{|E_0\rangle\langle E_0| + |E_1\rangle\langle E_1|}{2}$, ob-
 tained from the spectral decomposition above. For compar-
 ison, we also plot the Wigner function of the normal-
 ized operator $\hat{a}^\dagger(|\bar{0}\rangle + |\bar{1}\rangle)(\langle\bar{0}| + \langle\bar{1}|)\hat{a}$, which corresponds
 to the ideal error subspace generated by photon-addition
 errors. Such photon-addition processes correspond to
 heating noise in the cavity mode and were experimen-
 tally observed in the same platform for $t = 100, 200, 400$,
 and 800 QEC cycles in Ref. [3]. As shown in Fig. 8, the
 error-subspace Wigner function inferred from the DNN
 reconstruction exhibits a much clearer resemblance to the
 photon-addition error pattern than reconstructions ob-
 tained directly from sparse experimental measurements
 or even from the full experimental dataset.

2. Learning randomly prepared CV states

In this subsection, we apply our neural network model
 to learn the Wigner functions of a broader class of
 states, including CV states prepared by displacement
 and selective number-dependent arbitrary phase (SNAP)
 gates [44]. The combination of displacement operators
 and SNAP gates has been used to prepare many types
 of important single-mode non-Gaussian states in circuit
 QED [45]; therefore, the output states prepared by these
 gates serve as good testbeds for our DNN model.

For a single-mode CV state, the set of displacement
 operators $D(\alpha)$ and SNAP gates $\text{SNAP}(\theta)$ form a uni-
 versal gate set [46], which has been widely applied for
 preparing important classes of bosonic code states and
 Wigner-negative states [45, 47]. The displacement oper-

FIG. 7: Wigner functions of the logical and most probable error subspaces. We analyze the mixture $\rho_{\text{mix}}(t) = (\rho_0(t) + \rho_1(t))/2$ at QEC rounds $t = 0, 100, 200, 400, 800$. Within each subfigure, the left side shows the Wigner function of the normalized projection onto the experimental logical subspace $(|\tilde{0}\rangle\langle\tilde{0}| + |\tilde{1}\rangle\langle\tilde{1}|)/2$ (which deviates from the ideal subspace due to experimental imperfections), and the right side shows the normalized projection onto the most probable error subspace $(|E_0\rangle\langle E_0| + |E_1\rangle\langle E_1|)/2$ obtained from Eq. (31). These projected states are computed from ρ_{mix} via Maximum Likelihood Estimation (MLE) using three different inputs (from left to right): **a**, experimental data on a 27×27 grid; **b**, experimental data on an 81×81 grid; and **c**, DNN-predicted Wigner functions on an 81×81 grid upsampled from the 27×27 input.

ator $D(\alpha)$ is defined in Eq. (1). A SNAP gate is

$$\text{SNAP}(\theta) := \sum_{n \in \mathbb{N}} \exp(i\theta_n) |n\rangle\langle n|, \quad (33)$$

where $\theta = \{\theta_n\}_{n \in \mathbb{N}}$ denote the phases on different Fock basis.

Here we investigate learning the Wigner functions of quantum states prepared by a sequence of quantum gates consisting of displacement gates and SNAP gates. Each layer of gates consists of a displacement gate $D(\alpha)$ followed by a SNAP gate $\text{SNAP}(\theta)$. Here the displacement amount α in each displacement gate is randomly chosen within $|\alpha| \leq 1.5$, and each θ_i in θ are randomly selected within $[0, 2\pi)$. For each state, we truncate the Hilbert

space to $d = 30$. Given Wigner function values at points at 18×18 phase-space grid points, the neural network reconstruct the Wigner function at a finer grid of 81×81 within the same region in phase space.

Figure 9a shows the reconstruction fidelity as a function of the number of gate layers. As the circuit depth increases, the average reconstruction fidelity decreases from nearly unity to approximately 0.8 when the same amount of training data is used. Intuitively, applying additional gate layers generates increasingly intricate phase-space structures, making the corresponding Wigner functions more difficult to learn accurately. One possible measure of this complexity is the Wigner negativity [48], defined as $\int_{\mathbb{R}^2} dx dp |W_\rho(x, p)|$. To further examine this connec-

FIG. 8: The Wigner function of the projection onto the most probable error subspace. From left to right, we show the Wigner functions of $(|E_0\rangle\langle E_0| + |E_1\rangle\langle E_1|)/2$ computed from ρ_{mix} using experimental data on a 27×27 grid, using experimental data on an 81×81 grid, and using the Wigner function predictions on an 81×81 grid generated by our DNN model, respectively. The rightmost panel shows, for reference, the Wigner function of $\hat{a}^\dagger(|\bar{0}\rangle + |\bar{1}\rangle)(\langle\bar{0}| + \langle\bar{1}|)\hat{a}$, up to normalization.

tion, Fig. 9b plots the reconstruction fidelity versus the Wigner negativity for all generated states. The results show that small Wigner negativity has little observable effect on the reconstruction fidelity. However, beyond a certain regime, the reconstruction fidelity decreases approximately linearly as the Wigner negativity increases.

Figure 10 illustrates several examples of reconstructed Wigner functions together with the ground truth for different number of layers of quantum circuits. Instead of exhibiting a structural pattern, the patterns of the Wigner functions here are more random, but does not contain any high frequency oscillations. This feature makes our DNN model better fitted for learning these Wigner functions. Compared with the regression model using Gabor-frame feature map (see Fig. 14 and Fig. 15 in Appendix), our DNN model produces more accurate predictions typically.

We next consider an experimental CV state prepared by applying a SNAP gate to a coherent state. Here a coherent state $|\alpha\rangle$ is obtained by applying a displacement operation $D(\alpha)$ to a vacuum state $|0\rangle$, i.e. $|\alpha\rangle = D(\alpha)|0\rangle$. Specifically, the experimental state under consideration is prepared by applying a π phase shift to both the Fock components $|0\rangle$ and $|1\rangle$ of a coherent state $|\alpha\rangle$ with amplitude $\alpha = 1$. Note that this state is a special case of states considered in Fig. 9.

As Fig. 11 shows, using only 23×23 measurement points, the reconstruction overlap of our DNN model is above 0.98. This overlap is much higher than that reconstructed by our regression model, demonstrating the stronger robustness of the neural network model against experimental noise beyond GKP states. Remarkably, our method requires only approximately 500 measurement points (23×23), which is significantly fewer than the adversarial generative model [22]. Furthermore, the training of this neural network model is much more stable.

FIG. 9: Performance of the deep neural network model for output states prepared using random displacement and SNAP circuits. **a**, Reconstruction fidelity as a function of the number of circuit layers. **b**, Reconstruction fidelity versus the Wigner negativity of the corresponding output states.

FIG. 10: Examples of Wigner function reconstructions for states with various circuit depths L ranging from one to six, using a deep neural network model. Each pair of images shows the reconstructed Wigner function alongside the ground truth. The measurement data grid is also overlaid on the ground truth plots.

FIG. 11: Reconstructed of the measured Wigner function of an experimental state prepared by SNAP gate. From left to right: the training dataset downsampled to a 27×27 grid from the original experimental dataset; the full experimental data collected on a 81×81 grid; the Wigner function predicted by the regression models using Laguerre feature map, the Wigner function predicted by Gabor frame feature maps; and the Wigner function predicted by our neural network model.

V. DISCUSSIONS

In this paper, we have introduced two complementary machine learning algorithms for reconstructing Wigner functions from sparse pointwise measurements. The first is a sparse regression model, for which we theoretically

establish an upper bound on the training data complexity required to learn Wigner functions of states that are sparsely supported in both the Fock basis and the coherent state basis. The second is a neural network model that learns a neural implicit representation of the Wigner function from sparse data and can predict Wigner func-

tion values at arbitrary resolutions. This model is highly robust to practical noise and is applicable to experimental data. Despite their different implementations, both methods formulate Wigner-function reconstruction as a continuous-function learning problem, aiming to minimize the number of training samples required to achieve low expected generalization error while maintaining a small empirical error on the observed measurement data.

The two approaches differ slightly in their learning formalisms. In the first, theoretically motivated formalism, given measurement data at a set of points $\{\alpha_i\}$ randomly sampled from an arbitrary distribution $\mathbb{D}$, the learning model aims to minimize the expected prediction error of the Wigner function values $W(\alpha)$ when α is drawn from the same distribution $\mathbb{D}$. This formalism casts Wigner function learning as a PAC learning problem, for which we prove our main results in Theorem 1 and Theorem 2. In the second, experimentally motivated formalism, given measurement data on a coarse-grained grid, the learning model targets predicting Wigner function values on a fine-grained grid at arbitrary resolution beyond those encountered during training. This setting is closer to practical Wigner tomography experiments, in which measurements are typically performed over a grid of points within a region of phase space around the origin.

We demonstrate these two distinct learning models on various continuous-variable (CV) states. Below, we summarize and compare their performances on different types of states.

Binomial code states (sparse in the Fock basis). For these states, our regression model is provably efficient at reconstructing their Wigner functions. Numerical results in Fig. 2 show no apparent increase in measurement complexity as the system size grows. In contrast, the neural network model cannot faithfully reconstruct the Wigner functions of binomial code states using the same amount of measurement data. The Wigner functions of CV states with sparse Fock support are typically highly oscillatory in phase space, and our DNN model struggles to learn these high-frequency patterns. This is due to two reasons. First, we use smoothed interpolated data as training inputs, and this data bias leads the DNN model to favor learning smooth patterns in phase space. Second, the spectral bias of DNN models [49] makes them preferentially learn low-frequency patterns over high-frequency oscillatory ones.

Cat states (sparse in the coherent-state basis). Our regression model is also provably efficient for cat states. However, numerical results in Fig. 3 indicate that the measurement complexity scales faster than theoretically expected, primarily because the nonzero region of the Wigner function occupies a much smaller fraction of phase space as the system size increases. The measurement complexity required by our DNN model, as shown in Fig. 16, is substantially higher than that of the regression model. With limited data, the DNN model struggles to learn the highly oscillatory interference fringes near the phase-space origin, again due to the data bias and

spectral bias discussed above.

Practical GKP states. For these states, our DNN model requires lower measurement complexity than the regression model to achieve the same reconstruction accuracy (compare the performance of DNN model in Fig. 4 with that of the regression model using Laguerre feature maps in Fig. 13). Additionally, the DNN model exhibits greater robustness against statistical errors arising from finite measurement shots. On experimental data, the DNN model also provides much higher prediction accuracy relative to the experimental ground truth than the regression model.

Random CV states. The advantage of the DNN model over the regression model extends to general CV states prepared by random sequences of displacement and SNAP gates. Given the same amount of data, the DNN model achieves higher prediction accuracy in reconstructing their Wigner functions, as can be seen by comparing the results in Fig. 9 with those of a regression model using Gabor feature maps in Fig. 14.

In summary, the regression model provides rigorous theoretical guarantees for CV states with sparse support. However, its performance is not guaranteed for CV states beyond the sparse-support regime. In contrast, the DNN model performs better across a wider range of CV states, including GKP states and randomly prepared ones. It also exhibits strong noise robustness, enabling Wigner function reconstruction from noisy experimental data. Nevertheless, the DNN model lacks theoretical guarantees on its prediction accuracy, and numerical results suggest it struggles to learn Wigner functions with high-frequency oscillations, such as those of binomial code states. Thus, the two learning models are complementary: for states with sparse Fock-state or coherent-state support, the regression model should be applied; for other CV states, particularly noisy experimental ones, the DNN model is more suitable.

VI. CONCLUSIONS

This work is significant for characterizing continuous-variable (CV) quantum states from three perspectives.

First, we introduce a new paradigm for learning the phase-space representations of quantum states. Unlike approaches that reconstruct the density matrix or perform interpolation on pointwise measurement data, we develop learning models that directly predict continuous Wigner functions over phase space from a discrete set of pointwise measurements. Theoretically, this is the first work to formulate Wigner function reconstruction as a PAC learning problem. Practically, this work bridges the gap between reconstructing continuous phase-space functions of CV states and the availability of sparse pointwise measurement data.

Second, our approaches substantially reduce the measurement complexity required to characterize a wide range of important CV quantum states. We prove the-

oretically that for CV states with sparse Fock supports or sparse coherent-state supports, our regression model can efficiently and precisely learn their Wigner functions from pointwise measurements. For CV states that are not sparse on these supports, such as GKP states, numerical results indicate that our neural network model can accurately reconstruct the Wigner function using far fewer measurements than are required for information completeness.

Third, our neural network model provides a robust tool for reconstructing experimental CV states from sparse and noisy data, demonstrating strong noise resilience. We validate its performance using experimental data of GKP states originally employed to demonstrate beyond-break-even performance. Remarkably, we find that our model can correctly identify the most probable quantum error from only a few noisy data points.

Beyond measuring displaced parity, measuring the photon number distribution followed by applying a displacement operation, and optimizing the set of phase-space points by maximizing the condition number can in principle enhance the efficiency in reconstructing Wigner functions [50, 51]. How these improved approaches can be combined with our machine learning algorithms to further boost the efficiency in learning Wigner functions are beyond the scope of this paper and will be left for future investigation. On the other hand, developing classical surrogate models, including both theoretical machine learning algorithms and deep neural networks models, for predicting quantum properties of CV states beyond Wigner functions is another important direction to explore.

VII. APPENDIX

The appendix is structured as follows. Section VII A details the supervised learning setup of the regression model for learning sparsely supported states in the Fock basis and provides the proof of Theorem 1. Section VII B is dedicated to the training data complexity of learning states with sparse coherent state support. It is broken up into subsections that introduce various technical preliminaries, leading to the proof of Theorem 2. Section VII C explains the sample complexity of two conventional approaches, which we used as a baseline. Section VII D elaborates the DNN models, including the architecture and the training. Finally, Section VII E provides the details of the numerical examples presented in the main text and provides additional experiments for the regression models and DNN model.

A. Proof of Theorem 1

In this section, we elaborate the setup of the regression models in the supervised learning framework and provide the proof of Theorem 1, namely the training data complexity of the regression model for learning states with sparse Fock-basis support.

Recall that the task is to predict the Wigner function of a single mode state with sparse Fock support, given access to statistical estimates of different phase-space points. Mathematically, the density matrix is $\rho = \sum_{n,m=0}^{d-1} \rho_{mn} |m\rangle\langle n|$, and its Wigner function is

$$W_\rho(\alpha) = \sum_{n,m=0}^d \rho_{mn} W_{|m\rangle\langle n|}(\alpha), \quad (34)$$

where

$$W_{|m\rangle\langle n|}(\alpha) = \frac{1}{\pi} (-1)^m \sqrt{\frac{m!}{n!}} (2\alpha)^{n-m} L_m^{(n-m)}(4|\alpha|^2) \exp(-2|\alpha|^2). \quad (35)$$

$L_m^{(n-m)}$ is the generalized Laguerre polynomial, also known as the associated Laguerre polynomial, of degree m . Given this explicit function expansion, a simple regression model can be employed to learn the coefficients ρ_{mn} .

We formalize the regression problem in the super-

vised learning framework. Let the parameter space be a bounded region in the phase space $\mathcal{X} = \{\alpha \in \mathbb{R}^2 : |\alpha| \leq R\} = [0, R] \times [0, 2\pi)$ and the output space be $\mathcal{Y} = [-\frac{1}{\pi}, \frac{1}{\pi}]$, since the value of the Wigner function is bounded between $\frac{1}{\pi}$ and $-\frac{1}{\pi}$. To obtain real-valued basis functions from Eq (35), use the polar coordinate $\alpha = re^{i\phi}$

and note that

$$W_{|m\rangle\langle n|}(r, \phi) = \frac{1}{\pi}(-1)^m \sqrt{\frac{m!}{n!}} (2r)^{n-m} L_m^{(n-m)}(4r^2) \exp(-2r^2) \exp(i(n-m)\phi). \quad (36)$$

Finally, we decompose the exponential into trigonometric functions to obtain a real basis for learning real-valued Wigner functions, namely, for all $0 \leq n, m \leq d$, the feature map is composed of basis functions of the form

$$\Phi_{m,n,1}(r, \phi) = \frac{1}{\pi}(-1)^m \sqrt{\frac{m!}{n!}} (2r)^{n-m} L_m^{(n-m)}(4r^2) \exp(-2r^2) \cos((n-m)\phi), \quad (37)$$

$$\Phi_{m,n,-1}(r, \phi) = \frac{1}{\pi}(-1)^m \sqrt{\frac{m!}{n!}} (2r)^{n-m} L_m^{(n-m)}(4r^2) \exp(-2r^2) \sin((n-m)\phi). \quad (38)$$

Without loss of generality, each feature is indexed by $\omega \in \Omega := \{(n, m, \pm 1) : 0 \leq n \leq m \leq d\}$ and therefore $d_f = |\Omega| = (d+1)^2$. The feature map is given explicitly as $\Phi : \mathcal{X} \rightarrow \mathcal{D} = [-\frac{1}{\pi}, \frac{1}{\pi}]^{d_f}$. We refer to $\mathcal{D}$ as the feature space with dimension d_f . Note that this is a bold symbol corresponding to $\alpha \mapsto \Phi(\alpha) = [\Phi_{\omega_1}(\alpha), \Phi_{\omega_2}(\alpha), \dots, \Phi_{\omega_{d_f}}(\alpha)]$. The hypothesis class is given as the linear span of these basis functions with a one-norm regularization on the parameters:

$$\mathcal{H} = \left\{ h(\alpha) = \sum_{\omega \in \Omega} \eta_{\omega} \Phi_{\omega}(\alpha) : \|\eta\|_1 \leq t \right\}. \quad (39)$$

Given the dataset $\mathcal{T} = \{(\alpha_i, y_i)\}_{i=1}^{\mathcal{N}}$ where each α_i is sampled from the distribution $\mathbb{D}$, the surrogate $\widehat{W}$ is obtained by solving the following Lasso regression:

$$\min_{\eta} \sum_{i=1}^{\mathcal{N}} |\langle \eta, \Phi(\alpha_i) \rangle - y_i|^2, \text{ subject to } \|\eta\|_1 \leq t, \quad (40)$$

where $\langle \eta, \Phi(\alpha_i) \rangle = \sum_{\omega \in \Omega} \eta_{\omega} \Phi_{\omega}(\alpha_i)$. In other words, we are to minimize the empirical error on the dataset $\mathcal{T}$ given by

$$\widehat{R}_{\mathcal{T}}(\widehat{W}_{\eta}) := \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} |\widehat{W}_{\eta}(\alpha_i) - y_i|^2. \quad (41)$$

We are now ready to state the generalization error of the regression model, defined by

$$R(\widehat{W}) := \mathbb{E}_{\alpha \sim \mathbb{D}} |\widehat{W}(\alpha) - W(\alpha)|^2. \quad (42)$$

Theorem 3 (Restatement of Theorem 1). *Suppose the target state ρ satisfies $\sum_{n,m=0}^d \mathbb{1}\{\rho_{mn} \neq 0\} \leq s^2$ and all training data in $\mathcal{T}$ satisfies $|W(\alpha_i) - y_i| \leq \epsilon_0$. Let $\widehat{W}$ be the surrogate obtained by solving Eq. (7), and assume the empirical optimization satisfies*

$$\widehat{R}_{\mathcal{T}}(\widehat{W}) \leq \inf_{h \in \mathcal{H}} \widehat{R}_{\mathcal{T}}(h) + \epsilon_1. \quad (43)$$

Then, for any $\delta > 0$, with probability at least $1 - \delta$,

$$R(\widehat{W}) \leq \epsilon_0^2 + \epsilon_1 + \frac{16s^2}{\pi^2 \sqrt{\mathcal{N}}} \left(\sqrt{2 \log(2(d+1)^2)} + \sqrt{\frac{1}{2} \log \frac{1}{\delta}} \right). \quad (44)$$

In particular, if $\epsilon_0^2 \leq \frac{\epsilon}{4}$, $\epsilon_1 \leq \frac{\epsilon}{4}$, and

$$\mathcal{N} \geq \frac{512s^4}{\epsilon^2 \pi^4} \log \left(\frac{4(d+1)^4}{\sqrt{\delta}} \right), \quad (45)$$

then $R(\widehat{W}) \leq \epsilon$ with probability at least $1 - \delta$.

We use a standard result from statistical learning theory which bounds the generalization error of the Lasso regression as follows.

Lemma 1 (Ref. [52], Theorem 11.16). *Let $x \in \mathcal{X}$. Let the feature space be $\mathcal{D} \subseteq \mathbb{R}^{d_f}$ and the hypothesis class be $\mathcal{H} = \{\Phi(x) \in \mathcal{D} \mapsto h(x) = \langle \eta, \Phi(x) \rangle : \|\eta\|_1 \leq t\}$. Assume that there exists $r_{\infty} > 0$ such that for all $\Phi(x) \in \mathcal{D}$, $\|\Phi(x)\|_{\infty} \leq r_{\infty}$ and $M > 0$ such that $|h(x) - y| \leq M$ for all $(\Phi(x), y) \in \mathcal{D} \times \mathcal{Y}$. Then, for any $\delta > 0$, with probability at least $1 - \delta$, the following inequality holds for all $h \in \mathcal{H}$:*

$$R(h) \leq \widehat{R}_{\mathcal{T}}(h) + 2r_{\infty} t M \sqrt{\frac{2 \log(2d_f)}{\mathcal{N}}} + M^2 \sqrt{\frac{\log \frac{1}{\delta}}{2\mathcal{N}}}, \quad (46)$$

where $\widehat{R}_{\mathcal{T}}(h)$ is the training error of the hypothesis h on the dataset $\mathcal{T}$ with size $\mathcal{N}$, and $R(h)$ is the generalization error of h .

We will also employ the following lemma that bounds the empirical error on the dataset $\mathcal{T}$. It states that the training error can be bounded by the statistical error of the dataset.

Lemma 2 (Empirical error from approximate Lasso optimization). *Following the assumption in Theorem 3 and*

assume that the parameter t in Eq. (39) is chosen such that the true Wigner function is in $\mathcal{H}$, let $\widehat{W}(\alpha)$ be re-turned by solving Eq. (40) to an additive optimization accuracy ϵ_1 , i.e.

$$\widehat{R}_{\mathcal{T}}(\widehat{W}) \leq \inf_{\|\eta\|_1 \leq t} \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} |\langle \eta, \Phi(\alpha_i) \rangle - y_i|^2 + \epsilon_1. \quad (47)$$

If the data satisfy $|W(\alpha_i) - y_i| \leq \epsilon_0$ for all $i \in [\mathcal{N}]$, then

$$\widehat{R}_{\mathcal{T}}(\widehat{W}) \leq \epsilon_0^2 + \epsilon_1. \quad (48)$$

Proof.

$$\begin{aligned} & \inf_{\|\eta\|_1 \leq t} \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} |\langle \eta, \Phi(\alpha_i) \rangle - y_i|^2 \\ &= \inf_{h \in \mathcal{H}} \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} |h(\alpha_i) - y_i|^2 \\ &\leq \inf_{h \in \mathcal{H}} \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} (|h(\alpha_i) - W(\alpha_i)| + |W(\alpha_i) - y_i|)^2 \\ &= \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} |W(\alpha_i) - y_i|^2 \\ &\leq \epsilon_0^2, \end{aligned} \quad (49)$$

where the second equality comes from the fact that the target Wigner function is included in the hypothesis class following the choice of t . This implies $\inf_{h \in \mathcal{H}} |h(\alpha) - W(\alpha)| = |W(\alpha) - W(\alpha)| = 0$. $\square$

We these two lemmas, we are now ready to prove Theorem 3.

Proof of Theorem 3. The proof reduces to determining the relevant parameters t, r_∞ , and M in Lemma 1 in our setting. Then combining with the empirical error in Lemma 2 yields the result.

First, recall that the parameter t determines the size of the function in the hypothesis class $\mathcal{H}$ by regulating $\|\eta\|_1$. We should choose t such that the target Wigner function $W_\rho(\alpha) = \sum_{n,m=0}^d \rho_{mn} W_{|m\rangle\langle n|}(\alpha)$ that is s -sparse lies within the hypothesis class. In other words, we require $\sum_{n,m=0}^d |\rho_{mn}| \leq t$. Since we assume these coefficients satisfies $\sum_{n,m=0}^d \mathbb{1}\{\rho_{mn} \neq 0\} \leq s^2$, by Cauchy-Schwarz,

$$\begin{aligned} \sum_{n,m=0}^d |\rho_{mn}| &\leq \sqrt{s^2} \left(\sum_{n,m=0}^d |\rho_{mn}|^2 \right)^{1/2} \\ &= s \sqrt{\text{tr}(\rho^2)} \\ &\leq s \end{aligned} \quad (50)$$

where the equality follows from $\sum_{n,m=0}^d |\rho_{mn}|^2 = \text{tr}(\rho^\dagger \rho) = \text{tr}(\rho^2)$ and the last inequality is the consequence of the purity condition. Therefore, the value of

$t = s$ ensures that the hypothesis class encompasses the Wigner function of the s -sparse states under consideration.

Next, we determine the suitable value for r_∞ . From the definition of the Wigner function as $W_{|m\rangle\langle n|}(\alpha) = \frac{1}{\pi} \text{tr}(|m\rangle\langle n| D(-\alpha) (-1)^{\hat{n}} D(\alpha))$ where $(-1)^{\hat{n}}$ is the Parity operator, by Hölder's inequality, we have

$$\begin{aligned} & \text{tr}(|m\rangle\langle n| D(-\alpha) (-1)^{\hat{n}} D(\alpha)) \\ &\leq \| |n\rangle\langle m| \|_1 \| D(-\alpha) (-1)^{\hat{n}} D(\alpha) \|_\infty \\ &= \| |n\rangle\langle m| \|_1, \end{aligned} \quad (51)$$

since $D(-\alpha) (-1)^{\hat{n}} D(\alpha)$ is unitary. With $\| |n\rangle\langle m| \|_1 = 1$, we conclude that $\| \Phi(\alpha) \|_\infty = \sup_\alpha |W_{|n\rangle\langle m|}(\alpha)| \leq \frac{1}{\pi}$. Thus, we can take $r_\infty = \frac{1}{\pi}$.

Finally, we need a bound on M . For all $h \in \mathcal{H}$,

$$\begin{aligned} |h(\alpha) - y| &\leq |h(\alpha)| + |y| \\ &\leq |\langle \eta, \Phi(\alpha) \rangle| + |W(\alpha)| + \epsilon_0 \\ &\leq \|\eta\|_1 \|\Phi(\alpha)\|_\infty + \frac{1}{\pi} + \epsilon_0 \\ &\leq \frac{t}{\pi} + \frac{1}{\pi} + \epsilon_0 \\ &\leq \frac{2t}{\pi} \\ &\leq \frac{2s}{\pi} \end{aligned} \quad (52)$$

where the second inequality follows from the noisy estimate of the Wigner function and the third from Hölder's inequality. The fourth inequality employs the bound $\|\eta\|_1 \leq t$ and $\|\Phi(\alpha)\|_\infty \leq \frac{1}{\pi}$, respectively, which are found above.

Thus, it is sufficient to take $t = s$, $r_\infty = \frac{1}{\pi}$, and $M = \frac{2s}{\pi}$. Note that t and M depends nicely on the sparsity parameter s instead of the ambient dimension of the feature space d_f , which gives rise to the efficient training data complexity.

Now, inserting these values and Lemma 2 into Lemma 1 yields

$$R(\widehat{W}) \leq \epsilon_0^2 + \epsilon_1 + \frac{4s^2}{\pi^2 \sqrt{\mathcal{N}}} \left(\sqrt{2 \log(2(d+1)^2)} + \sqrt{\frac{\log \frac{1}{\delta}}{2}} \right). \quad (53)$$

To bound the generalization error by ϵ , we require that the estimation error from the data satisfies $\epsilon_0^2 \leq \epsilon/4$ and the additive optimization accuracy $\epsilon_1 \leq \epsilon/4$. This translates to a empirical error bounded by $\epsilon/2$. We separately bound the generalization term by requiring

$$\frac{4s^2}{\pi^2 \sqrt{\mathcal{N}}} \left(\sqrt{2 \log(2(d+1)^2)} + \sqrt{\frac{1}{2} \log \frac{1}{\delta}} \right) \leq \frac{\epsilon}{2}. \quad (54)$$

Rearranging the inequality and using $(\sqrt{A} + \sqrt{B})^2 \leq$

1364 $2(A + B)$, we get

$$\begin{aligned} \mathcal{N} &\geq \frac{512s^4}{\epsilon^2\pi^4} \left(2\log(2(d+1)^2) + \frac{1}{2}\log\frac{1}{\delta} \right) \\ &= \frac{512s^4}{\epsilon^2\pi^4} \log\left(\frac{4(d+1)^4}{\sqrt{\delta}} \right). \end{aligned} \quad (55)$$

1365

1366 Now we determine the sample complexity. Let us
1367 consider estimating the Wigner function at the point α
1368 with displaced parity measurement, i.e., measuring the
1369 observable $D(-\alpha)(-1)^{\hat{n}}D(\alpha)$. With the random vari-
1370 able $X_\alpha \in \{+1, -1\}$, the Wigner function is given as
1371 $W(\alpha) = \frac{1}{\pi} \text{tr}(\rho D(-\alpha)(-1)^{\hat{n}}D(\alpha)) = \frac{1}{\pi} \mathbb{E}[X_\alpha]$. There-
1372 fore, the average of M results of the random variable,
1373 denoted by $\hat{X}_\alpha$, can be used to approximate the Wigner
1374 function. Recall that we tolerate a pointwise estimation
1375 error no larger than $\sqrt{\epsilon}/4$. By Hoeffding's inequality,

$$\Pr\left(\left|\hat{X}_\alpha - \mathbb{E}[\hat{X}_\alpha]\right| \geq \sqrt{\frac{\epsilon}{4}}\right) \leq 2e^{-M\epsilon/8}. \quad (56)$$

1376 Finally, using the union bound, the probability that any
1377 of the estimates at $\mathcal{N}$ different phase-space point is off
1378 by more than $\sqrt{\epsilon}/4$ is at most $\mathcal{N} \cdot 2e^{-M\epsilon/8}$. Bounding
1379 this failure probability by δ , we get

$$M = O\left(\frac{1}{\epsilon} \log \frac{\mathcal{N}}{\delta}\right) \quad (57)$$

1380 for each pointwise estimation. Together, the total num-
1381 ber of samples needed to achieve $R(\hat{W}) \leq \epsilon$ with proba-
1382 bility at least $1 - 2\delta$ is

$$MN = O\left(\frac{s^4}{\epsilon^3} \log \frac{d^4}{\sqrt{\delta}} \left(\log \frac{s^4}{\epsilon^2\delta} + \log \log \frac{d^4}{\sqrt{\delta}}\right)\right) \quad (58)$$

1383 for an s -sparse state on a truncated Hilbert space of di-
1384 mension d .

1385 B. Proof of Theorem 2

1386 In this section, we provide the training data com-
1387 plexity bound for learning states with sparse coherent-
1388 state support. To do so, we first introduce frame theory
1389 (Sec. VII B 1) and Gabor frames (Sec. VII B 2). These
1390 preliminaries, together with four lemmas in Sec. VII B 3,
1391 culminate in the proof of Proposition 1 in Sec. VII B 4. Its
1392 corollaries (Sec. VII B 5) are pivotal in the proof of The-
1393 orem 2, which is presented lastly in Sec. VII B 6, along
1394 with the formal supervised learning setup.

1395

1. Frame theory

1396 Here, we present a minimal introduction to frame
1397 theory. See Refs. [35, 53] for more on frame theory.

1398 Frames can be regarded as an overcomplete basis in a
1399 Hilbert space. Some important frames in finite dimen-
1400 sional quantum computing include mutually unbiased
1401 bases (MUBs) and symmetric-informationally complete
1402 POVM (SIC-POVMs) [53].

1403 We start by recalling how to represent any element in a
1404 Hilbert space, which leads to the concept of a basis. For
□ 1405 example, if $\{e_j\}_{j \in J}$ is an orthonormal basis for a Hilbert
1406 space $\mathcal{H}$, then every $f \in \mathcal{H}$ admits a unique expansion

$$f = \sum_{j \in J} \langle f, e_j \rangle e_j, \quad (59)$$

1407 where $\langle \cdot, \cdot \rangle$ is the inner product. With the norm induced
1408 by the inner product, Parseval's identity gives

$$\|f\|^2 = \sum_{j \in J} |\langle f, e_j \rangle|^2. \quad (60)$$

1409 Thus, an orthonormal basis provides three useful proper-
1410 ties: every element can be represented, the representation
1411 is unique, and the coefficients are stable in the sense of
1412 Parseval's identity.

1413 However, in many applications, it is useful to work
1414 with systems that carry redundancy. Such systems are
1415 typically not linearly independent, so the coefficients of
1416 expansion need not be unique. As a result, the exact Par-
1417 seval identity for orthonormal bases must be replaced by
1418 a weaker stability condition: the coefficient energy should
1419 remain comparable to the norm of the vector. This leads
1420 to the definition of a frame.

1421 **Definition 1** (Frame). *Let $\mathcal{H}$ be a Hilbert space. A*
1422 *countable collection $\{\varphi_j\}_{j \in J} \subset \mathcal{H}$ is called a frame for*
1423 *$\mathcal{H}$ if there exist constants $0 < A \leq B < \infty$ such that, for*
1424 *every $f \in \mathcal{H}$,*

$$A\|f\|^2 \leq \sum_{j \in J} |\langle f, \varphi_j \rangle|^2 \leq B\|f\|^2. \quad (61)$$

1425 *The constants A and B are called frame bounds. If $A =$*
1426 *B , then $\{\varphi_j\}_{j \in J}$ is called a tight frame.*

1427 Intuitively, the lower bound ensures that there are no
1428 missing directions in the space that cannot be detected
1429 with the frame via the inner product. If all coefficients
1430 are small, then the function itself must be small. The
1431 upper bound prevents the coefficient sequence from being
1432 unstable or excessively large compared to the norm of the
1433 function. Together, these conditions ensure that a frame
1434 provides a stable but possibly redundant system for the
1435 Hilbert space. Note that an orthonormal basis is a tight
1436 frame with unit frame bounds.

1437 In contrast to an orthonormal basis, the general recon-
1438 struction of f with a frame $\{\varphi_j\}_{j \in J}$ is not simply given
1439 by $\sum_{j \in J} \langle f, \varphi_j \rangle \varphi_j$. Instead, a second frame is required,
1440 called the dual frame.

1441 **Definition 2** (Dual frame). *Let $\{\varphi_j\}_{j \in J}$ be a frame for*
1442 *$\mathcal{H}$. Another frame $\{\psi_j\}_{j \in J}$ for $\mathcal{H}$ is called a dual frame*

1443 of $\{\varphi_j\}_{j \in J}$ if, for every $f \in \mathcal{H}$,

$$f = \sum_{j \in J} \langle f, \psi_j \rangle \varphi_j = \sum_{j \in J} \langle f, \varphi_j \rangle \psi_j. \quad (62)$$

1444 In general, there are multiple dual frames that satisfy
1445 Eq. (62). A canonical choice is obtained from the frame
1446 operator S , defined by

$$Sf = \sum_{j \in J} \langle f, \varphi_j \rangle \varphi_j. \quad (63)$$

1447 The frame condition in Eq. (61) implies that S is
1448 bounded, positive, self-adjoint, and invertible, which we
1449 will not prove. One can think of the frame operator as the
1450 generalization of the resolution of the identity to a redun-
1451 dant system, which corresponds to $S = \sum_{j \in J} |\varphi_j\rangle\langle\varphi_j|$ in
1452 physics notation. Another characterization of the tight
1453 frame is such that S is proportional to the identity. Then
1454 observe that

$$f = S^{-1}Sf = \sum_{j \in J} \langle f, \varphi_j \rangle S^{-1}\varphi_j. \quad (64)$$

1455 Hence, by Eq. (62), the set

$$\{\tilde{\varphi}_j\}_{j \in J} = \{S^{-1}\varphi_j\}_{j \in J} \quad (65)$$

1456 forms a dual frame of $\{\varphi_j\}_{j \in J}$, called the canonical dual
1457 frame. From the definition, it can be shown that the
1458 canonical dual frame has frame bounds $1/B$ and $1/A$.
1459 Among all dual frames $\{\psi_j\}_{j \in J}$, the canonical dual pro-
1460 vides one with the minimal norm of $\sum_{j \in J} |\langle f, \psi_j \rangle|^2$.

1461 2. Gabor frame and STFT

1462 Before diving into the Gabor frame, it is expedient to
1463 introduce the central objects in time-frequency analysis:
1464 translation and modulation operators, and collect a few
1465 important properties of theirs along the way. An ex-
1466 cellent reference to the Gabor frame and the short-time
1467 Fourier transform is given by Ref. [34].

1468 Formally, for $x, \omega \in \mathbb{R}^d$ and $f \in L^2(\mathbb{R}^d)$, the transla-
1469 tion operator is defined as

$$T_x f(t) = f(t - x), \quad (66)$$

1470 and the modulation operator as

$$M_\omega f(t) = e^{2\pi i \omega \cdot t} f(t). \quad (67)$$

1471 The combinations $T_x M_\omega$ or $M_\omega T_x$ are called time-
1472 frequency shifts. They satisfy the commutation relation

$$T_x M_\omega = e^{-2\pi i \omega \cdot x} M_\omega T_x. \quad (68)$$

1473 For a window function $g \in L^2(\mathbb{R}^d)$, the Gabor system is
1474 generated by time-frequency shifts on the window func-
1475 tion given by $\mathcal{G}(g, a, b) = \{M_{bn} T_{ak} g : n, k \in \mathbb{Z}^d\}$.

1476 Here, the parameters $a, b \in (0, \infty)$ determine the size
1477 of the lattice and $\mathbb{Z}^d$ denotes the d -fold cartesian prod-
1478 uct of $\mathbb{Z}$. We work exclusively with the Gaussian window
1479 $g(x) = e^{-\pi|x|^2}$ where $|x|^2 = x \cdot x$. It is well known that
1480 if $ab < 1$, $\mathcal{G}(g, a, b)$ forms a frame for $L^2(\mathbb{R}^d)$ [34]. It
1481 is commonly referred to as a Gabor frame or a lattice
1482 Gabor frame to emphasize that the time-frequency shifts
1483 are periodic. An element of a Gabor frame is called a
1484 Gabor atom.

1485 For a Gabor frame $\mathcal{G}(g, a, b)$, the dual frame is another
1486 Gabor frame $\mathcal{G}(\gamma, a, b)$ with the dual window function
1487 $\gamma \in L^2(\mathbb{R}^d)$. For our purpose, we take $\mathcal{G}(\gamma, a, b)$ to be
1488 the canonical dual frame of $\mathcal{G}(g, a, b)$ with the Gaussian
1489 window g . In this case, the canonical dual window is
1490 related to the original window by $\gamma = S_{g,a,b}^{-1}g$ where $S_{g,a,b}$
1491 is the frame operator for $\mathcal{G}(g, a, b)$. Then, from Eq. (62),
1492 any $f \in L^2(\mathbb{R}^d)$ admits the Gabor expansion

$$f = \sum_{n,k \in \mathbb{Z}^d} \langle f, M_{bn} T_{ak} \gamma \rangle M_{bn} T_{ak} g. \quad (69)$$

1493 Next, to transform between the time and frequency
1494 domains, we recall the action of Fourier transforms.

1495 **Definition 3** (Fourier transform). *The Fourier trans-*
1496 *form of a function f is defined as*

$$\mathcal{F}(f(x)) = \hat{f}(\xi) = \int_{\mathbb{R}^d} f(x) e^{-2\pi i x \cdot \xi} dx. \quad (70)$$

1497 We use $\mathcal{F}$ when we wish to emphasize that it is a linear
1498 and unitary operator. For time-frequency shifts, we have
1499 the following identity

$$\mathcal{F}(M_\omega T_x f) = T_\omega M_{-x} \hat{f}. \quad (71)$$

1500 That is, the translation in the time domain corresponds
1501 to the modulation in the frequency domain and vice
1502 versa.

1503 The Fourier transform decomposes a function in the
1504 time domain into its frequency components. In doing
1505 so, however, we are completely ignorant of where these
1506 frequency components are localized in time. This limita-
1507 tion is important when the local oscillatory behavior of
1508 a function carries relevant information.

1509 The short-time Fourier transform, which provides a
1510 joint time-frequency representation, addresses this by
1511 first localizing the function with a window and then ap-
1512 plying the Fourier transform. More precisely, to probe
1513 the frequency content of f near a point x , one multi-
1514 plies f by a window function centered at x and computes
1515 the Fourier transform of the resulting localized function.
1516 Varying x yields a joint time-frequency description of f .

1517 **Definition 4** (Short-time Fourier transform). *Fixing a*
1518 *window function g , then the short-time Fourier transform*
1519 *(STFT) of f with respect to g is*

$$\mathcal{V}_g f(x, \omega) = \int_{\mathbb{R}^d} f(t) \overline{g(t - x)} e^{-2\pi i t \cdot \omega} dt, \quad \text{for } x, \omega \in \mathbb{R}^d. \quad (72)$$

Notice that the STFT is a map from $L^2(\mathbb{R}^d)$ to $L^2(\mathbb{R}^{2d})$, that is, the result is a function of both time and frequency. It can be equivalently expressed in terms of the translation and modulation operators as

$$\mathcal{V}_g f(x, \omega) = \langle f, M_\omega T_x g \rangle = \langle \hat{f}, T_\omega M_{-x} \hat{g} \rangle. \quad (73)$$

The first equality follows from the definition. For the second equality, we use the fact that the Fourier transform is a unitary operator, which implies

$$\begin{aligned} \langle f, M_\omega T_x g \rangle &= \langle f, \mathcal{F}^{-1} \mathcal{F}(M_\omega T_x g) \rangle \\ &= \langle \mathcal{F} f, \mathcal{F}(M_\omega T_x g) \rangle \\ &= \langle \hat{f}, T_\omega M_{-x} \hat{g} \rangle, \end{aligned} \quad (74)$$

where the last equality follows from Eq. (71).

As an interesting side note, observe that the Wigner function of a quantum state $\psi \in L^2(\mathbb{R})$ is just the STFT of $\psi(t)$ with the window function $\check{\psi} = \psi(-t)$ in disguise, up to a constant factor. By definition,

$$\mathcal{V}_{\check{\psi}} \psi(2x, 2p) = \int \psi(t) \overline{\psi(-(t-2x))} e^{-2\pi i t 2p} dt. \quad (75)$$

Using a change of variables $t = x + \frac{y}{2}$,

$$\begin{aligned} \mathcal{V}_{\check{\psi}} \psi(2x, 2p) &= \frac{1}{2} \int \psi\left(x + \frac{y}{2}\right) \overline{\psi\left(x - \frac{y}{2}\right)} e^{-2\pi i (x + \frac{y}{2}) 2p} dy \\ &= \frac{1}{2} e^{-4\pi i x p} \int \psi\left(x + \frac{y}{2}\right) \psi^*\left(x - \frac{y}{2}\right) e^{-2\pi i p y} dy \text{ for some } \epsilon > 0. \\ &= \frac{1}{2} e^{-4\pi i x p} W(x, p). \end{aligned} \quad (76)$$

Thus, the Wigner function is a joint distribution in position and momentum, obtained from the STFT of the wavefunction. However, in the following, we treat the Wigner function itself as the basic object. Consequently, the Gabor expansion in the following involves the STFT, or finding the localized patterns of the Wigner function, not the wavefunction.

3. Lemmas for Proposition 1

In this section, we provide four lemmas for the proof of Proposition 1. It is advised to first follow the proof of Proposition 1 and reference them accordingly with the appropriate context.

The first concern the decay of the STFT. Since we are dealing with well-behaved window functions like the Gaussians, it turns out that we can provide quantitative statements on the rate of decay for a class of functions enjoying the same property. It is well known in the STFT literature that if $f, g \in \mathcal{S}(\mathbb{R}^d)$ the Schwartz space, then $\mathcal{V}_g f \in \mathcal{S}(\mathbb{R}^{2d})$ [34]. The Schwartz class gives a superpolynomial type decaying. For (sub-)exponential decay, we need the functions to lie within a subspace of

the Schwartz space. One well studied example in time-frequency analysis is the so-called Gelfand-Shilov space.

Ref. [54] proved an equivalent characterization of the Gelfand-Shilov space in terms of the decaying properties of a function in the real space and the frequency space, which we take as the definition.

Definition 5 (Gelfand-Shilov space). *Let $s, r \geq 1/2$. The Gelfand-Shilov space $S_r^s(\mathbb{R}^d)$ consists of all functions $f \in C^\infty(\mathbb{R}^d)$ such that there exist constants $C, h, k > 0$ satisfying*

$$|f(x)| \leq C e^{-k|x|^{1/r}}, \quad |\hat{f}(\xi)| \leq C e^{-h|\xi|^{1/s}} \quad (77)$$

for all $x, \xi \in \mathbb{R}^d$.

The proof in the following only involves the symmetric Gelfand-Shilov space where $s = r = 1$, denoted as S_1^1 .

Lemma 3. *Let g, g_0 be Gaussian functions and $\mathcal{G}(g, a, b)$ be a lattice Gabor frame for $L^2(\mathbb{R}^d)$, then the canonical dual window $\gamma \in S_1^1(\mathbb{R}^d)$. Furthermore, $\mathcal{V}_\gamma g_0 \in S_1^1(\mathbb{R}^{2d})$. In particular,*

$$\mathcal{V}_\gamma g_0(z) \lesssim e^{-\epsilon|z|} \quad (78)$$

We use the notation $f \lesssim g$ to mean that there exists a constant $C > 0$ such that $f \leq C \cdot g$.

Proof. This result follows from combining a few known results. First, observe that for Gaussians, $g, g_0 \in S_{1/2}^{1/2} \subset S_1^1$. If $\gamma \in S_1^1$, then it is a known result from Ref. [55] that the STFT of g_0 with the window function γ remains in the same space. In other words, $\mathcal{V}_\gamma g_0 \in S_1^1$ and the proof is finished.

It remains to show that $\gamma \in S_1^1$. From Def. 5, we need to separately show $|\gamma(x)| \lesssim e^{-k|x|}$ and $|\hat{\gamma}(\xi)| \lesssim e^{-h|\xi|}$ for some $k, h > 0$. Writing the Frame operator for $\mathcal{G}(g, a, b)$ as $S_{g,a,b}$, we have $\gamma = S_{g,a,b}^{-1} g$. Notice that the Gaussian window satisfies $|g(x)| \lesssim e^{-\lambda|x|}$ for some $\lambda > 0$ trivially. The result from Ref. [56] then states that the canonical dual window also satisfies $|\gamma(x)| \lesssim e^{-k|x|}$ for some $k > 0$.

Next, we show that the Fourier transform $\hat{\gamma}$ also has the same decay. Taking the Fourier transform of γ , we have

$$\hat{\gamma} = \mathcal{F}\gamma = \mathcal{F}S_{g,a,b}^{-1}g = \mathcal{F}S_{g,a,b}^{-1}\mathcal{F}^{-1}\hat{g} = (\mathcal{F}S_{g,a,b}\mathcal{F}^{-1})^{-1}\hat{g}. \quad (79)$$

We study the operator $\mathcal{F}S_{g,a,b}\mathcal{F}^{-1}$ by inspecting its ac-

tion on some function f with $\mathcal{F}^{-1}f = h$. Then,

$$\begin{aligned}
 \mathcal{F}S_{g,a,b}\mathcal{F}^{-1}f &= \mathcal{F}S_{g,a,b}h \\
 &= \mathcal{F}\sum_{n,k}\langle h, M_{bn}T_{ak}g\rangle M_{bn}T_{ak}g \\
 &= \sum_{n,k}\langle h, M_{bn}T_{ak}g\rangle \mathcal{F}(M_{bn}T_{ak}g) \\
 &= \sum_{n,k}\langle \hat{h}, T_{bn}M_{-ak}\hat{g}\rangle \mathcal{F}(M_{bn}T_{ak}g) \\
 &= \sum_{n,k}\langle f, T_{bn}M_{-ak}\hat{g}\rangle T_{bn}M_{-ak}\hat{g} \\
 &= S_{\hat{g},b,a}f.
 \end{aligned} \tag{80}$$

The fourth equality employs the relation between STFT and the Fourier transform from Eq. (73) and the fifth follows from the Fourier transform of the time-frequency shifts in Eq. (71). The last equality uses the definition of

the frame operator in Eq. (63). Therefore, we show that $\mathcal{F}S_{g,a,b}\mathcal{F}^{-1} = S_{\hat{g},b,a}$ and consequently,

$$\hat{\gamma} = (\mathcal{F}S_{g,a,b}\mathcal{F}^{-1})^{-1}\hat{g} = S_{\hat{g},b,a}^{-1}\hat{g}. \tag{81}$$

This establishes that $\hat{\gamma}$ is the canonical dual window of $\hat{g}$ where g is our original Gaussian window. However, the Fourier transform of $g(x) = e^{-\pi|x|^2}$ is the same Gaussian in the frequency space, i.e., $\hat{g}(\xi) = e^{-\pi|\xi|^2}$. Invoking the result of Ref. [56] again, there exists some $h > 0$ such that $|\hat{\gamma}(\xi)| \lesssim e^{-h|\xi|}$. Finally, the characterization of the Gelfand-Shilov space in Def. 5 concludes that $\gamma \in S_1^1$. $\square$

Next, to bound the tail in the truncation involving infinite summation over exponential functions, we use the following lemma.

Lemma 4 (Uniform exponential lattice tail). *Let $a, \mu, R > 0$ with $aN > R$, then for any $|z| \leq R$, there exist constants $C, C' > 0$ such that*

$$\sum_{\|n\|_\infty > N} e^{-\mu|an-z|} \leq C(1 + aN - R)e^{-\mu(aN-R)} \leq C'e^{-\mu'(aN-R)} \tag{82}$$

for some $0 < \mu' < \mu$.

Proof. Given $aN > R$ and $|z| \leq R$. If $\|n\|_\infty > N$, then $|n| > N$, and by the reverse triangle inequality,

$$|an - z| \geq |a|n| - |z| > an - R. \tag{83}$$

Set $L := aN - R > 0$ and decompose the omitted two dimensional lattice points into shells with unit width

$$A_m^{(L)}(z) := \{n \in \mathbb{Z}^2 : L + m \leq |an - z| < L + m + 1\}. \tag{84}$$

Using $\#A_m^{(L)}(z)$ to denote the number of elements in $A_m^{(L)}(z)$, then,

$$\sum_{\|n\|_\infty > N} e^{-\mu L} \leq \sum_{m=0}^{\infty} \#A_m^{(L)}(z) e^{-\mu(L+m)}, \tag{85}$$

since by definition, each $n \in A_m^{(L)}(z)$ satisfies $|an - z| > L + m$.

Now, by an area argument, each $\#A_m^{(L)}(z)$ has a size

$$\pi(L + m + 1)^2 - \pi(L + m)^2 = 2\pi(L + m) + 1, \tag{86}$$

while each lattice cell has a size a^2 . Therefore, the number of points in $\#A_m^{(L)}(z)$ is bounded as

$$\#A_m^{(L)}(z) \leq \frac{2\pi(L + m) + 1}{a^2} \leq C_a(L + m + 1) \tag{87}$$

for some constant $C_a > 0$ independent of m .

Therefore,

$$\sum_{\|n\|_\infty > N} e^{-\mu L} \leq C_a \sum_{m=0}^{\infty} (1 + L + m) e^{-\mu(L+m)} \tag{88}$$

$$= C_a e^{-\mu L} \sum_{m=0}^{\infty} (1 + L + m) e^{-\mu m} \tag{89}$$

The summation involves a standard geometric series and its variant,

$$\begin{aligned}
 \sum_{m=0}^{\infty} (1 + L + m) e^{-\mu m} &= (1 + L) \sum_{m=0}^{\infty} e^{-\mu m} + \sum_{m=0}^{\infty} m e^{-\mu m} \\
 &= (1 + L) \frac{1}{1 - e^{-\mu}} + \frac{e^{-\mu}}{(1 - e^{-\mu})^2} \\
 &\leq C_\mu(1 + L)
 \end{aligned} \tag{90}$$

for some $C_\mu > 0$. Together, we have

$$\sum_{\|n\|_\infty > N} e^{-\mu L} \leq C_{\mu,a}(1 + L) e^{-\mu L} \tag{91}$$

for some $C_{a,\mu} > 0$. We can further remove the linear term $(1 + L)$ by choosing any $0 < \mu' < \mu$. Then,

$$(1 + L) e^{-\mu L} = (1 + L) e^{-(\mu - \mu')L} e^{-\mu' L}. \tag{92}$$

Now, since exponential decays faster than linear growth,

$$\sup_{L \geq 0} (1 + L)e^{-(\mu - \mu')L} := C_{\mu, \mu'} < \infty. \quad (93)$$

Therefore, $(1 + L)e^{-\mu L} \leq C_{\mu, \mu'}e^{-\mu' L}$ and the result follows. $\square$

The following two lemmas connect the coefficient of the sparse coherent state explicitly to the sparsity and the separation between coherent states. We begin with a definition.

Definition 6. Define the coherent state Gramian matrix G of size $s \times s$ associated with the state $|\psi\rangle = \sum_{i=1}^s a_i |\alpha_i\rangle$ by

$$G_{j\ell} := \langle \alpha_j | \alpha_\ell \rangle \quad (94)$$

for all $j, \ell \in [s]$.

Note that G is positive definite. $\lambda_{\min}(G)$ denotes the minimum eigenvalue of G .

Lemma 5. Let $|\psi\rangle = \sum_{i=1}^s a_i |\alpha_i\rangle$. Denoting the coefficient as $a := (a_1, \dots, a_s)$, then

$$\|a\|_1^2 \leq \frac{s}{\lambda_{\min}(G)}. \quad (95)$$

1645

Proof. Since the state is normalized, we have the following condition

$$\langle \psi | \psi \rangle = \sum_{j=1}^s \sum_{\ell=1}^s a_j^* a_\ell \langle \alpha_j | \alpha_\ell \rangle = \sum_{j,\ell=1}^s a_j^* a_\ell G_{j\ell} = 1. \quad (96)$$

Equivalently, in matrix notation,

$$a^\dagger G a = 1. \quad (97)$$

From the Rayleigh quotient bound,

$$a^\dagger G a \geq \lambda_{\min}(G) \|a\|_2^2. \quad (98)$$

Taken together, $\|a\|_2^2 \leq 1/\lambda_{\min}(G)$. Finally, by Cauchy-Schwarz,

$$\begin{aligned} \|a\|_1^2 &= \left(\sum_{j=1}^s |a_j| \right)^2 \\ &\leq \left(\sum_{j=1}^s 1 \right) \left(\sum_{j=1}^s |a_j|^2 \right) \\ &= s \|a\|_2^2 \\ &\leq \frac{s}{\lambda_{\min}(G)}. \end{aligned} \quad (99)$$

1652

$\square$ 1677

The final lemma relates the separation between coherent states in $|\psi\rangle$ to the smallest eigenvalue of the Gram matrix G .

Lemma 6. Let $|\psi\rangle = \sum_{i=1}^s a_i |\alpha_i\rangle$ and $\Delta_\alpha = \min_{j \neq \ell} |\alpha_j - \alpha_\ell|$ for all $j, \ell \in [s]$. For any fixed $\kappa \in (0, 1)$, if

$$\Delta_\alpha \geq \sqrt{2 \log \frac{s-1}{1-\kappa}}, \quad (100)$$

then $\lambda_{\min}(G) \geq \kappa$.

Proof. The coherent state Gramian matrix G captures all overlap between the coherent states that constitute the state $|\psi\rangle$. Recall that for coherent states,

$$\begin{aligned} \langle \alpha_j | \alpha_\ell \rangle &= \exp \left(-\frac{1}{2} (|\alpha_j|^2 + |\alpha_\ell|^2 - 2\alpha_j^* \alpha_\ell) \right) \\ &= \exp \left(-\frac{1}{2} (|\alpha_j - \alpha_\ell|^2 - 2i\Im[\alpha_j^* \alpha_\ell]) \right). \end{aligned} \quad (101)$$

Then, for all $j, \ell \in [s]$ with $j \neq \ell$,

$$|G_{j\ell}| = |\langle \alpha_j | \alpha_\ell \rangle| = \exp \left(-\frac{1}{2} |\alpha_j - \alpha_\ell|^2 \right) \leq e^{-\frac{1}{2} \Delta_\alpha^2}. \quad (102)$$

On the diagonal with $j \in [s]$, $|G_{jj}| = \langle \alpha_j | \alpha_j \rangle = 1$ for normalized coherent states.

Next, by Gershgorin circle theorem, every eigenvalue of G lies in one of the s discs at center G_{jj} with radius $\sum_{\ell \neq j} |G_{j\ell}|$. That is, if λ is an eigenvalue of G , then

$$|\lambda - G_{jj}| \leq \sum_{\ell \neq j} |G_{j\ell}| \quad (103)$$

for at least one $j \in [s]$. In particular

$$\lambda_{\min}(G) \geq 1 - \sum_{\ell \neq j} |G_{j\ell}|. \quad (104)$$

From Eq. (102), $|G_{j\ell}|$ is bounded for every pair $j \neq \ell$, then

$$\lambda_{\min}(G) \geq 1 - \sum_{\ell \neq j} e^{-\frac{1}{2} \Delta_\alpha^2} \geq 1 - (s-1)e^{-\frac{1}{2} \Delta_\alpha^2}. \quad (105)$$

We set the right hand side to be larger than κ to solve for $\lambda_{\min}(G) \geq \kappa$. Note that this is nontrivial only for $\kappa \in (0, 1)$. Rearranging the terms, we see that if

$$\Delta_\alpha \geq \sqrt{2 \log \frac{s-1}{1-\kappa}}, \quad (106)$$

then

$$e^{-\frac{1}{2} \Delta_\alpha^2} \leq \frac{1-\kappa}{s-1}. \quad (107)$$

Therefore, $1 - (s-1)e^{-\frac{1}{2} \Delta_\alpha^2} \geq 1 - (1-\kappa) \geq \kappa$, and hence,

$$\lambda_{\min}(G) \geq \kappa. \quad (108)$$

$\square$

4. Proposition 1: Truncation error with Gabor frame

Having introduced the relevant concepts of frame theory for Gabor frame and STFT, we are now in a position to bound the approximation error using a finite number of Gabor atoms. The lemmas needed can be referenced in Section VII B 3.

Proposition 1 (Truncation error bound). *Let $W_\psi \in L^2(\mathbb{R}^2)$ be the Wigner function of the state $|\psi\rangle = \sum_{i=1}^s a_i |\alpha_i\rangle$. Furthermore, assume that the magnitude of the coherent states lies in a bounded region in phase space, i.e., $|\alpha_j| \leq R$ for all $j \in [s]$ and the separation between any two coherent states is at least $\Delta_\alpha := \min_{j \neq \ell} |\alpha_j - \alpha_\ell|$ such that*

$$\Delta_\alpha \geq \sqrt{2 \log \frac{s-1}{1-\kappa}} \quad (109)$$

for some $\kappa \in (0, 1)$. Let $\mathcal{G}(g, a, b)$ be a Gabor frame with a two dimensional Gaussian window function $g(x) = e^{-\pi|x|^2}$ and the canonical dual frame be $\mathcal{G}(\gamma, a, b)$. We define the truncation lattice as

$$\Lambda_{N,K} = \{(n, k) \in \mathbb{Z}^2 \times \mathbb{Z}^2 : \|n\|_\infty \leq N, \|k\|_\infty \leq K\} \quad (110)$$

and the associated canonical approximation of W_ψ by

$$W_{N,K} = \sum_{(n,k) \in \Lambda_{N,K}} \langle W_\psi, M_{bn} T_{ak} \gamma \rangle M_{bn} T_{ak} g. \quad (111)$$

Then, there exist constants $C, p_z, p_\omega > 0$ such that

$$\|W_\psi - W_{N,K}\|_\infty \leq C \frac{s}{\kappa} \left[e^{-p_z(aK - \sqrt{2}R)} + e^{-p_\omega(bN - \frac{\sqrt{2}R}{\pi})} \right] \quad (112)$$

1697

Proof. Recall that the Gabor frame is given by $\mathcal{G}(g, a, b) = \{M_{bn} T_{ak} g : n, k \in \mathbb{Z}^2\}$ with the canonical dual frame $\mathcal{G}(\gamma, a, b) = \{M_{bn} T_{ak} \gamma : n, k \in \mathbb{Z}^2\}$. This provides the canonical Gabor expansion for any $W_\psi \in L^2(\mathbb{R}^2)$

$$W_\psi = \sum_{n,k \in \mathbb{Z}^2} c_{n,k} M_{bn} T_{ak} g, \quad (113)$$

where $c_{n,k}$ is calculated as the overlap between W and the dual frame

$$c_{n,k} = \langle W_\psi, M_{bn} T_{ak} \gamma \rangle. \quad (114)$$

In general, the summation carries infinitely many terms. However, our approximation considers a finite lattice centered at the origin, given by $\Lambda_{N,K}$. Then, the truncated approximation is

$$W_{N,K} = \sum_{(n,k) \in \Lambda_{N,K}} c_{n,k} M_{bn} T_{ak} g. \quad (115)$$

The goal is to bound the approximation error uniformly. By definition,

$$\|W - W_{N,K}\|_\infty = \left\| \sum_{(n,k) \notin \Lambda_{N,K}} c_{n,k} M_{bn} T_{ak} g \right\|_\infty \quad (116)$$

$$\leq \sum_{(n,k) \notin \Lambda_{N,K}} |c_{n,k}| \|M_{bn} T_{ak} g\|_\infty \quad (117)$$

$$= \sum_{(n,k) \notin \Lambda_{N,K}} |c_{n,k}| \|g\|_\infty \quad (118)$$

$$= \sum_{(n,k) \notin \Lambda_{N,K}} |c_{n,k}|, \quad (119)$$

where we use the triangle inequality on the second line. The second equality follows by noting that $M_{bn} T_{ak}$ is unitary and the unitarily invariance of the infinity norm, and the last equality from $\|g\|_\infty = 1$.

In order to bound the Gabor coefficients $c_{n,k}$, we now invoke our assumption that the target state is a superposition of coherent states.

Before continuing, we first set up some notations for working in real phase-space coordinates $r = (x, p) \in \mathbb{R}^2$. Specifically, let $|\psi\rangle = \sum_{j=1}^s a_j |\alpha_j\rangle$ be an s -sparse coherent-state superposition. We denote by $r_j = (x_j, p_j) \in \mathbb{R}^2$ the real phase-space center associated with $|\alpha_j\rangle$, given by $\alpha_j = (x_j + p_j)/\sqrt{2}$. Then the Wigner function of $|\psi\rangle$ is

$$W_\psi = \sum_{j,\ell=1}^s a_j a_\ell^* W_{j\ell}, \quad (120)$$

where we define $W_{j\ell} = W_{|\alpha_j\rangle \langle \alpha_\ell|}$. Recall that we have demonstrated the Wigner function of the coherent state operator in Eq. (160). With the notation here, we define

$$z_{j\ell} := \frac{r_j + r_\ell}{2}, \quad (121)$$

and the symplectic form $\sigma(u, v) := u_q v_p - u_p v_q$ for $u = (u_q, u_p)$ and $v = (v_q, v_p)$. Then, it can be shown that

$$W_{j\ell}(r) = \frac{1}{\pi} e^{-|r - z_{j\ell}|^2} \exp \left(iJ(r_\ell - r_j) \cdot r + \frac{i}{2} \sigma(r_\ell, r_j) \right). \quad (122)$$

where the symplectic matrix J is

$$J := \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}. \quad (123)$$

Therefore by defining $\theta_{j\ell} := \frac{1}{2} \sigma(r_\ell, r_j)$ and

$$\omega_{j\ell} := \frac{1}{2\pi} J(r_\ell - r_j), \quad (124)$$

we can express $W_{j\ell}$ (122) in terms of the translation and modulation operator as

$$W_{j\ell}(r) = e^{i\theta_{j\ell}} M_{\omega_{j\ell}} T_{z_{j\ell}} g_0(r), \quad (125)$$

where

$$g_0(r) = \frac{1}{\pi} e^{-|r|^2} \quad (126)$$

denotes the Gaussian Wigner function of a vacuum state.

Therefore, using the fact that $|\psi\rangle\langle\psi| = \sum_{j,\ell=1}^s a_j a_\ell^* |\alpha_j\rangle\langle\alpha_\ell|$, we can write the canonical Gabor coefficients of W_ψ explicitly as

$$c_{n,k} = \langle W_\psi, M_{bn} T_{ak} \gamma \rangle = \sum_{j,\ell=1}^s a_j^* a_\ell \langle W_{j\ell}, M_{bn} T_{ak} \gamma \rangle \quad (127)$$

For each coherent state operator $|\alpha_j\rangle\langle\alpha_\ell|$, define

$$d_{n,k}^{j\ell} = \langle W_{j\ell}, M_{bn} T_{ak} \gamma \rangle. \quad (128)$$

By linearity,

$$c_{n,k} = \sum_{j,\ell=1}^s a_j^* a_\ell d_{n,k}^{j\ell}. \quad (129)$$

Thus, Eq. (119) reduces to

$$\sum_{(n,k) \notin \Lambda_{N,K}} |c_{n,k}| \leq \sum_{j,\ell=1}^s |a_j| |a_\ell| \sum_{(n,k) \notin \Lambda_{N,K}} |d_{n,k}^{j\ell}| \quad (130)$$

This provides us with a concrete form of the Gabor coefficients in relation to the target state $|\psi\rangle$.

To proceed further, we recall the commutation relation

between the time-frequency shifts in Eq. (68),

$$\begin{aligned} |d_{n,k}^{j\ell}| &= |\langle M_{\omega_{j\ell}} T_{z_{j\ell}} g_0, M_{bn} T_{ak} \gamma \rangle| \\ &= |\langle g_0, T_{-z_{j\ell}} M_{-\omega_{j\ell}} M_{bn} T_{ak} \gamma \rangle| \\ &= |\langle g_0, T_{-z_{j\ell}} M_{bn-\omega_{j\ell}} T_{ak} \gamma \rangle| \\ &= |\langle g_0, M_{bn-\omega_{j\ell}} T_{ak-z_{j\ell}} \gamma \rangle|. \end{aligned} \quad (131)$$

Compared with Eq. (73), we observe that this is exactly the short-time Fourier transform of g_0 with the window function γ , evaluated at the point $(ak - z_{j\ell}, bn - \omega_{j\ell})$, i.e.

$$|d_{n,k}^{j\ell}| = |\mathcal{V}_\gamma g_0(ak - z_{j\ell}, bn - \omega_{j\ell})|. \quad (132)$$

The dual window cannot be found analytically as it involves the inversion of the frame operator, which is an infinite dimensional matrix. However, it turns out that when γ and g_0 are both sufficiently smooth and decay exponentially to infinity, the STFT also decays exponentially, although the exact constant cannot be obtained. Formally, we invoke the decaying properties of the STFT given by Lemma 3, which states that for “nice” functions γ and g_0 , there exist some $C, p_z, p_\omega > 0$ such that

$$|\mathcal{V}_\gamma g_0(ak - z_{j\ell}, bn - \omega_{j\ell})| \leq C e^{-p_z |ak - z_{j\ell}|} e^{-p_\omega |bn - \omega_{j\ell}|}. \quad (133)$$

Continuing from Eq. (130) we first bound the summation involving the truncated lattice,

$$\sum_{(n,k) \notin \Lambda_{N,K}} |d_{n,k}^{j\ell}| \leq C \sum_{(n,k) \notin \Lambda_{N,K}} e^{-p_z |ak - z_{j\ell}|} e^{-p_\omega |bn - \omega_{j\ell}|}. \quad (134)$$

Recalling the definition of the truncated lattice and using the union bound, we separate the sum as

$$\begin{aligned} \sum_{(n,k) \notin \Lambda_{N,K}} e^{-p_z |ak - z_{j\ell}|} e^{-p_\omega |bn - \omega_{j\ell}|} &\leq \sum_{n \in \mathbb{Z}^2} \sum_{\|k\|_\infty > K} e^{-p_z |ak - z_{j\ell}|} e^{-p_\omega |bn - \omega_{j\ell}|} + \sum_{\|n\|_\infty > N} \sum_{k \in \mathbb{Z}^2} e^{-p_z |ak - z_{j\ell}|} e^{-p_\omega |bn - \omega_{j\ell}|} \\ &= \left(\sum_{n \in \mathbb{Z}^2} e^{-p_\omega |bn - \omega_{j\ell}|} \right) \left(\sum_{\|k\|_\infty > K} e^{-p_z |ak - z_{j\ell}|} \right) + \left(\sum_{\|n\|_\infty > N} e^{-p_\omega |bn - \omega_{j\ell}|} \right) \left(\sum_{k \in \mathbb{Z}^2} e^{-p_z |ak - z_{j\ell}|} \right). \end{aligned} \quad (135)$$

The exponential tail sum can be bounded by Lemma 4, as some finite constant D' , that is, which asserts that there exist $D > 0$ and $0 < p'_z < p_z$ such that

$$\sum_{k \in \mathbb{Z}^2} e^{-p_z |ak - z_{j\ell}|} = D' < \infty. \quad (137)$$

$$\sum_{\|k\|_\infty > K} e^{-p_z |ak - z_{j\ell}|} \leq D e^{-p'_z (aK - |z_{j\ell}|)} \quad (136)$$

The same Lemma applies to the sum over $\|n\|_\infty > N$ and therefore there exists some $C', p'_z, p'_\omega > 0$ such that

$$\sum_{(n,k) \notin \Lambda_{N,K}} |d_{n,k}^{j\ell}| \leq C' (e^{-p'_z (aK - |z_{j\ell}|)} + e^{-p'_\omega (bN - |\omega_{j\ell}|)}) \quad (138)$$

This trivially translates to the infinite sum over $k \in \mathbb{Z}^2$

From our assumption that $|\alpha_j| \leq R$ for all $j \in [s]$, we then the tail bound simplifies to have $|r_j| = \sqrt{2}|\alpha_j| \leq R$. Then,

$$\max_{j,\ell} |z_{j\ell}| = \max_{j,\ell} \left| \frac{r_j + r_\ell}{2} \right| \leq \sqrt{2}R, \quad (139)$$

and

$$\max_{j,\ell} |\omega_{j\ell}| = \max_{j,\ell} \frac{1}{2\pi} |r_j - r_\ell| \leq \frac{\sqrt{2}R}{\pi}. \quad (140)$$

If

$$aK > \sqrt{2}R, \quad bN > \frac{\sqrt{2}R}{\pi}, \quad (141)$$

Therefore, we have

$$\begin{aligned} \sum_{(n,k) \notin \Lambda_{N,K}} |c_{n,k}| &\leq C' \sum_{j,\ell=1}^s |a_j| |a_\ell| \left[e^{-p'_z(aK - \sqrt{2}R)} + e^{-p'_\omega(bN - \frac{1}{\pi}\sqrt{2}R)} \right] \\ &\leq C'_{p'_z, p'_\omega, a, b} \|a\|_1^2 \left[e^{-p'_z(aK - \sqrt{2}R)} + e^{-p'_\omega(bN - \frac{1}{\pi}\sqrt{2}R)} \right]. \end{aligned} \quad (143)$$

From Lemma 5, we have $\|a\|_1^2 \leq s/\lambda_{\min}(G)$ where G is the coherent state Gram matrix corresponding to $|\psi\rangle$. Then, with the choice $t = O(\frac{s}{\kappa})$, $W_{N,K} \in \mathcal{H}_{N,K}$ where $W_{N,K}$ is given by Eq. (111).

Following our assumption on the separation of the coherent states, namely,

$$\Delta_\alpha \geq \sqrt{2 \log \frac{s-1}{\kappa-1}}, \quad (144)$$

where $\kappa \in (0, 1)$, Lemma 6 guarantees that $\lambda_{\min}(G) \geq \kappa$.

Therefore, $\|a\|_1^2 \leq \frac{s}{\kappa}$.

Finally, putting everything together and relabeling the constants, there exists some $C, p_z, p_\omega > 0$ such that the uniform error of the canonical Gabor expansion with the lattice $\Lambda_{N,K}$ satisfies

$$\|W - W_{N,K}\|_\infty \leq C \frac{s}{\kappa} \left[e^{-p_z(aK - \sqrt{2}R)} + e^{-p_\omega(bN - \frac{1}{\pi}\sqrt{2}R)} \right]. \quad (145)$$

Proof. For $W_{N,K}$ to be in the hypothesis class, we require t to be greater than one norm of the coefficient of $W_{N,K}$ From Eq. (130)

$$\begin{aligned} \|c_{N,K}\|_1 &= \sum_{(n,k) \in \Lambda_{N,K}} |c_{n,k}| \\ &\leq \sum_{j,\ell=1}^s |a_j| |a_\ell| \sum_{(n,k) \in \Lambda_{N,K}} |d_{n,k}^{j\ell}|. \end{aligned} \quad (147)$$

Let $B = \sum_{(n,k) \in \Lambda_{N,K}} |d_{n,k}^{j\ell}|$, which is a constant by Proposition 1. Then,

$$\|c_{N,K}\|_1 \leq B \|a\|_1^2 \leq B \frac{s}{\kappa}. \quad (148)$$

□

Therefore $t = O(\frac{s}{\kappa})$ ensures that the canonical expansion lies within the hypothesis class. □

5. Corollaries of Proposition 1

Two implications resulting from Proposition 1 are crucial to the generalization bound in Theorem 4. Specifically, they determine the value of t and the truncation parameter for N and K such that the empirical error can be made arbitrarily small.

Corollary 1. Define the hypothesis class $\mathcal{H}_{N,K}$ as

$$\mathcal{H}_{N,K} = \left\{ h(r) = \sum_{(n,k) \in \Lambda_{N,K}} \eta_{n,k} M_{bn} T_{ak} g(r) : \|\eta\|_1 \leq t \right\}. \quad (146)$$

Corollary 2. To obtain an error of

$$\|W_\psi - W_{N,K}\|_\infty \leq \sqrt{\frac{\varepsilon}{8}}, \quad (149)$$

it is sufficient for the lattice truncation parameters to satisfy

$$K = O\left(R + \frac{1}{p_z} \log\left(\frac{s}{\kappa\sqrt{\varepsilon}}\right)\right), \quad (150)$$

$$N = O\left(R + \frac{1}{p_\omega} \log\left(\frac{s}{\kappa\sqrt{\varepsilon}}\right)\right). \quad (151)$$

1807 *Proof.* From Eq. (145), we separately require each term 1815
1808 to be at most half of the target,

$$C \frac{s}{\kappa} e^{-p_z(aK - \sqrt{2}R)} \leq \frac{1}{4} \sqrt{\frac{\varepsilon}{2}}, \quad (152)$$

1809 and

$$C \frac{s}{\kappa} e^{-p_\omega(bN - \frac{1}{\pi}\sqrt{2}R)} \leq \frac{1}{4} \sqrt{\frac{\varepsilon}{2}}. \quad (153)$$

1810 Equivalently, it suffices that

$$aK - \sqrt{2}R \geq \frac{1}{p_z} \log \left(\frac{4\sqrt{2}Cs}{\kappa\sqrt{\varepsilon}} \right), \quad (154)$$

1811 and

$$bN - \frac{1}{\pi}\sqrt{2}R_\omega \geq \frac{1}{p_\omega} \log \left(\frac{4\sqrt{2}Cs}{\kappa\sqrt{\varepsilon}} \right). \quad (155)$$

1812 Finally, we have

$$K = O \left(R + \frac{1}{p_z} \log \left(\frac{s}{\kappa\sqrt{\varepsilon}} \right) \right), \quad (156)$$

1813 and

$$N = O \left(R + \frac{1}{p_\omega} \log \left(\frac{s}{\kappa\sqrt{\varepsilon}} \right) \right). \quad (157)$$

1814

6. Proof of Theorem 2

1816 In this section, we provide a rigorous guarantee for
1817 learning states with sparse coherent state support using
1818 Gabor frame. We first motivate the choice of this feature
1819 map by inspecting the Wigner function state. The setup
1820 and the main theorem are then introduced. Finally, we
1821 prove Theorem 2 with the help of Corollary 2 and Corol-
1822 lary 1.

1823 Recall that coherent states form an overcomplete basis
1824 for a CV state space with the resolution of the identity
1825 $\frac{1}{\pi} \int |\alpha\rangle\langle\alpha| d^2\alpha = \mathbb{1}$. In other words, coherent states form
1826 a continuous tight frame since the frame operator is pro-
1827 portional to the identity. This provides another conve-
1828 nient way to perform expansion:

$$\rho = \frac{1}{\pi^2} \int |\gamma\rangle\langle\gamma| \rho |\beta\rangle\langle\beta| d^2\gamma d^2\beta = \frac{1}{\pi^2} \int \rho_{\gamma\beta} |\gamma\rangle\langle\beta| d^2\gamma d^2\beta \quad (158)$$

1829 where $\rho_{\gamma\beta} = \langle\gamma|\rho|\beta\rangle$. Then the Wigner function can be
1830 expressed as

$$W_\rho(\alpha) = \frac{1}{\pi^2} \int \rho_{\gamma\beta} W_{|\gamma\rangle\langle\beta|} d^2\gamma d^2\beta. \quad (159)$$

1831 Note that since $\langle\gamma|\beta\rangle \neq 0$, this decomposition, i.e. the
1832 coefficients $\rho_{\gamma\beta}$ is not unique. Using the definition of the
1833 Wigner function, $W_A(\alpha) = \frac{1}{\pi} \text{tr}(D(\alpha))(-1)^{\hat{n}} D(-\alpha)A$,
1834 and the commutation relation between the displacement
□ 1835 operator, it is easy to show that

$$W_{|\gamma\rangle\langle\beta|}(\alpha) = \frac{1}{\pi} \exp \left(-2 \left| \alpha - \frac{\gamma + \beta}{2} \right|^2 \right) \exp \left(2i \Im \left[(\beta^* - \gamma^*)\alpha + \frac{1}{2}\beta^*\gamma \right] \right). \quad (160)$$

1836 Introducing the center $z = \frac{\gamma + \beta}{2}$ and the separation 1847
1837 $\omega = \frac{1}{\pi}(\beta - \gamma)$, the Wigner function becomes

$$W_{|\gamma\rangle\langle\beta|}(\alpha) = \frac{1}{\pi} e^{-2|\alpha - z|^2} \exp \left(2\pi i \Im \left[\omega^*(\alpha - \frac{z}{2}) \right] \right) \quad (161)$$

1838 where

$$\gamma = z - \frac{\pi\omega}{2}, \quad \beta = z + \frac{\pi\omega}{2}. \quad (162)$$

1839 Eq. (161) is composed of a Gaussian function cen-
1840 tered at z , modulated by a phase $e^{2\pi i \Im[\omega^*\alpha]}$. However, it
1841 does not furnish a suitable feature map for the regression
1842 model as the parameters γ and β are continuous complex
1843 values. This implies that infinitely many Gaussians and
1844 phase factors are needed. Naturally, we ask whether a
1845 discrete set of Gaussian modulated by Fourier series can
1846 still represent any state.

1847 To this end, we consider the appropriate discrete coun-
1848 terpart by covering the phase space with Gaussians situ-
1849 ated on a lattice modulated by Fourier series. This moti-
1850 vates the choice of Fourier series with Gaussian envelopes
1851 as the appropriate basis functions for learning states with
1852 sparse coherent state support, which is nothing but the
1853 Gabor frame introduced in Sec. VII B 2.

1854 In fact, John von Neumann considered the problem
1855 for $\psi \in L^2(\mathbb{R})$, using a square lattice in an attempt to
1856 find the most accurate simultaneous measurement of the
1857 position and momentum operator. He conjectured, which
1858 turned out to be correct, that $\mathcal{G}(g, 1, 1)$ is a complete
1859 system in $L^2(\mathbb{R})$, which is only a Riesz basis, but not a
1860 frame [34, 35, 57].

1861 Returning to our setting, the Gabor frame allows the
1862 expansion of the Wigner function (or more generally, any

1863 L^2 -integrable function) as

$$W(r) = \sum_{n,k \in \mathbb{Z}^2} c_{nk} M_{bn} T_{ak} g(r), \quad (163)$$

1864 where $r = (x, p)$. In general, for a frame, this decomposition is not unique and the coefficients $c_{nk} \neq \langle W, \Phi_{n,k} \rangle$.
1865 Intuitively, the Gabor frame covers the space with the
1866 lattice $\Lambda = a\mathbb{Z}^2 \times b\mathbb{Z}^2$. When the lattice is sufficiently
1867 fine, it is able to capture all information of the function.

1869 In terms of our supervised learning setting, we have
1870 $\mathcal{X} = \{\alpha \in \mathbb{R}^2 : |\alpha| \leq R\} = [0, R] \times [0, 2\pi]$ and the
1871 output space $\mathcal{Y} = [-\frac{1}{\pi}, \frac{1}{\pi}]$. For our learning problem, we
1872 truncate to a lattice of finite size

$$\Lambda_{N,K} = \{(n, k) \in \mathbb{Z}^2 \times \mathbb{Z}^2 : \|n\|_\infty \leq N, \|k\|_\infty \leq K\}. \quad (164)$$

This defines the feature map Φ . Explicitly, let $\omega \in \Omega : \{(n, k, \pm 1) : -N \leq n_1, n_2 \leq N, -K \leq k_1, k_2 \leq K\}$ where

$$\Phi_{n,k,1}(x, p) = \exp(-\pi(|x - ak_1| + |p - ak_2|)^2) \cos(2\pi(bn_1x + bn_2p)) \quad (165)$$

$$\Phi_{n,k,-1}(x, p) = \exp(-\pi(|x - ak_1| + |p - ak_2|)^2) \sin(2\pi(bn_1x + bn_2p)), \quad (166)$$

1875 where we use real basis functions for the regression to
1876 learn real-valued Wigner functions. The feature dimension is $d_f = |\Omega| = (2N + 1)^2(2K + 1)^2$ where the
1877 redundant features due to the parity of the trigonometric
1878 functions are removed. The linear span of these functions
1879 with a one-norm restriction constitutes the hypothesis class

$$\mathcal{H} = \left\{ h(r) = \sum_{\omega \in \Omega} \eta_\omega \Phi_\omega : \|\eta\|_1 \leq t \right\}. \quad (167)$$

1882 In the proof below, however, it is easier to work with
1883 complex-valued functions of the form

$$\mathcal{H} = \left\{ h(r) = \sum_{(n,k) \in \Lambda_{N,K}} \eta_{n,k} M_{bn} T_{ak} g(r) : \|\eta\|_1 \leq t \right\}. \quad (168)$$

1884 Finally, given the training data $\{(\alpha_i, y_i)\}_{i=1}^{\mathcal{N}}$, the regression model $\widehat{W}$ is obtained by solving

$$\min_{\eta} \sum_{i=1}^{\mathcal{N}} |\langle \eta, \Phi(\alpha_i) \rangle - y_i|^2, \text{ subject to } \|\eta\|_1 \leq t. \quad (169)$$

1886 **Theorem 4** (Restatement of Theorem 2). *Let the target state be $|\psi\rangle = \sum_{i=1}^s a_i |\alpha_i\rangle$ with $|\alpha_j| \leq R$ and $|\alpha_j - \alpha_\ell| \geq \Delta_\alpha$ for all $j, \ell \in [s]$ and $j \neq \ell$. Let $\kappa = 1 - (s-1)e^{-\frac{1}{2}\Delta_\alpha^2}$.
1889 Let $\widehat{W}$ be the surrogate obtained by solving Eq. (169). For any $\epsilon, \delta > 0$, assume that all training data in $\mathcal{T}$ satisfies
1891 $|W(\alpha_i) - y_i| \leq \sqrt{\epsilon/4}$, then a training data of size*

$$\mathcal{N} = O\left(\frac{s^4}{\epsilon^2 \kappa^4} \log \frac{4(R + \log(s/\kappa\sqrt{\epsilon}))^8}{\sqrt{\delta}}\right) \quad (170)$$

1892 suffices to achieve $R(\widehat{W}) \leq \epsilon$ for an arbitrary distribution
1893 $\mathbb{D}$ with probability at least $1 - \delta$.

1894 *Proof.* Again, we employ Lemma 1 to derive the generalization error. Thus, we begin by determining the suitable values for t, r_∞ and M . From Corollary 1, we take
1896 $t = O(s/\kappa)$ to ensure $W_{N,K} \in \mathcal{H}$ where $W_{N,K}$ is given
1898 by Eq. (111). Next, since

$$\|\Phi(\alpha)\|_\infty = \|(M_{bn} T_{ak} g)(\alpha)\|_\infty = \|g\|_\infty = 1, \quad (171)$$

1899 where the second equality follows from the unitarily invariance of the norm, we take $r_\infty = 1$. Lastly, for all
1901 $h \in \mathcal{H}$,

$$\begin{aligned} |h(\alpha) - y| &\leq |h(\alpha)| + |y| \\ &\leq |\langle \eta, \Phi(\alpha) \rangle| + |W(\alpha)| + \sqrt{\frac{\epsilon}{4}} \\ &\leq \|\eta\|_1 \|\Phi(\alpha)\|_\infty + \frac{1}{\pi} + \sqrt{\frac{\epsilon}{4}} \\ &\leq \frac{t}{\pi} + \frac{1}{\pi} + \sqrt{\frac{\epsilon}{4}}. \end{aligned} \quad (172)$$

1902 Therefore, we can take $M = O(t) = O(s/\kappa)$. Combining
1903 everything, we have

$$R(\widehat{W}) \leq \widehat{R}_{\mathcal{T}}(\widehat{W}) + O\left(\frac{t^2}{\sqrt{\mathcal{N}}} \left(\sqrt{2 \log(2d_f)} + \sqrt{\frac{1}{2} \log \frac{1}{\delta}}\right)\right). \quad (173)$$

Next, we need to determine the truncation values of N, K such that the empirical error can be bounded as

$$\widehat{R}_{\mathcal{T}}(\widehat{W}) \leq \frac{\epsilon}{2}. \quad (174)$$

1906 By definition, the model returned by the Lasso algorithm
1907 satisfies

$$\widehat{W} = \arg \min_{h \in \mathcal{H}} \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} |h(\alpha_i) - y_i|^2. \quad (175)$$

Since the choice of t ensures that the canonical truncation $W_{N,K}$ lies within the hypothesis class (Corollary 1), we can use it to upper bound the training error of $\widehat{W}$ as

$$\frac{1}{N} \sum_{i=1}^N |\widehat{W}(\alpha_i) - y_i|^2 \leq \frac{1}{N} \sum_{i=1}^N |W_{N,K}(\alpha_i) - y_i|^2 \leq |W_{N,K}(\alpha_{i^*}) - y_{i^*}|^2, \quad (176)$$

where (α_{i^*}, y_{i^*}) denotes the sample with the largest error. Then,

$$\begin{aligned} \widehat{R}_{\mathcal{T}}(\widehat{W}) &\leq |W_{N,K}(\alpha_{i^*}) - y_{i^*}|^2 \\ &\leq (|W(\alpha_{i^*}) - W_{N,K}(\alpha_{i^*})| + |W(\alpha_{i^*}) - y_{i^*}|)^2 \\ &\leq 2\|W - W_{N,K}\|_{\infty}^2 + \frac{\epsilon}{2}, \end{aligned} \quad (177)$$

where we use the assumption that all training data satisfies $|W(\alpha_i) - y_i| \leq \sqrt{\epsilon/4}$. From Corollary 2, by choosing

$$N, K = O\left(R + \log \frac{s}{\kappa\sqrt{\epsilon}}\right), \quad (178)$$

we have

$$\|W - W_{N,K}\|_{\infty} \leq \sqrt{\frac{\epsilon}{8}}. \quad (179)$$

Then, the empirical error can be bounded as

$$\widehat{R}_{\mathcal{T}}(\widehat{W}) \leq \frac{3\epsilon}{4}. \quad (180)$$

In this case, the feature dimension

$$d_f = O(N^2 K^2) = O\left(\left(R + \log \frac{s}{\kappa\sqrt{\epsilon}}\right)^4\right). \quad (181)$$

Finally, by requiring

$$O\left(\frac{t^2}{\sqrt{N}} \left(\sqrt{2\log(2d_f)} + \sqrt{\frac{1}{2}\log\frac{1}{\delta}}\right)\right) \leq \frac{\epsilon}{4} \quad (182)$$

and using $(\sqrt{A} + \sqrt{B})^2 \leq 2(A + B)$, we see that

$$\mathcal{N} = O\left(\frac{s^4}{\epsilon^2 \kappa^4} \log \frac{4(R + \log(s/\kappa\sqrt{\epsilon}))^8}{\sqrt{\delta}}\right). \quad (183)$$

is sufficient to guarantee $R(\widehat{W}) \leq \epsilon$ with probability at least $1 - \delta$. $\square$

C. Complexity of conventional approaches

For completeness, we discuss the sample complexity of two conventional approaches for estimating Wigner functions. The first approach discretizes the phase space into a dense grid and estimates the Wigner function value at any given point using nearest-neighbor estimation. The second approach performs estimation on a discrete set of points and then employs interpolation over this dataset to obtain an estimate at an arbitrary point. Some of the results presented here are inspired by the discussion in Ref. [46].

1. Dense sampling

A straightforward way to approximately reconstruct the Wigner function of an unknown state over a finite region Ω over the phase space is to first discretize the region Ω , for example, into a grid of squares Q_j equal size h^2 . Then at each center of the square, one can estimate the Wigner function value $W_p(c_j)$ by measuring displaced parity. When the grid is sufficiently fine-grained, we can use the measured Wigner function values to approximate the continuous Wigner function.

Specifically, partition Ω into N square cells of side length h and area $\Delta = h^2$. Let c_j denote the center of cell $Q_j := [(c_j)_1 - h/2, (c_j)_1 + h/2] \times [(c_j)_2 - h/2, (c_j)_2 + h/2]$. Then we use the piecewise-constant approximation $W_{pc}(\alpha) := W(c_j)$ for $\alpha \in Q_j$ as the estimation of the Wigner function in the entire region Ω . For each c_j , one can perform the measurement of displaced parity to get an unbiased estimator $\widehat{W}(c_j)$. The following proposition tells us how dense this partition on Ω should be to guarantee the overall estimation error is upper bounded.

Proposition 2 (Sample complexity of dense sampling Wigner function with bounded Hessian). *Let W be the Wigner function of a single-mode quantum state mainly supported on a bounded phase-space region $\Omega \in \mathbb{R}^2$ of area A , beyond which the Wigner function values are negligible. Suppose $\sup_{\alpha \in \Omega} \|HW(\alpha)\| \leq \Lambda$, where $HW(\alpha)$ is the 2×2 Hessian matrix of $W(\alpha)$. Then the piecewise-constant estimator W_{pc} of the Wigner function satisfies*

$$\int_{\Omega} |W(\alpha) - W_{pc}(\alpha)| d\alpha \leq \epsilon \quad (184)$$

with probability at least $1 - \delta$, using $\mathcal{N} = \Theta\left(\frac{\Lambda A^2}{\epsilon}\right)$ different point-wise measurements. When statistical estimation errors are considered, the total sample complexity is $O\left(\frac{\Lambda A^4}{\epsilon^3} \log \frac{\Lambda A^2}{\epsilon \delta}\right)$.

Proof. To show there exists such a reconstruction strategy satisfying the sample complexity,

By Taylor's theorem with with Lagrange form of the remainder, for all $u \in [-h/2, h/2] \times [-h/2, h/2]$, there exists $\xi_u \in Q_j$, such that

$$W(c_j + u) = W(c_j) + \nabla W(c_j) \cdot u + \frac{1}{2} u^\top HW(\xi_u) u, \quad (185)$$

$\nabla W(c_j)$ is the gradient of W at c_j . By symmetry,

$$\begin{aligned} &\int_{Q_j} \nabla W(c_j) \cdot u du \\ &= \nabla W(c_j) \int_{[-h/2, h/2] \times [-h/2, h/2]} u du \\ &= 0. \end{aligned} \quad (186)$$

Thus, taking integral of both sides of Eq. (185) over Q_j ,

we have

$$\begin{aligned} & \left| \int_{Q_j} W(\alpha) d\alpha - W(c_j) \Delta \right| \\ &= \left| \int_{Q_j} \nabla W(c_j) \cdot u du + \frac{1}{2} \int_{Q_j} u^\top H W(\xi_u) u du \right| \quad (187) \\ &\leq \frac{\Lambda}{2} \int_{Q_j} \|u\|^2 du. \end{aligned}$$

where we have used Eq. (186) and the upper bound $\sup_{\alpha \in \Omega} \|H W(\alpha)\| \leq \Lambda$. For each square cell, we have

$$\begin{aligned} \int_{Q_j} \|u\|^2 du &= \int_{[-h/2, h/2] \times [-h/2, h/2]} (u_1^2 + u_2^2) du_1 du_2 \\ &= \int_{[-h/2, h/2] \times [-h/2, h/2]} u_1^2 du_1 du_2 \\ &\quad + \int_{[-h/2, h/2] \times [-h/2, h/2]} u_2^2 du_1 du_2 \\ &= h \cdot \frac{h^3}{12} + h \cdot \frac{h^3}{12} \\ &= \frac{\Delta^2}{6}. \end{aligned} \quad (188)$$

Hence, by substituting Eq. (188) into (187), we have

$$\left| \int_{Q_j} W(\alpha) d\alpha - W(c_j) \Delta \right| \leq \frac{\Lambda \Delta^2}{12}. \quad (189)$$

Summing over all cells, we have

$$\int_{\Omega} |W(\alpha) - W_{\text{pc}}(\alpha)| d\alpha \leq \mathcal{N} \cdot \frac{\Lambda \Delta^2}{12} = \frac{\Lambda A \Delta}{12}. \quad (190)$$

Thus, by choosing $\Delta = \Theta\left(\frac{\varepsilon}{\Lambda A}\right)$ and $\mathcal{N} = \frac{A}{\Delta} = \Theta\left(\frac{\Lambda A^2}{\varepsilon}\right)$, we can ensure that $\int_{\Omega} |W(\alpha) - W_{\text{pc}}(\alpha)| d\alpha \leq \varepsilon/2$.

Up to now, we have not considered the statistical estimation error introduced by finite shot of measurements. It means that $W(c_j)$ is the above definition of W_{pc} is the exact value of the Wigner function. However, we cannot obtain the exact ground truth in real experiments. From now on, Let $\widehat{W}(c_j)$ be the empirical estimate at each cell center. Define $\widehat{W}(\alpha) := \widehat{W}(c_j)$ for $\alpha \in Q_j$ as the estimator of the Wigner function W . If $|\widehat{W}(c_j) - W(c_j)| \leq \eta$, then

$$\begin{aligned} & \int_{\Omega} |W_{\text{pc}}(\alpha) - \widehat{W}(\alpha)| d\alpha \\ &= \sum_{j=1}^N \int_{Q_j} |\widehat{W}(c_j) - W(c_j)| d\alpha \\ &\leq \sum_{j=1}^N \eta \Delta \\ &= A \eta. \end{aligned} \quad (191)$$

By choosing $\eta = \frac{\varepsilon}{2A}$, we can ensure $\int_{\Omega} |W_{\text{pc}}(\alpha) - \widehat{W}(\alpha)| d\alpha \leq \varepsilon/2$.

To ensure all $\mathcal{N}$ estimates succeed with probability $1 - \delta$, using the union bound, we have that for each phase-space point estimate, we need

$$M = O\left(\frac{\log(\mathcal{N}/\delta)}{\eta^2}\right) = O\left(\frac{A^2}{\varepsilon^2} \log \frac{\mathcal{N}}{\delta}\right) \quad (192)$$

samples. Thus, in total we need

$$M \mathcal{N} = O\left(\frac{\Lambda A^4}{\varepsilon^3} \log \frac{\Lambda A^2}{\varepsilon \delta}\right) \quad (193)$$

samples to ensure

$$\int_{\Omega} |W(\alpha) - \widehat{W}(\alpha)| d\alpha \leq \varepsilon/2 + \varepsilon/2 = \varepsilon. \quad (194)$$

□

Since in phase $A \sim d$ (note that $\hat{n} = \frac{\hat{x}^2 + \hat{p}^2 - 1}{2}$), the required number of phase-space points for reliable reconstruction of Wigner functions scales as $O(d^2)$. This is consistent with the fact that the minimum number of phase-space points required to estimate a density matrix on a truncated Hilbert space with dimension d . When considering the statistical error introduced by finite shots of pointwise measurements, the sample complexity scales as $O(d^4 \log d)$.

2. Interpolation

Here we briefly explain how the number of phase-space points required to reconstruct Wigner functions through polynomial interpolation scales at least faster than linearly with the truncation dimension d .

Proposition 3. Suppose $W(\alpha)$ is the Wigner function of a CV state supported within the region $\Omega \subset \mathbb{R}^2$ such that it is differential at least $n+1$ times. Denote the maximum $n+1$ th derivative of W within the region Ω as $\Sigma_n := \max_{\alpha \in \Omega, \|\eta\|=1} D_{\beta}^{n+1} W(\alpha)$, $D_{\beta} W$ denotes the derivative of W along the direction of unit vector $\beta \in \mathbb{R}^2$. Given the Wigner function values at $\mathcal{N}$ phase-space points ($\mathcal{N} \geq n$) within Ω , we can use a n -degree polynomial $P_n(\alpha)$ to approximate $W(\alpha)$ using polynomial interpolation. To ensure the estimation error $\int_{\Omega} |W(\alpha) - P_n(\alpha)| d\alpha \leq \varepsilon$, the required number of phase-space points scales at least as $\Omega\left(\frac{A^{1+2/n} \Sigma_n^{2/n}}{n^2}\right)$.

Proof. Suppose the Wigner function $W_{\rho}(\alpha)$ of a CV quantum state ρ is approximated through an n -degree polynomial $P_n(\alpha)$ over a grid of phase-space points with grid width h with maximal amplitude α_{max} . The approximation error at any phase-space point is bounded by the Lagrange remainder formula, i.e.,

$$|W_{\rho}(\alpha) - P_n(\alpha)| \leq \frac{\Sigma_n h^n}{(n+1)!}, \quad \forall \alpha \in \Omega, \quad (195)$$

To make the above estimation error bounded by ϵ , we only need to make sure

$$h \leq \frac{((n+1)!\epsilon)^{1/n}}{\Sigma_n^{1/n}}. \quad (196)$$

Without loss of generality, suppose the region Ω can partitioned into multiple square cells with each size h^2 . Then the number of measured point-wise Wigner function values is

$$N = \frac{A}{h^2} \geq \frac{A\Sigma_n^{2/n}}{((n+1)!\epsilon)^{2/n}} \in \Omega\left(\frac{A\Sigma_n^{2/n}}{n^2\epsilon^{2/n}}\right). \quad (197)$$

To ensure $\int_{\Omega} |W(\alpha) - P_n(\alpha)| d\alpha \leq \epsilon$, we replace ϵ by ϵ/A in the above inequality, and get the minimum of phase-space points is $\mathcal{N} = \Omega\left(\frac{A^{1+2/n}\Sigma_n^{2/n}}{n^2\epsilon^{2/n}}\right)$. $\square$

Using the relation $\hat{n} = \frac{\hat{x}^2 + \hat{p}^2 - 1}{2}$, we know that $d \sim A$. Consequently, for a fixed n -degree polynomial interpolation, the number of phase-space points at which the Wigner function is measured scales at least as $\Omega(d^{1+2/n})$.

D. Network Architecture and Training Details

This appendix provides additional details on the neural architecture and training procedure used for the single-mode super-resolution task. The model is formulated as a coordinate-conditioned implicit representation of the Wigner function: given a low-resolution input W_{LR} , the network predicts the value of the corresponding high-resolution phase-space function at an arbitrary query coordinate $\mathbf{x}$. The central object learned by the model is therefore a continuous phase-space function, rather than a discrete array tied to a fixed output grid.

The network consists of an encoder that extracts latent features from the low-resolution Wigner function and a decoder that maps the sampled latent feature, together with the query coordinate and the associated cell size, to the Wigner-function value at that point. The encoder is a four-layer two-dimensional residual convolutional network. Each layer consists of a 3×3 convolution, batch normalization, and a ReLU activation, together with a 1×1 projection on the residual branch for channel matching. Starting from a single-channel input, the feature width increases to 64, 128, and 256, with a final latent dimension of 256. At each query location, the decoder samples the encoder feature map and combines the sampled feature with the two-dimensional coordinate and the corresponding cell size through a multilayer perceptron. An auxiliary shallow branch is used to encode the geometric information carried by the coordinate and cell-size inputs before feature fusion.

The training data consist of precomputed Wigner-function arrays. For each original sample, both the low-resolution input and the supervision target are generated

by resampling the available measurement array to different grid sizes. In the experimental-data setting, this available array is the retained sparse measurement grid, while the dense experimental measurement is used only as an evaluation reference. The model is therefore trained across multiple resolution pairs rather than a single fixed scaling factor. Resampling is performed using spline interpolation. Query coordinates are normalized to the unit interval along each dimension, and the cell size is given by the inverse grid spacing of the target resolution. The model is trained with the mean-squared error loss and optimized with Adam. We use a cosine learning-rate schedule with warm-up, and model selection is performed using the validation loss. In addition to the regression loss, we monitor the state fidelity during validation and testing as a physically meaningful measure of reconstruction quality. See Fig. 12 for a summary of the learning procedure of our DNN model.

E. Details of numerical experiments

In this subsection, we provide details about the numerical experiments on both the regression model and the DNN model presented in the main text, along with additional numerical results for comparison between two learning models. This subsection is divided into three parts: learning simulated states with regression model; learning simulated states with neural network model and learning experimental states with neural network model.

1. Learning simulated states with regression models

The numerical study of the regression model is organized around a simple experimental question: how many phase-space sample points are needed for precise reconstruction, and how sensitive is the fit to finite shot noise at each sample point? We answer this question in two stages. We first test the feature map constructed from Wigner functions of Fock basis elements, equivalently the generalized Laguerre feature map, on states whose structure is sparse on the Fock basis. We then turn to the Gabor-frame feature map and ask how well the same sparse-regression principle works for states as superpositions of few coherent-states.

The first test is on binomial code states. These states give a controlled way to separate the Hilbert-space cutoff from the actual Fock support: fixing $N = 3$ while increasing S enlarges the truncation dimension $d = (N+1)(S+1)$ without increasing the number of occupied Fock components, whereas fixing $S = 3$ while increasing N makes the support itself grow. For each state, we draw training coordinates uniformly at random from $[-6, 6]^2$, evaluate the ideal Wigner function using QuTiP, and construct a finite Laguerre design matrix whose rows correspond to sampled phase-space coordinates and whose columns correspond to the retained Laguerre basis features evalu-

FIG. 12: The learning scheme for our DNN model inspired by high-resolution image reconstruction. During training, the model parameters are optimized in a self-supervised manner to minimize estimation errors in the mid-resolution Wigner function reconstructed from low-resolution input. During inference, the trained model is applied to reconstruct high-resolution Wigner functions.

ated at those coordinates. We then fit the corresponding coefficients using `sklearn.linear_model.Lasso`. Eq. (7) uses the constrained Lasso formulation, where the radius t bounds the ℓ_1 norm of the coefficient vector and therefore specifies the sparse hypothesis class used in the analysis. In the numerical experiments, the standard scikit-learn implementation instead solves the optimization:

$$\min_{\boldsymbol{\eta}} \hat{R}_{\mathcal{T}}(\hat{W}_{\boldsymbol{\eta}}) + \lambda \|\boldsymbol{\eta}\|_1, \quad (198)$$

which writes the same Lasso tradeoff in penalized form. The training error is minimized together with an ℓ_1 penalty, and the regularization hyperparameter λ determines how strongly sparsity is promoted. While there is no analytical relation between λ and t for the two Lasso formulations, the regularization strength λ plays the numerical role of choosing the constraint radius t : stronger λ corresponds to a smaller effective ℓ_1 budget and therefore a sparser fitted coefficient vector with smaller t , and vice versa.

The fidelity $\mathcal{F}$ is evaluated on a fixed 128×128 grid of ideal Wigner values, and we binary search over the number of training points to find the smallest set that reaches $\mathcal{F} \geq 0.99$. Figures 2a and 2b show that the required number of points is nearly flat when the Fock support is fixed and increases when the support grows, while remaining far below the $d^2 - 1$ reference for conventional tomography. Representative reconstructions are shown in Figs. 2c and 2d.

We next apply the same Laguerre-feature regression to simulated GKP states. This is a more stringent test, because GKP states are not exactly sparse in the Fock basis even though their Wigner functions have strong

structure in phase space. The training coordinates are drawn uniformly at random from $[-3, 3]^2$, and the truncation dimension is chosen as the smallest d satisfying $\text{Tr}(\Pi_d \rho) \geq 1 - 10^{-4}$, where $\Pi_d = \sum_{n=0}^{d-1} |n\rangle\langle n|$. The same fitting and fidelity-evaluation protocol is then used. Figs 13a,b show that this regression model still reconstructs both ideal and lossy GKP Wigner functions from substantially fewer phase-space points than conventional Wigner tomography would require.

The second stage uses the Gabor-frame feature map. We begin with even cat states, which are the canonical sparse coherent-state example. The simulated states are normalized superpositions $|\mathcal{C}_{\alpha}^{+}\rangle \propto |\alpha\rangle + |-\alpha\rangle$ with phase fixed to zero, using the four amplitudes $\alpha = 0.5854 + 0.5854i$, $0.8684 + 1.5041i$, $3.6722i$, and $5.5673 + 3.2143i$. For each amplitude, the phase-space window is chosen to contain the non-negligible support of the Wigner function, and training points are sampled randomly from a circular region inside that window. At these sampled coordinates, we evaluate the retained real-valued Gabor features to construct a finite design matrix, where each row corresponds to a sampled phase-space coordinate and each column corresponds to a retained Gabor feature evaluated at that coordinate. We then fit the corresponding expansion coefficients using the same penalized Lasso solver from scikit-learn described above. Fig. 3 shows the resulting sample-complexity scaling and representative reconstructions, demonstrating that the Gabor-frame feature map can efficiently capture both the coherent peaks and the interference fringes of the cat states.

Finally, we use the output states of multi-layered random displacement-SNAP circuits as a stress test for the coherent-state feature map. Each circuit layer consists

FIG. 13: Reconstruction of Wigner functions for simulated GKP states using a regression model. **a**, Comparison of the number of phase-space points required to achieve a fidelity of 0.99 for both a noiseless GKP state and a GKP state subject to photon loss, plotted against the dimension of the truncated Hilbert space. The scaling required for information completeness in conventional Wigner tomography ($d^2 - 1$) is shown as a reference. **b**, Detailed view of the data requirements presented in **a**, showing the number of phase-space points needed for reconstructing ideal and lossy GKP states as a function of truncation dimension. **c**, Fidelity of the reconstructed Wigner function as a function of the number of measurement shots per phase-space point, shown for GKP states with varying squeezing parameters and numbers of Gaussian peaks.

of a displacement gate $D(\alpha)$ followed by a SNAP gate placement, as in the main text, so the labels carry statistical noise. The fidelity $\mathcal{F}$ is still evaluated on the fixed SNAP(θ) = $\sum_{n=0}^{d-1} e^{i\theta_n} |n\rangle \langle n|$. We truncate the Hilbert space to $d = 30$, choose $L \in \{1, 2, 3, 4, 5, 6\}$ layers, sample ideal Wigner grid using noiseless Wigner values as the displacements with $|\alpha| \leq 1.5$, and draw the SNAP phases independently from $[0, 2\pi)$. Unlike cat states, these random circuits do not have an explicit small coherent-state support, and increasing the circuit depth produces increasingly structured Wigner functions. Figures 2e, 2f and 13c plot $\mathcal{F}$ versus the number of shots per sampled point for binomial and GKP states, respectively.

support, and increasing the circuit depth produces increasingly structured Wigner functions. Figure 14 reports the resulting reconstruction fidelity as a function of circuit depth and Wigner negativity, and Figure 15 shows representative reconstructions. The degradation with depth highlights the limitation of using a fixed sparse coherent-state feature map outside its natural regime.

To study finite shot noise, we rerun the regression at several fixed shot counts. For each count, the training target at every sampled phase-space point is the empirical mean of simulated parity measurements after a dis-

2. Learning simulated states with neural network models

We first test the neural network model on the same family of simulated even cat states described above. For each value of the coherent amplitude α , we train the implicit neural representation from sparse phase-space data and record the minimum number of training points required to achieve $\mathcal{F} \geq 0.99$. As shown in Fig. 16, the required number of data points follows an empirical scal-

FIG. 14: Performance of the Gabor-frame regression model for output states prepared random displacement and SNAP circuits. **a**, Reconstruction fidelity as a function of the number of circuit layers. **b**, Reconstruction fidelity versus the Wigner negativity of the corresponding output states.

FIG. 15: Example Wigner function reconstructions at various circuit depths using the Gabor-frame regression model. Here, L denotes the number of circuit layers. Each pair of images shows the reconstructed Wigner function alongside the ground truth. The measurement data grid is also overlaid on the ground truth plots. The green circles on the left panels correspond to the centers of the Gaussians for the Gabor frame.

ing close to quadratic in the truncation dimension d . This behavior contrasts with the regression model designed for CV states sparse in coherent-state support, and reflects that the neural network model does not explicitly use the two-component coherent-state structure of cat states.

FIG. 16: Required number of phase-space training points for the neural network model to reconstruct simulated cat states with fidelity $\mathcal{F} \geq 0.99$. The conventional Wigner tomography scaling $d^2 - 1$ is shown for comparison.

For the remaining simulated benchmarks, the neural network experiments reuse the simulated GKP preparation, the same $\mathcal{F}$ evaluation on the fixed 128×128 grid of ideal Wigner values from QuTiP introduced in Appendix VII E 1, and the finite shot protocol described there, but replace the regression surrogate with the self-supervised implicit network training of Sec. IV.

For $|\bar{0}\rangle$ states in Eq. (30), we generate low- and mid-resolution training maps by resampling a prescribed simulated measurement grid, train the decoder described in Sec. IV, and binary search the training resolution for the smallest grid that achieves $\mathcal{F} \geq 0.99$. The fidelity is evaluated on the same 128×128 grid of ideal Wigner values used in Appendix VII E 1. Note that the 128×128 grid serves only as a dense evaluation mesh, and the trained implicit map can still be queried at arbitrary coordinates in phase space. We report sample complexity versus d relative to $d^2 - 1$ for noiseless data and for data with photon loss, where the lossy state is obtained by solving the Lindblad master equation in QuTiP with zero Hamiltonian and a single photon-loss collapse operator. In this simulation, the loss rate is set to 0.001 and the state is evolved until time 20.0. We also include a representative MLE runtime comparison. Figure 4 shows the results obtained under these numerical settings.

To probe states without a fixed algebraic description, we use the same layered displacement-SNAP circuit ensemble and parameter choices as in Appendix VII E 1. For each L we draw ten random instances. The Wigner function of each instance is evaluated on an 18×18 grid over $[-5, 5]^2$; this resolution is both the measurement footprint used for self-supervised training and the scale at which coarse inputs are formed. After training, we query

the model on an 81×81 grid and report the state fidelity $\mathcal{F}$ and the Wigner negativity $\int_{\mathbb{R}^2} dx dp |W_\rho(x, p)|$ [48], which is approximated by the corresponding sum over the 81×81 predicted Wigner grid. Figure 9 shows how deeper circuits, which produce more complex phase-space patterns, affect these metrics.

3. Learning experimental states with neural network model

Having explored the DNN model on simulated Wigner functions in the preceding subsection, we now test it on experimental states. We use the same pipeline as in the main text: the implicit architecture and self-supervised super-resolution training of Sec. IV, with a sparse measured grid as input and the full experimental data used only as a dense reference for evaluation. The discussion below follows the same order as Sec. IV: reconstruction of an experimental GKP state, analysis of the noisy GKP states after multiple rounds of quantum error correction, and reconstruction of a non-Gaussian state prepared with a SNAP gate on a coherent state. In the test of GKP states, the experimental data come from the circuit-QED implementation of Ref. [3]. In every experimental test below, we use the same rule to construct the training data: although the recorded measurements are available on a dense 81×81 grid, we retain only every third sample along each axis to obtain a 27×27 sparse measurement grid for training. The remaining 81×81 data are kept hidden from the model and used only as the dense experimental reference for evaluation.

Reconstruction of an experimental GKP state. Figure 5 benchmarks the performance of our DNN model on reconstructing experimental GKP states by comparing it against bilinear interpolation, and two regression models in Sec. III A. The overlap with the full experimental data is 0.9993 for the DNN model, indicating that the DNN model preserves the fine lattice structure most faithfully. Training follows the multi-scale recipe: from the measured 27×27 map we form low- and mid-resolution pairs, with input sizes ranging from 20×20 to 25×25 and target sizes 26×26 or 27×27 ; after training, the DNN model predicts the 81×81 Wigner function used in the comparison. All subsequent experiments on real measurement data are trained using the same procedure, and we do not repeat these details below.

Analysis of noisy GKP states after multiple rounds of QEC. We first analyze the experimental GKP states $\rho_{\bar{0}}(t)$ after QEC cycle counts $t \in \{0, 100, 200, 400, 800\}$. Figure 6 compares the DNN-predicted 81×81 Wigner functions with the full experimental data at each cycle count. To compare the reconstructed Wigner functions with the physical properties analyzed in the main text, we use maximum likelihood estimation to obtain physical density matrices from both the DNN predictions and the full experimental data. Figure 17 shows the analysis of resulting GKP state $\rho_{\bar{0}}(t)$: panel **a** compares the fidelity with respect to the theoretical GKP state $|\bar{0}\rangle_{\text{GKP}}$

FIG. 17: **a**, Fidelity of the reconstructed state with respect to that of the theoretical target GKP state $|\bar{0}\rangle$ as a function of the squeezing parameter $\sigma \in [0.1, 0.5]$, shown for states after $t = 0, 100, 200, 400$, and 800 QEC cycles. For comparison, both the fidelities of states reconstructed from DNN prediction and full experimental data are shown respectively. **b**, The largest four eigenvalues in the spectral decomposition of the density matrix for the reconstructed GKP $|\bar{0}\rangle$ state after $t = 0, 100, 200, 400$, and 800 QEC cycles. For comparison, the density matrices reconstructed from the DNN predictions and from the full experimental data are both shown.

in Eq. (29) as a function of the squeezing parameter σ , while panel **b** compares the four leading eigenvalues of the reconstructed density matrices. The DNN-based estimates agree well with the full-data estimates for the leading logical components, whereas the smaller error-subspace eigenvalue curves in panel **b** show larger deviations. These deviations do not by themselves indicate poor reconstruction quality; the phase-space analysis below shows that the DNN prediction still identifies the dominant error subspace.

We then combine the $|\bar{0}\rangle$ and $|\bar{1}\rangle$ branches to analyze the logical and most probable error subspaces. This mixture removes the dependence on a particular logical state and allows the leading eigenspaces of the density matrix to identify the experimentally realized logical subspace and the dominant error subspace. For each QEC cycle count, we form

$$\rho_{\text{mix}}(t) = \frac{\rho_{\bar{0}}(t) + \rho_{\bar{1}}(t)}{2}. \quad (199)$$

Following the spectral decomposition in Eq. (31), the two leading eigenvectors define the experimental logical subspace, while the next two define the most probable error subspace.

To examine these inferred subspaces directly, Fig. 7 visualizes their Wigner functions in phase space. For each

QEC cycle, it plots the Wigner functions of the normalized projection onto the experimental logical subspace and the normalized projection onto the most probable error subspace, computed from three inputs: the sparse 27×27 experimental grid, the full 81×81 experimental data, and the DNN-predicted 81×81 Wigner function. This comparison shows how the DNN prediction propagates into the inferred logical and error subspaces, not merely into pointwise Wigner-function overlap.

The most probable error subspace is examined more closely in Fig. 8. There we focus on the projection $(|E_{\bar{0}}\rangle \langle E_{\bar{0}}| + |E_{\bar{1}}\rangle \langle E_{\bar{1}}|)/2$ and compare the Wigner functions obtained from the sparse 27×27 data, the full 81×81 data, and the DNN prediction. The rightmost panel shows the ideal photon-addition error pattern, proportional to $\hat{a}^\dagger(|\bar{0}\rangle + |\bar{1}\rangle)(\langle\bar{0}| + \langle\bar{1}|)\hat{a}$, as a reference for heating noise in the cavity mode. Consistent with the discussion in the main text, the DNN prediction recovers an error-subspace Wigner pattern closer to this photon-addition reference than the direct reconstructions from the sparse or full experimental grids.

Reconstruction of a state prepared with a SNAP gate on a coherent state. Finally, we revisit the experimental CV state prepared by applying a SNAP gate to a coherent state, as in the main text and Fig. 11. Using only the 27×27 sparse measurement grid as input, the DNN model reconstructs the Wigner function with overlap above 0.98 with respect to the full experimental data.

A Finite-Window Recovery Hierarchy for Local Quantum Memory

Zheng An

Abstract. Loss of on-site recoverability does not determine whether local quantum memory has been destroyed or merely displaced into a nearby neighborhood. We formulate this distinction as a finite-window channel-recovery task under a fixed access model consisting of local state preparation, many-body evolution, bounded-depth control on a radius- r window, and target-qubit Pauli readout. The resulting local variational recovery (LVR) score is compared with two CPTP benchmarks: the optimal on-site recovery and the optimal same-window recovery. In a disordered kicked-Ising Floquet benchmark, a five-site depth-6 decoder yields the hierarchy $Q_0^{\text{opt}} < Q_2^{\text{shallow}} < Q_2^{\text{opt}}$ across the crossover regime, while larger-chain tensor-network data show that the positive radius-2 certified gain is not confined to the exact-diagonalization size. Finite-window recovery therefore provides a local decoder benchmark for off-site recoverable memory rather than a background-independent phase diagnostic.

1 Problem

When information is no longer recoverable from a target qubit, two qualitatively different situations remain possible: the information may be lost, or it may survive in nearby degrees of freedom that are inaccessible to target-site readout alone. In disordered many-body systems this distinction is natural from both the localization and quantum-control viewpoints [1–4]. Existing diagnostics, including spectral statistics, local observables, and channel tomography, address related but different questions [5–7]. Here we instead ask an explicitly operational question: under a fixed local-access model, how much target-input memory can be recovered from a bounded window around the target?

2 Finite-Window Recovery Framework

Fix a target qubit i , a radius- r window $\Lambda_r(i)$, a product-state background $|\phi_{\text{bg}}\rangle$ on all non-target sites, and a many-body evolution U . The target-input channels to the target site and to the full recovery window are

$$\mathcal{E}_0(\rho) = \text{Tr}_i[U(\rho_i \otimes |\phi_{\text{bg}}\rangle\langle\phi_{\text{bg}}|_i)U^\dagger], \quad (1)$$

$$\mathcal{E}_r(\rho) = \text{Tr}_{\Lambda_r(i)}[U(\rho_i \otimes |\phi_{\text{bg}}\rangle\langle\phi_{\text{bg}}|_i)U^\dagger]. \quad (2)$$

We use a bounded-depth decoder $\mathcal{D}_{\hat{\theta},r,L}$ acting only on $\Lambda_r(i)$ and evaluate the recovered target channel with the six-state score

$$Q(\mathcal{N}) = 2F_6(\mathcal{N}) - 1, \quad (3)$$

where F_6 is the mean recovery fidelity over the six cardinal input states. This score is exactly the average channel fidelity with the identity channel on the input qubit.

The implemented shallow score and the exact CPTP benchmarks are

$$Q_r^{\text{shallow}} = Q(\mathcal{D}_{\hat{\theta},r,L} \circ \mathcal{E}_r), \quad (4)$$

$$Q_0^{\text{opt}} = \max_{\mathcal{D}_0 \text{ CPTP}} Q(\mathcal{D}_0 \circ \mathcal{E}_0), \quad Q_r^{\text{opt}} = \max_{\mathcal{D}_r \text{ CPTP}} Q(\mathcal{D}_r \circ \mathcal{E}_r). \quad (5)$$

The certified finite-window gain

$$\Delta_r^{\text{cert}} = Q_r^{\text{shallow}} - Q_0^{\text{opt}} \quad (6)$$

tests whether the chosen window contains recoverable information beyond the target output alone. If $\mathcal{E}_r = \mathcal{T}_r \circ \mathcal{E}_0$ for some CPTP map $\mathcal{T}_r$, then $Q_r^{\text{opt}} = Q_0^{\text{opt}}$; therefore any observed $\Delta_r^{\text{cert}} > 0$ rules out a purely target-site post-processing explanation. When the same-window optimum is available, we also define the accessibility fraction

$$\eta_r = \frac{Q_r^{\text{shallow}} - Q_0^{\text{opt}}}{Q_r^{\text{opt}} - Q_0^{\text{opt}}}, \quad (7)$$

which measures how much of the locally available window advantage is reached by the chosen shallow decoder.

3 Benchmark Results

We benchmark the framework in a disordered kicked-Ising Floquet chain, a standard interacting setting in which periodic driving, interactions, and disorder compete directly [9, 10]. The reference calculation uses $N = 12$, target site $i = 6$, a Néel background on the non-target spins, radius $r = 2$, decoder depth $L = 6$, and 100 disorder realizations per disorder point.

Figure 1 summarizes the main result. Across the crossover regime, the target-site optimum, shallow radius-2 decoder, and same-window optimum form a strict hierarchy,

$$Q_0^{\text{opt}} < Q_2^{\text{shallow}} < Q_2^{\text{opt}}. \quad (8)$$

The first inequality implies positive certified gain for the large majority of disorder realizations, so recoverable memory remains present outside the target site but inside the five-site window. The second inequality shows that this window advantage is not fully exhausted by the chosen

Figure 1: Main exact benchmark for a radius-2, depth-6 decoder in the disordered kicked-Ising chain. Left: the operational hierarchy $Q_0^{\text{opt}} < Q_2^{\text{shallow}} < Q_2^{\text{opt}}$ across the crossover regime. Middle: the certified gain Δ_2^{cert} . Right: the accessibility fraction η_2 . The figure separates what is recoverable from the target site alone, what is recovered by shallow local control, and what is recoverable in principle from the same window.

shallow decoder, and the corresponding η_2 values remain substantial across the exact benchmark.

This hierarchy is not redundant with more familiar diagnostics. Target-site persistence tracks what survives on the target output, while a tomographic channel-information increment $\Delta I_{c,2}$ counts additional channel content present in the window. By contrast, Δ_2^{cert} asks whether bounded local decoding can beat the optimal on-site baseline, and η_2 asks what fraction of the same-window optimum is already reached by the shallow circuit. These quantities can respond in overlapping disorder windows while addressing different access questions.

To check that the witness is not confined to the exact-diagonalization size, we also evaluated the same radius-2 task on longer open chains generated by an independent tensor-network backend. The positive radius-2 certified gain persists for $N = 24, 32$, and 40 , and on the subset where the same-window optimum was explicitly solved, the shallow decoder still captures a substantial fraction of the available window advantage. The larger-size data therefore support the narrower claim that the local witness remains nontrivial beyond the $N = 12$ exact benchmark.

4 Conclusion

The finite-window recovery benchmark separates three layers of locally retained information: what is recoverable from the target site alone, what is recovered by bounded-depth control on a finite window, and what is recoverable in principle from that same window. In the disordered kicked-Ising benchmark this yields a robust radius-2 hierarchy together with positive certified gain and substantial shallow accessibility. The framework is operational by construction and can be extended to other many-body evolutions or to block-encoded inputs without changing the underlying channel-recovery logic.

Abstract. Quantum simulation is a key application of quantum computing, but how quantum resources affect simulation fidelity remains unclear. We establish a rigorous link between entanglement, magic, and the statistics of Trotter-Suzuki errors in Hamiltonian simulation. Studying state ensembles with fixed entanglement entropy or non-stabilizerness, we find that Trotter-error variance decreases as entanglement grows, showing stronger error concentration. We further show that error kurtosis decreases linearly with magic, so highly magic states have lighter tails and fewer large deviations. Thus, resources that hinder classical simulation can enhance quantum-simulation robustness, revealing a constructive connection between computational complexity and stability.

Keywords: Quantum simulation, Entanglement, Magic

Quantum simulation is a foundational application of quantum computing, promising transformative advantages across quantum physics and chemistry [2, 3]. In the realm of classical simulation, quantum resources often serve as the fundamental bottlenecks that dictate simulation efficiency: entanglement necessitates exponential bond dimension in tensor networks [4, 5, 6, 7], and magic renders Clifford-based emulation exponentially hard [8, 9, 10, 11]. Paradoxically, while these resources are well-established bottlenecks for classical algorithms, their influence on the performance of quantum simulation algorithms themselves remains largely unexplored.

Recent studies have shifted focus from Hamiltonian-only bounds to state-dependent error analysis [12, 13, 14]. However, prior work suggests that quantum resources offer little advantage in terms of average Trotter error—highly entangled states perform similarly to random ones on average [14, 15, 16]. This raises a fundamental question: Do quantum resources influence the statistical landscape of simulation errors—such as their variance and rare-event tails—rather than just their mean?

In this Letter, we establish a rigorous connection between entanglement, magic, and the statistical stability of digital quantum simulation (FIG. 1). We demonstrate that the very resources that obstruct classical emulation actually enhance the robustness of quantum simulation. By analyzing ensembles with fixed resources, we uncover two key phenomena: (1) Entanglement suppresses the variance of the Trotter error, leading to stronger error concentration; (2) Magic reduces the kurtosis, resulting in lighter-tailed distributions and fewer extreme deviations (outliers).

Hamiltonian simulation with Trotter formula—The Trotter-Suzuki decomposition [18, 19] approximates the ideal evolution $\mathcal{U}_0(\delta t) = e^{-iH\delta t}$ by a product of

Figure 1: Entanglement reduces error size, while magic suppresses outliers. We use local-unitary-equivalent states (left) and global-Clifford-equivalent states (right) to fix entanglement and magic, respectively. Entanglement reduces the variance of error and lowers its upper bound. Meanwhile, high magic suppresses the tail of the error distribution, reducing the probability of errors that deviate significantly from the mean value.

individual exponentials $\mathcal{U}_p(\delta t)$. While worst-case spectral norm bounds $\|\mathcal{U}_0 - \mathcal{U}_p\|$ are standard, they often overstate the error for physical states with specific structures [12, 15]. We focus on the state-specific error $\|(\mathcal{U}_0 - \mathcal{U}_p)|\psi\rangle\|$, which reveals how initial-state resources influence simulation fidelity. For small δt , the error is dominated by the leading-order commutator term E :

$$\mathcal{U}_0(\delta t) - \mathcal{U}_p(\delta t) = E\delta t^{p+1} + \mathcal{O}(\delta t^{p+2}). \quad (1)$$

For local Hamiltonians, E can be decomposed into a sum of local error terms $E = \sum_j E_j$. To quantify how quantum resources in $|\psi\rangle$ impact performance, we define the squared leading-order error:

$$s_E(\psi) := |E|\psi\rangle|^2 = \langle\psi|E^\dagger E|\psi\rangle. \quad (2)$$

This quantity $s_E(\psi)$ serves as our primary statistical proxy for the simulation error. Our subsequent analy-

Figure 2: Entanglement reduces the variance of simulation errors. We simulate a 10-qubit system under the QIMF model with two parameter sets: one, $(h_x, h_y, J) = (0.8090, 0.9045, 1)$, causing rapid entanglement growth (a); and another, $(h_x, h_y, J) = (0, 0.9045, 1)$, with slow growth (b) [17]. The entanglement entropy of the state $|\psi_t\rangle = e^{iHt}|\psi_0\rangle$ (of the reduced density matrices on the first few qubits) is shown as the dashed lines (right Y-axis). For each time t , we take the state $|\psi_t\rangle$ and calculate the variance of s_E using the 1st-order Trotter method over the ensemble $\mathcal{E}_{LU}(\psi_t)$ in Eq. (3), shown as the solid line (left Y-axis).

sis treats $s_E(\psi)$ as a random variable over ensembles of states with fixed quantum resources.

Error Variance and Quantum Entanglement— We first discuss the impact of entanglement on quantum simulation, and are concerned with the statistical properties of the Trotter error exhibited by all states possessing a fixed amount of entanglement.

As such, we define the random state ensemble

$$\mathcal{E}_{LU}(\psi_0) := \left\{ \left(\bigotimes_{i=1}^N U_i \right) |\psi_0\rangle \right\} \quad (3)$$

where each U_i is a single-qubit Haar-random unitary [20, 21]. It is clear that all states in $\mathcal{E}_{LU}(\psi_0)$ are local-unitary-equivalent to $|\psi_0\rangle$, thus own the same entanglement. In this way, we can bound the variance of the simulation error in the following theorem.

Theorem 1 *For an initial state $|\psi_0\rangle$ and the leading error $E = \sum E_j$ of Hamiltonian simulation algorithm, the variance of the state error term $s_E(\psi)$ given in Eq. (2), evaluated under the distribution $\mathcal{E}_{LU}(\psi_0)$ defined in Eq. (3) is bounded by the entanglement entropy of sub-*

systems,

$$\text{Var}_{|\psi\rangle \sim \mathcal{E}_{LU}(\psi_0)}[s_E(\psi)] \leq \sum_{jj'} a_{jj'} \sqrt{2[\log(d_{jj'}) - S(\rho_{jj'})]}, \quad (4)$$

where $S(\rho) = -\text{Tr}[\rho \log(\rho)]$, and the reduced density matrix $\rho_{jj'} = \text{Tr}_{[N] \setminus \text{supp}(jj')}(|\psi_0\rangle\langle\psi_0|)$ and $d_{jj'} = 2^{|\text{supp}(jj')|}$, with $\text{supp}(jj') := \text{supp}(E_{jj'}^\dagger E_{jj'})$ for short.

Theorem 1 shows that for a set of states with higher entanglement, the variance of the error should be smaller than that for states with lower entanglement, as numerically certified in FIG. 2 with QIMF models. In addition, the local unitary introduced in Eq. (3) forms an 1-design, so $\mathbb{E}[s_E(\psi)] = \|E\|_F^2$ for any $|\psi_0\rangle$ [14], where we denote $\|A\|_F := \sqrt{\text{Tr}(A^\dagger A)/d}$ as the normalized Frobenius norm. This suggests that the Trotter errors of states with higher entanglement tend to cluster more closely around $\|E\|_F^2$. One can readily observe this by applying probabilistic inequalities such as Chebyshev's inequality, $\Pr_{|\psi\rangle \sim \mathcal{E}_{LU}(\psi_0)}[|s_E(\psi) - \|E\|_F^2| \geq k\sigma] \leq \frac{1}{k^2}$, where $\sigma = \sqrt{\text{Var}(s_E(\psi))}$ denotes the standard deviation.

Error Kurtosis and Quantum Magic— In resource theory, Clifford operations and stabilizer states are “free” due to their efficient classical simulability (Gottesman-Knill theorem [22]), whereas non-Clifford gates generate magic—the essential resource for universal quantum computation [23, 24]. Given a pure state $|\psi\rangle$, define the α -stabilizer purity $P_\alpha := \frac{1}{d} \sum_{P \in \mathcal{P}_N} |\langle \psi | P | \psi \rangle|^2$, and then linear α -stabilizer entropy shows $M_\alpha^{\text{lin}}(\psi) := 1 - P_\alpha$. In this Letter, we choose $M(\psi) := M_2^{\text{lin}}(\psi)$ with $\alpha = 2$ to quantify the magic of the state $|\psi\rangle$, which is a strong stabilizer monotone [25, 26, 27, 28, 29, 30, 31] and also feasible to compute.

Now we investigate the impact of magic on quantum simulation. By definition, one has the fact that $M(|\psi\rangle) = M(C|\psi\rangle)$ for all Clifford unitary C . We thus choose the random ensemble $\mathcal{E}_{GC}(\psi_0)$ with each state inside obtained by applying a random Clifford gate $C \in \text{Cl}(2^N)$ to a starting state $|\psi_0\rangle$,

$$\mathcal{E}_{GC}(\psi_0) := \{C|\psi_0\rangle\}. \quad (5)$$

The Clifford group forms a 3-design but not a 4-design [32, 33, 34], so the first three moments of $s_E(\psi)$ will not exhibit any dependence on different initial state $|\psi_0\rangle$. As a result, it is natural to consider the fourth moment, and we investigate the kurtosis of the error term here. The definition of the kurtosis of $s_E(\psi)$ shows [35],

$$\text{Kur}_{|\psi\rangle \sim \mathcal{E}_{GC}(\psi_0)}(s_E(\psi)) = \mathbb{E} \left[\left(\frac{s_E(\psi) - \mathbb{E}[s_E(\psi)]}{\sigma} \right)^4 \right], \quad (6)$$

with σ the standard deviation of $s_E(\psi)$. By applying the properties of the 4th-moment function of Clifford group [33, 34, 36], we can bound the kurtosis of the leading-order error term via the following Theorem 2.

Figure 3: Magic reduces the kurtosis of simulation errors of QIMF with $(h_x, h_y, J) = (0.8090, 0.9045, 1)$. (a) Error distributions for the ensemble in Eq. (5) using five starting states $|\psi_k\rangle$ with different magic values M_k . The inset clearly shows a higher proportion of outliers in the low-magic ensembles. (b) The corresponding relationship between kurtosis and magic, exhibiting a clear negative linear correlation, as predicted by Eq. (7).

Theorem 2 For an initial state $|\psi_0\rangle$ with magic $M(\psi_0)$ and leading error $E = \sum E_j$ of p th-order product formula the kurtosis of the error term $s_E(\psi)$ given in Eq. (6) under the distribution $\mathcal{E}_{GC}$ defined in Eq. (5) is linear with the magic $M(\psi_0)$. Specifically, the kurtosis satisfies

$$\text{Kur}_{|\psi\rangle \sim \mathcal{E}_{GC}(\psi_0)}[s_E(\psi)] = \alpha + \beta M(\psi_0), \quad (7)$$

where α, β are some coefficients only related to E . If E consists of at most $\text{poly}(N)$ terms, the dominant term of β is negative.

It is worth to note that the error terms of constant-order product formulas satisfy this requirement in Theorem 2 for the majority of Hamiltonian simulation scenarios.

A smaller kurtosis generally implies thinner tails, which means a lower probability of extreme values occurring [37, 38]. It is clearly certified by the numerical results in FIG. 3: a state with greater magic implies a smaller probability that its Trotter error deviates significantly from the mean value.

Long-time behavior— The previous discussion mainly focused on the one-step Trotter error, and we can apply the earlier conclusions to the long-time scenario.

For large time t , the full evolution interval can be uniformly partitioned into r steps of duration $\delta t = t/r$. The true evolution $\mathcal{U}_0(t) = \mathcal{U}_0(\delta t)^r$ is commonly approxi-

mated by the product $\mathcal{U}_p(\delta t)^r$ of the approximate unitary $\mathcal{U}_p(\delta t)$, abbreviated as $\mathcal{U}_p$ for brevity. The long-time Trotter error can be bounded via the triangle inequality. [39]

$$\|(\mathcal{U}_p^r - \mathcal{U}_0^r)|\psi_0\rangle\| \leq \sum_{k=0}^{r-1} \|(\mathcal{U}_p - \mathcal{U}_0)\mathcal{U}_p^k|\psi_0\rangle\|. \quad (8)$$

For simplicity, we denote $\sum_{k=0}^{r-1} \|(\mathcal{U}_p - \mathcal{U}_0)\mathcal{U}_p^k|\psi_0\rangle\|$ as e_r . We define $S_k = \{s \subseteq [N] | s = \text{supp}(\mathcal{U}_p^{\dagger k} E_j^\dagger E_j \mathcal{U}_p^k), \forall j, j'\}$ as the set of supports for each term in the expansion of operator $\mathcal{U}_p^{\dagger k} E^\dagger E \mathcal{U}_p^k$. Subsequently, we establish the following theorem.

Theorem 3 Given a state $|\psi_0\rangle$ with entanglement structure $S(\rho_A)$, neglecting the influence of higher-order terms in δt , the variance of the p -th order Trotter error under $\mathcal{E}_{LU}(\psi_0)$ satisfies

$$\text{Var}_{|\psi\rangle \sim \mathcal{E}_{LU}(\psi_0)}[e_r] \leq r \delta t^{2p+2} \sum_{k=0}^{r-1} \sqrt{\sum_{s \in S_k} c_s \sqrt{\log d_s - S(\rho_s)}}, \quad (9)$$

where c_s is a constant that is independent of the state ψ_0 .

When δt is negligibly small, the long-time behavior is similar to the one-step behavior.

Discussions and outlook— In this Letter, we establish a fundamental link between intrinsic quantum resources—entanglement and magic—and the statistical behavior of algorithmic error in digital quantum simulation. Entanglement suppresses the variance of Trotter error, while magic reduces its kurtosis, jointly stabilizing quantum dynamics. Thus, resources that obstruct classical simulation can, paradoxically, enhance quantum reliability.

As entanglement and magic typically proliferate under generic dynamics [17, 40, 41], most states are inherently biased toward favorable error statistics, rendering worst-case bounds statistically irrelevant. This intrinsic robustness suggests that realistic quantum simulations may be far more stable than pessimistic analyses imply. Looking ahead, extending this resource-based statistical framework to other algorithms and noisy devices could reveal how quantum resources not only empower computation but also protect it—hinting at a deeper unity between complexity, accuracy, and reliability in quantum dynamics.

Abstract

Quantum state tomography (QST) is one of the fundamental problems in quantum information. Among various metrics, sample complexity is widely used to evaluate QST algorithms. While multi-copy measurements are known to achieve optimal sample complexity, they are challenging to implement on near-term quantum devices. In practice, single-copy measurements with shallow-depth circuits are more feasible. Although a near-optimal QST algorithm under single-qubit measurements has recently been proposed, its sample complexity does not match the known lower bound for single-copy measurements. Here, we make two contributions by employing circuits with depth $\mathcal{O}(\log n)$ on an n -qubit system. First, QST for rank- r d -dimensional state ρ can be achieved with sample complexity $\mathcal{O}\left(\frac{dr^2 \ln d}{\epsilon^2}\right)$ to error ϵ in trace distance, which is near-optimal up to a $\ln d$ factor compared to the known lower bound $\Omega\left(\frac{dr^2}{\epsilon^2}\right)$. Second, for the general case of $r = d$, we can remove the $\ln d$ factor, yielding an optimal sample complexity of $\mathcal{O}\left(\frac{d^3}{\epsilon^2}\right)$.

I. INTRODUCTION

In quantum mechanics, the state space of an n -qubit system is given by the tensor product of the Hilbert spaces of the individual qubits, in accordance with the postulate for composite systems [1]. Thus, an n -qubit quantum state can in general be represented by a positive semidefinite matrix with unit trace, denoted by $\rho \in \mathbb{C}^{d \times d}$, where $d = 2^n$. A quantum state ρ can be decomposed as $\rho = \sum_{i=1}^r \lambda_i |\psi_i\rangle \langle \psi_i|$, where the rank $r \in \{1, 2, \dots, d\}$ and $\{|\psi_i\rangle\}_i$ is a set of orthonormal quantum states. If $r = 1$, the state is called a *pure state*, otherwise, it is a *mixed state*.

Although an n -qubit quantum state is formally represented by its density matrix, in experiments the state itself cannot be accessed directly and information can only be obtained through measurements. However, due to the Heisenberg uncertainty principle, the entire quantum state cannot be reconstructed from a single measurement basis alone, so multiple measurement bases are required. In addition, to reduce statistical shot noise within each basis, repeated measurements must be performed. This overall procedure of reconstructing the density matrix of a quantum state from measurement data is called quantum state

tomography (QST). In this context, the number of prepared copies of the quantum state ρ , referred to as the *sample complexity*, serves as a standard figure of merit for QST.

Since the number of parameters required to describe a state ρ grows exponentially with n , the sample complexity required for QST also scales exponentially. As a result, fully reconstructing the entire quantum state becomes infeasible for large n . Nevertheless, in the early stages of quantum computer development, QST has been widely employed for device benchmarking [2–4].

In some cases, however, it is sufficient to perform QST not on the entire n -qubit system but only on a specific subsystem. For example, in t -doped stabilizer state learning, once the stabilizer part is learned, full QST is required only on a certain subsystem [5–8]. Likewise, in tasks where one assumes access to a target quantum state and seeks to approximate the circuit that prepares it [9], subsystem QST is used as a subroutine. Therefore, while the exponential sample complexity required for QST cannot be avoided, finding methods to achieve the optimal sample complexity remains highly beneficial for a wide range of applications.

The accuracy of QST can be quantified using different metrics, among which fidelity and trace distance are most common [10, 11]. Here, we adopt the trace distance and formalize the QST problem as follows:

Definition 1. (ϵ, δ) -QST. Given $\epsilon > 0$ and $\delta \in (0, 1)$, let ρ denote the target quantum state and $\hat{\rho}_T$ its estimator. The goal is to determine a bound on the number of samples T such that

$$\Pr(\|\hat{\rho}_T - \rho\|_{\text{tr}} \geq \epsilon) \leq \delta.$$

For QST of a rank- r quantum state, it is known that multi-copy measurements over d^2 copies achieve the optimal sample complexity [10, 12] given by

$$T = \Theta(dr/\epsilon^2).$$

However, current quantum computers are still noisy and lack error correction, which limits the number of copies that can be used simultaneously. Consequently, implementing such an optimal QST strategy is highly challenging.

Follow-up research [13] has investigated scenarios in which there is a restriction on the number of copies t that can be prepared and measured simultaneously. It has been shown

FIG. 1. (Left) Previously, near-optimal quantum state tomography (QST) was studied using either the n -qubit Clifford group $\text{Cl}(n)$ or Pauli measurements (blue). Here, we show that shallow-depth circuits extend the near-optimal region (yellow), and that in the full-rank case $r = d$ they become optimal. (Right) We compute an upper bound on the number of samples required for QST, and show that with circuit depth $\mathcal{O}(\log n)$, this bound is close to the single-copy lower bound $\Omega(dr^2/\epsilon^2)$, up to a $\ln d$ factor.

that in such cases one needs $T = \tilde{\Theta}(d^3/\sqrt{t}\epsilon^2)$ in the full rank case, meaning that the benefit is only achieved once t becomes sufficiently large. Considering that even implementing 2-copy measurements ($t = 2$) is difficult on present-day quantum hardware, the practical limitations of QST using multi-copy measurements become evident.

Compared to the multi-copy measurements discussed above, a more practical approach is to employ single-copy measurements. In this case, the optimal sample complexity of QST is known to be $\Theta(dr^2/\epsilon^2)$. However, implementing this strategy requires somewhat complicated positive-operator valued measurements (POVMs) [10, 14] or projections onto random Haar states [15]. By performing projective measurements drawn from a state 2-design [16], a near-optimal strategy—incurring an additional $\ln(d)$ factor—can be obtained. Nevertheless, even this scheme demands circuits of depth $\mathcal{O}(n)$. Considering device connectivity and noise, such requirements remain impractical on current noisy quantum hardware.

In this letter, motivated by recent advances [17] in constructing approximate unitary designs with shallow depth circuits, we investigate whether shallow circuits can attain the optimal sample complexity for single-copy measurements [Fig. 1].

Previous studies have shown that, by using the biased estimator

$$\hat{\rho}_{\text{biased}} = \mathcal{M}_{\text{Haar}}^{-1}(U^\dagger |b\rangle\langle b| U) = (d+1)U^\dagger |b\rangle\langle b| U - I, \quad (1)$$

one can estimate the fidelity $\text{Tr}(|\psi\rangle\langle\psi|\rho)$ to within an additive error ϵ using only $\mathcal{O}(1/\epsilon^2)$ samples [17]. However, applying this approach to QST poses challenges. Specifically, if QST guarantees a small trace norm $\|\rho - \hat{\rho}\|_{\text{tr}} \leq \epsilon$, then for any operator O one must satisfy

$$|\text{Tr}(O\rho) - \text{Tr}(O\hat{\rho})| \leq \|O\|_{\text{op}} \epsilon. \quad (2)$$

In contrast, one can easily find counterexamples (e.g., when $O = P$) showing that with the biased estimator this guarantee cannot be maintained at depth $\mathcal{O}(\log n)$, and therefore a different estimator is required for QST [see Appendix B].

Constructing an unbiased estimator for ρ is not technically difficult in itself, but proving the concentration of its empirical average is nontrivial. In this work, instead of relying on approximate unitary designs, we leverage the same circuit ansatz used in prior studies [17, 18] and provide a proof of concentration for the unbiased estimator. Technically, our proof combines the Weingarten calculus [19] with the transfer matrix method [20]. We believe that this method will be useful for various analyses employing shallow randomized measurements.

II. PRELIMINARIES

We now define the variables and basic concepts required for the subsequent discussion. For more detailed explanations of each, the reader is referred to the relevant references.

First, to define the unbiased estimator of ρ , we use a shadow channel $\mathcal{M}$ [21] defined by

$$\mathcal{M}(\rho) = \mathbb{E}_{U \sim \mathcal{E}, b} U^\dagger |b\rangle\langle b| U, \quad (3)$$

where $\mathcal{E}$ is the unitary ensemble from which U is uniformly sampled and $b \in \{0, 1\}^n$ is the bitstring of the measurement outcome. Here, we use a unitary ensemble consisting only of Clifford gates [18]. Then, each Pauli operator $P \in \{I, X, Y, Z\}^n$ is an eigenoperator of the shadow channel $\mathcal{M}$, as follows:

$$\mathcal{M}(P) = m_P P, \quad (4)$$

where $m_P = \mathbb{E}_{U \sim \mathcal{E}} [\mathbf{1}\{UPU^\dagger \in \pm\mathcal{Z}\}]$, with $\mathbf{1}\{\text{True}\} = 1$ (and 0 otherwise), and $\mathcal{Z} = \{I, Z\}^n$. Using the shadow channel $\mathcal{M}$, the unbiased estimator of the quantum state ρ is given by

$$\hat{\rho} = \mathcal{M}^{-1}(U^\dagger |b\rangle\langle b| U). \quad (5)$$

If the unitary ensemble is informationally complete, $\mathcal{M}^{-1}$ exists and $\mathcal{M}^{-1}(P) = m_P^{-1}P$. For a given unitary ensemble $\mathcal{E}$, we define the Pauli correlation function $\tau(P, Q)$ as

$$\tau(P, Q; n) = \mathbb{E}_{U \sim \mathcal{E}} [\mathbf{1}\{UPU^\dagger \in \pm \mathcal{Z}\} \mathbf{1}\{UPQU^\dagger \in \pm \mathcal{Z}\}], \quad (6)$$

where n denotes the system size on which Pauli operators P and Q are defined. We omit n when clear from context. For example, in the case $\mathcal{E} = \text{Cl}(n)$, the n -qubit Clifford group, $\tau(P, Q; n)$ is given by

$$\tau(P, Q; n) = \begin{cases} 1 & P = I, Q = I \\ \frac{1}{2^n+1} & P = I, Q \neq I \quad \text{or} \quad P \neq I, Q = I \\ \frac{1}{2^n+1} & P = Q \neq I \\ \frac{2}{(2^n+1)(2^n+2)} & P \neq I, Q \neq I, P \neq Q, PQ = QP \\ 0 & PQ = -QP \end{cases} \quad (7)$$

and for $\mathcal{E} = \text{Cl}(k)^{\otimes n/k}$, $\tau(P, Q; n)$ is blockwise multiplicative, written as

$$\tau(P, Q; n) = \prod_{i=1}^{n/k} \tau(P[i], Q[i]; k), \quad (8)$$

where $P[i]$ and $Q[i]$ denote the Pauli operators acting on the i -th block. Here, we slightly abuse $\tau(P, Q)$ for notational simplicity. Throughout this paper, $\log$ denotes the logarithm to base 2, while $\ln$ denotes the natural logarithm. The $[n]$ stands for the set $\{1, 2, \dots, n\}$, and $\|A\|_{\text{op}} = \max_i(\sigma_i(A))$, $\|A\|_{\text{F}} = \sqrt{\sum_i \sigma_i(A)^2}$ and $\|A\|_{\text{tr}} = \sum_i \sigma_i(A)$, where $\{\sigma_i(A)\}$ are the singular values of A .

III. UNITARY ENSEMBLE

Here, we employ unitary ensemble generated from shallow depth circuits. The first one is $\mathcal{E} = \text{Cl}(k)^{\otimes n/k}$ [Fig. 2(a)], and the second is obtained by stacking k -qubit blocks in a brickwork manner [Fig. 2(b)]. Denoting the first unitary as U_1 and the second as U_2 , the overall unitary is given by $U = U_2 U_1$. In both cases, the circuit can be realized by a local quantum circuit of depth $\mathcal{O}(k)$ [22]. Therefore, if $k = \mathcal{O}(\log n)$, it ensures a shallow quantum circuit. Throughout this paper, we assume that k divides n , so that there are $m = n/k$ blocks in each layer, and that k is even, which allows each block to be further divided into two sub-blocks of size $k/2$.

FIG. 2. (a) Block random unitary ensemble, where each block is uniformly sampled from $\text{Cl}(k)$. (b) Two-layer block random unitary ensemble, with U_1 followed by U_2 on the staggered blocks, yielding $U = U_2 U_1$. The figures show the case $n = 8$, $k = 4$, and $m = n/k = 2$. In the main text, a single block in (b) is further divided into two sub-blocks, denoted, for example, as $c_1, \dots, c_4$.

For the unitary ensemble $\mathcal{E} = \text{Cl}(k)^{\otimes n/k}$, m_P is as follows:

$$m_P = (2^k + 1)^{-w_k(P)}, \quad (9)$$

where $w_k(P)$ denotes the number of blocks in which the Pauli operator P acts nontrivially. For the ensemble corresponding to Fig. 2(b), m_P can also be explicitly calculated [See Appendix F], but for our purpose its lower bound suffices, that is, the upper bound on m_P^{-1} :

$$m_P = \mathbb{E}_U \mathbf{1}\{U P U^\dagger \in \pm \mathcal{Z}\} \quad (10)$$

$$= \mathbb{E}_{U_1, U_2} \mathbf{1}\{U_2 U_1 P U_1^\dagger U_2^\dagger \in \pm \mathcal{Z}\} \quad (11)$$

$$= \mathbb{E}_{U_1} (2^k + 1)^{-w_{k,2}(U_1 P U_1^\dagger)} \quad (12)$$

$$\geq (2^k + 1)^{-n/k}, \quad (13)$$

where $w_{k,1(2)}(P)$ denotes the number of blocks on which P acts nontrivially in blocks of $U_{1(2)}$ layer of Fig. 2(b). $\tau_{1(2)}$ is defined in a similar way.

In both types of circuit architectures considered [Fig. 2], we restrict to Clifford gates. Then, the following two properties hold [18].

$$1. \quad (U, P, b) = (U, P, b) \mathbf{1}\{U P U^\dagger \in \pm \mathcal{Z}\} \quad (14)$$

$$2. \quad \sum_b \prod_i (U, P_i, b) = 2^n \delta_{\prod_i P_i, I} \prod_i \mathbf{1}\{U P_i U^\dagger \in \pm \mathcal{Z}\}, \quad (15)$$

where $(U, P, b) := \text{Tr}(U P U^\dagger |b\rangle\langle b|)$.

IV. SAMPLE COMPLEXITY ANALYSES

Our main technical results consist of two parts. First, for a quantum state of rank r , we show that by employing local random quantum circuits of depth $\mathcal{O}(\log n)$, one can achieve a near-optimal sample complexity of $\mathcal{O}(dr^2 \ln(d)/\epsilon^2)$, which is only slightly larger than the known lower bound $\Omega(dr^2/\epsilon^2)$ [16]. Second, in the absence of prior information about the rank r , we must set $r = d$. In this case, we prove that the optimal sample complexity $\Theta(d^3/\epsilon^2)$ can be achieved, again using local random quantum circuits of depth $\mathcal{O}(\log n)$. Interestingly, when $r = d$, one can achieve optimal sample complexity using the simpler circuits shown in Fig. 2(a), which do not form approximate unitary designs.

In the rank- r case, we establish concentration of the estimator via the matrix Bernstein inequality [15], while in the full-rank case ($r = d$) we apply McDiarmid's inequality [23]. From these, we obtain the following two theorems.

Theorem 1 (Rank r). *If the quantum state ρ has rank r , then using the measurement circuit of Fig. 2(b) with depth $\mathcal{O}(\log(n))$, one can perform (ϵ, δ) -QST provided the number of samples $T = \mathcal{O}\left(\frac{dr^2 \ln(d)}{\epsilon^2}\right)$.*

Proof. We use the unbiased estimator of ρ as $\hat{\rho} = \mathcal{M}^{-1}(U_1^\dagger U_2^\dagger |b\rangle\langle b| U_2 U_1)$. Then its operator norm $\|\hat{\rho}\|_{\text{op}}$ is bounded as follows:

$$\|\hat{\rho}\|_{\text{op}} = \left\| \mathcal{M}^{-1}(U_1^\dagger U_2^\dagger |b\rangle\langle b| U_2 U_1) \right\|_{\text{op}} \quad (16)$$

$$= \left\| \sum_P \frac{\text{Tr}(U_2 U_1 P U_1^\dagger U_2^\dagger |b\rangle\langle b|)}{2^n} m_P^{-1} P \right\|_{\text{op}} \quad (17)$$

$$\leq \sum_P \frac{|\text{Tr}(U_2 U_1 P U_1^\dagger U_2^\dagger |b\rangle\langle b|)|}{2^n} m_P^{-1} \quad (18)$$

$$\leq \max_P(m_P^{-1}) \sum_P \frac{\text{Tr}(U_2 U_1 P U_1^\dagger U_2^\dagger |b\rangle\langle b|)^2}{2^n} \quad (19)$$

$$\leq (2^k + 1)^{n/k}. \quad (20)$$

Using the property of the shadow channel $\mathcal{M}$, U_1 can be taken outward

$$\mathcal{M}^{-1}(U_1^\dagger U_2^\dagger |b\rangle\langle b| U_2 U_1) = U_1^\dagger \mathcal{M}^{-1}(U_2^\dagger |b\rangle\langle b| U_2) U_1. \quad (21)$$

Then, $\hat{\rho}^2$ is simplified to

$$\hat{\rho}^2 = (U_1^\dagger \mathcal{M}^{-1}(U_2^\dagger |b\rangle\langle b| U_2) U_1)^2 = U_1^\dagger \mathcal{M}^{-1}(U_2^\dagger |b\rangle\langle b| U_2)^2 U_1. \quad (22)$$

Using the above relation, we can compute the average $\mathbb{E}\hat{\rho}^2$ as follows:

$$\mathbb{E}_{U_1, U_2, b} \hat{\rho}^2 = \mathbb{E}_{U_1, U_2} \sum_b U_1^\dagger \mathcal{M}^{-1} \left(U_2^\dagger |b\rangle \langle b| U_2 \right)^2 U_1 \text{Tr} \left(\rho U_1^\dagger U_2^\dagger |b\rangle \langle b| U_2 U_1 \right) \quad (23)$$

$$= \mathbb{E}_{U_1, U_2} \sum_b \sum_{P, Q, R} \frac{m_P^{-1} m_Q^{-1}}{8^n} \text{Tr} \left(\rho U_1^\dagger R U_1 \right) (U_2, P, b) (U_2, Q, b) (U_2, R, b) U_1^\dagger P Q U_1 \quad (24)$$

$$= \mathbb{E}_{U_1, U_2} \sum_{P, Q} \frac{m_P^{-1} m_Q^{-1}}{4^n} \mathbf{1} \left\{ U_2 P U_2^\dagger \in \pm \mathcal{Z} \right\} \mathbf{1} \left\{ U_2 Q U_2^\dagger \in \pm \mathcal{Z} \right\} \text{Tr} \left(\rho U_1^\dagger P Q U_1 \right) U_1^\dagger P Q U_1 \quad (25)$$

$$= \mathbb{E}_{U_1} \sum_{P, Q} \frac{m_P^{-1} m_Q^{-1}}{4^n} \tau_2(P, Q) \text{Tr} \left(\rho U_1^\dagger P Q U_1 \right) U_1^\dagger P Q U_1 \quad (26)$$

$$= \sum_{P, Q} \frac{m_P^{-1} m_Q^{-1}}{4^n} \tau_2(P, Q) \sum_{B \subseteq A} \left(\frac{1}{4^k - 1} \right)^{|A|} (-1)^{|A| - |B|} (2^k)^{|B|} \rho_B \otimes I_{A-B}, \quad (27)$$

where $A = A(P, Q) \subseteq [n/k]$ denotes the set of block indices of the U_1 layer such that P and Q differ on that block. To obtain the last line, we use the property of unitary 2-designs.

Using the above relation, we can obtain an upper bound on $\|\mathbb{E}_{U_1, U_2, b} \hat{\rho}^2\|_{\text{op}}$ as follows:

$$\|\mathbb{E}_{U_1, U_2, b} \hat{\rho}^2\|_{\text{op}} \leq \sum_{P, Q} \frac{m_P^{-1} m_Q^{-1}}{4^n} \tau_2(P, Q) \left\| \sum_{B \subseteq A} \left(\frac{1}{4^k - 1} \right)^{|A|} (-1)^{|A| - |B|} (2^k)^{|B|} \rho_B \otimes I_{A-B} \right\|_{\text{op}} \quad (28)$$

$$\leq \sum_{P, Q} \frac{m_P^{-1} m_Q^{-1}}{4^n} \tau_2(P, Q) \left(\frac{1}{2^k - 1} \right)^{w_{k,1}(PQ)} \quad (29)$$

$$\leq \max_{P, Q} \left(\frac{m_P^{-1} m_Q^{-1}}{4^n} \right) \sum_{P, Q} \tau_2(P, Q) \left(\frac{1}{2^k - 1} \right)^{w_{k,1}(PQ)} \quad (30)$$

$$\leq \left(1 + \frac{1}{2^k} \right)^{2n/k} \sum_{P, Q} \tau_2(P, Q) f_1(P, Q), \quad (31)$$

where $f_1(P, Q; n) = (2^k - 1)^{-w_{k,1}(PQ)} = \prod_{i \in U_1 \text{ layer}} f(P[i], Q[i]; k)$, where $f(P, Q; k) = (2^k - 1)^{-\mathbf{1}\{P \neq Q\}}$. We can rewrite the sum over P and Q into a form that is more convenient to compute. First, we divide each k -qubit block into two parts. This gives a total of $2m$ sub-blocks. Then, τ_2 acts on the pairs independently $\{(1, 2), (3, 4) \dots, (2m-1, 2m)\}$, while f_1 acts on the pairs independently $\{(2, 3), (4, 5) \dots, (2m-2, 2m-1), (2m, 1)\}$. We denote by $\bullet$ the case when $P[i] = Q[i]$ within a i -th sub-blocks, and by $\times$ otherwise. Using this notation, the given sum $\sum_{P, Q}$ can be rewritten as a sum over configurations $\mathbf{c} \in \{\bullet, \times\}^{2m}$, together with a sum over pairs (P, Q) compatible with each $\mathbf{c}$, i.e., $\sum_{\mathbf{c}} \sum_{(P, Q) \text{ in } \mathbf{c}}$. Accordingly, the

above expression can be reorganized as follows:

$$\|\mathbb{E}\hat{\rho}^2\|_{\text{op}} \leq (1 + 1/2^k)^{2m} \sum_{P,Q} \tau_2(P, Q) f_1(P, Q) \quad (32)$$

$$= (1 + 1/2^k)^{2m} \sum_{\mathbf{c} \in \{\bullet, \times\}^{2m}} \sum_{(P,Q) \text{ in } \mathbf{c}} \tau_2(P, Q) f_1(P, Q) \quad (33)$$

$$= (1 + 1/2^k)^{2m} \sum_{\mathbf{c} \in \{\bullet, \times\}^{2m}} f_1(\mathbf{c}) \sum_{(P,Q) \text{ in } \mathbf{c}} \tau_2(P, Q) \quad (34)$$

$$= (1 + 1/2^k)^{2m} \sum_{\mathbf{c} \in \{\bullet, \times\}^{2m}} f_1(\mathbf{c}) g_2(\mathbf{c}) \quad (35)$$

$$= (1 + 1/2^k)^{2m} \sum_{c_1, c_2, \dots, c_{2m} \in \{\bullet, \times\}} f(c_1, c_2) f(c_3, c_4) \dots f(c_{2m-1}, c_{2m}) \times g(c_2, c_3) g(c_4, c_5) \dots g(c_{2m}, c_1) \quad (36)$$

$$= (1 + 1/2^k)^{2m} \text{Tr}((FG)^m) \quad (37)$$

$$= (1 + 1/2^k)^{2m} (\lambda_+^m + \lambda_-^m), \quad (38)$$

where $g_2(\mathbf{c}) = \sum_{(P,Q) \text{ in } \mathbf{c}} \tau_2(P, Q)$ and $g(c_i, c_{i+1}) = \sum_{(P,Q) \text{ in } (c_i, c_{i+1})} \tau_2(P, Q; k)$. Here, F and G are 2×2 matrices defined by

$$F = \begin{pmatrix} 1 & \frac{1}{2^k-1} \\ \frac{1}{2^k-1} & \frac{1}{2^k-1} \end{pmatrix}, \quad G = \frac{1}{2^k+1} \begin{pmatrix} 2^{2k} & 2^k(2^k-1) \\ 2^k(2^k-1) & 2^k(2^k-1)^2 \end{pmatrix} \quad (39)$$

and $\lambda_{\pm}$ are eigenvalues of FG and are given by

$$\lambda_{\pm} = \frac{2^k(2^{k+1} + 1 \pm \sqrt{2^{k+4} - 7})}{2(2^k + 1)} \quad (40)$$

$$\leq 2^k + \sqrt{5 \cdot 2^k}, \quad (41)$$

where the last inequality holds when $k \geq 2$. Combining Eq. (38) and Eq. (41) under the assumption $k2^{k/2} \geq n$, we obtain the following upper bound:

$$\|\mathbb{E}\hat{\rho}^2\|_{\text{op}} \leq (1 + 1/2^k)^{2m} (\lambda_+^m + \lambda_-^m) \quad (42)$$

$$\leq 2(1 + 1/2^k)^{2m} \lambda_+^m \quad (43)$$

$$\leq 2(1 + 1/2^k)^{2m} (2^k + \sqrt{5 \cdot 2^k})^m \quad (44)$$

$$\leq \exp(2 + \sqrt{5}) 2^{n+1} \quad (45)$$

$$\leq \mathcal{O}(2^n) \quad (46)$$

By applying the Matrix Bernstein inequality to $\hat{\rho}_T = \frac{1}{T} \sum_i \hat{\rho}_i$, the following bound holds:

$$\Pr(\|\hat{\rho}_T - \rho\|_{\text{op}} \geq \epsilon_{\text{op}}) \leq d \exp\left(-\frac{T\epsilon_{\text{op}}^2}{\|\mathbb{E}\hat{\rho}^2\|_{\text{op}} + \|\hat{\rho}\|_{\text{op}}\epsilon_{\text{op}}/3}\right). \quad (47)$$

Using the upper bounds on $\|\hat{\rho}\|_{\text{op}}$ and $\|\mathbb{E}\hat{\rho}^2\|_{\text{op}}$, and setting $\epsilon_{\text{op}} = \epsilon_{\text{tr}}/(2r)$, we can replace $\|\hat{\rho}_T - \rho\|_{\text{op}}$ with $\|\hat{\rho}_T - \rho\|_{\text{tr}}$. Consequently, the required total number of samples T is

$$T = \mathcal{O}\left(\frac{dr^2 \ln(d/\delta)}{\epsilon^2}\right). \quad (48)$$

□

For rank- r state, the known lower bound is $\Omega(dr^2/\epsilon^2)$ in single-copy, nonadaptive measurements [16]. Therefore, our upper bound yields near-optimal sample complexity for QST of rank- r states. Theorem 1 establishes that an overlap of exactly $\log(n)$ qubits between consecutive blocks is sufficient, which corresponds to choosing $k = 2\log(n)$.

In the above proof, we employed periodic boundary conditions (PBCs) for simplicity, whereas in most hardware settings open boundary conditions (OBCs) are more appropriate. We can show that even under OBCs, one still recovers a near-optimal sample complexity [see Appendix E].

In the worst case where the quantum state has full rank, we show that sample-optimal QST can be achieved using structurally simpler measurement circuits than those used in Theorem 1.

Theorem 2 (*Full rank*). *If the quantum state ρ has rank d , then using the measurement circuit of Fig. 2(a) with depth $\mathcal{O}(\log n)$, one can perform (ϵ, δ) -QST provided the number of samples satisfies $T = \mathcal{O}(d^3/\epsilon^2)$.*

Proof. We use an unbiased estimator different from Theorem 1. The unitary ensemble used here is constructed by selecting mutually unbiased bases within each block, so the total number of unitaries is given by $(2^k + 1)^{n/k}$. We further assume that for each basis we perform M repetitions of measurements. Therefore, we make use of a total of $T = M(2^k + 1)^{n/k}$ samples.

Let the experimental outcomes obtained from the T measurements be denoted by $\mathbf{X} = \{X_1, X_2, \dots, X_T\}$. For notational convenience, we denote by $\{Z_1, Z_2, \dots, Z_{M \cdot N_P}\}$ the subset of measurement outcomes that provide actionable information for a specific Pauli operator

P , where $Z_i \in \{-1, 1\}$ and $N_P = (2^k + 1)^{n/k - w_k(P)}$ is the number of actionable bases. Then, an unbiased estimator can be constructed as follows:

$$\hat{\rho} = \sum_P \frac{\mu_P}{2^n M N_P} P, \quad (49)$$

where $\mu_P = Z_1 + Z_2 + \dots + Z_{M \cdot N_P}$ with $\mathbb{E}[Z] = \text{Tr}(\rho P)$, $\mathbb{E}[Z^2] = 1$. Then, the following holds:

$$\mathbb{E}[\hat{\mu}_P^2] = N_P M (1 - \text{Tr}(\rho P)^2) + N_P^2 M^2 \text{Tr}(\rho P)^2. \quad (50)$$

Here, we try to upper bound on Frobenius norm $f(\rho) = f(\rho; \mathbf{X}) = \|\rho - \hat{\rho}\|_F$. By using block unitary ensemble [Fig. 2(a)], we can derive the following two key results.

$$1. \mathbb{E}[f(\rho)] \leq \frac{1}{\sqrt{M}} \left(\frac{4^k + 2^k - 1}{2^k + 1} \right)^{n/2k} \quad (51)$$

$$2. f(\rho; \mathbf{X}) - f(\rho; \mathbf{X}^{(i)}) \leq \frac{2(4^k + 2^k - 1)^{n/2k}}{M(2^k + 1)^{n/k}}, \quad (52)$$

where $\mathbf{X}^{(i)}$ denotes the case in which only X_i is different, while all others remain the same. Using Eq. (51) and Eq. (52), and applying McDiarmid's inequality, we obtain the following:

$$\Pr(f(\rho) \geq \epsilon_F) = \Pr(f(\rho) - \mathbb{E}f(\rho) \geq \epsilon_F - \mathbb{E}f(\rho)) \quad (53)$$

$$\leq \Pr\left(f(\rho) - \mathbb{E}f(\rho) \geq \epsilon_F - \sqrt{\frac{A(n, k)}{M}}\right) \quad (54)$$

$$\leq \exp\left(-\frac{2\left(\epsilon_F - \sqrt{\frac{A(n, k)}{M}}\right)^2}{M(2^k + 1)^{n/k} \left(\frac{2(4^k + 2^k - 1)^{n/2k}}{M(2^k + 1)^{n/k}}\right)^2}\right) \quad (55)$$

$$= \exp\left(-\frac{M}{2A(n, k)} \left(\epsilon_F - \sqrt{\frac{A(n, k)}{M}}\right)^2\right) \quad (56)$$

$$= \delta, \quad (57)$$

where $A(n, k) = \left(\frac{4^k + 2^k - 1}{2^k + 1}\right)^{n/k}$ and $M = \frac{(1 + \sqrt{2 \ln(1/\delta)})^2}{\epsilon_F^2} A(n, k)$. In order to replace $\|\cdot\|_F$ with $\|\cdot\|_{\text{tr}}$ in the above result, one can substitute $\epsilon_F = \frac{\epsilon_{\text{tr}}}{\sqrt{2^n}}$. Therefore, the total number of samples required for QST under the assumption $k2^k \geq n$ is as follows:

$$T = M(2^k + 1)^{n/k} \quad (58)$$

$$= \left(1 + \sqrt{2 \ln(1/\delta)}\right)^2 2^n (4^k + 2^k - 1)^{n/k} / \epsilon_{\text{tr}}^2 \quad (59)$$

$$= \left(1 + \sqrt{2 \ln(1/\delta)}\right)^2 8^n \left(1 + \frac{1}{2^k} - \frac{1}{4^k}\right)^{n/k} / \epsilon_{\text{tr}}^2 \quad (60)$$

$$\leq \left(1 + \sqrt{2 \ln(1/\delta)}\right)^2 8^n \left(1 + \frac{1}{2^k}\right)^{n/k} / \epsilon_{\text{tr}}^2 \quad (61)$$

$$\leq \mathcal{O}(8^n / \epsilon_{\text{tr}}^2) \quad (62)$$

□

In the full-rank case, even in the adaptive setting, the lower bound is $\Omega(d^3/\epsilon^2)$, and thus our upper bound is optimal in this regime. Unlike the rank- r case, for full-rank states the sample complexity saturates at the optimal scaling when the block size $k = \log n$, i.e., half of that in the rank- r case. For circuits with depth $d = o(\log n)$, we cannot prove optimality in sample complexity; however, by substituting $k = 1$ into our upper bound, we recover the near-optimal single-copy measurement sample complexity of $\mathcal{O}(10^n/\epsilon^2)$ [23], which is slightly larger than the known lower bound only by a factor of $\sqrt{n}$ [24]. Therefore, we expect that even in the regime $d = o(\log n)$, the circuit of Fig. 2(a) still provides sufficiently good scaling for QST.

V. CONCLUSION AND OUTLOOK

We have studied the sample complexity of QST with respect to the measurement circuit depth. Our results show that, with previously known biased estimators, QST with small trace distance cannot be achieved using circuits of depth $\mathcal{O}(\log n)$, whereas employing unbiased estimators overcomes this limitation. Although the construction of unbiased estimators is straightforward, establishing concentration bounds is technically non-trivial. We address this challenge by combining the existing Weingarten calculus with transfer matrix techniques to obtain a near-optimal sample complexity of $\mathcal{O}(dr^2 \ln(d)/\epsilon^2)$. Moreover, for full-rank quantum states, we demonstrated that the optimal sample complexity $\mathcal{O}(d^3/\epsilon^2)$ can be attained with structurally simpler circuits that do not form approximate unitary designs. Beyond QST, our results imply that they can be leveraged for provable classical ML on many-body systems with constant correlation length, allowing training with fewer data samples than previously needed [25].

Our work suggests several directions for future research. First, for rank- r states, it remains open whether the $\ln(d)$ factor in our upper bound can be eliminated. Second, while

biased estimators suffice for certain quantities such as fidelity [17] and purity [18], we showed that unbiased estimators are crucial for QST. Identifying other tasks where more refined estimators are required would be an interesting avenue for further study. Finally, in rank- r case, we relied on unitary ensembles capable of forming approximate unitary designs; however, our statistical analysis did not exploit the approximate designs property. It therefore remains to be understood whether QST with small trace distance is possible solely under the assumption of approximate unitary designs, regardless of the circuit structure, or whether the circuit architecture itself plays an essential role.

Appendix A: SHADOW CHANNEL

In this appendix, we will explain the important properties of shadow channel used in the main text. Shadow channel is defined by

$$\mathcal{M}(\rho) = \mathbb{E}_{U \sim \mathcal{E}, b} U^\dagger |b\rangle \langle b| U, \quad (\text{A1})$$

where $\mathcal{E}$ is the unitary ensemble from which U is sampled uniformly and $b \in \{0, 1\}^n$ is the measurement outcome on $U\rho U^\dagger$. By using (A1) and assuming the unitary ensemble $\mathcal{E}$ is informationally complete, we can construct an unbiased estimator of quantum state ρ as follows:

$$\hat{\rho} = \mathcal{M}^{-1}(U^\dagger |b\rangle \langle b| U). \quad (\text{A2})$$

With (A2), an unbiased estimator of the arbitrary observable O is as follows:

$$\hat{o} = \text{Tr}(O\hat{\rho}). \quad (\text{A3})$$

By definition, the shadow channel and its inverse depends on which unitary ensemble $\mathcal{E}$ we use. Therefore, adequately choosing unitary ensemble for owns on purpose is important. For examples, if we want to estimate low-weight observables $\{O\}$, then employing $\mathcal{E} = \text{Cl}(1)^{\otimes n/k}$, where $\text{Cl}(m)$ denotes the m -qubit Clifford group, is an appropriate choice. On the other hands, in case where the bounded trace norm observable O is of interest (e.g. $O = |\psi\rangle\langle\psi|$), $\mathcal{E} = \text{Cl}(n)$ is an appropriate choice.

In the main text, we assume that our unitary ensemble consists solely of Clifford gates. Under this assumption, the following two properties hold:

$$1. \quad (U, P, b) = (U, P, b) \mathbf{1}\{UPU^\dagger \in \pm\mathcal{Z}\} \quad (\text{A4})$$

$$2. \quad \sum_b \prod_i (U, P_i, b) = 2^n \delta_{\prod_i P_i, I} \prod_i \mathbf{1}\{UP_i U^\dagger \in \pm\mathcal{Z}\}, \quad (\text{A5})$$

where $(U, P, b) := \text{Tr}(UPU^\dagger |b\rangle\langle b|)$, $\mathcal{Z} = \{I, Z\}^n$ and $\mathbf{1}\{\text{True}\} = 1$, otherwise 0. Eq. (A4) is immediate since $UPU^\dagger$ is also a Pauli operator. It yields 0 unless it is a Pauli Z -string, and hence the indicator function can be freely inserted. Eq. (A5) is checked as follows:

$$\sum_b \prod_i (U, P_i, b) = \sum_b \prod_i (U, P_i, b) \mathbf{1}\{UP_i U^\dagger \in \pm\mathcal{Z}\} \quad (\text{A6})$$

$$= \sum_b \text{Tr} \left(\left(\prod_i UP_i U^\dagger \right) |b\rangle\langle b| \right) \prod_i \mathbf{1}\{UP_i U^\dagger \in \pm\mathcal{Z}\} \quad (\text{A7})$$

$$= \sum_b \text{Tr} \left(U \left(\prod_i P_i \right) U^\dagger |b\rangle\langle b| \right) \prod_i \mathbf{1}\{UP_i U^\dagger \in \pm\mathcal{Z}\} \quad (\text{A8})$$

$$= \text{Tr} \left(U \left(\prod_i P_i \right) U^\dagger \right) \prod_i \mathbf{1}\{UP_i U^\dagger \in \pm\mathcal{Z}\} \quad (\text{A9})$$

$$= 2^n \delta_{\prod_i P_i, I} \prod_i \mathbf{1}\{UP_i U^\dagger \in \pm\mathcal{Z}\}, \quad (\text{A10})$$

where δ denotes equality up to a phase. Using the above properties, we can show the Pauli operator P is an eigenoperator of the shadow channel $\mathcal{M}$ as follows:

$$\mathcal{M}(P) = \mathbb{E}_U \sum_b U^\dagger |b\rangle\langle b| U \cdot \text{Tr}(UPU^\dagger |b\rangle\langle b|) \quad (\text{A11})$$

$$= \mathbb{E}_U \sum_b \sum_Q \frac{Q}{2^n} \text{Tr}(UQU^\dagger |b\rangle\langle b|) \cdot \text{Tr}(UPU^\dagger |b\rangle\langle b|) \quad (\text{A12})$$

$$= \mathbb{E}_U \sum_b \sum_Q \frac{Q}{2^n} \text{Tr}(UQU^\dagger |b\rangle\langle b|) \cdot \text{Tr}(UPU^\dagger |b\rangle\langle b|) \mathbf{1}\{UPU^\dagger \in \pm\mathcal{Z}\} \mathbf{1}\{UQU^\dagger \in \pm\mathcal{Z}\} \quad (\text{A13})$$

$$= \mathbb{E}_U \sum_Q \mathbf{1}\{UPU^\dagger \in \pm\mathcal{Z}\} \mathbf{1}\{UQU^\dagger \in \pm\mathcal{Z}\} \delta_{PQ,I} Q \quad (\text{A14})$$

$$= \mathbb{E}_U \mathbf{1}\{UPU^\dagger \in \pm\mathcal{Z}\} P \quad (\text{A15})$$

$$= m_P P, \quad (\text{A16})$$

where $m_P := \mathbb{E}_U \mathbf{1}\{UQU^\dagger \in \pm\mathcal{Z}\}$.

In the main text of Theorem 1, to simplify $\hat{\rho}^2$, we use the following

$$V_1^\dagger \mathcal{M}(O) V_1 = \mathcal{M}(V_1^\dagger O V_1), \quad (\text{A17})$$

where V_1 is the unitary sampled from U_1 layer ($V_1 \in \text{Cl}(k)^{\otimes n/k}$). This can be checked as follows:

$$V_1^\dagger \mathcal{M}(O) V_1 = V_1^\dagger \mathbb{E}_{U_1, U_2} \sum_b U_1^\dagger U_2^\dagger |b\rangle\langle b| U_2 U_1 \cdot \text{Tr}(U_2 U_1 O U_1^\dagger U_2^\dagger) V_1 \quad (\text{A18})$$

$$= \mathbb{E}_{\tilde{U}_1, U_2} \sum_b \tilde{U}_1^\dagger U_2^\dagger |b\rangle\langle b| U_2 \tilde{U}_1 \cdot \text{Tr}(U_2 \tilde{U}_1 V_1^\dagger O V_1 \tilde{U}_1^\dagger U_2^\dagger) \quad (\text{A19})$$

$$= \mathcal{M}(V_1^\dagger O V_1), \quad (\text{A20})$$

where we set $\tilde{U}_1 = U_1 V_1$. By taking $O \leftarrow \mathcal{M}^{-1}(O)$ and applying $\mathcal{M}^{-1}$ to both sides, we obtain

$$\mathcal{M}^{-1}(V_1^\dagger O V_1) = V_1^\dagger \mathcal{M}^{-1}(O) V_1. \quad (\text{A21})$$

Appendix B: LIMITATIONS ON BIASED ESTIMATOR

Previous study [17] show that unitary ensemble $\mathcal{E}$ generated from shallow quantum circuit of depth $\mathcal{O}(\log(\frac{n}{\epsilon}) t \text{ poly log}(t))$ form ϵ -approximate unitary t -designs

$$(1 - \epsilon)\Phi_H \preceq \Phi_{\mathcal{E}} \preceq (1 + \epsilon)\Phi_H, \quad (\text{B1})$$

where $\Phi \preceq \Phi'$ means that $\Phi' - \Phi$ is a completely-positive map and $\Phi_{\mathcal{E}}(\cdot)$ is defined as

$$\Phi_{\mathcal{E}}(A) := \mathbb{E}_{U \sim \mathcal{E}} [U^{\otimes t} A U^{\dagger \otimes t}]. \quad (\text{B2})$$

Based on the above results, one naturally expects that circuits of depth $\mathcal{O}(\log n)$ can form approximate unitary 3-designs, and hence that the statistical behavior of shallow depth circuits closely approximates that of $\text{Cl}(n)$. Indeed, this has been shown in various examples

[17]. However, in settings such as randomized measurements [26], where random unitaries are applied followed by classical post-processing, one should be cautious in directly applying the above reasoning. As discussed in Appendix A, obtaining an unbiased estimator requires first determining the shadow channel $\mathcal{M}$. Notably, prior work has shown that by simply using the shadow channel $\mathcal{M}_{\text{Haar}}(\cdot) = \frac{1}{1+d}((\cdot) + \text{Tr}(\cdot)I)$ from Haar random unitaries ensemble, one can estimate the fidelity and, more generally, any observable O with bounded trace norm, with the same sample complexity as that obtained using $\mathcal{E} = \text{Cl}(n)$ [17]. A similar result also holds for purity estimation using multi-shot case [18].

One might expect that the above result remains valid for estimating other arbitrary physical quantities as well, but simple counterexamples can be found. First, in the single-shot case, when estimating purity using $\mathcal{M}_{\text{Haar}}$, the accuracy of estimation cannot be guaranteed due to the bias of the estimator, which is also consistent with numerical simulations [27]. Second, employing $\mathcal{M}_{\text{Haar}}$ for estimating a Pauli operator P can lead to large errors. For example, consider estimating the expectation value of $O = Z_1$ using the circuit in Fig. 2(b), where each block consists of k -qubit. In this case, the unbiased estimator is given by

$$\hat{o} = \text{Tr}(P\hat{\rho}) = \text{Tr}(P\mathcal{M}^{-1}(U^\dagger |b\rangle\langle b| U)) = m_P^{-1} \text{Tr}(UPU^\dagger |b\rangle\langle b|),$$

where $m_P = \frac{3 \cdot 2^k + 1}{(2^k + 1)^3}$ provided that $k \leq n/2$ and k divides n . However, if one uses $\mathcal{M}_{\text{Haar}}$ instead, which implies that m_P is taken to be $\frac{1}{2^n + 1}$, then the bias becomes large.

Here, we have identified the limitations of the biased estimator based on $\mathcal{M}_{\text{Haar}}$, but this does not imply that all biased estimators are problematic. Therefore, it may be possible to employ weakly biased estimators that allow for efficient classical post-processing while still admitting statistical guarantees for accurate estimation. We leave this for future work.

Appendix C: THEOREM 1

In this appendix, we will provide the missing details of the proof of Theorem.1 in the main text. We use unbiased estimator $\hat{\rho}$ of the target quantum state ρ , so we only need to care about how many samples do we need to concentrate enough to its mean. To this end, we employ the well-known matrix Bernstein inequality.

Theorem (Matrix Bernstein Inequality). *Let $X_1, X_2, \dots, X_T$ be independent random ma-*

FIG. 3. Case classification by matrix elements of G . Each vertical rectangle corresponds to a k -qubit Pauli operator, and two of them form a pair (e.g. $P[i]$ and $Q[i]$ in the main text). A single block is further divided into two sub-blocks by gray dashed line, and depending on whether the adjacent sub-blocks are identical or different, the cases are categorized as $\bullet$ or $\times$. I denotes the identity, while P, Q, R, S represent non-identity Pauli operators.

trices in $\mathbb{C}^{d \times d}$ satisfying $\mathbb{E}[X_i] = 0$, $\|X_i\|_{\text{op}} \leq R$ almost surely. Then for all $t \geq 0$,

$$\Pr\left(\left\|\sum_{i=1}^m X_i\right\|_{\text{op}} \geq t\right) \leq d \exp\left(\frac{-t^2/2}{\sigma^2 + Rt/3}\right),$$

where $\sigma^2 := \left\|\sum_{i=1}^T \mathbb{E}[X_i^2]\right\|_{\text{op}}$.

By setting $X = \hat{\rho} - \rho$, then $\|X\|_{\text{op}} \leq \|\hat{\rho}\|_{\text{op}}$ and $\|\mathbb{E}X^2\|_{\text{op}} \leq \|\mathbb{E}\hat{\rho}^2\|_{\text{op}}$. Therefore, it is enough to compute upper bounds for $\|\hat{\rho}\|_{\text{op}}$ and $\|\mathbb{E}\hat{\rho}^2\|_{\text{op}}$. First, $\|\hat{\rho}\|_{\text{op}}$ is bounded as follows:

$$\|\hat{\rho}\|_{\text{op}} \leq (2^k + 1)^{n/k} \quad (\text{C1})$$

In the main text, we bounded $\|\mathbb{E}\hat{\rho}^2\|_{\text{op}}$ by

$$\|\mathbb{E}\hat{\rho}^2\|_{\text{op}} \leq (1 + 1/2^k)^{2m} \sum_{\mathbf{c} \in \{\bullet, \times\}^{2m}} f_1(\mathbf{c}) g_2(\mathbf{c}) \quad (\text{C2})$$

$$\begin{aligned} &= (1 + 1/2^k)^{2m} \sum_{c_1, c_2, \dots, c_{2m} \in \{\bullet, \times\}} f(c_1, c_2) f(c_3, c_4) \dots f(c_{2m-1}, c_{2m}) \\ &\quad \times g(c_2, c_3) g(c_4, c_5) \dots g(c_{2m}, c_1) \end{aligned} \quad (\text{C3})$$

$$= (1 + 1/2^k)^{2m} \text{Tr}((FG)^m). \quad (\text{C4})$$

To compute the trace term, we need to determine the matrices F and G . Starting with the F matrix, we have $F(\bullet, \bullet) = 1$, while the remaining entries $F(\bullet, \times)$, $F(\times, \bullet)$, and $F(\times, \times)$

are all equal to $1/(2^k - 1)$, since the Pauli operators P_i and Q_i differ on each block. For the G matrix, where $G(c_1, c_2) = \sum_{(P, Q) \in (c_1, c_2)} \tau(P, Q; k)$, because $G(\bullet, \times) = G(\times, \bullet)$, it suffices to compute $G(\bullet, \bullet)$, $G(\bullet, \times)$, and $G(\times, \times)$.

In Fig. 3, we classify several cases in order to compute each matrix element of G . The two vertical rectangles correspond to the k -qubit Pauli operators acting on each block, which we denote by $P[i]$ and $Q[i]$ in the main text. Each block is further divided into two sub-blocks. For each sub-block, in both the $\bullet$ and $\times$, we classify according to whether the identity operator I is involved. For example, in the case of $(\bullet)$, the sub-block can be either (I, I) or (P, P) with $P \neq I$, while in the case of $(\times)$, it can be (I, P) , (P, I) , or (P, Q) with $P \neq I$, $Q \neq I$, and $P \neq Q$. Note that Pauli operator corresponding to each block (e.g. $P[i]$, $Q[i]$ in the main text) must commute in order to be nonzero (e.g. $\tau(P[i], Q[i]; k) = 0$ if they anti-commute). In $G(\times, \times)$, the last case must also be counted, where Pauli operators are anti-commute within the two sub-blocks but still commute at the block level. Contributions with the same value are represented in the same color, and using this classification we obtain

$$G(\bullet, \bullet) = [1] + \left[\frac{1}{2^k + 1} \cdot (2^k - 1) \cdot 2 \right] + \left[\frac{1}{2^k + 1} \cdot (2^k - 1)^2 \right] = \frac{2^{2k}}{2^k + 1} \quad (C5)$$

$$G(\bullet, \times) = \left[\frac{1}{2^k + 1} \cdot (2^k - 1) \cdot 2 \right] + \left[\frac{2}{(2^k + 1)(2^k + 2)} \cdot \frac{(2^k - 1)(2^k - 4)}{2} \right] \quad (C6)$$

$$+ \left[\frac{2}{(2^k + 1)(2^k + 2)} \cdot (2^k - 1)^2 \cdot 2 \right] + \left[\frac{2}{(2^k + 1)(2^k + 2)} \cdot \frac{(2^k - 1)^2(2^k - 4)}{2} \right] \quad (C7)$$

$$= \frac{2^k(2^k - 1)}{2^k + 1} \quad (C8)$$

$$G(\times, \times) = \left[\frac{1}{2^k + 1} \cdot (2^k - 1)^2 \cdot 2 \right] + \left[\frac{2}{(2^k + 1)(2^k + 2)} \cdot (2^k - 1)^2 \cdot 2 \right] \quad (C9)$$

$$+ \left[\frac{2}{(2^k + 1)(2^k + 2)} \cdot \frac{(2^k - 1)^2(2^k - 4)}{2} \cdot 4 \right] + \left[\frac{2}{(2^k + 1)(2^k + 2)} \cdot \frac{(2^k - 1)^2(2^k - 4)^2}{4} \right] \quad (C10)$$

$$+ \left[\frac{2}{(2^k + 1)(2^k + 2)} \cdot \frac{(2^k - 1)^2 2^{2k}}{4} \right] = \frac{2^k(2^k - 1)^2}{2^k + 1}. \quad (C11)$$

Therefore, F and G are

$$F = \begin{pmatrix} 1 & \frac{1}{2^k - 1} \\ \frac{1}{2^k - 1} & \frac{1}{2^k - 1} \end{pmatrix}, \quad G = \frac{1}{2^k + 1} \begin{pmatrix} 2^{2k} & 2^k(2^k - 1) \\ 2^k(2^k - 1) & 2^k(2^k - 1)^2 \end{pmatrix} \quad (C12)$$

as desired.

Appendix D: THEOREM 2

In the proof of Theorem 2, the concentration of $\hat{\rho}$ is established using McDiarmid's inequality.

Theorem (McDiarmid). *Let $X_1, \dots, X_T$ be independent random variables, with*

$$\sup_{X_1, \dots, X_T, X'_i} |f(X_1, \dots, X_i, \dots, X_T) - f(X_1, \dots, X'_i, \dots, X_T)| \leq C_i \quad (\text{D1})$$

for all $i=1, \dots, T$. Then

$$\Pr(|f(X_1, \dots, X_T) - \mathbb{E}f(X_1, \dots, X_T)| \geq t) \leq 2 \exp \left(-\frac{2t^2}{\sum_{i=1}^T C_i^2} \right). \quad (\text{D2})$$

To complete the proof of Theorem. 2. We need to prove two key results in Eq.(51) and Eq.(52)

$$1. \mathbb{E}[f(\rho)] \leq \frac{1}{\sqrt{M}} \left(\frac{4^k + 2^k - 1}{2^k + 1} \right)^{n/2k} \quad (\text{D3})$$

$$2. f(\rho; \mathbf{X}) - f(\rho; \mathbf{X}^{(i)}) \leq \frac{2(4^k + 2^k - 1)^{n/2k}}{M(2^k + 1)^{n/k}}, \quad (\text{D4})$$

where $f(\rho) = f(\rho; \mathbf{X}) = \|\hat{\rho} - \rho\|_F$ and $\mathbf{X} = \{X_j\}_{j=1}^T$, with X_j denoting the j -th measurement outcome.

proof of 1.

$$\mathbb{E}f(\rho) \leq [\mathbb{E}f(\rho)^2]^{1/2} \quad (\text{D5})$$

$$= [\mathbb{E}\text{Tr}(\hat{\rho}^2) - \text{Tr}(\rho^2)]^{1/2} \quad (\text{D6})$$

$$= \left[\sum_P \frac{MN_P(1 - \text{Tr}(\rho P)^2) + M^2 N_P^2 \text{Tr}(\rho P)^2}{2^n M^2 N_P^2} - \text{Tr}(\rho^2) \right]^{1/2} \quad (\text{D7})$$

$$= \left[\sum_P \frac{MN_P(1 - \text{Tr}(\rho P)^2) + M^2 N_P^2 \text{Tr}(\rho P)^2}{2^n M^2 N_P^2} - \text{Tr}(\rho^2) \right]^{1/2} \quad (\text{D8})$$

$$= \left[\sum_P \frac{1 - \text{Tr}(\rho P)^2}{2^n M N_P} + \sum_P \frac{\text{Tr}(\rho P)^2}{2^n} - \text{Tr}(\rho^2) \right]^{1/2} \quad (\text{D9})$$

$$\leq \left[\sum_P \frac{1}{2^n M N_P} \right]^{1/2} \quad (\text{D10})$$

$$= \frac{1}{\sqrt{M}} \left(\frac{4^k + 2^k - 1}{2^k + 1} \right)^{\frac{n}{2k}}, \quad (\text{D11})$$

where $N_P = (2^k + 1)^{n/k - w_k(P)}$ and $\sum_P \frac{1}{N_P}$ is computed as follows:

$$\sum_P \frac{1}{N_P} = \frac{1}{(2^k + 1)^{n/k}} \sum_{l=0}^{n/k} \binom{n/k}{l} (2^k + 1)^l (4^k - 1)^l \quad (\text{D12})$$

$$= \frac{(8^k + 4^k - 2^k)^{n/k}}{(2^k + 1)^{n/k}} \quad (\text{D13})$$

$$= \frac{2^n (4^k + 2^k - 1)^{n/k}}{(2^k + 1)^{n/k}}. \quad (\text{D14})$$

□

proof of 2.

$$f(\rho; \mathbf{X}) - f(\rho; \mathbf{X}^{(i)}) = \|\hat{\rho} - \rho\|_F - \|\hat{\rho}' - \rho\|_F \quad (\text{D15})$$

$$\leq \|\hat{\rho} - \hat{\rho}'\|_F \quad (\text{D16})$$

$$= [\text{Tr}((\hat{\rho} - \hat{\rho}')^2)]^{1/2} \quad (\text{D17})$$

$$= \left[\sum_{P \triangleright U_i} \frac{(\Delta \mu_P)^2}{2^n M^2 N_P^2} \right]^{1/2} \quad (\text{D18})$$

$$\leq \left[\frac{4}{2^n M^2} \sum_{P \triangleright U_i} \frac{1}{N_P^2} \right]^{1/2} \quad (\text{D19})$$

$$= \frac{2}{M} \cdot \frac{(4^k + 2^k - 1)^{\frac{n}{2k}}}{(2^k + 1)^{\frac{n}{k}}}, \quad (\text{D20})$$

where $P \triangleright U_i$ denotes the Pauli operator P for which the i -th measurement basis U_i provides actionable information and $\Delta \mu_P = \mu_P - \mu'_P$. Here, $\sum_{P \triangleright U_i} \frac{1}{N_P^2}$ is computed as follows:

$$\sum_{P \triangleright U_i} \frac{1}{N_P^2} = \frac{1}{(2^k + 1)^{2n/k}} \sum_{l=0}^{n/k} (2^k + 1)^{2l} (2^k - 1)^l \quad (\text{D21})$$

$$= \frac{(8^k + 4^k - 2^k)^{n/k}}{(2^k + 1)^{2n/k}} \quad (\text{D22})$$

$$= \frac{2^n (4^k + 2^k - 1)^{n/k}}{(2^k + 1)^{2n/k}}. \quad (\text{D23})$$

□

FIG. 4. (a) Two-layer patched brickwork circuit with periodic boundary. (b) and (c) Open boundary cases where a $\text{Cl}(k)$ block is split into $\text{Cl}(k/2)^{\otimes 2}$, in U_2 and U_1 , respectively.

Appendix E: OPEN BOUNDARY CONDITIONS

In Theorem 1, we assumed periodic boundary conditions (PBCs) when applying the unitary [Fig. 4(a)]. However, in the case of superconducting qubits, there exist connectivity constraints between qubits, which necessitate either forming a loop structure or employing additional SWAP gates. Therefore, it is currently more practical to consider open boundary conditions (OBCs). For OBCs, two cases are possible: the first is to split a $\text{Cl}(k)$ into $\text{Cl}(k/2)^{\otimes 2}$ in the U_2 layer [Fig. 4(b)], and the second is to divide a $\text{Cl}(k)$ in the U_1 layer [Fig. 4(c)]. Since $\text{Cl}(k/2)$ can be absorbed into the preceding or succeeding $\text{Cl}(k)$, it does not need to be physically implemented in an actual experiment. Nevertheless, for conceptual clarity, we keep them.

In the PBCs case, we have computed $\text{Tr}((FG)^m)$, where

$$F = \begin{pmatrix} 1 & \frac{1}{2^k-1} \\ \frac{1}{2^k-1} & \frac{1}{2^k-1} \end{pmatrix}, \quad G = \frac{1}{2^k+1} \begin{pmatrix} 2^{2k} & 2^k(2^k-1) \\ 2^k(2^k-1) & 2^k(2^k-1)^2 \end{pmatrix}, \quad (\text{E1})$$

which, in the OBCs setting, is replaced by

$$\text{Fig.4(b)} : \text{Tr} \left((FG)^{m-1} F \tilde{G} \right), \quad (\text{E2})$$

$$\text{Fig.4(c)} : \text{Tr} \left((FG)^{m-1} \tilde{F} G \right), \quad (\text{E3})$$

where

$$\tilde{F} = \begin{pmatrix} 1 & \frac{1}{2^{k/2}-1} \\ \frac{1}{2^{k/2}-1} & \frac{1}{(2^{k/2}-1)^2} \end{pmatrix}, \quad \tilde{G} = \begin{pmatrix} 2^k & 2^k(2^{k/2}-1) \\ 2^k(2^{k/2}-1) & 2^k(2^{k/2}-1)^2 \end{pmatrix}. \quad (\text{E4})$$

Let $h(X) = \text{Tr}((FG)^{m-1}X)$. We have

$$h(X) = \alpha_+ \lambda_+^{m-1} + \alpha_- \lambda_-^{m-1}, \quad (\text{E5})$$

where

$$\alpha_{\pm} = \frac{\text{Tr}(FGX) - \lambda_{\mp} \text{Tr}(X)}{\lambda_{\pm} - \lambda_{\mp}} \quad (\text{E6})$$

and $\lambda_{\pm}$ are eigenvalues of FG defined by

$$\lambda_{\pm} = \frac{2^k(2^{k+1} + 1 \pm \sqrt{2^{k+4} - 7})}{2(2^k + 1)}. \quad (\text{E7})$$

Then, $h(X)$ is bounded as follows:

$$h(X) \leq \lambda_+^{m-1}(\alpha_+ + \alpha_-) \quad (\text{E8})$$

$$= \lambda_+^{m-1} \text{Tr}(X) \quad (\text{E9})$$

$$= \lambda_+^m \left(\frac{\text{Tr}(X)}{\lambda_+} \right). \quad (\text{E10})$$

Since $\text{Tr}(F\tilde{G}) = 2^{k+1} = \Theta(2^k)$, $\text{Tr}(\tilde{F}G) = \frac{2^k}{2^{k+1}}(2^k + 4 \cdot 2^{k/2} + 3) = \Theta(2^k)$, and $\lambda_+ = \Theta(2^k)$, it follows that $h(F\tilde{G}) = \Theta(\lambda_+^m)$ and $h(\tilde{F}G) = \Theta(\lambda_+^m)$. Therefore, even in the OBCs setting, one can still recover near-optimal sample complexity for rank- r QST.

Appendix F: TWO-LAYER BRICKWORK UNITARY ENSEMBLE IN THE FULL RANK CASE

In this Appendix, we prove that using the random unitary ensemble from Fig.2(b) also achieves the optimal sample complexity of $\mathcal{O}(d^3/\epsilon^2)$ with the same circuit volume as in Fig. 2(a). Although the sample complexity is identical, the classical post-processing for QST is more practical when employing the block unitary ensemble [Fig.2(a)] [18]. For the proof, we need a tighter upper bound on m_P^{-1} than used in the main text. To do that, we can explicitly express m_P using tensor networks [28, 29] as follows:

$$m_P = \mathbb{E}_U \{ U P U^\dagger \in \pm \mathcal{Z} \} \quad (\text{F1})$$

$$= \mathbb{E}_{U_1, U_2} \{ U_2 U_1 P U_1^\dagger U_2^\dagger \in \pm \mathcal{Z} \} \quad (\text{F2})$$

$$= \text{Tr}(K_{(\mathbf{w}_{k,2}(P))_1} K_{(\mathbf{w}_{k,2}(P))_2} \dots K_{(\mathbf{w}_{k,2}(P))_{n/k}}), \quad (\text{F3})$$

$$(\text{F4})$$

where $\mathbf{w}_{k,2}(P) \in \{0, 1\}^{n/k}$ is a vector whose i -th component is 1 if P acts non-trivially on the i -th block of the U_2 layer, and 0 otherwise. Here, K_0 and K_1 are defined as follows:

$$K_0 = \frac{1}{2^k + 1} \begin{pmatrix} 2^k + 1 & 1 \\ 0 & 0 \end{pmatrix}, \quad K_1 = \frac{1}{(2^k + 1)^2} \begin{pmatrix} 1 & 1 \\ 2^{k+1} & 2^k \end{pmatrix} \quad (\text{F5})$$

Now, we can show that the minimum of the m_P happens when P acts non-trivially all the blocks, which means $\mathbf{w}_{k,2}(P) = (1, 1, \dots, 1)$.

Proof. We proceed by mathematical induction. Suppose that the matrix M_l obtained by multiplying K_0 or K_1 a total of l times has the form

$$M_l = \begin{pmatrix} A_l & B_l \\ C_l & D_l \end{pmatrix}, \quad (\text{F6})$$

with $A_l \geq B_l \geq 0$ and $C_l \geq D_l \geq 0$.

For $l = 1$, the statement can be verified directly. Assume that it holds for some l . Then, for $l + 1$, there are two possible cases:

$$K_0 M_l = \frac{1}{2^k + 1} \begin{pmatrix} (2^k + 1)A_l + C_l & (2^k + 1)B_l + D_l \\ 0 & 0 \end{pmatrix}, \quad (\text{F7})$$

$$K_1 M_l = \frac{1}{(2^k + 1)^2} \begin{pmatrix} A_l + C_l & B_l + D_l \\ 2^k(2A_l + C_l) & 2^k(2B_l + D_l) \end{pmatrix}. \quad (\text{F8})$$

If the induction hypothesis holds for M_l , it also holds for M_{l+1} . Therefore, any matrix obtained by products of a sequence of K_0 or K_1 satisfy Using this, we obtain

$$\text{Tr}(K_0 M_l) - \text{Tr}(K_1 M_l) = \frac{1}{(2^k + 1)^2} ((2^k + 1)^2 A_l + (2^k + 1)C_l - A_l - C_l - 2^k(2B_l + D_l)) \quad (\text{F9})$$

$$= \frac{1}{(2^k + 1)^2} (2^{2k} A_l + 2^{k+1}(A_l - B_l) + 2^k(C_l - D_l)) \quad (\text{F10})$$

$$\geq 0, \quad (\text{F11})$$

and hence the presence of K_0 in M_l always gives a larger value compared to the case without it. Therefore, the minimum of m_P occurs when $\mathbf{w}_{k,2}(P) = (1, 1, \dots, 1)$. $\square$

Using the above result, a minimum of m_P is given by

$$\min_P m_P = \text{Tr}(A_1^{n/k}) \quad (\text{F12})$$

$$= \mu_+^{n/k} + \mu_-^{n/k}, \quad (\text{F13})$$

where $\mu_{\pm}$ are eigenvalues of A_1 and are given by

$$\mu_{\pm} = \frac{z + 1 \pm \sqrt{z^2 + 6z + 1}}{2(z + 1)^2}, \quad (\text{F14})$$

where $z = 2^k$. Then, the maximum of m_P^{-1} is as follows:

$$\max_P m_P^{-1} = \frac{1}{\mu_+^{n/k} + \mu_-^{n/k}} \quad (\text{F15})$$

$$\leq \frac{1}{|\mu_+|^{n/k} - |\mu_-|^{n/k}} \quad (\text{F16})$$

$$= \frac{1}{|\mu_+|^{n/k}(1 - |\mu_-/\mu_+|^{n/k})} \quad (\text{F17})$$

$$\leq \mathcal{O}(1/|\mu_+|^{n/k}) \quad (\text{F18})$$

The last line holds for sufficiently large k , as $|\frac{\mu_-}{\mu_+}| = \Theta(2^{-k})$. And $1/|\mu_+|$ is bound on

$$1/|\mu_+| \leq z + \frac{3}{z + 1} \quad (\text{F19})$$

$$= 2^k + \frac{3}{2^k + 1}. \quad (\text{F20})$$

Therefore, when $k = \frac{1}{2} \log(n)$, we obtain

$$\max_P m_P^{-1} \leq \left(2^k + \frac{3}{2^k + 1}\right)^{n/k} \quad (\text{F21})$$

$$\leq 2^n \left(1 + \frac{3}{2^{2k}}\right)^{n/k} \quad (\text{F22})$$

$$\leq \mathcal{O}(2^n). \quad (\text{F23})$$

Based on this result, we can now prove the concentration inequality.

Let an unbiased estimator $\hat{\rho}_T$ be defined as

$$\hat{\rho}_T = \frac{1}{N_U} \sum_{i=1}^{N_U} \hat{\rho}_{U_i}, \quad (\text{F24})$$

$$\hat{\rho}_U = \frac{1}{N_S} \sum_{j=1}^{N_S} \mathcal{M}^{-1}(U^\dagger |b_j\rangle \langle b_j| U), \quad (\text{F25})$$

where N_U denotes the number of sampled unitaries, N_S denotes the number of repeated measurements for a given unitary U , and $T = N_U N_S$.

As before, the Frobenius norm

$$f(\rho) = f(\rho; \mathbf{X}) = \|\hat{\rho}_T - \rho\|_F$$

can be bounded using McDiarmid's inequality. Let $L := \max_P m_P^{-1}$. Then, the following two properties hold:

$$1. \mathbb{E}[f(\rho)] \leq \sqrt{\frac{2^n L}{N_U N_S}} + \frac{L}{N_U}, \quad (\text{F26})$$

$$2. f(\rho; \mathbf{X}) - f(\rho; \mathbf{X}^{(i)}) \leq \frac{2L}{N_U N_S}. \quad (\text{F27})$$

Applying these two properties to McDiarmid's inequality, we obtain

$$\Pr(f(\rho) \geq \epsilon_F) \leq \delta \quad (\text{F28})$$

whenever

$$N_U N_S = \frac{L}{\epsilon_F^2} \left(\sqrt{2^n + N_S} + L^{1/2} \ln(2/\delta) \right)^2. \quad (\text{F29})$$

Let us assume $N_S \leq \mathcal{O}(2^n)$, then

$$N_U N_S = \mathcal{O} \left(\frac{L}{\epsilon_F^2} \max(2^n, L) \right) \quad (\text{F30})$$

$$= \mathcal{O} \left(\frac{L^2}{\epsilon_F^2} \right). \quad (\text{F31})$$

Therefore, by taking $\epsilon_F = \epsilon_{\text{tr}}/\sqrt{2^n}$, we can ensure that

$$\Pr(\|\hat{\rho}_T - \rho\|_{\text{tr}} \geq \epsilon_{\text{tr}}) \leq \delta, \quad (\text{F32})$$

when $T = N_U N_S = \mathcal{O}(\frac{d^3}{\epsilon^2})$, $N_S = \mathcal{O}(2^n)$ and $k = \frac{1}{2} \log n$. Note that $k = \frac{1}{2} \log n$ in the two-layer brickwork unitary ensemble has the same circuit volume as $k = \log n$ in the block unitary ensemble.

Abstract. Executing large-scale quantum circuits on NISQ devices requires quantum circuit partitioning, but the sampling overhead grows exponentially with the number of gate and wire cuts. Existing SMT-based methods find optimal partitions yet scale poorly to large, dense circuits. We propose a scalable method that formulates partitioning as a shortest path problem solved by Dijkstra’s algorithm, combined with a simulated-annealing initial qubit placement. On QAOA MaxCut circuits, the proposed method produces high-quality partitions within 0.25 seconds even for 40-qubit fully-connected circuits, and on large dense circuits where SMT times out it reduces the sampling overhead by more than 10^{42} compared with the suboptimal solution returned by SMT at timeout.

Keywords: Quantum Circuit Partitioning, Wire Cut, Gate Cut, Shortest Path, Simulated Annealing

1 Introduction

Recently, research on quantum computation using quantum computers with tens to hundreds of qubits, known as Noisy Intermediate-Scale Quantum (NISQ) devices [1], has been actively studied. To execute large-scale quantum circuits on NISQ devices, quantum circuit partitioning is required; however, as the number of cuts increases, the number of executions of sub-circuits required to reconstruct the results of the original quantum circuit increases exponentially. Since finding the partition that minimizes this sampling overhead is NP-hard, existing methods use Satisfiability Modulo Theories (SMT) solvers [2] to find optimal solutions, but they lack scalability. Therefore, we propose a scalable method that finds high-quality cuts by modeling wire cuts and gate cuts in a quantum circuit diagram as graph edges and applying shortest path search. Experimental results on QAOA MaxCut circuits show that the proposed method produces high-quality partitions within 0.25 seconds even for 40-qubit fully-connected circuits, reducing the sampling overhead by more than 10^{42} compared with the suboptimal SMT solution at timeout.

2 Background

2.1 Quantum Circuit Partitioning

Quantum circuit partitioning [3] divides a large circuit into smaller sub-circuits by cutting specific locations with gate cuts and wire cuts, allowing circuits that exceed NISQ resources to be executed on smaller devices. However, the number of sub-circuit executions needed to reconstruct the original result grows exponentially with the number of cuts; this multiplicative factor is called

Table 1: Sampling overhead (k : number of cuts of each type).

Cut type	Sampling overhead
Wire cut	16^k
Gate cut	9^k

Figure 1: Examples of a wire cut and a gate cut (left: before, right: after).

the sampling overhead, whose per-cut values are listed in Table 1.

2.2 Wire Cut and Gate Cut

A wire cut [4], illustrated in Fig. 1(a), interrupts the temporal flow of a single qubit and transfers its state to a new qubit via a measurement-and-state-preparation pair or a two-qubit gate. With qubit reuse, only one additional ancilla qubit is required per wire cut. A gate cut [5], illustrated in Fig. 1(b), decomposes a two-qubit gate into a quasi-probability combination $\sum_i a_i F_i$ of single-qubit operations and measurements F_i with real weights a_i ; each term is sampled with probability $|a_i| / \sum_j |a_j|$ and combined with sign $\text{sign}(a_i)$ to estimate the original gate’s expectation value.

2.3 Knitting

Knitting [6] is the classical post-processing that reconstructs the expectation value of the original circuit by executing all sub-circuits and combining their measurement results with the weights from the quasi-probability decompositions.

3 Optimal Partitioning of Quantum Circuits using Gate Cuts and Wire Cuts

To find an optimal circuit partition, a method combining wire cuts and gate cuts has been proposed by Brandhofer et al. [2]. This method uses an SMT solver to exhaustively search for cuts that divide the cutting graph described below into the desired number of sub-circuits with the minimum sampling overhead.

3.1 Cutting Graph Construction

After removing single-qubit gates, each two-qubit gate g is represented by two vertices g_u, g_v joined by a gate-cut edge in G . For each pair of consecutive gates sharing a qubit, a directed wire-cut edge is added to W between the corresponding vertices along the time axis. Fig. 2 shows an example: the quantum circuit on the left is converted into the cutting graph on the right, where green edges are gate-cut edges and blue edges are wire-cut edges. Partitioning the circuit then corresponds to assigning every vertex to one of the sub-circuits and cutting the edges that cross the partition; the minimum-cost cut on this graph—weighting each cut edge by its sampling overhead—gives the optimal partition that minimizes the total sampling overhead. The SMT solver searches this cut space exhaustively, so its solution is guaranteed optimal whenever the search terminates.

3.2 SMT Formulation

On the cutting graph $\mathcal{G} = (V, G \cup W)$, the SMT model assigns each vertex to P_0 or P_1 via Boolean variables $O = \{o_v \mid v \in V\}$ ($o_v = \text{true}$ iff $v \in P_1$), with cut indicators $c_e := o_u \oplus o_v$ for $e = (u, v) \in E$.

Two constraints are imposed. A symmetry-breaking constraint fixes the first node: $\neg o_{v_0}$. A balance constraint $Q[P_0] \leq Q_{\max}$ and $Q[P_1] \leq Q_{\max}$ bounds each sub-circuit size, where

$$Q[P] = \sum_{q \in \mathcal{Q}} \mathbb{K}[\exists v \in \text{nodes}(q) : v \in P],$$

$$Q_{\max} = \left\lceil \frac{Q}{2} \right\rceil + \lfloor Q \cdot r_{\text{ancilla}} \rfloor.$$

Counting each qubit at most once per partition resolves the double-counting problem of prior work when a qubit zigzags such as $P_0 \rightarrow P_1 \rightarrow P_0$.

The objective minimizes the log sampling overhead:

$$\text{minimize} \sum_{(u,v) \in G} \log 9 \cdot c_{(u,v)} + \sum_{(u,v) \in W} \log 16 \cdot c_{(u,v)},$$

Figure 3: An example of a shortest path on the constructed graph (green: gate-cut edges; purple: wire-cut edges). The path corresponds to the set of cuts that partitions the quantum circuit.

equivalent to minimizing $9^{|G_{\text{cut}}|} \times 16^{|W_{\text{cut}}|}$.

4 Partitioning of Quantum Circuits via Dijkstra

4.1 Graph Construction

We arrange the n qubits on a line and call the space between adjacent qubits q_i, q_{i+1} a gap g_i ($i = 0, \dots, n-2$). Each gap is divided into intervals—contiguous time regions with no crossing CNOT gate—and a vertex is placed at each interval's start time: $V = \{(g, t) \mid g \in \{0, \dots, n-2\}, t \in P_g\}$, where P_g is the set of interval start times of gap g . Two edge types are defined. A within-gap edge connects consecutive intervals and corresponds to a gate cut, and a between-gap edge connects temporally overlapping intervals of adjacent gaps and corresponds to a wire cut. In Fig. 3, the green edges are gate-cut edges and the purple edges are wire-cut edges.

Any valid partition—one that completely separates the upper and lower sub-circuits—necessarily forms an uninterrupted boundary from the beginning to the end of the circuit in the qubit-time plane. Our graph construction represents this boundary as a single path on the graph; conversely, any path from a time-0 vertex to a final-time vertex on the graph corresponds to a valid partition. Fig. 3 illustrates this correspondence: traversing a green within-gap edge produces a gate cut, traversing a purple between-gap edge produces a wire cut, and the entire path realizes a valid partition of the circuit.

4.2 Shortest Path Formulation and Algorithm

Each gate-cut edge is weighted $\log 9$ and each wire-cut edge $\log 16$, so that the total path cost $|G_{\text{cut}}| \log 9 + |W_{\text{cut}}| \log 16$ equals the logarithm of the sampling overhead $9^{|G_{\text{cut}}|} \times 16^{|W_{\text{cut}}|}$; minimizing the path cost thus minimizes the overhead. We solve this minimum-cost path problem with Dijkstra's algorithm. Since the optimal start and end gaps are not known in advance, we add a virtual source S and sink T with zero-cost edges to the time-0 and final-time nodes of all candidate gaps, as shown in Fig. 3, so that a single search finds the minimum-cost path.

4.3 Handling the Balance Constraint

Since both sub-circuits must fit on a NISQ device, whether a partition is executable is determined by the larger sub-circuit, $\max(|P_0|, |P_1|)$. For a fixed total of

Figure 4: Effect of the initial qubit arrangement. Left: original arrangement (high-cost partition). Right: optimized arrangement (low-cost partition).

Q qubits, this maximum is smallest when the two sub-circuits are as balanced as possible; an even split therefore achieves the greatest reduction in the required number of qubits. We thus bound each sub-circuit size by $Q_{\max} = \lceil Q/2 \rceil + \lceil Q \cdot r_{\text{ancilla}} \rceil$ and steer the cut toward the center via a two-stage restriction of the search range. First, S and T connect only to gaps within radius r of the central gap $\lfloor (n-2)/2 \rfloor$ ($r = 2$, i.e. 5 gaps), keeping the partition near balanced. Second, at a cut placed at gap g , the two sub-circuits contain $g+1$ and $n-1-g$ original qubits; requiring both to be at most $Q_{\max}$ restricts the reachable gap range to $[\max(0, n-1-Q_{\max}), \min(n-2, Q_{\max}-1)]$. Since $Q_{\max}$ already incorporates the ancilla budget, this range implicitly caps the number of wire cuts; the positive wire-cut weight ($\log 16$) further suppresses unnecessary wire cuts.

4.4 Initial Qubit Arrangement

The input qubit ordering strongly affects the result. When frequently interacting qubit pairs are placed far apart, the two-qubit gates connecting them cross near the center of the circuit and force many gate cuts, as illustrated in Fig. 4. Reducing the number of gates that cross the central region is therefore desirable. To this end, we seek an ordering that minimizes the weighted Manhattan distance $M = \sum_{i < j} f_{ij} |p_i - p_j|$, where p_i is the position of qubit q_i and f_{ij} is their interaction count. A small M places interacting pairs close together, which reduces the gates crossing the center and hence the gate cuts the path must incur. Since minimizing M is the NP-hard Minimum Linear Arrangement problem, among several heuristics we examined the most effective was to combine SABRE’s greedy placement, which provides a good initial chain for SA, with a simulated annealing (SA) local search that swaps qubit pairs under a cooling schedule.

5 Empirical Evaluation

We evaluate the proposed method on QAOA MaxCut circuits ($p = 1$) generated from random connected graphs with edge densities of 10%, 30%, 50%, and 100%, for circuit sizes of 10, 20, 30, 40 qubits. Two seeds (42 and 123) are used to generate the random graphs. The ancilla ratio is fixed to $r_{\text{ancilla}} = 0.10$, which gives $Q_{\max} = \lceil Q/2 \rceil + \lceil 0.1Q \rceil$. The SMT solver (Z3) is given a time limit of 1 hour. For the proposed method, the reported

Figure 5: Distribution of (a) sampling overhead and (b) computation time over all densities (10–100%) and both seeds (log scale). SMT boxes include only solved cases; black $\times$ marks SMT timeouts (1 h). SP + SA stays consistently low and finishes within 0.25 s.

time includes both the initial qubit arrangement and the Dijkstra search.

5.1 Comparison of the Three Methods

Fig. 5 summarizes the results. SMT returns optimal solutions on small or sparse circuits in well under a second, but its cost and runtime vary by orders of magnitude: every 100%-density circuit with $Q \geq 20$ hits the one-hour time limit and returns a highly suboptimal solution (sampling overhead up to $\sim 10^{60}$ at $Q = 40$). This timeout occurs only on dense circuits; sparse ones remain tractable, which explains SMT’s wide box spanning many orders of magnitude. Raw SP always terminates in under 0.04 s but, with the original qubit ordering, the shortest path traverses many gate-cut edges, giving overheads of 10^9 to 10^{22} . Adding the SA-based placement (initialized by SABRE) before the Dijkstra search roughly halves the gate cuts and enables cheaper wire cuts, while keeping the total time below 0.25 s. On large dense circuits intractable for SMT, it reduces the sampling overhead by over 10^{36} (seed 42) and 10^{42} (seed 123) at $Q = 40$ compared with the suboptimal SMT solution. The two methods are thus complementary: SMT for small or sparse circuits where it terminates, and SP + SA for large dense circuits in well under a second.

Abstract. We prove the decidability results for a sub-class of local state transformation problems, a fundamental problem in quantum information theory and quantum communication complexity. A local state transformation is specified by two bipartite quantum states ρ^{AB} and σ^{AB} . Two non-communicating parties, Alice and Bob are provided with unbounded copies of the source state ρ^{AB} . The goal is to determine whether they can generate the target state that is arbitrarily close to the target state σ^{AB} without communication.

Ghazi, Kamath, and Sudan [10] initiated the study of the decidability of the classical counterpart, non-interactive simulation of joint distributions, by introducing a machinery built on the theory of analysis on Boolean functions. With such a machinery, the decidability of non-interactive simulation of joint distributions was fully resolved by subsequent works [4, 9]. However, the decidability of local state transformations remains largely open. Qin and Yao [12, 13] resolved the case where the source state ρ^{AB} is a noisy maximally entangled state.

In this work, we show that whenever the source state ρ^{AB} is classical, then local state transformations are decidable. Specifically, given $\delta > 0$, the algorithm either outputs local operations that transform the source state to a state that is δ -close to the target state or asserts that such local operations do not exist.

Keywords: Local State Transformation, Quantum Computational Complexity, Quantum Information Theory

1 Introduction

Non-interactive simulation of joint distributions is a fundamental problem in information theory and communication complexity: two non-communicating parties, Alice and Bob, are provided with sequences $\{\mathbf{X}_i\}_{i=1}^\infty$ and $\{\mathbf{Y}_i\}_{i=1}^\infty$, where $(\mathbf{X}_i, \mathbf{Y}_i)$ are independently drawn from some joint distribution p . Without exchanging messages, what joint distribution q can Alice and Bob jointly simulate?

The study of non-interactive simulation of joint distributions has a long history. The continuous version, where the target distribution is Gaussian, was resolved by Witsenhausen [11]. Witsenhausen proved that the largest correlation, i.e., the correlation of the target Gaussian distribution that can be generated by a source distribution is characterized by *maximal correlation* introduced by Hirschfeld [11] and Gebelbein [8] and Rényi [14]. The study of general non-interactive simulation goes back to classic works by Gács and Körner [7] and Wyner [15]. Specifically, Gács and Körner investigated the case where the target distribution is a perfectly correlated uniform distribution, i.e., (X, X) satisfies X is uniformly distributed over $\{0, 1\}$. They showed that the simulation rate is equal to what is now known as the Gács-Körner common information. On the other hand, Wyner studied the case where the source distribution is a perfectly correlated uniform distribution, and showed that the simulation rate in this case is now known as *Wyner common*

information. Non-interactive simulation is also studied in the setting of non-interactive correlation distillation. Readers may refer to [10] and references therein for a more detailed introduction about the history.

Ghazi, Kamath, and Sudan [10] initiated the study of the decidability of non-interactive simulation of joint distribution, where they introduced a machinery built on the theory of analysis on Boolean functions and resolved the case that the target distribution q is over $\{0, 1\} \times \{0, 1\}$. For larger target alphabets $[k] \times [k]$, where $k \geq 2$, De, Mossel, and Neeman [4] gave an upper bound n_0 on the copies of sources that suffice for players to sample the target distribution jointly. However, the upper bound is not primitive recursive and has an Ackermann-type growth (which is introduced by their application of the regularity lemma from [5]). This upper bound was later improved by Ghazi Kamath and Raghavendra [9], who gave an explicit bound that is exponential in k . Recently, the decidability of non-interactive simulation of joint distributions has also found applications in information-theoretic multiparty computation [1, 2].

This paper investigates *local state transformations*, which are the quantum counterpart of non-interactive simulation of joint distributions. In the setting of local state transformations, two non-communicating parties, Alice and Bob, are provided with infinitely many copies of the bipartite state ρ^{AB} , and the target state is σ^{AB} . A natural question is whether the local state transformations are decidable. However, this problem remains largely unresolved. Delgosha and Beigi initiated the study of this problem and provided a necessary condition for the exact local state transformations [6]. Qin and Yao [12] proved the decidability for the case when the

source state ρ^{AB} is a noisy maximally entangled state and the target state σ^{AB} is classical. Later, the same set of authors removed the restriction that σ^{AB} is classical [13]. To our knowledge, this is all that is known about the decidability of local state transformations.

In this paper, we study the case where the source state is classical and the target state is an arbitrary quantum state.

2 Our Results

We prove that quantum local state transformations are decidable when the source states are classical. When the maximal correlation of the source state is exactly 1, the set of simulatable target states is exactly the set of separable quantum states. To demonstrate this, the target state must be separable, as no communication between Alice and Bob is allowed. Alice and Bob can jointly sample a perfectly correlated uniform distribution $(\mathbf{X}, \mathbf{X})$, where $\mathbf{X}$ is uniformly distributed over $\{0, 1\}^n$ for arbitrary n when the maximal correlation of the source distribution p is 1. Thus, they can jointly simulate an arbitrary bipartite distribution. For any separate state $\sigma^{AB} = \sum_i q_i \sigma_i^A \otimes \sigma_i^B$, they jointly sample $i \sim q_i$, and then generate states σ_i^A and σ_i^B , separately.

Hence, our main results focus on the case where the maximal correlation of the source states is strictly less than 1. We extend the framework of the invariance principle and dimension reduction used in the works [9, 12, 13], and derive an explicit upper bound n_0 on the number of copies of source states required by a nearly optimal strategy.

Gaussian source We first state our result when the source states are ρ -correlated Gaussian. We prove that there exists an explicit upper bound n_0 on the number of copies of source states, such that it suffices to enumerate all strategies that use at most n_0 copies of the source state.

Problem 1 *Given as input the following:*

- A real number $\rho \in [0, 1]$, indicating the source state is ρ -correlated Gaussians.
- The description of a bipartite quantum state σ , which is the target state to be simulated.
- Parameters $0 < \beta < \beta + \varepsilon < 1$.

The goal is to distinguish between the two cases:

- *Yes case: There exists an integer N , such that with N copies of the source state, Alice and Bob can generate a quantum state that is β close to σ .*
- *No case: For any integer N , with N copies of the source state, Alice and Bob can not generate a quantum state that is $\beta + \varepsilon$ close to σ .*

Theorem 2 *theorem 1 is decidable. In particular, there exists an explicit upper bound $n_0 = \exp\left(\text{poly}\left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}\right)\right)$, where k is the dimension of output quantum state σ .*

Discrete source We further investigate the case where the source is a distribution over a discrete set.

Problem 3 *Given as input the following:*

- The description of a discrete bipartite alphabet $\mathcal{Z} \times \mathcal{Z}$ with a joint distribution μ .
- The description of a bipartite quantum state σ .
- Parameters $0 < \beta < \beta + \varepsilon < 1$.

The goal is to distinguish between the two cases:

- *Yes case: There exists an integer N , such that with N copies of the source state, Alice and Bob can generate a quantum state that is β close to σ .*
- *No case: For any integer N , with N copies of the source state, Alice and Bob cannot generate a quantum state that is $\beta + \varepsilon$ close to σ .*

Theorem 4 *theorem 3 is decidable. In particular, there exists an explicit upper bound $n_0 = \exp\left(\text{poly}\left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}, \log\left(\frac{1}{\alpha}\right)\right)\right)$, where k is dimension of the output quantum state σ , and $\rho = \rho(\mu)$ is the maximal correlation of μ , and $\alpha = \alpha(\mu)$ is the minimum non-zero probability in the distribution μ .*

3 Proof Overview

In this work, we extend the framework of Ghazi, Kamath, and Raghavendra [9] to the case of matrix-valued functions. The original framework of [9] consists of several transformations for functions mapping from $\mathbb{R}^n$ to vectors. These include a smoothing transformation that can effectively decrease the degree of the function, a multilinearization transformation that can transform any low-degree functions to low-degree multilinear functions, and the crucial dimension reduction transformation that reduces dimension n for low-degree and multilinear functions. All these transformations should maintain the property that

(1) the function outputs should be close to a distribution.

(2) The generated target state remains unchanged.

We generalize these transformations to the set of functions mapping $\mathbb{R}^n$ to $k \times k$ matrices. The key point is that we now need to maintain the property that after the transformations, the function outputs should still be close to density operators.

4 Summary and Open Problems

In this work, we prove the decidability of local state transformations with classical source states. Several interesting problems related to local state transformations remain open.

1. A natural open problem is whether local state transformations are decidable in general. To generalize the current framework, it requires employing the theory of biased Pauli analysis, a generalization of biased Boolean analysis to the space of matrices. Recently, Chen, Pont, Hsieh, Huang, Lange, and Li [3] initiated the study of biased Pauli analysis in the context of quantum learning and prediction. It would be interesting to see whether the current framework could be fully generalized to biased Pauli analysis.
2. Dimension reduction is a crucial step in the framework to reduce the number of copies. However, we only know the dimension reduction for polynomials in Gaussian spaces. Is it possible to establish a dimension reduction for polynomials over discrete variables so that we could avoid the invariance principle and save the running time exponentially?
3. Recently, researchers have studied secure non-interactive simulation and found applications in secure multiparty computation [2, 1]. Does local state transformation have applications in quantum secure multiparty computation?
4. Is multiparty local state transformation decidable? Note that the decidability of non-interactive simulation of k -partite distributions for $k \geq 3$ remains open.

Local State Transformations with Classical Source States are Decidable

Yuxiang Chen^{*} Yangjing Dong[†] Zhaofeng Su[‡] Penghui Yao^{§¶}

May 29, 2026

Abstract

We prove the decidability results for a sub-class of local state transformation problems, a fundamental problem in quantum information theory and quantum communication complexity. A local state transformation is specified by two bipartite quantum states ρ^{AB} and σ^{AB} . Two non-communicating parties, Alice and Bob are provided with unbounded copies of the source state ρ^{AB} . The goal is to determine whether they can generate the target state that is arbitrarily close to the target state σ^{AB} without communication.

Ghazi, Kamath, and Sudan [GKS16] initiated the study of the decidability of the classical counterpart, non-interactive simulation of joint distributions, by introducing a machinery built on the theory of analysis on Boolean functions. With such a machinery, the decidability of non-interactive simulation of joint distributions was fully resolved by subsequent works [DMN18, GKR18]. However, the decidability of local state transformations remains largely open. Qin and Yao [QY21, QY23] resolved the case where the source state ρ^{AB} is a noisy maximally entangled state.

In this work, we show that whenever the source state ρ^{AB} is classical, then local state transformations are decidable. Specifically, given $\delta > 0$, the algorithm either outputs local operations that transform the source state to a state that is δ -close to the target state or asserts that such local operations do not exist.

1 INTRODUCTION

Non-interactive simulation of joint distributions is a fundamental problem in information theory and communication complexity: two non-communicating parties, Alice and Bob, are provided with sequences $\{\mathbf{X}_i\}_{i=1}^\infty$ and $\{\mathbf{Y}_i\}_{i=1}^\infty$, where $(\mathbf{X}_i, \mathbf{Y}_i)$ are independently drawn from some joint distribution p . Without exchanging messages, what joint distribution q can Alice and Bob jointly simulate?

The study of non-interactive simulation of joint distributions has a long history. The continuous version, where the target distribution is Gaussian, was resolved by Witsenhausen [Hir35]. Witsenhausen proved that the largest correlation, i.e., the correlation of the target Gaussian distribution that can be generated by a source distribution is characterized by *maximal correlation* (in Definition 2.2) introduced by Hirschfeld [Hir35] and Gebelbein [Geb41] and Rényi [Rén59]. The study of general non-interactive simulation goes back to classic works by Gács and Körner [GK73] and Wyner [Wyn75]. Specifically, Gács and Körner investigated the case where the target distribution is a perfectly correlated uniform distribution, i.e., (X, X) satisfies X is uniformly distributed over $\{0, 1\}$. They showed that the simulation rate is equal to what is now known as the Gács-Körner common information. On the other hand, Wyner studied the case where the source distribution is a perfectly correlated uniform distribution, and showed that the simulation rate in this case is now known as *Wyner common information*. Non-interactive simulation is also studied in the setting of non-interactive correlation distillation. Readers may refer to [GKS16] and references therein for a more detailed introduction about the history.

Ghazi, Kamath, and Sudan [GKS16] initiated the study of the decidability of non-interactive simulation of joint distribution, where they introduced a machinery built on the theory of analysis on Boolean functions and resolved the case that the target distribution q is over $\{0, 1\} \times \{0, 1\}$. For larger target alphabets $[k] \times [k]$, where $k \geq 2$, De, Mossel, and Neeman [DMN18] gave an upper bound n_0 on the copies of sources that suffice for players to sample the target distribution jointly. However, the upper bound is not primitive recursive and has an Ackermann-type growth (which is introduced by their application of the regularity lemma from [DS14]). This upper bound was later improved by Ghazi Kamath and Raghavendra [GKR18], who gave an explicit bound that is exponential in k . Recently, the decidability of non-interactive simulation of joint distributions has also found applications in information-theoretic multiparty computation [ANP⁺22, AKMN22].

This paper investigates *local state transformations*, which are the quantum counterpart of non-interactive simulation of joint distributions. In the setting of local state transformations, two non-communicating parties, Alice and Bob, are provided with infinitely many copies of the bipartite state ρ^{AB} , and the target state is σ^{AB} . A natural question is whether the local state transformations are decidable. However, this problem remains largely unresolved. Delgosha and Beigi initiated the study of this problem and provided a necessary condition for the exact local state transformations [DB14]. Qin and Yao [QY21] proved the decidability for the case when the source state ρ^{AB} is a noisy maximally entangled state and the target state σ^{AB} is classical. Later, the same set of authors removed the restriction that σ^{AB} is classical [QY23]. To our knowledge, this is all that is known about the decidability of local state transformations.

In this paper, we study the case where the source state is classical and the target state is an arbitrary quantum state.

1.1 OUR RESULTS

We prove that quantum local state transformations are decidable when the source states are classical. When the maximal correlation of the source state is exactly 1, the set of simulatable target states is exactly the set of separable quantum states. To demonstrate this, the target state must be separable, as no communication between Alice and Bob is allowed. Alice and Bob can jointly sample a perfectly correlated uniform distribution $(\mathbf{X}, \mathbf{X})$, where $\mathbf{X}$ is uniformly distributed over $\{0, 1\}^n$ for arbitrary

n when the maximal correlation of the source distribution p is 1. Thus, they can jointly simulate an arbitrary bipartite distribution. For any separate state $\sigma^{AB} = \sum_i q_i \sigma_i^A \otimes \sigma_i^B$, they jointly sample $i \sim q_i$, and then generate states σ_i^A and σ_i^B , separately.

Hence, our main results focus on the case where the maximal correlation of the source states is strictly less than 1. We extend the framework of the invariance principle and dimension reduction used in the works [GKR18, QY21, QY23], and derive an explicit upper bound n_0 on the number of copies of source states required by a nearly optimal strategy.

Gaussian source We first state our result when the source states are ρ -correlated Gaussian. We prove that there exists an explicit upper bound n_0 on the number of copies of source states, such that it suffices to enumerate all strategies that use at most n_0 copies of the source state.

Problem 1.1 (Local state transformation with Gaussian sources). Given as input the following:

- A real number $\rho \in [0, 1]$, indicating the source state is ρ -correlated Gaussians.
- The description of a bipartite quantum state σ , which is the target state to be simulated.
- Parameters $0 < \beta < \beta + \varepsilon < 1$.

The goal is to distinguish between the two cases:

- Yes case: There exists an integer N , such that with N copies of the source state, Alice and Bob can generate a quantum state that is β close to σ .
- No case: For any integer N , with N copies of the source state, Alice and Bob can not generate a quantum state that is $\beta + \varepsilon$ close to σ .

Theorem 1.2. *Problem 1.1 is decidable. In particular, there exists an explicit upper bound $n_0 = \exp\left(\text{poly}\left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}\right)\right)$, where k is the dimension of output quantum state σ .*

Discrete source We further investigate the case where the source is a distribution over a discrete set.

Problem 1.3 (Local state transformation with discrete sources). Given as input the following:

- The description of a discrete bipartite alphabet $\mathcal{Z} \times \mathcal{Z}$ with a joint distribution μ .
- The description of a bipartite quantum state σ .
- Parameters $0 < \beta < \beta + \varepsilon < 1$.

The goal is to distinguish between the two cases:

- Yes case: There exists an integer N , such that with N copies of the source state, Alice and Bob can generate a quantum state that is β close to σ .
- No case: For any integer N , with N copies of the source state, Alice and Bob cannot generate a quantum state that is $\beta + \varepsilon$ close to σ .

Theorem 1.4. *Problem 1.3 is decidable. In particular, there exists an explicit upper bound $n_0 = \exp\left(\text{poly}\left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}, \log\left(\frac{1}{\alpha}\right)\right)\right)$, where k is dimension of the output quantum state σ , and $\rho = \rho(\mu)$ is the maximal correlation of μ as defined in Definition 2.2, and $\alpha = \alpha(\mu)$ is the minimum non-zero probability in the distribution μ .*

1.2 PROOF OVERVIEW

In this work, we extend the framework of Ghazi, Kamath, and Raghavendra [GKR18] to the case of matrix-valued functions. The original framework of [GKR18] consists of several transformations for functions mapping from $\mathbb{R}^n$ to vectors. These include a smoothing transformation that can effectively decrease the degree of the function, a multilinearization transformation that can transform any low-degree functions to low-degree multilinear functions, and the crucial dimension reduction transformation that reduces dimension n for low-degree and multilinear functions. All these transformations should maintain the property that

- (1) the function outputs should be close to a distribution.
- (2) The generated target state remains unchanged.

We generalize these transformations to the set of functions mapping $\mathbb{R}^n$ to $k \times k$ matrices. The key point is that we now need to maintain the property that after the transformations, the function outputs should still be close to density operators.

Starting with the ρ -correlated Gaussian case, the strategies by the two players can be represented by two matrix-valued functions $A, B : \mathbb{R}^n \rightarrow \mathcal{D}_k$, where we use $\mathcal{D}_k$ to denote the set of $k \times k$ density operators, which are positive semi-definite matrices with trace equal to one. On input $x \in \mathbb{R}^n$, Alice outputs the quantum state $A(x)$, and Bob outputs the quantum state $B(x)$. Then the final output state will be distributed as

$$\sigma = \mathbb{E}_{(x,y) \sim \mathcal{G}_\rho^{\otimes n}} [A(x) \otimes B(y)].$$

We wish to reduce the dimension n on the Gaussian space, to produce an n_0 that is irrelevant to n such that: There exists functions $\tilde{A}, \tilde{B} : \mathbb{R}^{n_0} \rightarrow \mathcal{D}_k$ such that, let the final output state with this strategy be

$$\tilde{\sigma} = \mathbb{E}_{(x,y) \sim \mathcal{G}_\rho^{\otimes n_0}} [\tilde{A}(x) \otimes \tilde{B}(y)],$$

we have

$$\|\sigma - \tilde{\sigma}\|_1 \leq \varepsilon.$$

For $e_1, e_2, f_1, f_2 \in [k]$, the entries of the quantum state $\tilde{\sigma}$ are represented by

$$\langle e_1, e_2 | \sigma | f_1, f_2 \rangle = \mathbb{E}_{(x,y) \sim \mathcal{G}_\rho^{\otimes n}} [A_{e_1, f_1}(x) \cdot B_{e_2, f_2}(y)],$$

where $A_{e_1, f_1}(x) = \langle e_1 | A(x) | f_1 \rangle$ and $B_{e_2, f_2}(y) = \langle e_2 | B(y) | f_2 \rangle$. So if we can apply the dimension reduction in [GKR18], with the error parameter $\varepsilon = \delta/k^2$, then we are done. However, to apply this dimension reduction result, we need that the functions A and B are both low-degree and multilinear, and in general these may not be true. So we need the following steps:

Smoothing. The first step we apply a smoothing operator that can reduce the degree of a function, which is done by “adding noise” to the function. In particular, we apply the Ornstein-Uhlenbeck operator U_γ to the functions A and B , with some constant $\gamma < 1$, and then preserve the low-degree part of $U_\gamma A$ and $U_\gamma B$. After the Ornstein-Uhlenbeck operator the high-degree part of the functions A and B will decrease exponentially fast. Also, for every input $x \in \mathbb{R}^n$, the output of $U_\gamma A(x)$ is a mixture of $A(y)$ where y is distributed according to some distribution related to x . So it is immediate that $U_\gamma A(x)$ is a density operator as long as $A(y)$ is a density operator for any $y \in \mathbb{R}^n$. The correlation between A and B will be preserved. This is because as long as we choose γ to be large enough, then the correlation introduced by the low-degree part of A and B will not change too much. On the other hand, the correlation introduced by the high-degree part of A and B is already exponentially small, because the correlation $\rho(\mu)$ of the source state is strictly less than 1.

Multilinearization. Now we have a low-degree function, which may be not multilinear. The idea is for each input x_i , introduce several new random variables $y_{i1}, \dots, y_{it}$, and replace each x_i by $(y_{i1} + \dots + y_{it})/\sqrt{t}$. For example, it may have terms like $x_1^3 x_2^5$, which are replaced by $(y_{11} +$

$\cdots + y_{1t})^3(y_{21} + \cdots + y_{2t})^5/t^4$. Expanding these terms, the majority of the resulting terms will be multilinear in terms of the new random variables $\{y_{ij}\}_{i \in [n], j \in [t]}$. So we can now truncate the non-multilinear part without changing the output of this function too much. Since the output is not changed (too much), all the properties will be preserved.

Dimension reduction & rounding. Since now the resulting functions A and B are low-degree and multilinear, we can apply the dimension reduction transformation of [GKR18]. The resulting functions will use at most n_0 copies of the source state, where n_0 is an upper bound irrelevant to n . Finally, since these steps will introduce some error, and the output states are no longer perfect density operators, we need to round these output states to density operators.

Now we turn to the case where we have arbitrary discrete distributions as source states. The canonical way is to reduce it to Gaussian source states by an invariance principle [GKS16, DMN18, GKR18]. In this work, we employ a new invariance principle for matrix-valued functions. Let (Ω, μ) be any finite discrete distribution. For any functions $A, B : \Omega^n \rightarrow \mathcal{D}_k$, we show that it can be replaced by functions $\tilde{A}, \tilde{B} : \mathbb{R}^{O(n)} \rightarrow \mathcal{D}_k$, while preserving the correlation.

1.3 SUMMARY AND OPEN PROBLEMS

In this work, we prove the decidability of local state transformations with classical source states. Several interesting problems related to local state transformations remain open.

1. A natural open problem is whether local state transformations are decidable in general. To generalize the current framework, it requires employing the theory of biased Pauli analysis, a generalization of biased Boolean analysis to the space of matrices. Recently, Chen, Pont, Hsieh, Huang, Lange, and Li [CdH⁺25] initiated the study of biased Pauli analysis in the context of quantum learning and prediction. It would be interesting to see whether the current framework could be fully generalized to biased Pauli analysis.
2. Dimension reduction is a crucial step in the framework to reduce the number of copies. However, we only know the dimension reduction for polynomials in Gaussian spaces. Is it possible to establish a dimension reduction for polynomials over discrete variables so that we could avoid the invariance principle and save the running time exponentially?
3. Recently, researchers have studied secure non-interactive simulation and found applications in secure multiparty computation [AKMN22, ANP⁺22]. Does local state transformation have applications in quantum secure multiparty computation?
4. Is multiparty local state transformation decidable? Note that the decidability of non-interactive simulation of k -partite distributions for $k \geq 3$ remains open.

1.4 ORGANIZATION

In Section 2, we define the notion of matrix-valued functions, and some of the lemmas that we need in this work. In Section 3, we present the reductions needed to achieve dimension reduction for local state transformation. In Section 4, we prove that local state transformation with gaussian sources is computable. In Section 5, we prove that local state transformation with discrete sources is computable.

2 PRELIMINARIES

In quantum mechanics, quantum systems are associated with finite-dimensional Hilbert spaces. In this work, we will use $\mathcal{M}_{n,m}$ to represent the set of linear operators mapping an m -dimension Hilbert space to an n -dimension Hilbert space, which also corresponds to the set of $n \times m$ matrices with complex number entries. For square matrices, we will use $\mathcal{M}_n$ to represent $\mathcal{M}_{n,n}$. An important class of operators is the Hermitian operators, which are the self-adjoint operators in a Hilbert space and are denoted as $\mathcal{H}_n$. We use Pos_n to denote the positive semi-definite matrices. The quantum states in a quantum system correspond to the *density operators* over a Hilbert space, which are the positive semi-definite operators with trace equal to one. We use $\mathcal{D}_n$ to denote the set of density operators. The trace of a square matrix $A \in \mathcal{M}_d$ is $\text{Tr}[A] = \sum_{i=1}^d A_{ii}$. The normalized trace is $\tau[A] = \frac{1}{d} \text{Tr}[A]$.

Definition 2.1 (Schatten p -norms). For $p \geq 1$, we define the Schatten p -norm and the normalized Schatten p -norm as

$$\|A\|_p = (\text{Tr}[|A|^p])^{1/p} \quad \text{and} \quad \|A\|_p = (\tau[|A|^p])^{1/p},$$

respectively. For $p = \infty$ The spectral norm $\|A\|_\infty$ is defined to be the largest singular value of A . We will use $\|A\| = \|A\|_\infty$ to represent the spectral norm.

We will use bold letters such as $\mathbf{X}$ and $\mathbf{x}$ to represent random variables. For a random variable $\mathbf{X}$ and $p \geq 1$, we define the p -norm as

$$\|\mathbf{X}\|_p = \left(\mathbb{E}[|\mathbf{X}|^p] \right)^{1/p}.$$

In this work, we consider bipartite random variables that are correlated. For a bipartite joint probability space $(\mathcal{Z} \times \mathcal{Z}, \mu)$ and two functions $f, g : \mathcal{Z} \rightarrow \mathbb{R}$, the correlation between f and g is defined as

$$\langle f, g \rangle_\mu = \mathbb{E}_{(\mathbf{x}, \mathbf{y}) \sim \mu} [f(\mathbf{x}) \cdot g(\mathbf{y})].$$

We use the *maximal correlation* as the metric for correlation in our work, which was first introduced by Hirschfeld [Hir35] and Gebelein [Geb41] and then studied by Rényi [Rén59].

Definition 2.2 (Maximal Correlation). Let $(\mathcal{Z} \times \mathcal{Z}, \mu)$ be a joint probability space, and variables $\mathbf{X}$ and $\mathbf{Y}$ satisfy that $(\mathbf{X}, \mathbf{Y}) \sim \mu$. We define the maximal correlation $\rho(\mu)$ as

$$\rho(\mu) = \sup_{f, g} \left\{ \langle f, g \rangle_\mu \mid \begin{array}{ll} f : \mathcal{Z} \rightarrow \mathbb{R}, & \mathbb{E}[f] = \mathbb{E}[g] = 0 \\ g : \mathcal{Z} \rightarrow \mathbb{R}, & \text{Var}[f] = \text{Var}[g] = 1 \end{array} \right\}.$$

Although the above definition is stated for discrete distributions, it extends naturally to the case where $\mathcal{Z} = \mathbb{R}$. In particular, for any $-1 \leq \rho \leq 1$, we use $\mathcal{G}_\rho$ to represent the ρ -correlated Gaussian distribution, which is a 2-dimensional Gaussian distribution

$$(\mathbf{X}, \mathbf{Y}) \sim N \left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1, \rho \\ \rho, 1 \end{pmatrix} \right).$$

It is easy to verify that the maximal correlation of $\mathcal{G}_\rho$ is exactly $|\rho|$.

2.1 MATRIX VALUED FUNCTIONS

In a quantum local state transformation with a classical source state and a quantum target state, the strategies of Alice and Bob can be described by functions mapping classical sources to quantum states. In particular, let $(\mathcal{Z} \times \mathcal{Z}, \mu)$ be a bipartite probability space, a strategy that uses n copies of this source state can be described by a pair of functions of the form $A, B : \mathcal{Z}^n \rightarrow \mathcal{D}_k$. On input $(\mathbf{x}, \mathbf{y}) \in \mathcal{Z} \times \mathcal{Z}$ distributed as μ , the quantum state generated by Alice and Bob is $A(\mathbf{x}) \otimes B(\mathbf{y})$. So in this work, the main objects of research are the functions of the form $P : \mathcal{Z}^n \rightarrow \mathcal{M}_k$. We will take a Fourier analysis approach to these matrix-valued functions. First, we define the notion of a Fourier basis in terms of matrix-valued functions.

Let (Ω, μ) be a probability space. For any $f, g : \Omega \rightarrow \mathbb{R}$, we define $\langle f, g \rangle = \mathbb{E}_{\mathbf{x} \sim \mu}[f(\mathbf{x})g(\mathbf{x})]$. It is easy to verify that $\langle \cdot, \cdot \rangle$ is an inner product for the space $L^2(\Omega, \mu) = (\{f : \Omega \rightarrow \mathbb{R}\}, \langle \cdot, \cdot \rangle)$. Here we assume that all functions considered in this paper are integrable if Ω is infinite.

Definition 2.3 (Orthonormal basis). Let (Ω, μ) be a probability space with $|\Omega| = q$. If Ω is an infinite set, we have $q = \infty$. We call $\mathcal{X} = \{\mathcal{X}_0, \dots, \mathcal{X}_{q-1}\}$ an *orthonormal basis* for the space of functions $\Omega \rightarrow \mathbb{R}$ if each $\mathcal{X}_i : \Omega \rightarrow \mathbb{R}$ is a function such that $\mathcal{X}_0 = 1$ and for any $i, j \in \{0, \dots, q-1\}$, we have

$$\langle \mathcal{X}_i, \mathcal{X}_j \rangle = \mathbb{E}_{\mu}[\mathcal{X}_i \cdot \mathcal{X}_j] = \delta_{i,j},$$

where here $\delta_{i,j}$ is the Kronecker delta function.

Remark 2.4. When $\Omega = \mathbb{R}$ and μ is the standard Gaussian distribution, we have an infinite number of functions $\mathcal{X}_i$ in the orthonormal basis, which are the Hermite polynomials defined as

$$H_0(x) = 1; \quad H_1(x) = x; \quad H_r(x) = \frac{(-1)^r}{\sqrt{r!}} e^{x^2/2} \cdot \frac{d^2}{dx^2} e^{-x^2/2}.$$

For a joint probability space $(\mathcal{Z} \times \mathcal{Z}, \mu)$, we use μ_A and μ_B to denote the marginal distributions respectively. Although we could choose the orthonormal basis for $L^2(\mathcal{Z}, \mu_A)$ and $L^2(\mathcal{Z}, \mu_B)$ arbitrary, we choose the basis $\mathcal{X} = (\mathcal{X}_0, \dots, \mathcal{X}_{q-1})$ and $\mathcal{Y} = (\mathcal{Y}_0, \dots, \mathcal{Y}_{q-1})$ such that

$$\langle \mathcal{X}_i, \mathcal{Y}_j \rangle_{\mu} = \rho_i \delta_{ij}, \quad (1)$$

where $\rho_{q-1} \leq \dots \leq \rho_1 \leq \rho_0$ are real numbers, $\rho_1 = \rho(\mu)$ is the maximal correlation of μ , and $\rho_0 = 1$.

It is easy to check that, for any integer n , and $\sigma \in \{0, \dots, q-1\}^n$, the functions $\{\mathcal{X}_{\sigma}\}_{\sigma \in \{0, \dots, q-1\}^n}$ defined as $\mathcal{X}_{\sigma} = \prod_{i \in \sigma} \mathcal{X}_i$ forms an orthonormal basis for the functions from the probability space (Ω^n, μ^n) to $\mathbb{R}$. Fix an orthonormal basis $\mathcal{X} = \{\mathcal{X}_0, \dots, \mathcal{X}_{q-1}\}$. Then $P : \Omega^n \rightarrow \mathcal{M}_k$ admits the Fourier expansion

$$P = \sum_{\sigma \in \{0, \dots, q-1\}^n} \hat{P}(\sigma) \mathcal{X}_{\sigma}. \quad (2)$$

where each $\hat{P}(\sigma) \in \mathcal{M}_k$. We define the following quantities for matrix-valued functions in terms of a Fourier expansion:

Definition 2.5. Let (Ω, μ) be a probability space equipped with an orthonormal basis $\mathcal{X} = (\mathcal{X}_1, \dots, \mathcal{X}_{q-1})$. Let $P : \Omega^n \rightarrow \mathcal{M}_k$ be a multilinear polynomial with Fourier expansion as Eq. (2). For $\sigma \in \{0, \dots, q-1\}^n$, we define $|\sigma| = |\{i : \sigma_i \neq 0\}|$. The degree of P is defined as

$$\deg(P) = \max \left\{ |\sigma| : \hat{P}(\sigma) \neq 0 \right\}.$$

For $p \geq 1$, we define the p -norm as

$$\|P\|_p = \mathbb{E}_{x \sim \mu} \left[\|P(x)\|_p^p \right]^{1/p}.$$

And the variance of P is

$$\text{Var} [P] = \sum_{\sigma} \left\| \hat{P}(\sigma) \right\|_2^2 = \|P\|_2^2.$$

Finally, for $i \in [n]$, the influence is

$$\text{Inf}_i (P) = \sum_{\sigma: \sigma_i \neq 0} \left\| \hat{P}(\sigma) \right\|_2^2.$$

The following is a well-known fact in analysis on Boolean functions.

Fact 2.6. Let (Ω, μ) be a probability space with orthonormal basis $\mathcal{X} = (\mathcal{X}_1, \dots)$, and $P : \Omega^n \rightarrow \mathcal{M}_k$ a matrix-valued function with Fourier expansion

$$P = \sum_{\sigma \in \{0, \dots, q-1\}^n} \hat{P}(\sigma) \mathcal{X}_{\sigma}.$$

Then

$$\sum_{i=1}^n \text{Inf}_i (P) \leq \deg (P) \text{Var} [P].$$

Remember that we are primarily interested in functions that map to density operators. We use the rounding operator defined as follows, to round a function $P : \Omega^n \rightarrow \mathcal{M}_k$ to the nearest function $\tilde{P} : \Omega^n \rightarrow \mathcal{D}_k$.

Definition 2.7 (Rounding Operator). The rounding operator $\mathcal{R}^k : \mathcal{M}_k \rightarrow \mathcal{D}_k$ maps any matrix $P \in \mathcal{M}_k$ to its closest density operator. In particular, it is the identity map on $\mathcal{D}_k$. We will drop the superscript, as k is fixed throughout this paper.

For some matrix entry $e \in [k] \times [k]$, we use $P_e(\mathbf{x})$ to denote the function that outputs the e entry of $P(\mathbf{x})$. When used together with the rounding operator, we will use $\mathcal{R}_e(P)$ to denote the e entry of $\mathcal{R}(P)$. The following lemma follows immediately by the same proof in [GKR18, Lemma 2.4], since for any $e, f \in [k] \times [k]$ we have $\|A_e\|_2 \leq \|A\|_2$.

Lemma 2.8. *Given any joint probability space $(\mathcal{Z} \times \mathcal{Z}, \mu)$. Let $A, \tilde{A}, B, \tilde{B} : \mathcal{Z}^n \rightarrow \mathcal{M}_k$ be matrix-valued polynomials such that $\|A\|_2, \|\tilde{A}\|_2, \|B\|_2, \|\tilde{B}\|_2 \leq 1$. If $\|A - \tilde{A}\|_2 \leq \varepsilon$ and $\|B - \tilde{B}\|_2 \leq \varepsilon$, then for any $e_1, e_2, f_1, f_2 \in [k]$ it holds that,*

$$\left| \left\langle \tilde{A}_{e_1, f_1}, \tilde{B}_{e_2, f_2} \right\rangle_{\mu^{\otimes n}} - \left\langle A_{e_1, f_1}, B_{e_2, f_2} \right\rangle_{\mu^{\otimes n}} \right| \leq 2\varepsilon.$$

Fact 2.9. [Sch13, Theorem 1.2.1]

For any $A, B \in \mathcal{M}_k$, we have that

$$\|\mathcal{R}(A) - \mathcal{R}(B)\| \leq \|A - B\|$$

Namely, the rounding operation is a contraction.

3 REDUCTIONS FOR LOCAL STATE TRANSFORMATION

As stated in the introduction, to give the upper bound for local state transformation, we will need to go through a series of reductions. In this section we state the reduction steps needed in our work.

3.1 FROM GENERAL POLYNOMIALS TO LOW-DEGREE POLYNOMIALS

In this subsection we prove our smoothing lemma which can reduce general polynomials to low-degree polynomials, while preserving the correlation and the distance to “valid strategies”.

Lemma 3.1 (Smoothing Lemma). *For every $\rho \in (0, 1)$, $\delta \in (0, 1)$ and $k \in \mathbb{Z}$, there is a computable $d = d(\rho, k, \delta)$ such that:*

Correlated Discrete Hypercube: *Let $(\mathcal{Z} \times \mathcal{Z}, \mu)$ be a bipartite probability space with maximum correlation ρ . Let $A, B : \mathcal{Z}^n \rightarrow \mathcal{D}_k$ be matrix functions such that for all $e, f \in [k]$, we have $\text{Var}[A_{e,f}] \leq 1$ and $\text{Var}[B_{e,f}] \leq 1$. Then there exists function $A^{(1)}$ and $B^{(1)}$ such that statements 1-4 below hold.*

Correlated Gaussian: *Let $A, B : \mathbb{R}^n \rightarrow \mathcal{D}_k$ be matrix functions such that for all $e, f \in [k]$, we have $\text{Var}[A_{e,f}] \leq 1$ and $\text{Var}[B_{e,f}] \leq 1$. Then there exists function $A^{(1)}$ and $B^{(1)}$ such that statements 1-4 below hold.*

In particular, we may take $d = O\left(\frac{k \log^2(k^2/\delta)}{\delta(1-\rho)}\right)$.

1. $A^{(1)}$ and $B^{(1)}$ have degree at most d .
2. For any $e, f \in [k]$, it holds that $\text{Var}[A_{e,f}^{(1)}] \leq \text{Var}[A_{e,f}] \leq 1$ and $\text{Var}[B_{e,f}^{(1)}] \leq \text{Var}[B_{e,f}] \leq 1$.
3. $\|\mathcal{R}(A^{(1)}) - A^{(1)}\|_2 \leq \delta$ and $\|\mathcal{R}(B^{(1)}) - B^{(1)}\|_2 \leq \delta$.
4. For any $e_1, e_2, f_1, f_2 \in [k]$, for the case of correlated discrete hypercube, we have

$$\left| \langle A_{e_1, f_1}^{(1)}, B_{e_2, f_2}^{(1)} \rangle_{\mu^{\otimes n}} - \langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mu^{\otimes n}} \right| \leq \delta.$$

For the case of correlated Gaussian, we have

$$\left| \langle A_{e_1, f_1}^{(1)}, B_{e_2, f_2}^{(1)} \rangle_{\mathcal{G}_\rho^{\otimes n}} - \langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mathcal{G}_\rho^{\otimes n}} \right| \leq \delta.$$

The general idea of this low-degree reduction is to apply a noise operator on the function, and then truncating the high-degree part. Hence we define the noise operator as follows:

Definition 3.2. Let (Ω, μ) be a distribution. Let $\rho \in [0, 1]$. For any $x \in \Omega$, we define the distribution $N_\rho(x)$ to be such that it is x with probability ρ , and distributed independently according to μ with probability $1 - \rho$. Formally, for any $x \in \Omega$ define the single-point distribution e_x as

$$e_x(y) = \begin{cases} 1 & \text{if } y = x. \\ 0 & \text{otherwise.} \end{cases}$$

Then we define the distribution $N_\rho(x)$ as

$$N_\rho(x) = \rho \cdot e_x + (1 - \rho) \cdot \mu.$$

For $x \in \Omega^n$, we slightly abuse notation and also use $N_\rho(x)$ to denote the distribution where we act N_ρ independently on all x_i . That is $N_\rho(x) = N_\rho(x_1) \otimes \cdots \otimes N_\rho(x_n)$.

Definition 3.3 (Noise Operator). Let (Ω, μ) be a distribution. Let $P : \Omega^n \rightarrow \mathcal{M}_k$ be a matrix-valued function. Then for $\rho \in [0, 1]$, define $T_\rho P$ as for any $x \in \Omega^n$,

$$T_\rho P(x) = \mathbb{E}_{\mathbf{y} \sim N_\rho(x)} [P(\mathbf{y})].$$

The noise operator is useful because it can decrease the Fourier weight of the high-degree part of a function exponentially. This effect has a nice interpretation in terms of Fourier expansions:

Fact 3.4. Let (Ω, μ) be a distribution equipped with an orthonormal basis $\mathcal{X} = \{\mathcal{X}_i\}$. Suppose $P : \Omega^n \rightarrow \mathcal{M}_k$ has Fourier expansion

$$P = \sum_{\sigma \in \{0, \dots, q-1\}^n} \widehat{P}(\sigma) \mathcal{X}_\sigma.$$

Then for any $\rho \in [0, 1]$, we have

$$T_\rho P = \sum_{\sigma \in \{0, \dots, q-1\}^n} \rho^{|\sigma|} \widehat{P}(\sigma) \mathcal{X}_\sigma.$$

Proof. Since the operator T_ρ is linear, we only need to check for a single $\mathcal{X}_i$. Recall that for $\mathcal{X}_0$, it is $\mathcal{X}_0 = 1$. So we have $T_\rho \mathcal{X}_0 = T_\rho 1 = 1$. For $i \neq 0$, consider any input $x \in \Omega$.

$$\begin{aligned} T_\rho \mathcal{X}_i(x) &= \mathbb{E}_{\mathbf{y} \sim N_\rho(x)} [\mathcal{X}_i(\mathbf{y})] \\ &= \rho \mathcal{X}_i(x) + (1 - \rho) \mathbb{E}_{\mathbf{y} \sim \mu} [\mathcal{X}_i(\mathbf{y})] \\ &= \rho \mathcal{X}_i(x). \end{aligned}$$

The last equation follows since $\mathbb{E}_\mu[\mathcal{X}_i] = 0$ for any $i \neq 0$. $\square$

The following fact states that if $P : \Omega \rightarrow \mathcal{D}_k$ is a density operator-valued function, then for any $\rho \in [0, 1]$, the corresponding function $T_\rho P$ also maps to density operators. The proof is immediate from Definition 3.3.

Fact 3.5. Let (Ω, μ) be a probability space and $P : \Omega^n \rightarrow \mathcal{D}_k$ be a matrix-valued function. For any $\rho \in [0, 1]$ and any $x \in \Omega^n$, we have $T_\rho P(x) \in \mathcal{D}_k$.

We are now ready to prove Lemma 3.1.

Proof of Lemma 3.1. We only prove this theorem in the case of correlated discrete hypercube. The proof for correlated Gaussian is identical.

Noising step. In this step, we obtain intermediate functions $\overline{A}$ and $\overline{B}$ satisfying

- $\overline{A}$ and $\overline{B}$ have decaying Fourier tails. In particular, $\|\overline{A}^{>d}\|_2^2 \leq \delta/2$ and $\|\overline{B}^{>d}\|_2^2 \leq \delta/2$.
- For any $e, f \in [k]$, we have $\text{Var}[\overline{A}_{e,f}] \leq \text{Var}[A_{e,f}] \leq 1$ and $\text{Var}[\overline{B}_{e,f}] \leq \text{Var}[B_{e,f}] \leq 1$.
- $\overline{A}(x) \in \text{Pos}_k$ and $\overline{B}(x) \in \text{Pos}_k$ for all input x .
- For any $e_1, e_2, f_1, f_2 \in [k]$, we have $|\langle \overline{A}_{e_1, f_1}, \overline{B}_{e_2, f_2} \rangle_{\mu^{\otimes n}} - \langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mu^{\otimes n}}| \leq \delta/2$.

Choose $\nu = 1 - C \frac{(1-\rho)\delta}{\log(1/\delta)}$. Choose d large enough such that $\nu^{2d} \leq \delta/(2k^2)$. That is

$$d = O\left(\frac{\log(k^2/\delta)}{\log(1/\nu)}\right) = O\left(\frac{k \log^2(k^2/\delta)}{(1-\rho)\delta}\right).$$

We let $\overline{A} = T_\nu A$ and $\overline{B} = T_\nu B$. For item 1, for any $e, f \in [k]$ we have

$$\|\overline{A}_{e,f}^{>d}\|_2^2 = \sum_{\sigma: |\sigma| > d} \nu^{2|\sigma|} A_{e,f}(\sigma)^2 \leq \nu^{2d} \text{Var}[A_{e,f}] \leq \delta/(2k^2).$$

So

$$\left\| \overline{A}^{>d} \right\|_2^2 = \sum_{e,f \in [k]} \left\| \overline{A}_{e,f}^{>d} \right\|_2^2 \leq \delta/2.$$

Item 2 follows by definition. Item 3 follows from Fact 3.5. For item 4 we have

$$\begin{aligned} & \left| \langle \overline{A}_{e_1,f_1}, \overline{B}_{e_2,f_2} \rangle_{\mu^{\otimes n}} - \langle A_{e_1,f_1}, B_{e_2,f_2} \rangle_{\mu^{\otimes n}} \right| \\ &= \left| \sum_{\sigma} \rho_{\sigma} \nu^{2|\sigma|} \widehat{A}_{e_1,f_1}(\sigma) \widehat{B}_{e_2,f_2}(\sigma) - \sum_{\sigma} \rho_{\sigma} \widehat{A}_{e_1,f_1}(\sigma) \widehat{B}_{e_2,f_2}(\sigma) \right| \\ &\leq \sum_{\sigma} \rho^{|\sigma|} (1 - \nu^{2|\sigma|}) \left| \widehat{A}_{e_1,f_1}(\sigma) \widehat{B}_{e_2,f_2}(\sigma) \right| \\ &\leq \frac{\delta}{2} \sqrt{\text{Var}[A]_{e_1,f_1} \text{Var}[B]_{e_2,f_2}} \leq \delta/2, \end{aligned}$$

where $\rho_{\sigma} = \prod_{i=1}^n \rho_{\sigma_i}$, and ρ_{σ_i} is defined as in Eq. (1). The first inequality follows since $\rho_{\sigma} \leq \rho^{|\sigma|}$ for any $\sigma \in \{0, \dots, q-1\}^n$. The second inequality follows by observing that $\rho^{|\sigma|} (1 - \nu^{2|\sigma|}) \leq \delta/2$ for any $\sigma \in \{0, \dots, q-1\}^n$.

Low degree truncation step. In this step we obtain the final $A^{(1)}$ and $B^{(1)}$ satisfying

- $A^{(1)}$ and $B^{(1)}$ have degree at most d .
- For any $e, f \in [k]$, $\text{Var}[A_{e,f}^{(1)}] \leq \text{Var}[\overline{A}_{e,f}] \leq 1$ and $\text{Var}[B_{e,f}^{(1)}] \leq \text{Var}[\overline{B}_{e,f}] \leq 1$.
- $\|\mathcal{R}(A^{(1)}) - A^{(1)}\|_2 \leq \delta/2$ and $\|\mathcal{R}(B^{(1)}) - B^{(1)}\|_2 \leq \delta/2$.
- For each $e_1, e_2, f_1, f_2 \in [k]$, we have $\left| \langle \overline{A}_{e_1,f_1}, \overline{B}_{e_2,f_2} \rangle_{\mu^{\otimes n}} - \langle A_{e_1,f_1}^{(1)}, B_{e_2,f_2}^{(1)} \rangle_{\mu^{\otimes n}} \right| \leq \delta/2$.

In this step, we let $A^{(1)} = \overline{A}^{\leq d}$ and $B^{(1)} = \overline{B}^{\leq d}$. Item 1 and item 2 hold according to definition. For item 3, we have

$$\left\| \mathcal{R}(A^{(1)}) - A^{(1)} \right\|_2 \leq \left\| \mathcal{R}(\overline{A}) - \overline{A} \right\|_2 + \left\| A^{(1)} - \overline{A} \right\|_2 \leq \left\| \mathcal{R}(\overline{A}) - \overline{A} \right\|_2 + \delta/2 = \delta/2.$$

The same holds for $B^{(1)}$ and $\overline{B}$. For item 4, we have that $\|\overline{A} - A^{(1)}\|_2 \leq \delta/2$ and $\|\overline{B} - B^{(1)}\|_2 \leq \delta/2$. So by Lemma 2.8.

$$\left| \langle \overline{A}_{e_1,f_1}, \overline{B}_{e_2,f_2} \rangle_{\mu^{\otimes n}} - \langle A_{e_1,f_1}^{(1)}, B_{e_2,f_2}^{(1)} \rangle_{\mu^{\otimes n}} \right| \leq \delta.$$

□

3.2 MULTILINEARIZATION

In this subsection we prove the following lemma which can transform a general low-degree polynomial into a multilinear low-degree polynomial.

Lemma 3.6. *Let $\rho \in [0, 1]$, $\delta > 0$, $d, k \in \mathbb{Z}_{\geq 0}$ be any given constant parameters. There exists an explicit $t = t(k, d, \delta)$ such that the following holds:*

Let $A : \mathbb{R}^n \rightarrow \mathcal{M}_k$ and $B : \mathbb{R}^n \rightarrow \mathcal{M}_k$ be degree- d polynomials, such that, for any $e, f \in [k]$: $\text{Var}[A_{e,f}] \leq 1$. Then there exists functions $A^{(1)} : \mathbb{R}^{nt} \rightarrow \mathcal{M}_k$ and $B^{(1)} : \mathbb{R}^{nt} \rightarrow \mathcal{M}_k$ such that the following hold.

1. $A^{(1)}$ and $B^{(1)}$ are multilinear with degree d .

2. For any $e, f \in [k]$, it holds that $\text{Var} [A_{e,f}^{(1)}] \leq \text{Var} [A_{e,f}] \leq 1$ and $\text{Var} [B_{e,f}^{(1)}] \leq \text{Var} [B_{e,f}] \leq 1$.
3. $\|\mathcal{R}(A^{(1)}) - A^{(1)}\|_2 \leq \|\mathcal{R}(A) - A\|_2 + \delta$ and $\|\mathcal{R}(B^{(1)}) - B^{(1)}\|_2 \leq \|\mathcal{R}(B) - B\|_2 + \delta$.
4. For any $\ell \in [nt]$ and $e, f \in [k]$, it holds that $\text{Inf}_\ell (A_{e,f}^{(1)}) \leq \delta$ and $\text{Inf}_\ell (B_{e,f}^{(1)}) \leq \delta$.
5. For any $e_1, e_2, f_1, f_2 \in [k]$,

$$\left| \left\langle A_{e_1, f_1}^{(1)}, B_{e_2, f_2}^{(1)} \right\rangle_{\mathcal{G}_{\rho}^{nt}} - \langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mathcal{G}_{\rho}^n} \right| \leq \delta.$$

In particular, one may take $t = O\left(\frac{k^4 d^2}{\delta^2}\right)$.

To prove Lemma 3.6, we use the following lemma by [GKR18].

Lemma 3.7 ([GKR18, Lemma C.2]). *Given parameters $\rho \in [0, 1]$, $\delta > 0$ and $d \in \mathbb{Z}_{\geq 0}$, there exists $t = t(d, \delta)$ such that the following holds:*

Let $A, B : \mathbb{R}^n \rightarrow \mathbb{R}$ be degree- d polynomials, such that $\|A\|_2, \|B\|_2 \leq 1$. Define polynomials $\bar{A}, \bar{B} : \mathbb{R}^{nt} \rightarrow \mathbb{R}$ over variables $\bar{\mathbf{X}} = \{X_j^{(i)} : (i, j) \in [i] \times [t]\}$ and $\bar{\mathbf{Y}} = \{Y_j^{(i)} : (i, j) \in [i] \times [t]\}$ respectively, as

$$\bar{A}(\bar{\mathbf{X}}) = A(X^{(1)}, \dots, X^{(n)}) \quad \text{and} \quad \bar{B}(\bar{\mathbf{Y}}) = B(Y^{(1)}, \dots, Y^{(n)})$$

where $X^{(i)} = (X_1^{(i)}, \dots, X_t^{(i)})/\sqrt{t}$ and $Y^{(i)} = (Y_1^{(i)}, \dots, Y_t^{(i)})/\sqrt{t}$. Note that, intuitively this doesn't change the "structure" of A and B . In particular, it is easy to see that,

$$\langle \bar{A}, \bar{B} \rangle_{\mathcal{G}_{\rho}^{\otimes n}} = \langle A, B \rangle_{\mathcal{G}_{\rho}^{\otimes n}} \quad \text{and} \quad \|\bar{A}\|_2 = \|A\|_2 \quad \text{and} \quad \|\bar{B}\|_2 = \|B\|_2.$$

Next, let $A^{(1)}$ and $B^{(1)}$ be the multilinear truncations of $\bar{A}$ and $\bar{B}$ respectively. Then the following hold

1. $A^{(1)}$ and $B^{(1)}$ are multilinear with degree d .
2. $\text{Var} [A^{(1)}] \leq \text{Var} [A] \leq 1$ and $\text{Var} [B^{(1)}] \leq \text{Var} [B] \leq 1$.
3. $\|A^{(1)} - \bar{A}\|, \|B^{(1)} - \bar{B}\| \leq \delta/2$.
4. For all $(i, j) \in [n] \times [t]$, it holds that $\text{Inf}_{X_j^{(i)}} (A^{(1)}) \leq \delta$ and $\text{Inf}_{Y_j^{(i)}} (B^{(1)}) \leq \delta$.
5. $\left| \langle A^{(1)}, B^{(1)} \rangle_{\mathcal{G}_{\rho}^{\otimes nt}} - \langle A, B \rangle_{\mathcal{G}_{\rho}^{\otimes n}} \right| \leq \delta$.

In particular, one may take $t = O\left(\frac{t^2}{d^2}\right)$.

Proof of Lemma 3.6. We apply the transformation in Lemma 3.7, with parameter δ being δ/k , to each of the k^2 entries of $A : \mathbb{R}^n \rightarrow \mathcal{M}_k$ and $B : \mathbb{R}^n \rightarrow \mathcal{M}_k$ to get function $A^{(1)} : \mathbb{R}^{nt} \rightarrow \mathcal{M}_k$ and $B^{(1)} : \mathbb{R}^{nt} \rightarrow \mathcal{M}_k$.

It is easy to verify that items 1, 2, 4, 5 follow immediately from Lemma 3.7. For item 3, for any $e, f \in [k]$, we have that $\left\| A_{e,f}^{(1)} - \bar{A}_{e,f} \right\|_2 \leq \delta/k$. Thus

$$\left\| A^{(1)} - \bar{A} \right\|_2^2 = \sum_{e, f \in [k]} \left\| A_{e,f}^{(1)} - \bar{A}_{e,f} \right\|_2^2 \leq \delta^2.$$

So

$$\left\| \mathcal{R}(A^{(1)}) - A^{(1)} \right\|_2 \leq \left\| \mathcal{R}(\bar{A}) - \bar{A} \right\|_2 + \delta = \left\| \mathcal{R}(A) - A \right\|_2 + \delta.$$

Using the same argument we also have

$$\left\| \mathcal{R}(B^{(1)}) - B^{(1)} \right\|_2 \leq \left\| \mathcal{R}(B) - B \right\|_2 + \delta.$$

□

3.3 REGULARITY

Definition 3.8 (Restriction). Given a matrix-valued polynomial $A : \mathcal{Z}^n \rightarrow \mathcal{M}_k$, a subset of indices $H \subseteq [n]$ such that $|H| = h$, and an assignment $\xi \in \mathcal{Z}^{\otimes h}$, the restricted function A^ξ is defined as $A^\xi : \mathcal{Z}^{n-h} \rightarrow \mathcal{M}_k$, such that for $x \in \mathcal{Z}^{n-h}$, we have $A^\xi(x) = A(\xi, x)$.

The following lemma is immediate from [GKR18, Lemma D.4].

Lemma 3.9 ([GKR18, Lemma D.4]). Let $(\mathcal{Z} \times \mathcal{Z}, \mu)$ be a joint probability space. Let $k, d \in \mathbb{N}$ and $\tau > 0$ be any constant parameters. There exists $h = h(\mu, k, d, \tau)$ such that the following holds:

For all degree- d matrix-valued polynomials $A : \mathcal{Z}^n \rightarrow \mathcal{M}_k$ and $B : \mathcal{Z}^n \rightarrow \mathcal{M}_k$ such that, $\text{Var}[P_{e,f}] \leq 1$ and $\text{Var}[Q_{e,f}] \leq 1$ for all $e, f \in [k]$, there exists a subset of indices $H \subseteq [n]$, with $|H| = h$ such that with probability at least $1 - \tau$ over the assignment $(\xi_A, \xi_B) \sim \mu^{\otimes h}$, the following holds for any $e, f \in [k]$ (where we denote $T = [n] \setminus H$),

- the restriction $A_{e,f}^{\xi_A}(x_T)$ is such that for all $i \in T$, it holds that $\text{Inf}_i \left(A_{e,f}^{\xi_A}(x_T) \right) \leq \tau$,
- the restriction $B_{e,f}^{\xi_B}(x_T)$ is such that for all $i \in T$, it holds that $\text{Inf}_i \left(B_{e,f}^{\xi_B}(x_T) \right) \leq \tau$.

In particular, one may take $h = \frac{dk^4}{\tau} \cdot \left(\frac{C_4(\alpha)}{\alpha} \log \frac{C_4(\alpha) \cdot k}{\alpha \cdot d \cdot \tau} \right)^{O(d)}$, and $\alpha = \alpha(\mu)$ is the minimum probability in μ .

3.4 DIMENSION REDUCTION

We directly use the dimension reduction from [GKR18].

Lemma 3.10 ([GKR18, Theorem 3.1]). Given parameters $d \in \mathbb{Z}_{\geq 0}$, $\rho \in [0, 1]$ and $\delta > 0$, there exists an explicitly computable $D = D(d, \delta)$ such that:

Let $A : \mathbb{R}^N \rightarrow \mathbb{R}$ and $B : \mathbb{R}^N \rightarrow \mathbb{R}$ be degree- d multilinear polynomials such that $\|A\|_2, \|B\|_2 \leq 1$. Let $M \in \mathbb{R}^{N \times D}$. We define $A_M : \mathbb{R}^D \rightarrow \mathbb{R}$ and $B_M : \mathbb{R}^D \rightarrow \mathbb{R}$ as

$$A_M(\mathbf{a}) = A \left(\frac{M\mathbf{a}}{\|\mathbf{a}\|_2} \right) \quad \text{and} \quad B_M(\mathbf{b}) = B \left(\frac{M\mathbf{b}}{\|\mathbf{b}\|_2} \right).$$

Sample $M \sim \mathcal{N}(0, 1)^{\otimes N \times D}$. Then with probability at least $1 - \delta$ over the choice of M , it holds that,

$$\left| \langle A_M, B_M \rangle_{\mathcal{G}_\rho^{\otimes D}} - \langle A, B \rangle_{\mathcal{G}_\rho^{\otimes N}} \right| < \delta.$$

In particular, we can take $D = \frac{d^{O(d)}}{\delta^4}$.

The following lemma is immediate following the same proof in [GKR18, Proposition 3.2].

Lemma 3.11. Let $A : \mathbb{R}^N \rightarrow \mathcal{M}_k$ and $B : \mathbb{R}^N \rightarrow \mathcal{M}_k$, such that $\|\mathcal{R}(A) - A\|_2, \|\mathcal{R}(B) - B\|_2 \leq \delta$. Let $A_M : \mathbb{R}^D \rightarrow \mathcal{M}_k$ and $B_M : \mathbb{R}^D \rightarrow \mathcal{M}_k$ be defined analogously in Lemma 3.10, in an entry-by-entry fashion. For $M \sim \mathcal{N}(0, 1)^{\otimes N \times D}$, with probability at least $1 - 2\delta$, it holds that

$$\|\mathcal{R}(A_M) - A_M\|_2 \leq \sqrt{\delta} \quad \text{and} \quad \|\mathcal{R}(B_M) - B_M\|_2 \leq \sqrt{\delta}.$$

3.5 INVARIANCE PRINCIPLE

In this subsection we give an invariance principle that is similar to [GKR18, Lemma 3.1], and follows as a special case of known invariance principle statements [MOO10, Mos10, IM12].

Lemma 3.12. *Let $\mathcal{Z} \times \mathcal{Z}$ be a finite joint probability space, such that $|\mathcal{Z}| = q$ and $\alpha = \alpha(\mu) > 0$ is the minimum probability of any atom in μ . Given parameters $k, d \in \mathbb{N}$ and $\delta > 0$, there exists $\tau = \tau(\mu, k, d, \delta)$ such that the following holds:*

Let $A, B : \mathcal{Z}^n \rightarrow \mathcal{M}_k$ be degree- d multilinear polynomials, such that $\text{Var}[A_{e,f}], \text{Var}[B_{e,f}] \leq 1$ and $\text{Inf}_\ell(A_{e,f}), \text{Inf}_\ell(B_{e,f}) \leq \tau$ for all $\ell \in [n]$ and $e, f \in [k]$. Then, there exist degree- d multilinear polynomials $\tilde{A}, \tilde{B} : \mathbb{R}^{n \cdot (q-1)} \rightarrow \mathcal{M}_k$, such that for all $e_1, e_2, f_1, f_2 \in [k]$, it holds that

$$\left| \left\langle \mathcal{R}_{e_1, f_1}(\tilde{A}), \mathcal{R}_{e_2, f_2}(\tilde{B}) \right\rangle_{\mathcal{G}_\rho^{\otimes n(q-1)}} - \left\langle \mathcal{R}_{e_1, f_1}(A), \mathcal{R}_{e_2, f_2}(B) \right\rangle_{\mu^{\otimes n}} \right| \leq \delta, \quad (3)$$

where $\rho = \rho(\mu)$ is the maximal correlation of μ . In particular, one may take $\tau = O\left(\frac{\delta^{1.5} \cdot \alpha^{d/2}}{2^{O(d)} \cdot 2^{O(k)}}\right)$

Additionally, the theorem also works in reverse, namely, given degree- d multilinear polynomials $\tilde{A}, \tilde{B} : \mathbb{R}^n \rightarrow \mathcal{M}_k$, such that $\text{Var}[\tilde{A}_{e,f}], \text{Var}[\tilde{B}_{e,f}] \leq 1$ and $\text{Inf}_\ell(\tilde{A}_{e,f}), \text{Inf}_\ell(\tilde{B}_{e,f}) \leq \tau$ for all $\ell \in [n]$ and $e, f \in [k]$, there exist $A, B : \mathcal{Z}^n \rightarrow \mathcal{M}_k$, such that Eq. (3) holds.

The proof is identical to the proof of [GKR18, Lemma E.1]. We only need to check that for any $e \in [k] \times [k]$ the map $\mathcal{R}_e$ has Lipschitz constant at most 1. Notice that $\mathcal{D}_k$ is a convex body. By Fact 2.9 hence $\mathcal{R}$ is a contraction, whose Lipschitz constant is at most 1.

4 LOCAL STATE TRANSFORMATION WITH GAUSSIAN SOURCES

In this section, we prove that in the task of non-interactive simulation over ρ -correlated Gaussian sources with $\rho < 1$, there exists an explicit upper bound n_0 on the number of source states, such that we need to use to approximate the optimal strategy. Formally, we have the following theorem.

Theorem 4.1. *Given parameters $k \geq 2, \rho \in [0, 1]$ and $\varepsilon > 0$, there exists an explicitly computable $n_0 = n_0(\rho, k, \varepsilon)$, such that the following holds:*

For any N , and any $A : \mathbb{R}^N \rightarrow \mathcal{D}_k$ and $B : \mathbb{R}^N \rightarrow \mathcal{D}_k$, there exist functions $\tilde{A} : \mathbb{R}^{n_0} \rightarrow \mathcal{D}_k$ and $\tilde{B} : \mathbb{R}^{n_0} \rightarrow \mathcal{D}_k$ such that,

$$\left\| (A(\mathbf{x}), B(\mathbf{y}))_{(\mathbf{x}, \mathbf{y}) \sim \mathcal{G}_\rho^{\otimes N}} - (\tilde{A}(\mathbf{a}), \tilde{B}(\mathbf{b}))_{(\mathbf{a}, \mathbf{b}) \sim \mathcal{G}_\rho^{\otimes n_0}} \right\|_1 \leq \varepsilon.$$

Moreover, there exists $d_0 = d_0(\rho, k, \varepsilon)$ for which there are degree- d_0 polynomials $A_0 : \mathbb{R}^{n_0} \rightarrow \mathcal{M}_k$ and $B_0 : \mathbb{R}^{n_0} \rightarrow \mathcal{M}_k$, such that, $\tilde{A}(\mathbf{a}) = \mathcal{R}\left(A_0\left(\frac{\mathbf{a}}{\|\mathbf{a}\|_2}\right)\right)$ and $\tilde{B}(\mathbf{b}) = \mathcal{R}\left(B_0\left(\frac{\mathbf{b}}{\|\mathbf{b}\|_2}\right)\right)$. In particular, one may take $n_0 = \exp\left(\text{poly}\left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}\right)\right)$ and $d_0 = \text{poly}\left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}\right)$.

Proof of Theorem 4.1. Let $e_1, e_2, f_1, f_2 \in [k]$. We will focus on the quantity $\langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mathcal{G}_\rho^{\otimes n}}$, which corresponds to the value of the (e_1, e_2, f_1, f_2) -entry of the final output quantum state in $\mathcal{M}_{k^2}$. Note that there are k^4 entries in the final output quantum state, so we preserve each entry up to an additive error ε/k^4 . This will result in an ε additive error to the final Schatten 1-norm.

We will transform the functions A and B through several steps, as explained in Section 1.2. At each step, we will preserve the correlation $\langle A_{e_1, f_1}, B_{e_2, f_2} \rangle$ for any $e_1, e_2, f_1, f_2 \in [k]$. Additionally, recall that a valid strategy will also require that the output to be density operators. So we will also bound the quantity $\|\mathcal{R}(A) - A\|_2$, and $\|\mathcal{R}(B) - B\|_2$, which are the distances of these functions to “valid strategies” – those functions that output density operators.

1. **Smoothing:** According to Lemma 3.1, there exist functions $A^{(1)} : \mathbb{R}^N \rightarrow \mathcal{M}_k$ and $B^{(1)} : \mathbb{R}^N \rightarrow \mathcal{M}_k$ that are at most degree d with $d = O\left(\frac{k \log^2(k^2/\delta)}{\delta(1-\rho)}\right)$. Moreover, we have that for every $e_1, e_2, f_1, f_2 \in [k]$,

$$\left| \langle A_{e_1, f_1}^{(1)}, B_{e_2, f_2}^{(1)} \rangle_{\mathcal{G}_\rho^{\otimes n}} - \langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mathcal{G}_\rho^{\otimes n}} \right| \leq \delta.$$

Additionally,

$$\left\| \mathcal{R}(A^{(1)}) - A^{(1)} \right\|_2 \leq \delta \quad \text{and} \quad \left\| \mathcal{R}(B^{(1)}) - B^{(1)} \right\|_2 \leq \delta.$$

2. **Multilinearization:** We apply Lemma 3.6 with parameter δ , and let t be $t = O\left(\frac{k^4 d^2}{\delta^2}\right)$ as required. Then we can apply multilinearization operation on $A^{(1)}$ and $B^{(1)}$ to get $A^{(2)} : \mathbb{R}^{nt} \rightarrow \mathcal{M}_k$ and $B^{(2)} : \mathbb{R}^{nt} \rightarrow \mathcal{M}_k$ satisfying for any $e_1, e_2, f_1, f_2 \in [k]$,

$$\left| \left\langle A_{e_1, f_1}^{(2)}, B_{e_2, f_2}^{(2)} \right\rangle_{\mathcal{G}_\rho^{Nt}} - \left\langle A_{e_1, f_1}^{(1)}, B_{e_2, f_2}^{(1)} \right\rangle_{\mathcal{G}_\rho^N} \right| \leq \delta.$$

Additionally,

$$\left\| \mathcal{R}(A^{(2)}) - A^{(2)} \right\|_2 \leq \left\| \mathcal{R}(A^{(1)}) - A^{(1)} \right\|_2 + \delta \leq 2\delta$$

and

$$\left\| \mathcal{R}(B^{(2)}) - B^{(2)} \right\|_2 \leq \left\| \mathcal{R}(B^{(1)}) - B^{(1)} \right\|_2 + \delta \leq 2\delta.$$

3. **Dimension Reduction:** We apply Lemma 3.10 with parameter δ/k^4 and let n_0 satisfy $n_0 = \frac{d^{O(d)}}{\delta^4}$ as required. to the functions $A^{(2)}$ and $B^{(2)}$ to get $A^{(3)} : \mathbb{R}^{n_0} \rightarrow \mathcal{M}_k$ and $B^{(3)} : \mathbb{R}^{n_0} \rightarrow \mathcal{M}_k$.

Taking a union bound, with probability at least $1 - \delta$, we can have the following inequality for any $e_1, e_2, f_1, f_2 \in [k]$:

$$\left\| \langle A_{e_1, f_1}^{(3)}, B_{e_2, f_2}^{(3)} \rangle_{\mathcal{G}_\rho^{\otimes n_0}} - \langle A_{e_1, f_1}^{(2)}(x), B_{e_2, f_2}^{(2)}(y) \rangle_{(x, y) \sim \mathcal{G}_\rho^{\otimes Nt}} \right\| \leq \frac{\delta}{k^4}.$$

Additionally, according to Lemma 3.11, with probability at least $1 - 4\delta$ by the choice of M :

$$\left\| \mathcal{R}(A^{(3)}) - A^{(3)} \right\|_2 \leq \sqrt{2\delta} \quad \text{and} \quad \left\| \mathcal{R}(B^{(3)}) - B^{(3)} \right\|_2 \leq \sqrt{2\delta}.$$

4. **Rounding to $\mathcal{D}_k$:** Let $A^{(4)}$ be $\mathcal{R}(A^{(3)})$ and $B^{(4)}$ be $\mathcal{R}(B^{(3)})$. Then with Lemma 2.8, the following statement holds:

With probability at least $1 - 4\delta$,

$$\left| \langle A_{e_1, f_1}^{(4)}, B_{e_2, f_2}^{(4)} \rangle - \langle A_{e_1, f_1}^{(3)}, B_{e_2, f_2}^{(3)} \rangle \right| \leq 2\sqrt{2\delta}$$

At last, combine the result of each step together. Let $\epsilon = O(\sqrt{\delta}/k^4)$, $\tilde{A} = A^{(4)}$ and $\tilde{B} = B^{(4)}$, then we can get the result of Theorem 4.1.

□

5 LOCAL STATE TRANSFORMATION WITH DISCRETE SOURCES

In this section, we prove that in the task of non-interactive simulation over arbitrary ρ -correlated discrete sources with $\rho < 1$, there exists an explicit upper bound n_0 on the number of source states, such that we need to use to approximate the optimal strategy. Formally, we have the following theorem.

Theorem 5.1. *Let $(\mathcal{Z} \times \mathcal{Z}, \mu)$ be a joint probability space. Given parameters $k \geq 2$ and $\varepsilon > 0$, there exists a computable $n_0 = n_0(\mu, k, \varepsilon)$, such that the following holds:*

For any N , let matrix-valued polynomials $A : \mathcal{Z}^N \rightarrow \text{Pos}_k$ and $B : \mathcal{Z}^N \rightarrow \text{Pos}_k$. Then there are functions $\tilde{A} : \mathcal{Z}^{n_0} \rightarrow \text{Pos}_k$ and $\tilde{B} : \mathcal{Z}^{n_0} \rightarrow \text{Pos}_k$ such that,

$$\left\| \mathbb{E}_{(x,y) \sim \mu^{\otimes N}} [A(x) \otimes B(y)] - \mathbb{E}_{(x,y) \sim \mu^{\otimes n_0}} [\tilde{A}(x) \otimes \tilde{B}(y)] \right\|_1 \leq \varepsilon.$$

In particular, n_0 is explicitly upper bounded by $\exp\left(\text{poly}\left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}, \log\left(\frac{1}{\alpha}\right)\right)\right)$, where $\alpha = \alpha(\mu)$ is the smallest probability of an atom in μ , and $\rho = \rho(\mu)$ is the maximal correlation of μ .

Proof. The proof will reduce the arbitrary discrete correlation to Gaussian correlation, hence reducing to Theorem 4.1, via our invariance principle (Lemma 3.12). Our invariance principle requires that the function to be low-degree and have low influence. So in the first step we will transform the matrix-valued functions A and B to be low-degree by Lemma 3.1, and then have low influence by Lemma 3.9. As in the proof of Theorem 4.1, we also need to preserve the quantum $\langle A_e, B_f \rangle_{\mu^{\otimes n}}$ for any entry $e \in [k] \times [k]$ and $f \in [k] \times [k]$, and to upper bound the distance to “valid strategies” which is $\|\mathcal{R}(A) - A\|_2$ and $\|\mathcal{R}(B) - B\|_2$.

Let δ be a parameter to be specified later.

1. **Smoothing (over discrete space):** We invoke Lemma 3.1 to get low-degree versions $A^{(1)} : \mathcal{Z}^N \rightarrow \mathcal{M}_k$ and $B^{(1)} : \mathcal{Z}^N \rightarrow \mathcal{M}_k$. This guarantees that $A^{(1)}$ and $B^{(1)}$ has degree at most d . For each $e_1, e_2, f_1, f_2 \in [k]$, we have

$$\left| \left\langle A_{e_1, f_1}^{(1)}, B_{e_2, f_2}^{(1)} \right\rangle_{\mu^{\otimes N}} - \langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mu^{\otimes N}} \right| \leq \delta/k.$$

Additionally,

$$\left\| \mathcal{R}(A^{(1)}) - A^{(1)} \right\|_2 \leq \delta \text{ and } \left\| \mathcal{R}(B^{(1)}) - B^{(1)} \right\|_2 \leq \delta.$$

2. **Regularity Lemma:** Let τ be the small enough parameter required in Lemma 3.12. We use Lemma 3.9 to identify a subset $H \subseteq [N]$ with $|H| = h$, such that for a random restriction $(\mathbf{x}_H, \mathbf{y}_H) \sim \mu^{\otimes h}$, it holds with probability at least $1 - \tau$, that the restricted functions $\left(A_e^{(1)}\right)^{\mathbf{x}_H} : \mathcal{Z}^{N-h} \rightarrow \mathbb{R}$ and $\left(B_e^{(1)}\right)^{\mathbf{y}_H} : \mathcal{Z}^{N-h} \rightarrow \mathbb{R}$ have all individual influences smaller than τ , for any $e \in [k] \times [k]$. We call a restriction $(\mathbf{x}_H, \mathbf{y}_H)$ “good” in this case, and “bad” otherwise. We then focus on this case. For convenience, we define $N_1 = N - h$.
3. **Invariance Principle (from $\mathcal{Z}$ to $\mathbb{R}$):** For a good $(\mathbf{x}_H, \mathbf{y}_H)$, we apply Lemma 3.12 on $\left(A^{(1)}\right)^{\mathbf{x}_H}$ and $\left(B^{(1)}\right)^{\mathbf{y}_H}$ to get functions $A^{(2)} : \mathbb{R}^{N_2} \rightarrow \mathcal{D}_k$ and $B^{(2)} : \mathbb{R}^{N_2} \rightarrow \mathcal{D}_k$, where $N_2 = N_1 \cdot (q - 1)$. For any e_1, e_2, f_1, f_2 , we have

$$\left| \left\langle A_{e_1, f_1}^{(2)}, B_{e_2, f_2}^{(2)} \right\rangle_{\mathcal{G}_\rho^{\otimes N_2}} - \left\langle \mathcal{R}_{e_1, f_1} \left(A^{(1)} \right), \mathcal{R}_{e_2, f_2} \left(B^{(1)} \right) \right\rangle_{\mu^{\otimes N_1}} \right| \leq \delta.$$

4. **Dimension Reduction:** We apply Lemma 3.10, to get functions $A^{(3)} : \mathcal{R}^D \rightarrow \mathcal{D}_k$ and $B^{(3)} : \mathcal{R}^d \rightarrow \mathcal{D}_k$ satisfying for all $e_1, e_2, f_1, f_2 \in [k]$,

$$\left| \left\langle A_{e_1, f_1}^{(3)}, B_{e_2, f_2}^{(3)} \right\rangle_{\mathcal{G}_\rho^{\otimes D}} - \left\langle A_{e_1, f_1}^{(2)}, B_{e_2, f_2}^{(2)} \right\rangle_{\mathcal{G}_\rho^{\otimes N_2}} \right| \leq \delta.$$

This is the only randomized step in the entire transformation, and succeeds with probability at least $1 - 4\delta$, in which case we call it “lucky”. So with probability at least $1 - 5\delta$, the sampled $(\mathbf{x}_H, \mathbf{y}_H)$ are both “good” and “lucky”.

5. **Smoothing (over Gaussian space):** We apply Lemma 3.1 again, to get degree- d functions $A^{(4)} : \mathbb{R}^D \rightarrow \mathcal{M}_k$ and $B^{(4)} : \mathbb{R}^d \rightarrow \mathcal{M}_k$. For each $e_1, e_2, f_1, f_2 \in [k]$, we have

$$\left| \left\langle A_{e_1, f_1}^{(4)}, B_{e_2, f_2}^{(4)} \right\rangle_{\mathcal{G}_\rho^{\otimes D}} - \left\langle A_{e_1, f_1}^{(3)}, B_{e_2, f_2}^{(3)} \right\rangle_{\mathcal{G}_\rho^{\otimes N_2}} \right| \leq \delta/k.$$

Additionally,

$$\left\| \mathcal{R}(A^{(4)}) - A^{(4)} \right\|_2 \leq \delta \text{ and } \left\| \mathcal{R}(B^{(4)}) - B^{(4)} \right\|_2 \leq \delta.$$

6. **Multilinearization:** We apply Lemma 3.6, to get degree- d and multilinear functions $A^{(5)} : \mathbb{R}^{D_1} \rightarrow \mathcal{M}_k$ and $B^{(5)} : \mathbb{R}^{D_1} \rightarrow \mathcal{M}_k$, where $D_1 = Dt$. For each $e_1, e_2, f_1, f_2 \in [k]$, we have

$$\left| \left\langle A_{e_1, f_1}^{(5)}, B_{e_2, f_2}^{(5)} \right\rangle_{\mathcal{G}_\rho^{\otimes D_1}} - \left\langle A_{e_1, f_1}^{(4)}, B_{e_2, f_2}^{(4)} \right\rangle_{\mathcal{G}_\rho^{\otimes D}} \right| \leq \delta/k.$$

Additionally,

$$\left\| \mathcal{R}(A^{(5)}) - A^{(5)} \right\|_2 \leq 2\delta \text{ and } \left\| \mathcal{R}(B^{(5)}) - B^{(5)} \right\|_2 \leq 2\delta.$$

7. **Invariance Principle (from $\mathbb{R}$ to $\mathcal{Z}$):** We apply Lemma 3.12, to get functions $A^{(6)} : \mathcal{Z}^{D_1} \rightarrow \mathcal{D}_k$ and $B^{(6)} : \mathcal{Z}^{D_1} \rightarrow \mathcal{D}_k$, such that for every $e_1, e_2, f_1, f_2 \in [k]$,

$$\left| \left\langle A_{e_1, f_1}^{(6)}, B_{e_2, f_2}^{(6)} \right\rangle_{\mu^{\otimes D_1}} - \left\langle A_{e_1, f_1}^{(5)}, B_{e_2, f_2}^{(5)} \right\rangle_{\mathcal{G}_\rho^{\otimes D_1}} \right| \leq \delta/k.$$

Putting it together. We now show how we combine these steps above to get our final conclusion. Recall that $A^{(6)}$ and $B^{(6)}$ are functions that depend on $\mathbf{x}_H$ and $\mathbf{y}_H$. So we may as well write them as $(A^{(6)})^{\mathbf{x}_H}$ and $(B^{(6)})^{\mathbf{y}_H}$. Let $\tilde{A}(\mathbf{x}) = \tilde{A}(\mathbf{x}_H, \mathbf{x}_R) = (A^{(6)})^{\mathbf{x}_H}(\mathbf{x}_R)$ and $\tilde{B}(\mathbf{y}) = \tilde{B}(\mathbf{y}_H, \mathbf{y}_R) = (B^{(6)})^{\mathbf{y}_H}(\mathbf{y}_R)$. For each $e_1, e_2, f_1, f_2 \in [k]$, we have

$$\begin{aligned} \left\langle \tilde{A}_{e_1, f_1}, \tilde{B}_{e_2, f_2} \right\rangle_{\mu^{n_0}} &= \mathbb{E}_{(\mathbf{x}_H, \mathbf{y}_H) \sim \mu^{\otimes h}} \left[\left\langle A_{e_1, f_1}^{(6)}, B_{e_2, f_2}^{(6)} \right\rangle_{\mu^{\otimes D_1}} \right] \\ &= \Pr \left[\begin{array}{c} (\mathbf{x}, \mathbf{y}) \text{ is} \\ \text{good and lucky} \end{array} \right] \cdot \mathbb{E}_{(\mathbf{x}_H, \mathbf{y}_H | \text{good and lucky}) \sim \mu^{\otimes h}} \left[\left\langle A_{e_1, f_1}^{(6)}, B_{e_2, f_2}^{(6)} \right\rangle_{\mu^{\otimes D_1}} \right] \\ &= \langle A_{e_1, f_1}, B_{e_2, f_2} \rangle_{\mu^{\otimes N}} \pm O(\delta). \end{aligned}$$

Thus, more strongly, if we instantiate δ as $O(\varepsilon/k^4)$, then we get that

$$\left\| \mathbb{E}_{(x, y) \sim \mu^{\otimes N}} [A(x) \otimes B(y)] - \mathbb{E}_{(x, y) \sim \mu^{\otimes n_0}} [\tilde{A}(x) \otimes \tilde{B}(y)] \right\|_1 \leq \varepsilon.$$

Finally, we get an upper bound on n_0 .

$$\begin{aligned}
n_0 &= h + D_1 \\
&\leq \frac{dk^4}{\tau} \alpha^{-O(d)} \left(\log \left(\frac{k}{d\tau} \right) \right)^{O(d)} + Dt \\
&\leq (dk^4) \frac{2^{O(d+k)}}{\delta^{1.5\alpha^{d/2}}} (\log(k))^{O(d)} + \frac{d^{O(d)}}{\delta^4} \\
\left(d = O \left(\frac{k \log^2(k^2/\delta)}{\delta(1-\rho)} \right) \right) &\leq \exp \left(\text{poly} \left(k, \frac{1}{\varepsilon}, \frac{1}{1-\rho}, \log \left(\frac{1}{\alpha} \right) \right) \right).
\end{aligned}$$

Abstract.

Storing unknown quantum computations in quantum states and retrieving them later is a challenging task, limited by the no programming theorem. While previous work studied probabilistic storage and retrieval of unitary channels, we investigate this task for unitary *superchannels*, that is, sequences of unitary gates with intermediate interventions. This setting requires a form of “retrospective intervention” on the superchannel. We propose two protocols: *partial teleportation*, which is optimal for a small number of storage queries, and *staircase backstitch*, which achieves unit success probability asymptotically as the number of queries increases. We also derive a universal inversion protocol for unitary superchannels.

Keywords: storage and retrieval, quantum superchannel, port-based teleportation, retrospective intervention

1 Background

A convenient feature of programmable processors is their ability to store programs and execute them at any later time. Quantum extensions of programmable processors have been studied in a wide range of scenarios [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12], leading to no-programming theorems that clarify the limits on their performance. Nevertheless, at the cost of success probability or accuracy, it is possible to write a quantum program whose length is set by the desired precision and execute the computation later at the desired time.

Whether in classical computation or quantum computation, the programmer needs to be aware of the concise description of the computation. It is not necessarily possible to write down the entire program at once and thus to suspend computation when the computation is unknown to the agent and is provided as a black box. Bisio et. al. [13] studied the approximate accuracy of deterministically retrieving a unitary channel from quantum states prepared by multiple calls to black-box unitary channels.

Framing the storage-and-retrieval of black boxes in the probabilistic exact setting shows a clear distinction from the deterministic approximate ones. Probabilistic storage-and-retrieval (pSAR) protocols were recognized early on as a method to circumvent the no-programming theorem by introducing a relaxation to probabilistic success [1, 2]. Sedlak et al. [14] studied the success probability in stor-

ing the action of an unknown unitary channel from multiple calls to the black boxes implementing the unknown unitary channel and in retrieving the exact action later. The maximum success probability is achieved by the quantum teleportation protocol [15, 16] when only a single use of the black box is allowed, and by the port-based teleportation protocol [8, 17, 18, 19] when multiple calls to the black boxes are available. This task of probabilistic storage-and-retrieval (pSAR) is also formulated for black boxes restricted to specific classes of unitary gates [20, 21].

2 Formulating pSAR of quantum superchannels

In this work, we initiate the study of pSAR tasks for unknown quantum computations with *intervention functionality*. This is equivalent to considering pSAR tasks for definite causal quantum superchannels, also known as quantum networks and quantum combs [22, 23, 24]. Quantum superchannels are a mathematical model of higher-order quantum computation, describing transformations that map quantum channels to quantum channels. Superchannels with definite causal order are physically implemented as concatenations of quantum memory channels, allowing the computing agent to intervene between successive stages (see Figure 1) [22, 23, 24]. The intervals in which the superchannel accepts intervention is called the (open) slots of the superchannel, and the superchannel with K slots are simply referred to as a K -slot superchannel. Unlike

*jisho.miyazaki@phys.s.u-tokyo.ac.jp

a mere sequence of channels applied at intervals, a quantum superchannel includes memory subsystems that are inaccessible to the agent.¹

Figure 1: K -slot quantum superchannel

SAR protocols of quantum superchannels effectively allow the input operations inserted into the superchannel to intervene “retrospectively” in the computation. The intervention is *retrospective* in the sense that the action of superchannel has already been completed by the time these intervening operations are applied. We first analytically show that such retrospective intervention is possible with non-zero probability without error by constructing two pSAR protocols for unitary superchannels. We then numerically calculate the maximum success probabilities for pSAR of unitary superchannels and of particular unitary channels referred to as “unitary staircases.” The gap between these two values reflects the difficulty of retrospective intervention.

The pSAR task of unitary superchannels is formulated analogously to that of unitary channels. The storage and retrieval circuits are treated as fixed quantum superchannels as shown in Figure 2. In this work, we do not allow an indefinite causal structure in the storage and retrieval circuits. A storage superchannel can accommodate N identical unknown unitary superchannels $\tilde{\mathcal{U}}$ as sequences of black boxes, and produce a quantum state $\sigma_{\tilde{\mathcal{U}}}$ in the memory system $\mathcal{M}$. A retrieval superchannel receives the state $\sigma_{\tilde{\mathcal{U}}}$ and exactly implements the original unitary superchannels $\mathcal{U}$ with some probability. We say a pair of storage and retrieval superchannels achieves the pSAR of unitary superchannels with probability p when the retrieval is successful for any unitary superchannels of the same type and with the same overall probability p .

What appears challenging about the pSAR of unitary superchannels is that the temporal structure of the computation must be stored in and retrieved from quantum states, which are temporally static objects. That is, starting the retrieval at the desired time is a part of the task; we need the ability to

¹All the superchannels are restricted to be of definite causal in this work.

Figure 2: Storage and retrieval superchannels

Figure 3: Unitary staircase obtained from 2-slot superchannel

pause-and-resume in the retrieval part so that other operations can intervene while paused. Therefore, result of [14] for the channel pSAR does not simply generalize to the superchannel pSAR.

3 Results

3.1 Construction of pSAR protocols

We present two protocols, i.e. pairs of storage and retrieval superchannels, achieving the pSAR of unitary superchannels. An idea underlying both protocols is to call the channel pSAR as a subroutine. That is, we separate the protocol into channel-superchannel and state-channel conversions and employ channel pSAR for implementing the latter.

To be more precise, a unitary channel, which is referred to as a “unitary staircase,” is obtained from a unitary superchannel by first preparing ancillary systems for input ports and then intervening with swap operations at each slot, exchanging the output port to the ancilla of input port as in Figure 3. Since a unitary staircase is a channel, its input should be prepared simultaneously as a multipartite state, and there is no room to intervene. Therefore, unitary staircases are unitary superchannels without the intervention functionality.

The channel pSAR can then be applied to the unitary staircase, giving back several unitary staircases if needed. We consider two protocols to retrieve the unitary superchannel from the corresponding unitary staircase by activating the intervention functionality. These protocols are, respectively, called “partial teleportation” and “staircase backstitch”, and their schematics are shown in Figures 4 and 5.

Each of these protocols has its own strengths and weaknesses. The partial teleportation is applicable for small N (the number of calls to the black box

Figure 4: Partial teleportation

Figure 5: Staircase backstitch

that implements the unknown unitary superchannel), in fact, even for $N = 1$. However, the success probability has a constant overhead for any N due to the use of standard teleportation without correction. The protocol based on the staircase backstitch requires several additional calls to the black box to start with, partly because it includes a subroutine implementing the higher-order operation of “unitary inversion” [25, 26, 27]. However, given a sufficiently many but constant number of unitary staircases, the channel-to-superchannel conversion of the staircase backstitch succeeds deterministically. By virtue of this, the success probability of the entire pSAR protocol based on the staircase backstitch is not overhead and approaches 1 as N tends to ∞ . The protocol based on the staircase backstitch overcomes that based on the partial teleportation for sufficiently large N , in terms of the success probability.

Beyond the pSAR of unitary superchannels, the staircase backstitch protocol demonstrates the feasibility of “superchannel inversion.” This higher-order transformation reverses the action of a unitary superchannel while preserving its intervention structure. Specifically, given a finite number of calls to an unknown superchannel, its inverse can be implemented both deterministically and exactly.

3.2 Maximum success probability

We numerically calculate the maximum success probabilities for pSAR of unitary superchannels and

unitary staircases for problems of small sizes, without addressing the protocols to achieve them. Since unitary staircases are unitary superchannels without intervention functionality, the gap between the maximum success probabilities indicates the difficulty of retrospective intervention. Although the general optimization problem over quantum circuits is difficult to analyze numerically, the current problem is transformed into a tractable semidefinite programming (SDP) using the comb formalism of quantum superchannels [22, 23, 24] and the symmetry of the problem [28, 29, 30].

Within the range of numerical calculations, such as $K \leq 2$ and $N \leq 3$, the maximum success probability for pSAR of unitary staircases appears to be achieved by the port-based teleportation [17], which was shown to be optimal for pSAR of unitary channels [14]. This result follows the lineage of studies on the SAR of restricted unitary channels, such as [20] and [21]. Contrary to these two works, the restriction to unitary staircases does not improve the success probability of pSAR within the range of numerical calculation.

Within the same range, the maximum success probability for pSAR of unitary superchannels appears to be achieved by the partial teleportation protocol. This result confirms that port-based teleportation, an optimal strategy for channel pSAR, does not work for superchannel pSAR. From our numerical calculation on the unitary staircase and unitary superchannels, the cost of the retrospective intervention may be considered to originate from the gap between port-based teleportation and partial teleportation for small N .

However, more importantly, we know that this explanation of the gap is not universal, as the protocol based on the staircase backstitch outperforms partial teleportation for sufficiently large N . It is conceivable that the staircase backstitch may become the optimal protocol for large N , or there might be a new variant of port-based teleportation protocol with the ability to delay several slots at different times. It remains open how the protocol based on partial teleportation connects to some different optimal pSAR protocol as N grows, as the range of numerical analysis was too limited to witness the transition. Our study encourages exploration of the new protocol for retrospective intervention beyond partial and port-based teleportation, as well as to develop a more stable and precise numerical analysis of larger size problems.

Quantum engineering of massive spatial superpositions for precision acceleration sensing and for benchtop tests of quantum gravity

Jason Twamley¹ *

¹ *Quantum Machines Unit, Okinawa Institute of Science and Technology, Okinawa, Japan*

Abstract. One of the most challenging topics in quantum mechanics revolves around the interplay between gravity and quantum mechanics. To explore this one must engineer quantum states of motion of massive bodies. Such a task is technically challenging as motional superpositions have only been observed for atomic and molecular systems which possess too low a mass for gravity to play an important role. We seek to use magnetic levitation to trap and cool the motion of a massive object towards the quantum regime of motion. We show theory and experimental results towards this goal using diamagnetic levitation.

Keywords: Quantum sensors, Macroscopic quantum superpositions, Gravity, Levitation, Feedback cooling

The creation of macroscopic quantum states of massive systems allows one to begin to explore the boundaries between the classical and quantum worlds and, in particular, how gravity may interface with quantum mechanics. Levitated systems permit extreme isolation from decoherence [1], and such systems can be useful for quantum sensing such as in ultra-precise inertial sensors or for the detection of dark matter and forces [2], for quantum transduction and quantum memory where the quantum information is stored in the long lived motional states of the levitated body and for more fundamental studies exploring the relationship between low-energy gravity and quantum mechanics [3, 4].

We will present our recent theory and experiments on engineering massive (milligram) objects into quantum states of motion using magnetic forces.

This includes diamagnetic levitation at room temperature of milligram objects in high vacuum. We show routes to obtain high motional Q -factors by engineering the object to suppress eddy currents [5, 6], and how we can apply feedback forces on them to control and cool their motion.

We demonstrate that certain types of systems can avoid the generation of eddy currents completely and thus completely remove eddy damping in-principle. We demonstrate how an axially symmetric levitated system need not generate any eddy currents at all [7], and investigate the practical limits of such an experimental system.

Using an optomechanical system - where light is coupled to the motion of an optical element - usually a mirror, can be used as exquisite sensors. LIGO is perhaps humanity's most precise sensor ever made and

this is an optomechanical system. LIGO's 40kg mirrors are almost free, being suspended by long thin wires, but we seek to go one step further and levitate the end mirror of an optical cavity. If we consider a macroscopic optical mirror with large mass, then typically there could be severe challenges to cool the motion of such a large mass to its motional ground state. We adopt a standard optical cavity control method - called the Pound-Drever-Hall cavity locking technique, to show how it can, at least theoretically, cool the motion of such a levitated mirror to the ground state. We detail plans for such an optomechanical system with levitated mirror cooled to the ground state of motion using PDH feedback [8].

To generate macroscopic superpositions researchers have suggested using Stern-Gerlach spin dependent forces and recently observed spin dependent torques in small micro diamonds [9]. We have proposed two methods to engineer very large quantum spatial superpositions using superconducting qubits that can generate magnetic fields which are quantum superposition [10]. Our proposals go into great detail regarding the various sources of noise and decoherence which need to be controlled in order to observe such massive spatial superpositions.

Using these spin-forces we have theoretically studied the levitation of a nanodiamond with an embedded spin and by using the spin-polarization properties under irradiation by green light we study how such a system can be turned into a quantum battery and quantum heat engine with high efficiency [11].

Finally, we describe our most recent experiments at demonstrating how large spin-forces can move macroscopic objects by significant displacements. We experimentally levitate a massive diamond containing a large ensemble of NV defects sitting in a magnetic field gradient. By illuminating the diamond with pulses of green

*jason.twamley@oist.jp

light we can periodically polarize the NV ensemble, imparting a large periodic force on the levitated diamond, which can drive the motion of the diamond to oscillate on the micron-scale, due to the spin-force alone [12]. Such experiments are still far from the motional quantum regime but demonstrate that spin-force in levitated massive objects can be engineered and controlled.

Abstract. We present an efficient quantum circuit implementing the random dilation superchannel, transforming parallel queries of an unknown quantum channel into the same number of parallel queries of a randomly chosen dilation isometry of the input channel. Our circuit is based on the quantum Fourier transform over the symmetric group and the quantum Schur transform. Our construction extends to quantum superchannels and has applications in efficient storage-and-retrieval of unknown quantum channels. We also prove a no-go theorem for exact sequential dilation with subexponential overhead, showcasing a fundamental difference between the parallel and sequential cases. The technical manuscript is available at [1].

Keywords: Quantum algorithms, Quantum supermaps, Stinespring dilation

1 Introduction and Summary of results

Any d -dimensional quantum state ρ can be represented as a reduced state of a pure state $|\psi\rangle \in \mathbb{C}^d \otimes \mathbb{C}^d$ called a purification of ρ , whose choice is not unique. Although universal transformation from a mixed state to a single purification is impossible [2], recent works have shown that there exists a quantum channel that transforms n copies of an unknown quantum state ρ into n copies of a *randomly chosen* purification of ρ [3, 4, 5]. We call such a quantum channel the *random purification channel*, following Ref. [6]. This technique has proved useful for analyzing various operational tasks: It is used to lift the sample access to the query access of a state preparation unitary [5], construct the optimal mixed state tomography [7] and channel tomography [8], and show Uhlmann's theorem for quantum divergences [6] with extensions to the fermionic and bosonic systems [9, 10].

This series of developments motivates us to extend the notion of random purification to quantum channels. Any quantum channel Λ admits its Stinespring representation $\Lambda(\cdot) = \text{Tr}_{\mathcal{E}}[V(\cdot)V^\dagger]$ using a dilation isometry $V : \mathcal{I} \rightarrow \mathcal{E} \otimes \mathcal{O}$, where $\mathcal{I}, \mathcal{O}, \mathcal{E}$ are the input, output, and auxiliary systems, respectively. Given that the Stinespring dilation can be considered as a natural generalization of the purification, we consider the following analogous task: given n queries of an unknown quantum channel $\Lambda : \mathcal{L}(\mathcal{I}) \rightarrow \mathcal{L}(\mathcal{O})$, implement n queries of a randomly chosen dilation isometry of Λ . We call such a

universal transformation the *random dilation superchannel*, where superchannels are universal transformations of a channel to another channel implementable within quantum mechanics [11, 12, 13, 14]. Since processing unknown quantum channels in a quantum circuit is often more challenging than processing their Stinespring dilation [15, 16], it is of great interest to decide if such a random dilation superchannel exists and if it is efficiently implementable. Indeed, the feasibility of constructing random dilation superchannels was posed as an important open problem in Ref. [5]. In Ref. [17], a transformation of a quantum tester, a special type of quantum superchannel that transforms a quantum channel to a measurement outcome, is presented. However, it is difficult to assess whether it is efficiently implementable in a quantum circuit, since it relies on an existence proof in representation theory, and no explicit quantum circuit is provided.

This work provides a partial answer to the above open problem by constructing an efficient quantum circuit implementing the random dilation superchannel that transforms n parallel queries of an unknown quantum channel Λ into n parallel queries of a randomly chosen dilation isometry of Λ . Our construction is based on the quantum Fourier transform over the symmetric group and the quantum Schur transform, both of which can be efficiently implemented [18, 19, 20, 21, 22]. As an application, we show an efficient storage-and-retrieval of an unknown quantum channel, which improves the program cost exponentially in the retrieval error ϵ .

On the other hand, we also show that the exact random dilation of sequential queries of an unknown

*satoshiyoshida.phys@gmail.com

†ryotaro.niwa@phys.s.u-tokyo.ac.jp

quantum channel is *impossible* with subexponential overhead $o(\text{poly}(\min\{d_{\mathcal{I}}, d_{\mathcal{O}}\}))$ in the number of queries. This no-go theorem is based on the no-go theorem of simulating the quantum switch [23] by a quantum circuit whose causal order is classically controlled [24]. This result partially disproves the conjecture in Ref. [5] that the random dilation of any type of queries is possible with polynomial queries, and also shows a fundamental difference between the parallel and sequential cases of the random dilation. It also contrasts with the random purification channel, where the parallel and sequential cases are equivalent.

2 Main result 1: Parallel random dilation superchannel

2.1 Random dilation superchannel

We first present our main result—an efficient quantum circuit implementing the random dilation of an unknown quantum channel.

Theorem 1 *The quantum circuit shown in Fig. 1 implements the random dilation superchannel Ξ that transforms n parallel queries of an unknown quantum channel $\Lambda : \mathcal{L}(\mathcal{I}) \rightarrow \mathcal{L}(\mathcal{O})$ with Kraus rank at most r into n parallel queries of a randomly chosen dilation isometry of Λ , i.e.,*

$$\Xi(\Lambda^{\otimes n}) = \mathbb{E}_{V \sim \text{Dil}_r(\Lambda)} [\mathcal{V}^{\otimes n}], \quad (1)$$

where the expectation is taken over the uniform distribution on the set of dilation isometries of Λ :

$$\text{Dil}_r(\Lambda) := \{\mathcal{V}(\cdot) := V(\cdot)V^\dagger \mid |V\rangle\rangle \in \text{Pur}_r(J_\Lambda)\}. \quad (2)$$

Here, Pur_r denotes the set of rank r purifications,

$$\text{Pur}_r(\rho) := \{|\psi\rangle \in \mathcal{E} \otimes \mathcal{H} \mid \rho = \text{Tr}_{\mathcal{E}}[|\psi\rangle\langle\psi|]\} \quad (3)$$

and $|V\rangle\rangle$ is the Choi vector of $V : \mathcal{I} \rightarrow \mathcal{E} \otimes \mathcal{O}$ defined by $|V\rangle\rangle := (\mathbb{I} \otimes V)|\mathbb{I}_{d_I}\rangle\rangle$ with $\dim(\mathcal{E}) = r$, $d_I = \dim(\mathcal{I})$ and $|\mathbb{I}_{d_I}\rangle\rangle := \sum_i |i\rangle \otimes |i\rangle$, and $J_\Lambda := (\mathbb{I} \otimes \Lambda)(|\mathbb{I}_{d_I}\rangle\rangle\langle\mathbb{I}_{d_I}|)$ is the Choi matrix of Λ . The circuit complexity of implementing Ξ is $O(\text{poly}(n, \log d_I, \log d_O))$, where $d_O = \dim(\mathcal{O})$.

Figure 1: Quantum circuit implementing the random dilation superchannel Ξ that transforms n parallel queries of an unknown quantum channel $\Lambda : \mathcal{L}(\mathcal{I}) \rightarrow \mathcal{L}(\mathcal{O})$ into n parallel queries of a randomly chosen dilation isometry of Λ .

Sketch of proof. To implement the random dilation superchannel, we first construct an alternative circuit for the random purification channel. Our approach is based on the quantum Fourier transform over the symmetric group and the quantum Schur transform, as shown in Fig. 2. This construction is different from the original construction in Ref. [5], and is more suitable for our construction of the random dilation superchannel.

Theorem 2 *The quantum circuit shown in Fig. 2 implements the random purification channel Φ that transforms n copies of an unknown quantum state $\rho \in \mathcal{L}(\mathbb{C}^d)$ with rank at most r into n copies of a randomly chosen purification of ρ , i.e.,*

$$\Phi(\rho^{\otimes n}) = \mathbb{E}_{|\psi\rangle \sim \text{Pur}_r(\rho)} [|\psi\rangle\langle\psi|^{\otimes n}]. \quad (4)$$

The circuit complexity of implementing the quantum channel Φ is $O(\text{poly}(n, \log d))$.

Figure 2: Quantum circuit implementing the random purification channel Φ . Here, ctrl- π represents the controlled permutation unitary ctrl- π , $\text{QFT}_{\mathfrak{S}_n}$ represents the quantum Fourier transform over the symmetric group, and U_{Sch} represents the quantum Schur transform U_{Sch} . The quantum state $|+_{\mathfrak{S}_n}\rangle$ is a uniform superposition of all permutation elements, and $\pi_{\mathcal{U}_\Lambda}$ represents the maximally mixed state.

Using Theorem 2, we can show that the circuit in Fig.1 implements the desired random dilation superchannel, based on the one-to-one correspondence between the purification of the Choi matrix J_Λ and the dilation of Λ shown in Eq. (2). Indeed, consider the Choi matrix $\mathcal{J}_V$ of the channel implemented by the circuit in Fig.1, i.e., apply the channel to one half of the maximally entangled state (MES). Then, the “transpose trick” for the MES transforms the ctrl- π^T operation into a ctrl- π on the other arm, which allows us to conclude from Thm.2 that $\mathcal{J}_V$ is a random purification of J_Λ . $\square$

2.2 Random dilation supersuperchannel

The above strategy can be straightforwardly extended to the case of quantum superchannels: We

can construct the random dilation supersuperchannel Σ that transforms n parallel queries of an unknown quantum superchannel $\mathcal{C}$ into n parallel queries of a randomly chosen dilation superchannel of $\mathcal{C}$ as shown in Fig.3 of the technical manuscript [1].

2.3 Application: Efficient storage-and-retrieval of unknown quantum channels

We use our main result, Thm. 1, to construct an efficient storage-and-retrieval of an unknown quantum channel $\Lambda : \mathcal{L}(\mathcal{I}) \rightarrow \mathcal{L}(\mathcal{O})$ with Kraus rank at most r , which is a task of storing the action of Λ into a quantum state called the program state and retrieving the action of Λ from the program state later only using operations independent of Λ [25, 26, 27, 28, 29, 30]. The size of the program state is called the program cost. The previous best-known result requires $O(d_{\mathcal{I}}^2/\sqrt{\varepsilon})$ queries of Λ with the program state in $O(d_{\mathcal{I}}^2/\sqrt{\varepsilon})$ qubits, where ε is the diamond-norm error of the retrieved channel [31]. If the input channel is an isometry channel, the program cost can be reduced to $\frac{d_{\mathcal{I}}d_{\mathcal{O}}-1}{2} \log O(\varepsilon^{-1})$ qubits with the same query complexity [31]. Combining this result with Thm. 1, we can reduce the program cost for general quantum channels as follows.

Theorem 3 *There exists a storage-and-retrieval algorithm of an unknown quantum channel $\Lambda : \mathcal{L}(\mathcal{I}) \rightarrow \mathcal{L}(\mathcal{O})$ with Kraus rank at most r by using $O(d_{\mathcal{I}}^2/\sqrt{\varepsilon})$ queries of Λ with the program state in $\frac{d_{\mathcal{I}}d_{\mathcal{O}}-1}{2} \log O(\varepsilon^{-1})$ qubits, where ε is the retrieval error in the diamond norm, $d_{\mathcal{I}} = \dim(\mathcal{I})$, and $d_{\mathcal{O}} = \dim(\mathcal{O})$.*

This shows an exponential reduction of the program cost in ε compared to the previous best-known result [31].

3 Main result 2: No-go theorem on sequential random dilation

As a natural extension of the parallel random dilation superchannel, we consider the task of sequential random dilation of quantum channels. With n queries of an unknown quantum channel $\Lambda : \mathcal{L}(\mathcal{I}) \rightarrow \mathcal{L}(\mathcal{O})$, we aim to exactly implement sequential m queries of the dilation isometry V of Λ , where V is randomly chosen from $\text{Dil}_r(\Lambda)$. To avoid ambiguity, we define an $n \rightarrow m$ random dilation superchannel $\mathcal{S}$ as an $(n + m - 1)$ -slot QC-CC superchannel such that $\mathcal{S}(\Lambda^{\otimes n} \otimes (\cdot))$ is a probabilistic mixture of $\mathcal{C}_V$ with $V \in \text{Dil}_r(\Lambda)$ for any Λ . For the special case of

weak $n \rightarrow m$ random dilation superchannels, environmental systems $\mathcal{E}_i$ are not fed back to the inputs of Φ_j for $i \in [m], j \in [m - 1]$.

Figure 3: (a): The general case. (b): Weaker case.

We show that exactly implementing the $n \rightarrow m$ sequential random dilation is impossible for any $m \geq 2$ and $n \leq \max(2, 2^{\lfloor \log_2 \min(d_{\mathcal{I}}, d_{\mathcal{O}}) \rfloor} - 1)$ within the conventional quantum circuit model, where $d_{\mathcal{I}} = \dim(\mathcal{I})$ and $d_{\mathcal{O}} = \dim(\mathcal{O})$.

Theorem 4 *For any $N \geq 1$, there is no weak sequential $n \rightarrow 2$ random dilation superchannel for N -qubit quantum channels if*

$$n \leq \max(2, 2^N - 1). \quad (5)$$

The proof is based on the no-go result on switch simulation [24]. Indeed, if two exact sequential queries of a dilation isometry V of Λ and a single query to Φ is available, the quantum circuit shown in Fig. 4 implements the quantum switch. Thus, the existence of a random dilation superchannel $\mathcal{S}$ with a polynomial overhead contradicts the switch no-go theorem [24].

Figure 4: Quantum circuit implementing $\mathcal{S}_{\text{switch}}(\Lambda \otimes \Phi)$ by two weak sequential queries to a dilation isometry V of Λ and a single query to Φ .

The no-go theorem above can be extended to arbitrary-dimensional quantum channels. See Thm.8 of the technical manuscript [1].

Abstract. Randomness amplification extracts private uniform bits from biased seeds partly known to an adversary, a fundamental task in cryptography. We demonstrate the first semi-device-independent (SDI) randomness amplification on an integrated silicon photonic chip, reaching 92.2 Mbps for practical use. This is enabled by a new SDI entropy-certification method that gives strictly tighter von Neumann entropy bounds than existing approaches and remains secure even when preparation and measurement devices share quantum correlations. This work advances portable quantum cryptographic hardware for telecom.

Keywords: randomness amplification, semi-device-independent, quantum cryptographic chip

Introduction

Randomness amplification—the task of extracting private and uniform bits from biased and partly compromised seeds—has applications in cryptographic primitives, as well as in randomized algorithms, scientific computation, and online gaming [1, 2, 3, 4]. While randomness cannot be amplified in the world of classical physics, quantum mechanics provides an unprecedented opportunity to generate high-quality, cryptographically secure randomness. The highest level of security is achieved by device-independent (DI) protocols, which guarantee unpredictability against general attackers without making any assumption on the internal functioning of the devices [5, 6]. Recently, proof-of-principle demonstrations of DI randomness amplification have been provided [7, 8, 9]. A practical limitation of DI protocols, however, is that they typically have demanding requirements, including high-visibility entanglement, loophole-free detection, stringent noise suppression, and spacelike separation between two or more measurement stations, which typically results into bulky setups. These requirements limit scalability, and tend to result in low generation rates that significantly restrict potential applications.

A promising approach is provided by semi-device-independent (SDI) protocols [10, 11], which maintain most of the features of DI security while making minimal assumptions on the devices, such as bounds on the amount of energy used by them [11, 12]. Leveraging this limited knowledge, SDI protocols can greatly enhance the speed of randomness amplification and remove the need of spacelike separation, thereby enabling fast and compact setups. However, experimental demonstrations of such fast and compact setups remain absent. Chip-scale realizations are notably lacking, as existing SDI protocols have not yet been adapted to the constraints of integrated photonics. In particular, miniaturization and high-speed operation demand optimized entropy

bounds under realistic noise and loss profiles [13, 14, 15], which however have been lacking so far.

Results

In this paper, we report the first implementation of SDI randomness amplification on a fully integrated silicon photonic chip, based on an energy-constrained prepare-and-measure protocol[12]. As shown in Fig. 1, the chip has dimensions of 3 mm × 11 mm × 11 mm, incorporates quantum state preparation and measurement, and achieves amplification for sources with a Santha-Vazirani (SV) structure [16] in which each bit can deviate from the uniform distribution by an amount up to $\varepsilon \leq 0.3$. As a typical example, for an initial bit string of 10^{11} bits with a practically relevant bias of $\varepsilon = 0.12$, our setup produces an output string of length 1.06×10^{10} that is $\varepsilon' \leq 10^{-12}$ -close to uniform, at an overall rate of 92.2 Mbps, suitable for applications such as VPNs, digital signatures, and gaming.

The high rate of our setup is enabled not only by advances in the photonic hardware, but also by a novel technique for certifying the amount of randomness present in the output bits. The technique, a variational version of the Gauss-Radau method for bounding nonlinear quantities [17], offers tighter bounds on the single-round von Neumann entropy of the output bits, and works even in the presence of prior correlations between the state preparation and the measurement devices.

More specifically, the problem with the standard Gauss-Radau method is that it adopts a fixed choice of nodes, whose locations is uniquely determined once and for all as soon as the total number of nodes is fixed. This approach works well in the fully DI setting, where there is no assumption on the internal functioning of the devices. However, it tends to provide loose bounds in the SDI scenario, where the constraint over the energy has major consequences on the evaluation of the integral. In our settings, the condition that the energy of the prepared states is less than the energy of the first excited state,

Figure 1: Energy-constrained on-chip semi-device-independent quantum randomness amplification. (a) Photograph of the integrated photonic chip implementing energy-constrained semi-device-independent randomness amplification. The chip consists of electronic circuits and an optical QRA chip where the main quantum operations take place. Both the electronics and optics are powered by a DC current. The optical QRA chip receives attenuated coherent states from an external fiber (labelled as “optical input” in the figure), and modulates them, adding a $0/\pi$ phase based on a radiofrequency (RF) signal. The modulated coherent states exit from an optical fiber (labelled as “optical output”). (b) Optical microscope image of the optical QRA chip. The chip performs two main tasks: state manipulation and measurement. The state manipulation part starts with an initial phase fixed by a phase shifter. Depending on an external RF signal (the “driver”), a $0/\pi$ phase is then added by a Mach-Zehnder interferometer, made of four waveguides. The state measurement part starts with an edge coupler, which enables mode-field coupling from the external optical fiber to the chip waveguide. The input quantum state then passes through a power monitoring module before entering the heterodyne measurement module. The resulting photocurrent is amplified by a transimpedance amplifier (TIA) and subsequently connected to an external oscilloscope or post-processing unit. (c) Experimental optical setup for on-chip energy-constrained semi-device-independent randomness amplification. A narrow-linewidth 1550 nm laser emits a continuous-wave, which is then passed through a variable optical attenuator (VOA) to set the optical power required for preparing energy-constrained coherent states. The attenuated light is subsequently coupled into the chip through the optical input port. Inside the chip, the light is split into two parts with a 30:70 tunable splitting ratio. A small portion of the light is phase-modulated to generate energy-constrained coherent states, while the remaining portion is used as the local oscillator (LO). The modulated quantum states exit the chip through the optical output port and sequentially pass through external energy monitoring and polarization-control modules. The external energy-monitoring module consists of a 90:10 beam splitter (BS), where a small fraction of the light is directed to an optical power meter for real-time monitoring, while the majority of the light passes through an optical isolator (ISO), which prevents backscattered photons from interfering with the energy monitoring, and then through a polarization controller (PC) for spatial polarization alignment with the LO. The signal is then injected into the measurement side of the chip through another optical input port via an edge coupler. It subsequently enters the heterodyne measurement module, where the generated photocurrent is amplified by a transimpedance amplifier (TIA) and then output.

implies that the prepared states are close to the ground state. As a consequence, these states are nearly pure, and can have small, near-zero eigenvalues. Since the logarithm function has a singularity at zero, the overall estimation of the entropy becomes very sensitive to these small eigenvalues. However, the standard Gauss-Radau method fails to place sufficiently many integration points near the origin to efficiently resolve the logarithmic singularity, and therefore results into unstable extrapolations, yielding relatively loose bounds on the entropy. In the standard method, the only way to improve the accuracy of the estimation is to increase the total number of nodes, which makes numerical evaluation computationally challenging.

To address the above problems, we introduce an upgraded version of the Gauss-Radau method. Our framework is applicable to the evaluation of the von Neumann entropy in the energy-constrained scenario, and, more generally, to other nonlinear functions in the presence of a constraint on the expectation value of a given observable. The idea is to adjust the distribution of the nodes, making them more dense in the regions of the spectrum that match the physical constraints in the SDI scenario, and assigning higher weights to the nodes that contribute more significantly to the estimation of the function of interest (in our specific problem, the conditional von Neumann entropy).

Discussion

This work establishes a scalable route toward on-chip quantum randomness amplification by jointly advancing entropy certification and integrated photonic implementation under semi-device-independent constraints. The observed enhancement in certified randomness rates does not arise from isolated device improvements, but rather from a combination of device engineering and entropy certification techniques, provided by the variable-node Gauss-Radau framework. Overall, our results establish a scalable integrated photonic platform for quantum randomness amplification, opening up a route towards secure SDI randomness generation in portable devices such as laptops and mobile phones.

Abstract. We construct an autonomous quantum error-correction protocol for a hybrid qubit that encodes quantum information spin-oscillator system. The engineered Lindbladian stabilizes the code space as a steady-state subspace, providing exponential suppression of the logical phase-error rate as the coherent-state amplitude increases. Our protocol employs a single correlated jump operator, reducing dissipation-engineering overhead. We show that concatenating noise-biased hybrid qubits can efficiently suppress both logical errors. Even without concatenation, the strongly biased error profile enables preservation of the quantum Fisher information beyond the standard quantum limit. Our construction leverages experimentally demonstrated primitives, offering a practical route toward hardware-efficient quantum error correction.

Keywords: Autonomous quantum error correction, Dissipation engineering, Quantum metrology, Quantum computing

Hybrid Qubit The hybrid qubit encodes a single logical qubit into a spin-oscillator composite system [1, 2]:

$$\begin{aligned} |+\rangle_L &:= |+\rangle_s \otimes |\alpha\rangle_b, \\ |-\rangle_L &:= |-\rangle_s \otimes |-\alpha\rangle_b. \end{aligned} \quad (1)$$

Here, $|\pm\rangle_s$ are the X -eigenstates of the discrete variable (DV) spin system and $|\pm\alpha\rangle_b$ are continuous variable (CV) coherent states of the oscillator mode defined by $\hat{D}(\alpha)|0\rangle_b$ with the displacement operator $\hat{D}(\alpha) := e^{\alpha\hat{a}^\dagger - \alpha^*\hat{a}}$. $\hat{a}$ and $\hat{a}^\dagger$ are bosonic annihilation and creation operators, respectively, and without loss of generality, we focus on real-valued α . Subscripts s and b denote spin and bosonic oscillator systems, respectively.

Such a hybrid encoding across CV and DV quantum systems has been explored in photonics [1–4] to overcome the non-orthogonality between small amplitude coherent states ($\langle\alpha|-\alpha\rangle_b \neq 0$) and the complication of their phase operation ($|\pm\alpha\rangle_b \rightarrow \pm|\pm\alpha\rangle_b$), with applications in quantum communication [5, 6] and quantum error correction (QEC) [7, 8]. Superposition of these hybrid qubits was also realized in superconducting circuits [9], revealing hybrid entanglement between the spin and oscillator systems.

Encoding quantum information from a spin qubit into the hybrid qubit can be implemented by applying the controlled displacement operator $\hat{U}_{\text{CD}} := \hat{D}(\alpha\hat{\sigma}_x) = |+\rangle\langle+|_s \otimes \hat{D}(\alpha) + |-\rangle\langle-|_s \otimes \hat{D}(-\alpha)$ on the initial product state as $|\psi\rangle_L = \hat{U}_{\text{CD}}(|\psi\rangle_s \otimes |0\rangle_b)$. Decoding of the logical information can be implemented through the inverse unitary $\hat{U}_{\text{CD}}^\dagger$, enabling measurement on the hybrid qubit through local measurement on the spin subsystem. Alternatively, the encoding and decoding can be realized by controlled parity operation $|+\rangle\langle+|_s \otimes \hat{\Pi}_b + |-\rangle\langle-|_s \otimes \hat{\Pi}_b$ acting on $|\psi\rangle_s \otimes |\alpha\rangle_b$, where $\hat{\Pi}_b = (-1)^{\hat{n}}$.

The logical X operation ($\hat{X}_L$) is implemented by applying a Pauli X operation $\hat{\sigma}_x$ on the spin qubit. The logical Z operation ($\hat{Z}_L$) can be implemented by either a product of the spin phase-flip and the oscillator parity operator, i.e., $\hat{\sigma}_z \otimes \hat{\Pi}_b$, or a spin-dependent displacement followed by a phase-flip, i.e., $\hat{\sigma}_z \hat{D}(-2\alpha\hat{\sigma}_x)$. The displacement-type logical Z operation can be realized by using a spin-dependent force [10, 11] that is native to the trapped-ion systems and also realizable for superconducting systems [12]. For entangling operations between multiple logical qubits, an XX interaction between the DV subsystems $e^{-i\frac{\theta}{2}\hat{\sigma}_x \otimes \hat{\sigma}_x}$ is sufficient to form a universal gate set when combined with logical single-qubit gates.

AutoQEC of the Hybrid Qubit We consider the dynamics of the spin-oscillator hybrid system described by the Lindblad master equation [13]:

$$\frac{d\hat{\rho}}{dt} = \mathcal{L}(\hat{\rho}) := -i[\hat{H}, \hat{\rho}] + \sum_k \kappa_k \mathcal{D}[\hat{L}_k](\hat{\rho}),$$

where $\hat{H}$ denotes the Hamiltonian of the system, $\mathcal{D}[\hat{L}](\hat{\rho}) := \hat{L}\hat{\rho}\hat{L}^\dagger - \frac{1}{2}\{\hat{L}^\dagger\hat{L}, \hat{\rho}\}$ describes dissipation given by a jump operator $\hat{L}$, and κ_k are the dissipation rates for each $\hat{L}_k$. Also, $[\cdot, \cdot]$ ($\{\cdot, \cdot\}$) denotes the canonical (anti-)commutator. We decompose the quantum Liouvillian into two parts,

$$\mathcal{L} = \mathcal{L}_E + \mathcal{L}_R,$$

where $\mathcal{L}_E$ describes the uncontrollable noise of the system that induces errors, and $\mathcal{L}_R$ is engineered dissipation that stabilizes the code space and recovers it from errors. To design AutoQEC for the logical qubit spanned by the hybrid states described in Eq. (1), we construct $\mathcal{L}_R := \kappa_R \mathcal{D}[\hat{R}]$ with the correlated jump operator,

$$\hat{R} := \hat{\sigma}_z(\alpha - \hat{\sigma}_x \otimes \hat{a}). \quad (2)$$

Physical noise	γ_X	γ_Z
$\kappa_{\hat{\sigma}_x} \mathcal{D}[\hat{\sigma}_x]$	$\kappa_{\hat{\sigma}_x}$	0
$\kappa_{\hat{\sigma}_z} \mathcal{D}[\hat{\sigma}_z]$	0	$\frac{\kappa_{\hat{\sigma}_z}}{1+2I(\alpha)} \sim \frac{\kappa_{\hat{\sigma}_z}}{\sqrt{2\pi}\alpha} e^{-2\alpha^2}$
$\kappa_{\hat{a}} \mathcal{D}[\hat{a}]$	$\kappa_{\hat{a}} \alpha^2$	0
$\kappa_{\hat{a}^\dagger} \mathcal{D}[\hat{a}^\dagger]$	$\kappa_{\hat{a}^\dagger} (\alpha^2 + 1)$	$\frac{\kappa_{\hat{a}^\dagger}}{1+2I(\alpha)} \sim \frac{\kappa_{\hat{a}^\dagger}}{\sqrt{2\pi}\alpha} e^{-2\alpha^2}$
$\kappa_{\hat{n}} \mathcal{D}[\hat{n}]$	0	$\frac{\kappa_{\hat{n}} \alpha^2}{1+2I(\alpha)} \sim \frac{\kappa_{\hat{n}}}{\sqrt{2\pi}} \alpha e^{-2\alpha^2}$

Table 1: First order approximation of logical bit (phase) error rates γ_X (γ_Z) induced by each physical error channel in the rapid dissipation limit ($\kappa_R/\kappa_E \gg 1$). Here, we define $I(\alpha) := \alpha \sqrt{\pi/2} e^{2\alpha^2} \text{erf}(\sqrt{2}\alpha)$ with $\text{erf}(x) := 2/\sqrt{\pi} \int_0^x dt e^{-t^2}$.

We note that for such recovery Liouvillian $\mathcal{L}_R$, every density operator $\hat{\rho}_L$ in the 2-dimensional code space spanned by $\{|\pm\rangle_L\}$ becomes a stationary point, i.e., $\mathcal{L}_R(\hat{\rho}_L) = 0$.

The code space can be interpreted as the ground state manifold of the Hamiltonian $\propto \hat{R}^\dagger \hat{R}$, where the stability of states $|\psi\rangle$ outside the code space can be characterized by the effective potential $\Gamma(\psi) = \langle \psi | \hat{R}^\dagger \hat{R} | \psi \rangle$. For a coherent state ansatz $|\psi\rangle := |\theta\rangle_s \otimes |\beta\rangle_b$, with a spin state $|\theta\rangle$ such that $\langle \hat{\sigma}_x \rangle_\theta = \sin \theta$, we obtain

$$\Gamma(\psi) = \alpha^2 - 2\alpha \text{Re}[\beta] \sin \theta + |\beta|^2,$$

which is minimized for $\text{Im}[\beta] = 0$ and forms an attractive potential around $(\theta, \beta) = (\pm\pi/2, \pm\alpha)$.

As having a 2-dimensional stationary code space, the recovery dynamics has four conserved quantities, $\hat{J}_{0,1,2,3}$ such that $\mathcal{L}_R^\dagger(\hat{J}_{0,1,2,3}) = 0$ [14], including the trivial one $\hat{J}_0 = \hat{\mathbb{I}}_s \otimes \hat{\mathbb{I}}_b$ from the trace-preserving condition. Also, a strong symmetry under the hybrid parity $\hat{\Pi}_h := \hat{\sigma}_z \otimes \hat{\Pi}_b$, satisfying $[\hat{\Pi}_h, \hat{R}] = [\hat{\Pi}_h, \hat{R}^\dagger] = 0$, leads to $\hat{J}_3 = \hat{\Pi}_h$. The remaining two conserved quantities are $\hat{J}_1 = |+\rangle\langle +|_s \otimes \hat{K} - |-\rangle\langle -|_s \otimes \hat{\Pi}_b \hat{K} \hat{\Pi}_b$ and $\hat{J}_2 = \hat{J}_3 \hat{J}_1 = -|+\rangle\langle -|_s \otimes \hat{K} \hat{\Pi}_b + |-\rangle\langle +|_s \otimes \hat{\Pi}_b \hat{K}$, where $\hat{K}$ is the solution of

$$(\hat{a}^\dagger - \alpha) \hat{\Pi}_b \hat{K} \hat{\Pi}_b (\hat{a} - \alpha) + \frac{1}{2} \{(\hat{a}^\dagger - \alpha)(\hat{a} - \alpha), \hat{K}\} = 0,$$

with normalization $\langle \alpha | \hat{K} | \alpha \rangle_b = 1$. We note that $\text{Tr}[\hat{J}_{1,2,3} \hat{\rho}_L]$ for $\hat{\rho}_L$ in the code space corresponds to its logical Pauli expectation values in x , y , and z -axes, respectively.

Dynamics of the Hybrid Qubit under Noise We analyze the logical error rates under local Markovian errors given by the following Liouvillian:

$$\mathcal{L}_E := \mathcal{L}_{\text{th}} + \kappa_{\hat{n}} \mathcal{D}[\hat{n}] + \kappa_{\hat{\sigma}_x} \mathcal{D}[\hat{\sigma}_x] + \kappa_{\hat{\sigma}_z} \mathcal{D}[\hat{\sigma}_z]. \quad (3)$$

Here, $\mathcal{L}_{\text{th}} := \kappa_{\hat{a}} \mathcal{D}[\hat{a}] + \kappa_{\hat{a}^\dagger} \mathcal{D}[\hat{a}^\dagger]$ with $\kappa_{\hat{a}} = \kappa_{\text{th}}(n_{\text{th}} + 1)$ and $\kappa_{\hat{a}^\dagger} = \kappa_{\text{th}} n_{\text{th}}$ describes the thermal noise channel for a bosonic system coupled to a thermal environment state with the mean excitation number n_{th} . A classical field noise model corresponding to the infinite-temperature bath weakly coupled to the system, i.e.,

Figure 1: Logical (a) bit error rates and (b) phase error rates of the hybrid qubit and the cat qubit under AutoQEC dynamics.

$\mathcal{L}_{\text{th}} = \gamma_{\text{th}}(\mathcal{D}[\hat{a}] + \mathcal{D}[\hat{a}^\dagger])$ with $\kappa_{\text{th}} n_{\text{th}} = \gamma_{\text{th}}$ in the limit of $n_{\text{th}} \rightarrow \infty$, is widely accepted for trapped-ion system [15]. For a circuit-QED system [16], the cryogenic environment of the superconducting circuit corresponds to a mean thermal photon number $n_{\text{th}} \approx 10^{-3}$, indicating a loss-dominant thermal noise channel.

We illustrate how a single jump operator $\hat{R}$ in Eq. (2) can suppress phase noise from both qubit and oscillator systems, by analyzing the effect of the recovery operation on the logical state $|\psi\rangle_L$ under jump operators corresponding to the spin and oscillator systems' phase noise. For the spin phase flip $\hat{\sigma}_z \otimes \hat{\mathbb{I}}_b$, we have

$$(\hat{\sigma}_z \otimes \hat{\mathbb{I}}_b) |\psi\rangle_L \xrightarrow[\text{recovery}]{\hat{R}} \hat{R}(\hat{\sigma}_z \otimes \hat{\mathbb{I}}_b) |\psi\rangle_L = 2\alpha |\psi\rangle_L,$$

so that the logical state is recovered to the code space. For the oscillator noise $\hat{\mathbb{I}}_s \otimes \hat{n}$, we observe that

$$\begin{aligned} (\hat{\mathbb{I}}_s \otimes \hat{n}) |\psi\rangle_L &\xrightarrow[\text{recovery } 1]{\hat{R}} \hat{R}(\hat{\mathbb{I}}_s \otimes \hat{n}) |\psi\rangle_L = -\alpha(\hat{\sigma}_z \otimes \hat{\mathbb{I}}_b) |\psi\rangle_L \\ &\xrightarrow[\text{recovery } 2]{\hat{R}} -\alpha \hat{R}(\hat{\sigma}_z \otimes \hat{\mathbb{I}}_b) |\psi\rangle_L = -2\alpha^2 |\psi\rangle_L, \end{aligned}$$

where the oscillator's phase noise is converted into the spin phase noise and then recovered to the code space. Such a noise suppression mechanism also applies to induced phase errors from thermal noise.

More rigorously, using first-order perturbation theory in the limit $\kappa_R \gg \kappa_{\hat{\sigma}_z}, \kappa_{\hat{n}}$ and the conserved quantity $\hat{J}_1$, we demonstrate that the logical phase-error rate γ_Z is exponentially suppressed as α^2 increases (see Table 1 for details). Here, γ_Z is defined as the population decay rate of the eigenstate initially prepared in $|+\rangle_L$, i.e., $p_Z(t) = \text{Tr}[|+\rangle\langle +|_L e^{(\mathcal{L}_R + \mathcal{L}_E)t} |+\rangle\langle +|_L] = (1 + e^{-2\gamma_Z t})/2$. Especially for the bosonic phase noise, our protocol provides consistently better noise suppression ($\gamma_Z \approx \alpha e^{-2\alpha^2}$) compared to the cat code with two-photon subtraction ($\gamma_Z \approx \alpha^2 e^{-2\alpha^2}$) [17] with factor α .

Meanwhile, the recovery dynamics is not able to recognize the qubit bit-flip noise $\hat{\sigma}_x$, as $[\mathcal{D}[\hat{\sigma}_x], \mathcal{D}[\hat{R}]] = 0$. The thermal loss $\hat{a}, \hat{a}^\dagger$ translates into a logical bit-flip rate that scales linearly with α^2 [18], since loss acts as a logical X -operation, i.e., $(\hat{\mathbb{I}}_s \otimes \hat{a}) |\psi\rangle_L = \alpha \hat{X}_L |\psi\rangle_L$, similarly to the AutoQEC applied to the cat code [19, 20]. We summarize the logical X and Z error rates for each element in Eq. (3) in Table 1.

Figure 2: The error probabilities of concatenated hybrid qubits ($d = 5$) after $t = 1$ ms for trapped-ions [21] and $t = 1$ μ s for superconducting circuits [22].

Concatenation of the Hybrid qubit The bit errors amplified from the proposed AutoQEC can be further suppressed by the concatenation of the hybrid qubit using a conventional QEC code. Such a proposal has been made for cat codes [23] and was recently realized in superconducting systems [16]. As the simplest example, we consider a repetition code, $|\mu\rangle_{\text{rep}} := |\mu\rangle_L^{\otimes d}$, $\mu \in \{0, 1\}$ with distance d . The bit repetition code suppresses the bit errors, but makes the logical information more susceptible to phase-flip errors as each phase-flip in $|\mu\rangle_L$ induces a logical phase error. This compensates the exponential-linear tradeoff between the phase-bit error rates in hybrid qubits $|\mu\rangle_L$ via the proposed AutoQEC dynamics, which leads to efficient suppression of both logical phase and bit errors after the concatenation (see Fig. 2).

AutoQEC for noise-suppressed quantum metrology Exponential phase-noise suppression of the hybrid qubit via the proposed AutoQEC dynamics can also be applied to quantum metrology. We particularly focus on the estimation of the displacement [24] with parameter β for $\hat{D}(i\beta)$ acting on the oscillator system in the p -direction. The quantum Cramér-Rao bound (QCRB) [25] determines the ultimate sensitivity of a given probe state $\hat{\rho}$ in terms of quantum Fisher information $\mathcal{F}_Q(\hat{\rho})$ as, $(\Delta\beta)^2 \geq 1/\mathcal{F}_Q(\hat{\rho})$.

For the noiseless case, a spin-oscillator entangled state in the code space, $|0\rangle_L = \frac{1}{\sqrt{2}}(|+\rangle_s \otimes |\alpha\rangle_b + |-\rangle_s \otimes |-\alpha\rangle_b)$ achieves the precision $(\Delta\beta)^2 \geq 1/\mathcal{F}_Q(|0\rangle_L) = 1/(16\alpha^2 + 4)$, surpassing the standard quantum limit (SQL), $(\Delta\beta)^2 \geq 1/4$, whenever $\alpha^2 > 0$. While such an advantage can be easily washed out when the probe state is exposed to the noise, our AutoQEC dynamics effectively protects the probe state against external noise to maintain sub-SQL [26]. Figure 3 shows that, for a given time $\tau = 1$ ms, the QFI of the noise-suppressed probe state, $\hat{\rho}_{\text{supp}} := e^{(\mathcal{L}_E + \mathcal{L}_R)\tau}(|0\rangle_L)$, is more robust

Figure 3: (a) QCRB of the ideal probe state $|0\rangle_L$ and the noise-suppressed ($\hat{\rho}_{\text{supp}}$) and unsuppressed ($\hat{\rho}_{\text{bare}}$) states exposed to noise for $\tau = 1$ ms. The noise-suppressed probe state (blue triangle) consistently outperforms the bare probe state (red circle). (b) Regime where sub-SQL displacement sensitivity is achievable using $\hat{\rho}_{\text{bare}}$ (dark grey) and $\hat{\rho}_{\text{supp}}$ (light grey).

against noise than that of the unsuppressed state, $\hat{\rho}_{\text{bare}} := e^{\mathcal{L}_E\tau}(|0\rangle_L)$.

Experimental implementation The recovery Liouvillian $\mathcal{L}_R$ can be realized by interacting the spin-oscillator system with an additional dissipative mode [27, 28]. The following Hamiltonian implements the dissipation $\kappa_R \mathcal{D}[\hat{R}]$ for stabilizing the hybrid qubit,

$$\hat{H}_{\text{SB}} = g\hat{R}\hat{b}^\dagger + \text{h.c.} = g[\alpha\hat{\sigma}_z\hat{b}^\dagger - i\hat{\sigma}_y\hat{a}\hat{b}^\dagger] + \text{h.c.},$$

where $\hat{b}$ is the annihilation operator of the bath mode under strong dissipation $\gamma_b \mathcal{D}[\hat{b}]$ and h.c. denotes the Hermitian conjugate. In the strong dissipation limit ($\gamma_b \gg g$), adiabatic elimination translates the system-bath coupling into an effective dissipation rate $\kappa_R \approx 4g^2/\gamma_b$ [29]. $\hat{H}_{\text{SB}}$ consists of a spin-dependent displacement [10–12] and a controlled beam-splitter interaction, which has been realized in trapped-ion systems [30, 31]. Strong, continuous relaxation of the motional mode can be realized in trapped-ion systems through Raman sideband cooling [32] or cooling by electromagnetically induced transparency [33]. In a superconducting system, a lossy bath mode can be realized using superconducting quantum interference devices [34, 35].

Remarks We have proposed an AutoQEC architecture for stabilizing a hybrid qubit encoded in spin states and oscillator coherent states. Our formalism provides measurement-free exponential suppression of phase noise from both the spin and oscillator systems via a single correlated jump operator, which is implementable with elements already realized in trapped-ion systems. The resulting noise-biased hybrid qubits provide a promising resource for concatenated quantum error correction and quantum metrology. We attach a technical manuscript to provide more detail.

We construct an autonomous quantum error-correction protocol for a hybrid qubit that encodes quantum information in spin states and oscillator coherent states. The engineered Lindbladian continuously stabilizes the code space as a steady-state subspace, which results in exponential suppression of the logical phase-error rate as the coherent-state amplitude increases. Remarkably, our protocol employs a single correlated jump operator to suppress phase noise from both the spin and oscillator systems, reducing dissipation-engineering overhead. While exponential phase-noise suppression comes with a linear increase in bit-error rate, we show that concatenating noise-biased hybrid qubits can efficiently suppress both logical errors. Even without concatenation, the strongly biased error profile enables metrological applications that preserve quantum Fisher information beyond the standard quantum limit. Our construction leverages experimentally demonstrated primitives, such as controlled beam-splitter operations readily realizable in trapped-ion systems, offering a practical route toward hardware-efficient quantum error correction.

Protecting quantum states from decoherence is a quintessential task in both the fundamental study of quantum information and its practical applications. However, preserving quantum information is more challenging than preserving classical information, as decoherence and measurement itself can easily disturb information encoded in coherence or interference [1–3]. Quantum error correction (QEC) utilizes syndrome measurements to identify physical errors for correction [3, 4], without destroying the quantum information encoded in the code space. Despite remarkable progress on experimental demonstrations of QEC, for example, reporting the break-even between encoded qubits and physical qubits [5] and a sub-threshold scaling [6–8], realizing a large-scale fault-tolerant quantum computing remains a challenging goal. A major technical barrier is that syndrome measurements and decoding require significant resources in both time and physical qubits, which generally introduce additional errors in the system [9–11].

Autonomous quantum error correction (AutoQEC) [12, 13] proposes a measurement-free alternative to protect quantum information by designing a passive channel to stabilize the code space. Such a channel can be realized via engineered dissipation [14–16] by coupling the system to a highly dissipative bath system. AutoQEC protocols have been proposed for both discrete-variable (DV) [17–20] and continuous-variable (CV) [21–28] quantum systems, where the latter are typically described by harmonic oscillators. In superconducting cavity QED systems, the generation of noise-biased bosonic cat qubits using AutoQEC, which enables efficient concatenation [29, 30], was recently realized in experiment [6].

A major challenge in realizing AutoQEC is implementing strong, collective dissipative interactions. Stabilizing DV QEC codes, where the logical information is encoded in the correlations between physical qubits, generally re-

quires multi-qubit interactions. These multi-qubit interactions, along with strong couplings to bath systems to realize engineered dissipation, limit the scalability of AutoQEC for DV systems. For CV QEC codes, instead of multi-qubit interactions, strong nonlinear dissipation in the oscillator, such as two-photon dissipation for stabilizing cat states [21], is necessary [31] for realizing AutoQEC.

In this Letter, we propose a novel CV–DV hybrid AutoQEC protocol that effectively suppresses phase noise in both DV spin and CV oscillator systems using a single jump operator. We demonstrate that the AutoQEC protocol induces a biased noise profile in the code space spanned by product states of spin states and coherent states, where the logical phase-error rate is exponentially suppressed as the coherent-state amplitude increases. While this comes at the cost of a linearly increasing bit-error rate, we demonstrate that a concatenation of hybrid qubits effectively suppresses both logical bit and phase errors. The noise-biased hybrid states can also be applied to quantum metrology, as the proposed AutoQEC dynamics effectively suppress phase noise, preserving the quantum Fisher information of hybrid entangled states beyond the standard quantum limit.

We highlight that our AutoQEC protocol is experimentally feasible with readily accessible elements in the trapped-ion system, such as controlled beam-splitter interaction [32, 33], spin-dependent oscillator displacement [34], and a highly dissipative bath. More generally, the CV–DV hybrid construction of AutoQEC can exploit intrinsic DV degrees of freedom, such as the internal atomic levels of trapped-ions [34] and the artificial atoms of superconducting circuits [35], which can be advantageous compared to the CV-only architecture in terms of performance and implementation. Our hybrid framework coherently combines the infinite redundancy of the CV system with nonlinear operations enabled by

coupling to the DV system, creating a distinctive synergy for hardware-efficient error correction.

Hybrid qubit.— The hybrid qubit encodes a single logical qubit into a spin-oscillator composite system [36, 37]:

$$\begin{aligned} |+\rangle_L &:= |+\rangle_s \otimes |+\alpha\rangle_b, \\ |-\rangle_L &:= |-\rangle_s \otimes |-\alpha\rangle_b. \end{aligned} \quad (1)$$

Here, $|\pm\rangle_s$ are the X -eigenstates of the DV spin system and $|\pm\alpha\rangle_b$ are CV coherent states of the oscillator mode defined by $\hat{D}(\alpha)|0\rangle_b$ with the displacement operator $\hat{D}(\alpha) := e^{\alpha\hat{a}^\dagger - \alpha^*\hat{a}}$. $\hat{a}$ and $\hat{a}^\dagger$ are bosonic annihilation and creation operators, respectively, and without loss of generality, we focus on real-valued α . Subscripts s and b denote spin and bosonic oscillator systems, respectively.

Such a hybrid encoding across CV and DV quantum systems has been explored in photonics [36–39] to overcome the non-orthogonality between small amplitude coherent states ($\langle\alpha|-\alpha\rangle_b \neq 0$) and the complication of their phase operation ($|\pm\alpha\rangle_b \rightarrow \pm|\pm\alpha\rangle_b$), with applications in quantum communication [40, 41] and QEC [42, 43]. Superposition of these hybrid qubits was also realized in superconducting circuits [44], revealing hybrid entanglement between the spin and oscillator systems.

Encoding quantum information from a spin qubit into the hybrid qubit can be implemented by applying the controlled displacement operator $\hat{U}_{CD} := \hat{D}(\alpha\hat{\sigma}_x) = |+\rangle\langle+|_s \otimes \hat{D}(\alpha) + |-\rangle\langle-|_s \otimes \hat{D}(-\alpha)$ on the initial product state as $|\psi\rangle_L = \hat{U}_{CD}(|\psi\rangle_s \otimes |0\rangle_b)$. Decoding of the logical information can be implemented through the inverse unitary $\hat{U}_{CD}^\dagger$, enabling measurement on the hybrid qubit through local measurement on the spin subsystem. Alternatively, the encoding and decoding can be realized by controlled parity operation $|+\rangle\langle+|_s \otimes \hat{\Pi}_b + |-\rangle\langle-|_s \otimes \hat{\Pi}_b$ acting on $|\psi\rangle_s \otimes |\alpha\rangle_b$, where $\hat{\Pi}_b = (-1)^{\hat{n}}$.

The logical X operation ($\hat{X}_L$) is implemented by applying a Pauli X operation $\hat{\sigma}_x$ on the spin qubit. The logical Z operation ($\hat{Z}_L$) can be implemented by either a product of the spin phase-flip and the oscillator parity operator, i.e., $\hat{\sigma}_z \otimes \hat{\Pi}_b$, or a spin-dependent displacement followed by a phase-flip, i.e., $\hat{\sigma}_z \hat{D}(-2\alpha\hat{\sigma}_x)$. The displacement-type logical Z operation can be realized by using a spin-dependent force [45, 46] that is native to the trapped-ion systems and also realizable for superconducting systems [47]. For entangling operations between multiple logical qubits, an XX interaction between the DV subsystems $e^{-i\frac{\theta}{2}\hat{\sigma}_x \otimes \hat{\sigma}_x}$ is sufficient to form a universal gate set when combined with logical single-qubit gates.

AutoQEC of the hybrid qubit.— We consider the dynamics of the spin-oscillator hybrid system described by the Lindblad master equation [48]:

$$\frac{d\hat{\rho}}{dt} = \mathcal{L}(\hat{\rho}) := -i[\hat{H}, \hat{\rho}] + \sum_k \kappa_k \mathcal{D}[\hat{L}_k](\hat{\rho}),$$

where $\hat{H}$ denotes the Hamiltonian of the system, $\mathcal{D}[\hat{L}](\hat{\rho}) := \hat{L}\hat{\rho}\hat{L}^\dagger - \frac{1}{2}\{\hat{L}^\dagger\hat{L}, \hat{\rho}\}$ describes dissipation given

by a jump operator $\hat{L}$, and κ_k are the dissipation rates for each $\hat{L}_k$. Also, $[\cdot, \cdot]$ ($\{\cdot, \cdot\}$) denotes the canonical (anti-)commutator. We decompose the quantum Liouvillian into two parts,

$$\mathcal{L} = \mathcal{L}_E + \mathcal{L}_R,$$

where $\mathcal{L}_E$ describes the uncontrollable noise of the system that induces errors, and $\mathcal{L}_R$ is engineered dissipation that stabilizes the code space and recovers it from errors. To design AutoQEC for the logical qubit spanned by the hybrid states described in Eq. (1), we construct $\mathcal{L}_R := \kappa_R \mathcal{D}[\hat{R}]$ with the correlated jump operator,

$$\hat{R} := \hat{\sigma}_z(\alpha - \hat{\sigma}_x \otimes \hat{a}). \quad (2)$$

We note that for such recovery Liouvillian $\mathcal{L}_R$, every density operator $\hat{\rho}_L$ in the 2-dimensional code space spanned by $\{|\pm\rangle_L\}$ becomes a stationary point, i.e., $\mathcal{L}_R(\hat{\rho}_L) = 0$.

The code space can be interpreted as the ground state manifold of the Hamiltonian $\propto \hat{R}^\dagger \hat{R}$, where the stability of states $|\psi\rangle$ outside the code space can be characterized by the effective potential $\Gamma(\psi) = \langle\psi| \hat{R}^\dagger \hat{R} |\psi\rangle$. For a coherent state ansatz $|\psi\rangle := |\theta\rangle_s \otimes |\beta\rangle_b$, with a spin state $|\theta\rangle$ such that $\langle\hat{\sigma}_x\rangle_\theta = \sin\theta$, we obtain

$$\Gamma(\psi) = \alpha^2 - 2\alpha\text{Re}[\beta]\sin\theta + |\beta|^2,$$

which is minimized for $\text{Im}[\beta] = 0$ and forms an attractive potential around $(\theta, \beta) = (\pm\pi/2, \pm\alpha)$ (see Fig. 1(a)).

As having a 2-dimensional stationary code space, the recovery dynamics has four conserved quantities, $\hat{J}_{0,1,2,3}$ such that $\mathcal{L}_R^\dagger(\hat{J}_{0,1,2,3}) = 0$ [49], including the trivial one $\hat{J}_0 = \hat{\mathbb{I}}_s \otimes \hat{\mathbb{I}}_b$ from the trace-preserving condition. Also, a strong symmetry under the hybrid parity $\hat{\Pi}_h := \hat{\sigma}_z \otimes \hat{\Pi}_b$, satisfying $[\hat{\Pi}_h, \hat{R}] = [\hat{\Pi}_h, \hat{R}^\dagger] = 0$, leads to $\hat{J}_3 = \hat{\Pi}_h$. The

FIG. 1. (a) $\Gamma(\psi)$ of ansatz states $|\theta\rangle_s \otimes |\beta\rangle_b$ as a function of β and θ . The only pure stationary states having $\Gamma = 0$ are $|\psi\rangle_L \in \text{span}\{|\pm\rangle_L\}$. (b) Schematic diagram of the AutoQEC dynamics of a hybrid qubit.

Physical noise	Bit error rate (γ_X)	Phase error rate (γ_Z)
$\kappa_{\hat{\sigma}_x} \mathcal{D}[\hat{\sigma}_x]$	$\kappa_{\hat{\sigma}_x}$	0
$\kappa_{\hat{\sigma}_z} \mathcal{D}[\hat{\sigma}_z]$	0	$\frac{\kappa_{\hat{\sigma}_z}}{1+2I(\alpha)} \sim \frac{\kappa_{\hat{\sigma}_z}}{\sqrt{2\pi}\alpha} e^{-2\alpha^2}$
$\kappa_{\hat{a}} \mathcal{D}[\hat{a}]$	$\kappa_{\hat{a}} \alpha^2$	0
$\kappa_{\hat{a}^\dagger} \mathcal{D}[\hat{a}^\dagger]$	$\kappa_{\hat{a}^\dagger} (\alpha^2 + 1)$	$\frac{\kappa_{\hat{a}^\dagger}}{1+2I(\alpha)} \sim \frac{\kappa_{\hat{a}^\dagger}}{\sqrt{2\pi}\alpha} e^{-2\alpha^2}$
$\kappa_{\hat{n}} \mathcal{D}[\hat{n}]$	0	$\frac{\kappa_{\hat{n}} \alpha^2}{1+2I(\alpha)} \sim \frac{\kappa_{\hat{n}}}{\sqrt{2\pi}} \alpha e^{-2\alpha^2}$

TABLE I. First order approximation of logical bit (phase) error rates γ_X (γ_Z) induced by each physical error channel in the rapid dissipation limit ($\kappa_R/\kappa_E \gg 1$). Here, we define $I(\alpha) := \alpha \sqrt{\pi/2} e^{2\alpha^2} \text{erf}(\sqrt{2}\alpha)$ with $\text{erf}(x) := 2/\sqrt{\pi} \int_0^x dt e^{-t^2}$.

remaining two conserved quantities are $\hat{J}_1 = |+\rangle \langle +|_s \otimes \hat{K} - |-\rangle \langle -|_s \otimes \hat{\Pi}_b \hat{K} \hat{\Pi}_b$ and $\hat{J}_2 = \hat{J}_3 \hat{J}_1 = -|+\rangle \langle -|_s \otimes \hat{K} \hat{\Pi}_b + |-\rangle \langle +|_s \otimes \hat{\Pi}_b \hat{K}$, where $\hat{K}$ is the solution of

$$(\hat{a}^\dagger - \alpha) \hat{\Pi}_b \hat{K} \hat{\Pi}_b (\hat{a} - \alpha) + \frac{1}{2} \left\{ (\hat{a}^\dagger - \alpha) (\hat{a} - \alpha), \hat{K} \right\} = 0,$$

with normalization $\langle \alpha | \hat{K} | \alpha \rangle_b = 1$ (see Supplemental Material (SM) [50] for details). We note that $\text{Tr} [\hat{J}_{1,2,3}^\dagger \hat{\rho}_L]$ for $\hat{\rho}_L$ in the code space corresponds to its logical Pauli expectation values in x , y , and z -axes, respectively.

Dynamics of the hybrid qubit under noise.— We analyze the logical error rates under local Markovian errors given by the following Liouvillian:

$$\mathcal{L}_E := \mathcal{L}_{\text{th}} + \kappa_{\hat{n}} \mathcal{D}[\hat{n}] + \kappa_{\hat{\sigma}_x} \mathcal{D}[\hat{\sigma}_x] + \kappa_{\hat{\sigma}_z} \mathcal{D}[\hat{\sigma}_z]. \quad (3)$$

Here, $\mathcal{L}_{\text{th}} := \kappa_{\hat{a}} \mathcal{D}[\hat{a}] + \kappa_{\hat{a}^\dagger} \mathcal{D}[\hat{a}^\dagger]$ with $\kappa_{\hat{a}} = \kappa_{\text{th}}(n_{\text{th}} + 1)$ and $\kappa_{\hat{a}^\dagger} = \kappa_{\text{th}} n_{\text{th}}$ describes the thermal noise channel for a bosonic system coupled to a thermal environment state with the mean excitation number n_{th} . A classical field noise model corresponding to the infinite-temperature bath weakly coupled to the system, i.e., $\mathcal{L}_{\text{th}} = \gamma_{\text{th}} (\mathcal{D}[\hat{a}] + \mathcal{D}[\hat{a}^\dagger])$ with $\kappa_{\text{th}} n_{\text{th}} = \gamma_{\text{th}}$ in the limit of $n_{\text{th}} \rightarrow \infty$, is widely accepted for trapped-ion system [51]. For a circuit-QED system [6], the cryogenic environment of the superconducting circuit corresponds to a mean thermal photon number $n_{\text{th}} \approx 10^{-3}$, indicating a loss-dominant thermal noise channel.

We illustrate how a single jump operator $\hat{R}$ in Eq. (2) can suppress phase noise from both qubit and oscillator systems, by analyzing the effect of the recovery operation on the logical state $|\psi\rangle_L$ under jump operators corresponding to the spin and oscillator systems' phase noise. For the spin phase flip $\hat{\sigma}_z \otimes \hat{\Pi}_b$, we have

$$(\hat{\sigma}_z \otimes \hat{\Pi}_b) |\psi\rangle_L \xrightarrow{\text{recovery } \hat{R}} \hat{R}(\hat{\sigma}_z \otimes \hat{\Pi}_b) |\psi\rangle_L = 2\alpha |\psi\rangle_L,$$

so that the logical state is recovered to the code space. For the oscillator noise $\hat{\Pi}_s \otimes \hat{n}$, we observe that

$$\begin{aligned} (\hat{\Pi}_s \otimes \hat{n}) |\psi\rangle_L &\xrightarrow{\text{recovery } 1} \hat{R}(\hat{\Pi}_s \otimes \hat{n}) |\psi\rangle_L = -\alpha (\hat{\sigma}_z \otimes \hat{\Pi}_b) |\psi\rangle_L \\ &\xrightarrow{\text{recovery } 2} -\alpha \hat{R}(\hat{\sigma}_z \otimes \hat{\Pi}_b) |\psi\rangle_L = -2\alpha^2 |\psi\rangle_L, \end{aligned}$$

FIG. 2. Logical (a) bit error rates and (b) phase error rates of the hybrid qubit and the cat qubit under AutoQEC dynamics. The simulation parameters can be found in End Matter.

where the oscillator's phase noise is converted into the spin phase noise and then recovered to the code space. Such a noise suppression mechanism also applies to induced phase errors from thermal noise, where a more detailed structure of the hybrid AutoQEC dynamics under noise can be found in End Matter.

More rigorously, using first-order perturbation theory in the limit $\kappa_R \gg \kappa_{\hat{\sigma}_z}, \kappa_{\hat{n}}$ and the conserved quantity $\hat{J}_1$, we demonstrate that the logical phase-error rate γ_Z is exponentially suppressed as α^2 increases (see Table I and SM [50] for details). Here, γ_Z is defined as the population decay rate of the eigenstate initially prepared in $|+\rangle_L$, i.e., $p_Z(t) = \text{Tr} [|+\rangle \langle +|_L e^{(\mathcal{L}_R + \mathcal{L}_E)t} |+\rangle \langle +|_L] = (1 + e^{-2\gamma_Z t})/2$. Especially for the bosonic phase noise, our protocol provides consistently better noise suppression ($\gamma_Z \approx \alpha e^{-2\alpha^2}$) compared to the cat code with two-photon subtraction ($\gamma_Z \approx \alpha^2 e^{-2\alpha^2}$) [24] with factor α .

Meanwhile, the recovery dynamics is not able to recognize the qubit bit-flip noise $\hat{\sigma}_x$, as $[\mathcal{D}[\hat{\sigma}_x], \mathcal{D}[\hat{R}]] = 0$. The thermal loss $\hat{a}, \hat{a}^\dagger$ translates into a logical bit-flip rate that scales linearly with α^2 [50], since loss acts as a logical X -operation, i.e., $(\hat{\Pi}_s \otimes \hat{a}) |\psi\rangle_L = \alpha \hat{X}_L |\psi\rangle_L$, similarly to the AutoQEC applied to the cat code [21, 22]. We summarize the logical X and Z error rates for each element in Eq. (3) in Table I.

Figure 2 depicts a numerical simulation of logical error rates using realistic experimental parameters given in End Matter, which clearly demonstrates an exponential-linear tradeoff between the phase-bit error rates. The constant gap in the logical bit error rate between the hybrid qubit and cat qubits described in Fig. 2(a) stems from the spin noise $\mathcal{D}[\hat{\sigma}_x]$, which only applies to the hybrid qubit. We also note that the residual phase errors can be further reduced by utilizing the decoding operation $\hat{U}_{\text{CD}}^\dagger$. Since the bosonic mode after disentangling is irrelevant, any superposition of $\hat{U}_{\text{CD}}(|\psi\rangle_s \otimes |n\rangle_b)$ can contribute to the measurement result without applying corrections to their bosonic modes (equivalent to the gauge group arising in degenerate stabilizer codes [52]). Our numerical simulation shows that our AutoQEC protocol outperforms the AutoQEC of the cat code ($|\mu\rangle_{\text{cat}} :=$

FIG. 3. The error probabilities of concatenated hybrid qubits ($d = 5$) after $t = 1$ ms for trapped-ions [53] and $t = 1$ μ s for superconducting circuits [54]. Noise parameters for each platform is given in End Matter.

$|\alpha\rangle_b + (-1)^\mu |\alpha\rangle_b$, $\mu \in \{0, 1\}$) using the two-photon dissipation [21] for any coherent state amplitudes with $\alpha^2 \leq 6$ with the same noise parameters.

Concatenation of the hybrid qubit.— The bit errors amplified from the proposed AutoQEC can be further suppressed by the concatenation of the hybrid qubit using a conventional QEC code. Such a proposal has been made for cat codes [29] and was recently realized in superconducting systems [6]. As the simplest example, we consider a repetition code, $|\mu\rangle_{\text{rep}} := |\mu\rangle_L^{\otimes d}$, $\mu \in \{0, 1\}$ with distance d . The bit repetition code suppresses the bit errors, but makes the logical information more susceptible to phase-flip errors as each phase-flip in $|\mu\rangle_L$ induces a logical phase error. More precisely, the logical error probabilities (P_X, P_Z) in terms of unconcatenated error probabilities (q_X, q_Z) for each $|\mu\rangle_L$ is given as,

$$P_Z = \frac{1}{2}(1 - (1 - 2q_Z)^d),$$

$$P_X = \sum_{k=\lfloor \frac{d+1}{2} \rfloor}^d \binom{d}{k} q_X^k (1 - q_X)^{d-k}.$$

Especially for $q_X, q_Z \ll 1$, $P_Z \propto dq_Z$, $P_X \propto q_X^{(d+1)/2}$. This compensates the exponential-linear tradeoff between the phase-bit error rates in hybrid qubits $|\mu\rangle_L$ via the proposed AutoQEC dynamics, which leads to efficient suppression of both logical phase and bit errors after the concatenation (see Fig. 3).

AutoQEC for noise-suppressed quantum metrology.— Exponential phase-noise suppression of the hybrid qubit via the proposed AutoQEC dynamics can also be applied to quantum metrology. We particularly focus on the es-

FIG. 4. (a) QCRB of the ideal probe state $|0\rangle_{\text{L}}$ and the noise-suppressed ($\hat{\rho}_{\text{supp}}$) and unsuppressed ($\hat{\rho}_{\text{bare}}$) states exposed to noise for $\tau = 1$ ms. The noise-suppressed probe state (blue triangle) consistently outperforms the bare probe state (red circle). (b) Regime where sub-SQL displacement sensitivity is achievable using $\hat{\rho}_{\text{bare}}$ (dark grey) and $\hat{\rho}_{\text{supp}}$ (light grey). Experimental parameters are considered for ion-trap systems (see End Matter).

timization of the displacement [55] with parameter β for $\hat{D}(i\beta)$ acting on the oscillator system in the p -direction. The quantum Cramér-Rao bound (QCRB) [56] determines the ultimate sensitivity of a given probe state $\hat{\rho}$ in terms of quantum Fisher information $\mathcal{F}_Q(\hat{\rho})$ as, $(\Delta\beta)^2 \geq 1/\mathcal{F}_Q(\hat{\rho})$ (see End Matter for details).

For the noiseless case, a spin-oscillator entangled state in the code space, $|0\rangle_{\text{L}} = \frac{1}{\sqrt{2}}(|+\rangle_s \otimes |\alpha\rangle_b + |-\rangle_s \otimes |-\alpha\rangle_b)$ achieves the precision $(\Delta\beta)^2 \geq 1/\mathcal{F}_Q(|0\rangle_{\text{L}}) = 1/(16\alpha^2 + 4)$, surpassing the standard quantum limit (SQL), $(\Delta\beta)^2 \geq 1/4$, whenever $\alpha^2 > 0$. While such an advantage can be easily washed out when the probe state is exposed to the noise, our AutoQEC dynamics effectively protects the probe state against external noise to maintain sub-SQL [57]. Figure 4 shows that, for a given time $\tau = 1$ ms, the QFI of the noise-suppressed probe state, $\hat{\rho}_{\text{supp}} := e^{(\mathcal{L}_E + \mathcal{L}_R)\tau}(|0\rangle_{\text{L}})$, is more robust against noise than that of the unsuppressed state, $\hat{\rho}_{\text{bare}} := e^{\mathcal{L}_E\tau}(|0\rangle_{\text{L}})$.

Experimental implementation.— The recovery Liouvillian $\mathcal{L}_R$ can be realized by interacting the spin-oscillator system with an additional dissipative mode [14, 15] (see also Fig. 1(b)). The following Hamiltonian implements the dissipation $\kappa_R \mathcal{D}[\hat{R}]$ for stabilizing the hybrid qubit,

$$\hat{H}_{\text{SB}} = g\hat{R}\hat{b}^\dagger + \text{h.c.} = g[\alpha\hat{\sigma}_z\hat{b}^\dagger - i\hat{\sigma}_y\hat{a}\hat{b}^\dagger] + \text{h.c.},$$

where $\hat{b}$ is the annihilation operator of the bath mode under strong dissipation $\gamma_b \mathcal{D}[\hat{b}]$ and h.c. denotes the Hermitian conjugate. In the strong dissipation limit ($\gamma_b \gg g$), adiabatic elimination translates the system-bath coupling into an effective dissipation rate $\kappa_R \approx 4g^2/\gamma_b$ [58]. $\hat{H}_{\text{SB}}$ consists of a spin-dependent displacement [45–47] and a controlled beam-splitter interaction, which has been realized in trapped-ion systems for spin z -direction [32] and an arbitrary direction of the xy -plane [33]. In the superconducting system, the controlled

beam-splitter term in the $\hat{H}_{\text{SB}}$ can be, in principle, realized by utilizing the nondegenerate three-wave mixing from native nonlinear elements of circuit QED [23, 59]. Strong, continuous relaxation of the motional mode can be realized in trapped-ion systems through Raman sideband cooling [60] or cooling by electromagnetically induced transparency [61]. In a superconducting system, a lossy bath mode can be realized using superconducting quantum interference devices [23, 59].

Remarks.— We have proposed an AutoQEC architecture for stabilizing a hybrid qubit encoded in spin states and oscillator coherent states. Our formalism provides measurement-free exponential suppression of phase noise from both the spin and oscillator systems via a single correlated jump operator, which is implementable with elements already realized in trapped-ion systems. The resulting noise-biased hybrid qubits provide a promising resource for concatenated quantum error correction and quantum metrology.

Our hybrid AutoQEC framework offers a hardware-efficient pathway for harnessing the advantages of the infinite-dimensional structure of bosonic modes activated by spin-mediated controllability, enabling capabilities inaccessible to approaches based on DV or CV systems alone. This new framework also opens a wide range of future research directions, including designing more efficient noise-biased QEC codes for concatenation [62], developing error-bias-preserving gate operations [63, 64] for hybrid qubits, and engineering CV–DV interfaces for efficient physical implementation.

END MATTER

AutoQEC dynamics under noise. We define a couple of bases that span the spin-oscillator system using the controlled-displacement unitary operator $\hat{U}_{\text{CD}} = \hat{D}(\alpha\hat{\sigma}_x)$, as follows:

$$\begin{aligned} |\pm, \vec{n}\rangle &:= \hat{U}_{\text{CD}}|\pm\rangle_s \otimes |n\rangle_b = \hat{D}(\pm\alpha)|\pm\rangle_s \otimes |n\rangle_b, \\ |\pm, \overleftarrow{n}\rangle &:= \hat{U}_{\text{CD}}^\dagger|\pm\rangle_s \otimes |n\rangle_b = \hat{D}(\mp\alpha)|\pm\rangle_s \otimes |n\rangle_b. \end{aligned}$$

We note that the both bases satisfy the orthogonality relation, $\langle\mu, \vec{n}|\nu, \vec{m}\rangle = \delta_{\mu\nu}\delta_{nm}$, $\langle\mu, \overleftarrow{n}|\nu, \overleftarrow{m}\rangle = \delta_{\mu\nu}\delta_{nm}$ and the completeness relation, $\sum_{\mu,n} |\mu, \overleftarrow{n}\rangle\langle\mu, \overleftarrow{n}| = \sum_{\mu,n} |\mu, \vec{n}\rangle\langle\mu, \vec{n}| = \hat{\mathbb{I}}_s \otimes \hat{\mathbb{I}}_b$.

We calculate the action of jump operators in the set $\mathcal{E}$ on relevant pure states. For the spin system's jump operators, we have

$$\begin{aligned} \hat{\sigma}_x|\pm, \vec{n}\rangle &= \pm|\pm, \vec{n}\rangle, \\ \hat{\sigma}_x|\pm, \overleftarrow{n}\rangle &= \pm|\pm, \overleftarrow{n}\rangle, \\ \hat{\sigma}_z|\pm, \vec{n}\rangle &= |\mp, \overleftarrow{n}\rangle, \\ \hat{\sigma}_z|\pm, \overleftarrow{n}\rangle &= |\mp, \vec{n}\rangle. \end{aligned}$$

For the oscillator system's jump operator, we have

$$\begin{aligned} \hat{a}|\pm, \vec{n}\rangle &= \sqrt{n}|\pm, \overleftarrow{n-1}\rangle \pm \alpha|\pm, \vec{n}\rangle, \\ \hat{a}^\dagger|\pm, \vec{n}\rangle &= \sqrt{n+1}|\pm, \overrightarrow{n+1}\rangle \pm \alpha|\pm, \vec{n}\rangle, \\ \hat{n}|\pm, \vec{n}\rangle &= \pm\alpha\sqrt{n+1}|\pm, \overrightarrow{n+1}\rangle + (n+\alpha^2)|\pm, \vec{n}\rangle \\ &\quad \pm \alpha\sqrt{n}|\pm, \overleftarrow{n-1}\rangle. \end{aligned}$$

Inverting the direction of arrows for the above gives the equation for $|\pm, \overleftarrow{n}\rangle$. Finally, for $\hat{R}$ and $\hat{R}^\dagger$, we have

$$\begin{aligned} \hat{R}|\pm, \vec{n}\rangle &= \mp\sqrt{n}|\mp, \overleftarrow{n-1}\rangle, \\ \hat{R}|\pm, \overleftarrow{n}\rangle &= 2\alpha|\mp, \vec{n}\rangle \mp\sqrt{n}|\mp, \overrightarrow{n-1}\rangle, \\ \hat{R}^\dagger|\pm, \vec{n}\rangle &= 2\alpha|\mp, \overleftarrow{n}\rangle \pm\sqrt{n+1}|\mp, \overleftarrow{n+1}\rangle, \\ \hat{R}^\dagger|\pm, \overleftarrow{n}\rangle &= \pm\sqrt{n+1}|\mp, \overrightarrow{n+1}\rangle. \end{aligned}$$

Assuming subsequent collapse or measurement right after the jump, we describe the stochastic jump direction and probability between states in Fig. 5.

A pure state $|\psi\rangle$ can be a steady state of the dynamics generated by $\mathcal{D}[\hat{R}]$ if and only if $|\psi\rangle$ is a right eigenstate of $\hat{R}$ and, in addition, either the corresponding eigenvalue is zero or $|\psi\rangle$ is also the matching eigenstate of $\hat{R}^\dagger$. Now, observe that $\hat{R}^2 = \alpha^2 - \hat{a}^2$ and $\hat{R}|\psi\rangle = \lambda|\psi\rangle \rightarrow \hat{R}^2|\psi\rangle = \lambda^2|\psi\rangle$. Since the only eigenspace satisfying the stationary condition of the two-photon jump operator is $\text{span}(|\pm\alpha\rangle_b)$ with zero eigenvalue, our candidate of steady states reduces to elements of the $\text{span}(|\phi\rangle_s \otimes (c_+|\alpha\rangle_b + c_-|\alpha\rangle_b))$. Calculating the action of $\hat{R}$ on such states reveals that the pure states can be steady only if they are in $\text{span}(|\pm, \vec{0}\rangle)$.

FIG. 5. Approximate Markov diagram of states up to excitation. The coherence of post-jump states is neglected. Numbers in arrows correspond to the rates of the corresponding jumps. Every transition involves a phase flip.

Table of experimental parameters. We present the parameters used throughout the numerical analysis in Table II, which are obtained from recent relevant experimental studies.

(a) Hyperfine qubits and motional modes of trapped-ions	
Thermal noise ($\gamma_{\text{th}}/2\pi$).	0.014 – 4.7 Hz
Bosonic dephasing ($\kappa_{\hat{n}}/2\pi$).	1.6 – 4.0 Hz
Qubit bit flip ($\kappa_{\hat{\sigma}_x}/2\pi$).	< 0.03 Hz
Qubit phase flip ($\kappa_{\hat{\sigma}_z}/2\pi$).	< 0.27 Hz
Controlled beam-splitting ($g/2\pi$)	0.31 – 0.87 kHz
Bath relaxation ($\gamma_b/2\pi$)	$\approx$ 13.4 kHz
(b) Qubits and bosonic modes of the superconducting cavity	
Photon loss ($\kappa'_{\text{th}}/2\pi$)	2.1 – 2.3 kHz
Bosonic dephasing ($\kappa'_{\hat{n}}/2\pi$)	0.37 – 0.73 kHz
Qubit bit flip ($\kappa'_{\hat{\sigma}_x}/2\pi$)	0.25 – 0.95 kHz
Qubit phase flip ($\kappa'_{\hat{\sigma}_z}/2\pi$)	0.08 – 1.6 kHz
3-wave mixing SNAIL ($g'/2\pi$)	0.3 – 60 MHz
Bath relaxation ($\gamma'_b/2\pi$)	$\approx$ 10.7 MHz

TABLE II. System parameters considered for the concatenated hybrid/cat qubit. We considered parameters related to the trapped-ion system [32, 33] (up). Relevant rates of the superconducting cavity and qubits (down) [23, 59, 65, 66].

Displacement sensing with noise-suppressed hybrid states. For a given state $\hat{\rho}$, the QFI $\mathcal{F}_Q(\hat{\rho})$ with respect to an observable $\hat{O}$ is defined [67]

$$\mathcal{F}_Q(\hat{\rho}) = 2 \sum_{k,l} \frac{(\lambda_k - \lambda_l)^2}{(\lambda_k + \lambda_l)} |\langle k|\hat{O}|l\rangle|^2,$$

where λ_k and $|k\rangle$ are the eigenvalue and eigenvector of a given state $\hat{\rho}$. The summation goes for all k and l such

that $\lambda_k + \lambda_l > 0$. For a pure state $|\psi\rangle$, QFI reduces to the variance of the observable: $\mathcal{F}_Q = 4(\Delta\hat{O})^2 = 4(\langle\hat{O}^2\rangle_\psi - \langle\hat{O}\rangle_\psi^2)$. QFI designates the ultimate achievable precision in estimating the parameter β using $\hat{\rho}_\beta := e^{-i\beta\hat{O}}\hat{\rho}e^{i\beta\hat{O}}$ as a probe, which is the QCRB, as stated in the main text ($(\Delta\beta)^2 \geq 1/\mathcal{F}_Q$). QCRB of certain quantum states can be lower than the standard quantum limit (SQL), the maximum precision achievable by a classical probe, indicating the possibility of parameter estimation with classically intractable precision.

For the displacement sensing, an entanglement between a discrete-variable (DV) system and a continuous-variable (CV) system can be utilized to obtain beyond-classical sensitivity [55, 68]. For a pure entangled probe state $|0\rangle_L := \frac{1}{\sqrt{2}}(|+\rangle_s \otimes |\alpha\rangle_b + |-\rangle_s \otimes |-\alpha\rangle_b)$, the quantum Fisher information $\mathcal{F}_Q$ with respect to the observable $\hat{X} := \hat{a} + \hat{a}^\dagger$, the generator of p -displacement, can be readily obtained as $\mathcal{F}_Q = 4(\Delta\hat{X})^2 = 16\alpha^2 + 4$, which is larger than $\mathcal{F}_Q(|\alpha'\rangle\langle\alpha'|) = 4$, the maximum QFI for displacement sensing obtained from the coherent state probe.

SUPPLEMENTAL MATERIAL FOR “AUTONOMOUS QUANTUM ERROR CORRECTION OF SPIN-OSCILLATOR HYBRID QUBITS”

I. CONSERVED QUANTITIES OF $\mathcal{L}_R$

Observe that the hybrid parity, defined as following; $\hat{\Pi}_h := \hat{\sigma}_z \otimes \hat{\Pi}_b$, where $\hat{\Pi}_b := e^{i\pi\hat{n}} = \sum (-1)^n |n\rangle\langle n|_b$ is the bosonic parity operator, commutes with $\hat{R}$, $\hat{R}^\dagger$. Therefore, it is in kernel of the adjoint Liouvillian $\mathcal{L}_R^\dagger$ ($\mathcal{L}_R^\dagger \hat{\Pi}_h = 0$) where the action of the adjoint Liouvillian $\mathcal{L}_R^\dagger$ on an operator $\hat{J}$ can be formally written

$$\mathcal{L}_R^\dagger \hat{J} = \hat{R}^\dagger \hat{J} \hat{R} - \frac{1}{2} \{ \hat{R}^\dagger \hat{R}, \hat{J} \}. \quad (4)$$

As any state $\hat{\rho}$ satisfying $\mathcal{L}_R \hat{\rho} = 0$ is a steady state of the dynamics generated by $\mathcal{L}_R$, any operator $\hat{J}$ satisfying $\mathcal{L}_R^\dagger \hat{J} = 0$ is a conserved quantity of the dynamics. Since the steady subspace of the dynamics is 4-dimensional (in the superoperator sense), an equal number of conserved quantities are expected [49]. Imposing the orthogonality condition given by the Hilbert-Schmidt inner product $\text{Tr}[\hat{J}_{\mu\nu}^\dagger \hat{M}_{\mu'\nu'}] = \delta_{\mu\mu'} \delta_{\nu\nu'}$ to establish a correspondence between steady states and conserved quantities. The hybrid parity is connected to the two diagonal conserved quantities of the following:

$$\begin{aligned} \hat{J}_{00} &:= \frac{1 + \hat{\Pi}_h}{2} = \sum_{\mu \in \{0,1\}, n} |\mu\rangle\langle\mu|_s \otimes |2n + \mu\rangle\langle 2n + \mu|_b, \\ \hat{J}_{11} &:= \frac{1 - \hat{\Pi}_h}{2} = \sum_{\mu \in \{0,1\}, n} |\mu\rangle\langle\mu|_s \otimes |2n + 1 + \mu\rangle\langle 2n + 1 + \mu|_b. \end{aligned}$$

The remaining conserved quantities cannot be generated from $\hat{\Pi}_h$. Let us define

$$\hat{R} = \hat{\sigma}_y (\hat{a} - \alpha \hat{\sigma}_x) = i \begin{pmatrix} 0 & -\hat{b}_+ \\ \hat{b}_- & 0 \end{pmatrix} = i \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \begin{pmatrix} 0 & \hat{b}_- \\ \hat{b}_- & 0 \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix},$$

in a block matrix form in the x -basis $\hat{A} = \begin{pmatrix} \hat{A}_{++} & \hat{A}_{+-} \\ \hat{A}_{-+} & \hat{A}_{--} \end{pmatrix}$ where $\hat{A}_{ij} := \text{Tr}_s[\hat{A}(|i\rangle\langle j|_s \otimes \hat{\Pi}_b)]$ are the bosonic operators obtained from projecting onto the spin- x subspace and we define $\hat{b}_\pm = \hat{a} \pm \alpha = -\hat{\Pi}_b \hat{b}_\mp \hat{\Pi}_b$. The choice of x -basis is to better reflect the structure of $\hat{R}$. For the anticommutator part of Eq. (4),

$$\hat{R}^\dagger \hat{R} = \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_-^\dagger \hat{b}_- \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} = \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_+^\dagger \hat{b}_+ \end{pmatrix},$$

which is a shifted number operator with their direction of shift conditioned on the spin- x eigenvalue.

$$\mathcal{L}_R^\dagger \hat{J} = \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \begin{pmatrix} 0 & \hat{b}_-^\dagger \\ \hat{b}_-^\dagger & 0 \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \hat{J} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \begin{pmatrix} 0 & \hat{b}_- \\ \hat{b}_- & 0 \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} - \frac{1}{2} \hat{J} \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_+^\dagger \hat{b}_+ \end{pmatrix} - \frac{1}{2} \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_+^\dagger \hat{b}_+ \end{pmatrix} \hat{J} = 0.$$

By conjugation of controlled-parity unitary $\begin{pmatrix} \hat{\mathbb{I}}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix}$, we define $\hat{J} = \begin{pmatrix} \hat{\mathbb{I}}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \hat{J} \begin{pmatrix} \hat{\mathbb{I}}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} = \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\mathbb{I}}_b \end{pmatrix} \hat{J} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\mathbb{I}}_b \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix}$, we have

$$\begin{pmatrix} 0 & \hat{b}_-^\dagger \\ \hat{b}_-^\dagger & 0 \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \hat{J} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \begin{pmatrix} 0 & \hat{b}_- \\ \hat{b}_- & 0 \end{pmatrix} - \frac{1}{2} \hat{J} \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_-^\dagger \hat{b}_- \end{pmatrix} - \frac{1}{2} \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_-^\dagger \hat{b}_- \end{pmatrix} \hat{J} = 0.$$

We then apply the Hadamard transformation $\hat{H} = \frac{1}{\sqrt{2}} \begin{pmatrix} \hat{\mathbb{I}}_b & \hat{\mathbb{I}}_b \\ \hat{\mathbb{I}}_b & -\hat{\mathbb{I}}_b \end{pmatrix}$, which leads to

$$\begin{pmatrix} \hat{b}_-^\dagger & 0 \\ 0 & -\hat{b}_-^\dagger \end{pmatrix} \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} (\hat{H} \hat{J} \hat{H}) \begin{pmatrix} \hat{\Pi}_b & 0 \\ 0 & \hat{\Pi}_b \end{pmatrix} \begin{pmatrix} \hat{b}_- & 0 \\ 0 & -\hat{b}_- \end{pmatrix} - \frac{1}{2} (\hat{H} \hat{J} \hat{H}) \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_-^\dagger \hat{b}_- \end{pmatrix} - \frac{1}{2} \begin{pmatrix} \hat{b}_-^\dagger \hat{b}_- & 0 \\ 0 & \hat{b}_-^\dagger \hat{b}_- \end{pmatrix} (\hat{H} \hat{J} \hat{H}) = 0.$$

By defining $H \tilde{J} H = \begin{pmatrix} \hat{A} & \hat{B} \\ \hat{C} & \hat{D} \end{pmatrix}$, we have the following four independent equations:

$$\begin{aligned} \hat{b}_-^\dagger \hat{\Pi}_b \hat{A} \hat{\Pi}_b \hat{b}_- - \frac{1}{2} \{\hat{b}_-^\dagger \hat{b}_-, \hat{A}\} &= 0 \\ \hat{b}_-^\dagger \hat{\Pi}_b \hat{B} \hat{\Pi}_b \hat{b}_- + \frac{1}{2} \{\hat{b}_-^\dagger \hat{b}_-, \hat{B}\} &= 0 \\ \hat{b}_-^\dagger \hat{\Pi}_b \hat{C} \hat{\Pi}_b \hat{b}_- + \frac{1}{2} \{\hat{b}_-^\dagger \hat{b}_-, \hat{C}\} &= 0 \\ \hat{b}_-^\dagger \hat{\Pi}_b \hat{D} \hat{\Pi}_b \hat{b}_- - \frac{1}{2} \{\hat{b}_-^\dagger \hat{b}_-, \hat{D}\} &= 0. \end{aligned}$$

Solving for diagonal equations, we have $\hat{A} \propto \hat{\mathbb{I}}_b$ and $\hat{D} \propto \hat{\mathbb{I}}_b$ since the only conserved quantity of photon loss channel is $\hat{\mathbb{I}}_b$, the trivial solution, corresponding to the trivial unique steady state $|0\rangle\langle 0|_b$ of the photon loss channel. We then take the following two linear combinations: $\hat{H} \hat{J} \hat{H} = \begin{pmatrix} \hat{\mathbb{I}}_b & 0 \\ 0 & \hat{\mathbb{I}}_b \end{pmatrix} = \hat{\mathbb{I}}_s \otimes \hat{\mathbb{I}}_b$ and $\begin{pmatrix} \hat{\mathbb{I}}_b & 0 \\ 0 & -\hat{\mathbb{I}}_b \end{pmatrix} = \hat{\sigma}_x \otimes \hat{\mathbb{I}}_b$ to obtain the conserved quantities $\hat{J}_0 = \begin{pmatrix} \hat{\mathbb{I}}_b & 0 \\ 0 & \hat{\mathbb{I}}_b \end{pmatrix}$ and $\hat{J}_3 = \begin{pmatrix} 0 & \hat{\Pi}_b \\ \hat{\Pi}_b & 0 \end{pmatrix} = \hat{\sigma}_z \otimes \hat{\Pi}_b$ which give aforementioned diagonal conserved quantities $\hat{J}_{00}$, $\hat{J}_{11}$. The remaining two solutions are in the form of $\hat{J}_1 = \begin{pmatrix} \hat{K} & 0 \\ 0 & -\hat{\Pi}_b \hat{K} \hat{\Pi}_b \end{pmatrix}$ and $\hat{J}_2 = \begin{pmatrix} 0 & -\hat{K} \hat{\Pi}_b \\ \hat{\Pi}_b \hat{K} & 0 \end{pmatrix} = \hat{J}_3 \hat{J}_1 = -\hat{J}_1 \hat{J}_3$ where $\hat{K}$ is the solution of the off-diagonal equation, taken to be Hermitian without loss of generality, given by

$$\hat{b}_-^\dagger \hat{\Pi}_b \hat{K} \hat{\Pi}_b \hat{b}_- + \frac{1}{2} \{\hat{b}_-^\dagger \hat{b}_-, \hat{K}\} = 0. \quad (5)$$

Taking $\hat{B}$, $\hat{C}$ to be $\hat{K}$ and taking their sum (subtraction) gives $\hat{J}_1$ ($\hat{J}_2$). Orthogonality relations regarding off-diagonal quantities write

$$\text{Tr}[\hat{J}_1^\dagger |0\rangle\langle 1|_L] = \text{Tr}[\hat{J}_1^\dagger |1\rangle\langle 0|_L] = \text{Tr}[\hat{J}_2^\dagger |0\rangle\langle 1|_L] = -\text{Tr}[\hat{J}_2^\dagger |1\rangle\langle 0|_L] = \langle \alpha | \hat{K} | \alpha \rangle_b,$$

fixing $\langle \alpha | \hat{K} | \alpha \rangle_b = 1$ without loss of generality, we obtain the remaining off-diagonal conserved quantities $\hat{J}_{01} = \frac{1}{2}(\hat{J}_1 + \hat{J}_2)$ and $\hat{J}_{10} = \frac{1}{2}(\hat{J}_1 - \hat{J}_2)$.

II. LOGICAL ERROR RATES OF PHYSICAL NOISE

The error process $\mathcal{L}_E$ perturbatively manifests and induces the decay of the population of the initial state prepared to be the logical eigenstate. The symmetric transition rate γ_i between $|\psi_0^i\rangle$ and $|\psi_1^i\rangle$, the eigenstates of $\hat{\sigma}_i$, is given by the rate equation below:

$$\begin{aligned} \dot{p}_0^i &= -\gamma_i p_0^i + \gamma_i p_1^i, \\ \dot{p}_1^i &= \gamma_i p_0^i - \gamma_i p_1^i. \end{aligned}$$

Here, $p_j^i := \langle \psi_j^i | \hat{\rho} | \psi_j^i \rangle$ are population of each eigenstate for a given ensemble $\hat{\rho}$. Explicitly solving for t yields $p_j^i(t) = 1/2 + (p_j^i(0) - 1/2)e^{-2\gamma_i t}$.

Conserved quantities of the recovery dynamics can be used to perturbatively obtain the logical error rate for a given physical error channel $\kappa_E \mathcal{D}[\hat{E}]$, as they produce the population of the corresponding logical eigenstate in a given $\hat{\rho}(t)$, by taking the inner product:

$$\begin{aligned}\gamma_Z(\hat{E}) &\approx - \left(\frac{d}{dt} \text{Tr}[\hat{J}_{++}^\dagger e^{(\mathcal{L}_R + \mathcal{L}_E)t} |+\rangle \langle +|_L] \right) \Big|_{t=0} = -\kappa_E \text{Tr}[\hat{J}_{++}^\dagger \mathcal{D}[\hat{E}] (|+\rangle \langle +|_L)], \\ \gamma_X(\hat{E}) &\approx - \left(\frac{d}{dt} \text{Tr}[\hat{J}_{00}^\dagger e^{(\mathcal{L}_R + \mathcal{L}_E)t} |0\rangle \langle 0|_L] \right) \Big|_{t=0} = -\kappa_E \text{Tr}[\hat{J}_{00}^\dagger \mathcal{D}[\hat{E}] (|0\rangle \langle 0|_L)],\end{aligned}$$

respectively, and $\hat{J}_{++} := \frac{1}{2}(\hat{J}_0 + \hat{J}_1)$ satisfying $\text{Tr}[\hat{J}_{++}^\dagger |+\rangle \langle +|_L] = 1$. We start with the spin-z noise, the simplest error channel:

$$\gamma_Z(\hat{\sigma}_z) = \frac{\kappa_{\hat{\sigma}_z}}{2} (1 + \langle -\alpha | \hat{K} | -\alpha \rangle_b)$$

Then, evaluating $\langle -\alpha | \hat{K} | -\alpha \rangle$ is enough for calculating the first-order approximation of the error rate on the code space. We start from the Eq.(5) in the displaced frame ($\hat{A}' = \hat{D}^\dagger(\alpha) \hat{A} \hat{D}(\alpha)$).

$$\hat{a}^\dagger \hat{\Pi}'_b \hat{K}' \hat{\Pi}'_b \hat{a} + \frac{1}{2} \{ \hat{a}^\dagger \hat{a}, \hat{K}' \} = 0$$

Note that boundary terms other than $\langle 0 | \hat{K}' | 0 \rangle = \langle \alpha | \hat{K} | \alpha \rangle = 1$ banish $\langle m > 0 | \hat{K}' | 0 \rangle = \langle 0 | \hat{K}' | n > 0 \rangle = 0$. Let us define $F(z, w) := \langle z | \hat{K}' | w \rangle_B = e^{\frac{1}{2}(|z|^2 + |w|^2)} \langle z | \hat{K}' | w \rangle$, where $|z\rangle_B := e^{\frac{|z|^2}{2}} |z\rangle_b$ is the unnormalized coherent state [69] satisfying $\hat{a} |z\rangle_B = z |z\rangle_B$, $\hat{a}^\dagger |z\rangle_B = \partial_z |z\rangle_B$. The corresponding differential relation regarding the above equation is now written

$$z w e^{-4\alpha^2 - 2\alpha(z+w)} F(-2\alpha - z, -2\alpha - w) + \frac{1}{2} (z \partial_z + w \partial_w) F(z, w) = 0.$$

Introducing the relevant single variable function $h(x) := e^{-x^2} F(x, x) = \langle x | \hat{K}' | x \rangle_b$,

$$\frac{d}{dx} h(x) + 2x h(x) = -2x h(-2\alpha - x),$$

since $\frac{d}{dx} F(x, x) = (\partial_z + \partial_w) F(z, w) \Big|_{z=w=x}$. Defining $S(x) := h(x) + h(-2\alpha - x)$,

$$\frac{d}{dx} S(x) = -4(x + \alpha) S(x) \Rightarrow S(x) = e^{-4\alpha x - 2x^2} S(0).$$

Where $S(0) = h(0) + h(-2\alpha) = 1 + \langle -\alpha | \hat{K} | -\alpha \rangle$. Now evaluating $\int_0^{-2\alpha} dx h'(x)$ gives

$$\langle -\alpha | \hat{K} | -\alpha \rangle_b - 1 = -2(1 + \langle -\alpha | \hat{K} | -\alpha \rangle_b) \int_0^{-2\alpha} dx (x e^{-4\alpha x - 2x^2}).$$

Solving for $\langle -\alpha | \hat{K} | -\alpha \rangle$, we arrive at

$$\langle -\alpha | \hat{K} | -\alpha \rangle_b = \frac{1 - 2I(\alpha)}{1 + 2I(\alpha)}, \quad (6)$$

where

$$\begin{aligned}I(\alpha) &:= \int_0^{-2\alpha} dx (x e^{-4\alpha x - 2x^2}) = \alpha \sqrt{\frac{\pi}{2}} e^{2\alpha^2} \text{erf}(\sqrt{2}\alpha), \\ \text{erf}(x) &:= \frac{2}{\sqrt{\pi}} \int_0^x dt e^{-t^2},\end{aligned}$$

concluding derivation of $\gamma_Z(\hat{\sigma}_z) = \kappa_{\hat{\sigma}_z} / (1 + 2I(\alpha))$. Note that $\gamma_X(\hat{\sigma}_z) = 0$, since $\hat{J}_{00}^\dagger \mathcal{D}[\hat{\sigma}_z] \hat{\rho} = \mathcal{D}[\hat{\sigma}_z] (\hat{J}_{00}^\dagger \hat{\rho})$ and trace of dissipator is always zero.

For spin-x noise, $\mathcal{D}[\hat{\sigma}_x](|0\rangle\langle 0|_L) = |1\rangle\langle 1|_L - |0\rangle\langle 0|_L$ yields $\gamma_X(\hat{\sigma}_x) = \kappa_{\hat{\sigma}_x}$, and $\gamma_Z(\hat{\sigma}_x) = 0$ since $\mathcal{D}[\hat{\sigma}_x](|+\rangle\langle +|_L) = 0$. For loss,

$$\begin{aligned}\gamma_X(\hat{a}) &= -\kappa_{\hat{a}} \text{Tr}[\hat{J}_{00}^\dagger \mathcal{D}[\hat{a}] (|0\rangle\langle 0|_L)] \\ &= -\frac{\kappa_{\hat{a}}}{4} \text{Tr}[\mathcal{D}[\hat{a}] (|\alpha\rangle\langle \alpha|_b + |-\alpha\rangle\langle -\alpha|_b) + \hat{\Pi}_b \mathcal{D}[\hat{a}] (|\alpha\rangle\langle -\alpha|_b + |-\alpha\rangle\langle \alpha|_b)] \\ &= \kappa_{\hat{a}} \alpha^2, \\ \gamma_Z(\hat{a}) &= -\kappa_{\hat{a}} \text{Tr}[\hat{J}_{++}^\dagger \mathcal{D}[\hat{a}] (|+\rangle\langle +|_L)] \\ &= \frac{1}{2} \left(\alpha^2 - \frac{1}{2} \text{Tr}[\hat{K} \{ \hat{a}^\dagger \hat{a}, |\alpha\rangle\langle \alpha|_b \}] \right) \\ &= 0,\end{aligned}$$

where we used $\langle \alpha | \{ \hat{K}, \hat{a}^\dagger \hat{a} \} | \alpha \rangle = 2\alpha^2$, obtained from Eq. (5) and the boundary condition on $\hat{K}$, $\langle m > 0 | \hat{K}' | 0 \rangle = \langle 0 | \hat{K}' | n > 0 \rangle = 0$.

$$\langle \alpha | \hat{K} \hat{a}^\dagger \hat{a} | \alpha \rangle_b = \langle 0 | \hat{K}' (\hat{a}^\dagger + \alpha) (\hat{a} + \alpha) | 0 \rangle_b = \alpha^2,$$

and the same for $\hat{a}^\dagger \hat{a} \hat{K}$. Logical error rates from heating can be similarly obtained

$$\begin{aligned}\gamma_X(\hat{a}^\dagger) &= -\kappa_{\hat{a}^\dagger} \text{Tr}[\hat{J}_{00}^\dagger \mathcal{D}[\hat{a}^\dagger] (|0\rangle\langle 0|_L)] = \kappa_{\hat{a}^\dagger} (\alpha^2 + 1), \\ \gamma_Z(\hat{a}^\dagger) &= -\kappa_{\hat{a}^\dagger} \text{Tr}[\hat{J}_{++}^\dagger \mathcal{D}[\hat{a}^\dagger] (|+\rangle\langle +|_L)] = \frac{1}{1 + 2I(\alpha)},\end{aligned}$$

where we used Eq.(6). For bosonic dephasing,

$$\begin{aligned}\gamma_X(\hat{n}) &= -\kappa_{\hat{n}} \text{Tr}[\hat{J}_{00}^\dagger \mathcal{D}[\hat{n}] |0\rangle\langle 0|_L] \\ &= -\kappa_{\hat{n}} \text{Tr}[\mathcal{D}[\hat{n}] (\hat{J}_{00}^\dagger |0\rangle\langle 0|_L)] \\ &= 0, \\ \gamma_Z(\hat{n}) &= -\kappa_{\hat{n}} \text{Tr}[\hat{J}_{++}^\dagger \mathcal{D}[\hat{n}] |+\rangle\langle +|_L] \\ &= -\kappa_{\hat{n}} \text{Tr}[\hat{K} \mathcal{D}[\hat{n}] (|\alpha\rangle\langle \alpha|_b)] \\ &= \frac{\kappa_{\hat{n}} \alpha^2}{1 + 2I(\alpha)}.\end{aligned}$$

For the last equality in the derivation of $\gamma_Z(\hat{n})$, we used $\langle \alpha | \hat{n} \hat{K} \hat{n} | \alpha \rangle_b = \alpha^4 + \alpha^2 \langle 0 | \hat{a} \hat{K}' \hat{a}^\dagger | 0 \rangle_b = \alpha^4 - \alpha^2 \langle -\alpha | \hat{K}' | -\alpha \rangle_b = \alpha^4 - \alpha^2 \frac{1 - 2I(\alpha)}{1 + 2I(\alpha)}$ and $\langle \alpha | \hat{K} \hat{n}^2 | \alpha \rangle_b = \langle \alpha | \hat{n}^2 \hat{K} | \alpha \rangle_b = \alpha^4 + \alpha^2$, where $\langle 0 | \hat{a} \hat{K}' \hat{a}^\dagger | 0 \rangle_b = -\langle -\alpha | \hat{K}' | -\alpha \rangle_b$ can be obtained recursively from Eq. (5). Figure 6 shows the simulation result of AutoQEC dynamics in the rapid dissipation limit ($\kappa_R/\kappa_E = 10^4$), which agrees well with the perturbatively derived results.

FIG. 6. Logical error rates with respect to the state mean photon number $|\alpha|^2$. Simulations (real lines) are obtained in a rapid dissipation limit ($\kappa_R/\kappa_E = 10^4$). Theoretical estimates (dashed) derived in Section II and simulation results of dynamically stabilized cat states under equivalent parameters (dot-dashed) are also presented for comparison.

Optimal performance in resource-restricted correlation games

Abstract. We introduce and characterise a new class of correlation games where a player transforms a bipartite state into one approximating a maximally correlated state by acting on only one subsystem, where the player may have limited access to quantum resources, and closeness quantified with the fidelity. We derive the optimal achievable performance under these restrictions and show that these scenarios are governed by the noisy robustness; a measure defined relative to free and noise sets. The free set consists of states with local maximally mixed state, whilst the noise set is determined by the resources available to the player.

Keywords: Correlation games, resource theories, resource measures, entanglement, Schmidt number

Quantum *state correlation games* refer to operational tasks where a player is asked to transform a bipartite state into a state as close as possible to the maximally correlated state, this, by implementing transformations on only one side of the state, and by quantifying closeness in terms of the quantum fidelity [1]. This operational task was first put forward, to the best of our knowledge, in 2009 in the work of König, Renner, and Schaffner [1], which furthermore provided a characterisation of the optimal performance that a player can achieve in terms of the resource measure known as the *generalised* robustness of resource which, in particular, also allowed them to provide an operational interpretation to the min entropy. In this standard setup, it is assumed that the player is able to optimise over *all* possible local state transformations (local channels). In other words, that the player in question is a very capable agent who has access to *all* possible resources.

One natural and physically-motivated question that emerges from the above-mentioned scenario, concerns with the possibility of allowing situations where the player may now have limited access to resources. This is a physically relevant consideration to make, as the player in question may have only access to noisy or imperfect devices, and would consequently not be capable of implementing *all* possible game strategies that are in principle possible. In Fig. 1 we further describe and illustrate these resource-restricted scenarios.

In this work we follow this line of thought to introduce and characterise a new form of correlation games which we coin as *resource-restricted* correlation games, where the player is considered to have limited access to resources. We model this limited access to resources by invoking quantum resource theories (QRTs) of entanglement in terms of states with Schmidt number at most k ,

Figure 1: Resource-restricted quantum state correlation game. Single lines represent quantum information (quantum states). A referee asks a player to transform a fixed bipartite state ρ^{AB} into a state as close as possible to the maximally correlated state $\phi_+^{AA'}$, by means of local channels $\Lambda^{B \rightarrow A'}$. The states that the player can achieve are therefore of the form $\rho_{\Lambda}^{AA'} := (\text{id}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$. The player however has limited access to quantum resources and can only implement a subset of all possible local channels (CPTP maps) given by channels that can potentially degrade entanglement, and are therefore modelled by k -Schmidt number breaking and trace-preserving maps $\Lambda^{B \rightarrow A'} \in \mathcal{EB}_k - \mathcal{TP}$. What is the optimal performance that this resource-restricted player can achieve in this task? [Result 1](#) provides an answer to this question.

as well as the QRT of k -Schmidt number breaking channels. QRTs involving the Schmidt number depend on an integer k , with $k = 1$ recovering the standard QRT of entangled states, as well as the QRT of entanglement breaking channels, thus representing a fine-grained treatment of QRTs of entanglement. These QRTs are particularly appealing for correlation games because they naturally interpolate between the standard QRTs of entanglement (where the free set is the set of separable operators) and non-restricted scenarios (where the free set is trivially the set of all quantum states), thus modelling a wide range of resource-restricted agents, and consequently allowing for additional expressiveness of the

*andres.dg@ntu.edu.sg

†alejandro.aristizabal@correounivalle.edu.co

‡john.reina@correounivalle.edu.co

models. The main general result that we derive is that these physically-motivated *resource-restricted* extended correlation games, similarly to their non-restricted counterparts, can also elegantly be characterised by suitable resource measures, in this case by a resource measure that depends both on a free set and a noise set, which we here address as the *noisy* robustness of resource, and which we describe next.

1 Resource measures, Schmidt number at most k , and correlation games

We start by addressing some elements of quantum resource theories (QRTs) of states, resource measures, and describe state correlation games. Let $\mathcal{L}(\mathcal{H})$, $\mathcal{L}_S(\mathcal{H})$, $\mathcal{L}_+(\mathcal{H})$, be the sets of all linear, self-adjoint (Hermitian), and positive semi-definite operators, respectively, with $\mathcal{H}$ a finite-dimensional complex Hilbert space. Given a cone $\mathcal{F} \subseteq \mathcal{L}_S$, we use the notation $\overline{\mathcal{F}} := \{O \in \mathcal{F} \mid \text{Tr}[O] = 1\}$, and so $\overline{\mathcal{L}}_+$ is the set of quantum states. For closed convex cones $\mathcal{N} \subseteq \mathcal{L}_S$ and $\mathcal{F} \subseteq \mathcal{L}_+$, we now consider the resource measure of $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness of a quantum state ρ as:

$$R_{\mathcal{F}}^{\mathcal{N}}(\rho) := \min_{\substack{r \geq 0 \\ \sigma^F \in \overline{\mathcal{F}} \\ \sigma^N \in \overline{\mathcal{N}}}} \left\{ r \mid \rho + r \sigma^N = (1+r) \sigma^F \right\}. \quad (1)$$

We note that taking $\mathcal{N} \rightarrow \mathcal{L}_+$ recovers the *generalised robustness* (also known as global robustness), whilst $\mathcal{N} \rightarrow \mathcal{F}$ recovers the *free robustness* (also known as standard robustness). We address $\mathcal{N}$ as the “noise set”, and $\mathcal{F}$ as the “free set”. We now address QRTs of entanglement. Let $\mathcal{S}_k$, $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$ be the set of bipartite operators with Schmidt number at most k :

$$\mathcal{S}_k := \{O^{AB} \in \mathcal{L}_+(\mathcal{H}) \mid SN(O^{AB}) \leq k\}, \quad (2)$$

with the Schmidt number of a bipartite operator as [2]:

$$SN(O^{AB}) := \min_{\{p_k, \psi_k^{AB}\}} \max_k SR(\psi_k^{AB}), \quad (3)$$

with the minimisation over all possible decompositions of O^{AB} into (unnormalised) pure states $O^{AB} = \sum_k p_k \psi_k^{AB}$, p_K a probability mass function (PMF), and the Schmidt rank of a pure (unnormalised) state as $SR(\psi^{AB}) = k$ whenever the Schmidt decomposition is given by $|\psi\rangle^{AB} = \sum_{i=1}^k \sqrt{\lambda_i} |a\rangle_i^A |b\rangle_i^B$, $\lambda_i \geq 0$, $\forall i$, $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$, with $\{|a\rangle_m^A\}$ and $\{|b\rangle_n^B\}$ orthonormal bases of $\mathcal{H}^A$, $\mathcal{H}^B$, respectively [3]. Having defined the cones of bipartite operators with Schmidt number at most k , it is also going to be useful to invoke the set of maps that “break” this type of entanglement. A k -Schmidt number breaking map Λ is a completely-positive map such that $(\text{id}_k \otimes \Lambda)(O^{SA}) \in \mathcal{S}_k$, $\forall O^{SA} \in \mathcal{L}_+(\mathcal{H}^{SA})$. We denote the set of k -Schmidt number breaking maps as $\mathcal{SB}_k$. We note that $k = 1$ recovers the standard set of entanglement-breaking maps. Finally, an important set later on is the cone of bipartite operators with identity on party A:

$$\text{IA} := \{\mathbb{1}^A \otimes \tilde{\sigma}^B \mid \tilde{\sigma}^B \in \mathcal{L}_+\}. \quad (4)$$

Bipartite states with Schmidt number at most k have been explored as QRTs of states [4]. Entanglement breaking and more generally k -Schmidt number breaking channels have also been explored as a QRT of channels (or memories) [5, 6, 7]. We now describe state correlation games.

Definition 1. (*State correlation games* [1]) A state correlation game is an operational task where a player is asked to take a bipartite state ρ^{AB} as close as possible to the maximally correlated state $\phi_+^{AA'} = |\phi_+\rangle\langle\phi_+|^{AA'}$, $|\phi_+\rangle^{AA'} := (1/\sqrt{d_A}) \sum_{i=1}^{d_A} |ii\rangle^{AA'}$ by implementing actions on only one side of the state, say B , so that the accessible states are $\rho_{\Lambda}^{AA'} := (\text{id}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$, with $\Lambda \equiv \Lambda^{B \rightarrow A'}$ a CPTP map [1]. The figure of merit for this game is the fidelity between the final state and the maximally correlated state as $F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'})$. In a state correlation game the goal of the player is therefore to maximise such fidelity.

State correlation games were first introduced by König, Renner, and Schaffner [1]. In particular, state correlation games were studied in [1] by allowing the player to optimise over all possible local channels. In this work we take one further step and consider *resource-restricted* state correlation games which we describe below.

Definition 2. (*Resource-restricted state correlation games*) Similarly to their un-restricted counterparts, a resource-restricted state correlation game is an operational task where a player is asked to take the bipartite state ρ^{AB} as close as possible to the maximally correlated state $\phi_+^{AA'}$, by implementing actions on only one side of the state, say B , so that the accessible states are $\rho_{\Lambda}^{AA'} := (\text{id}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$. The main difference is that now the player may have limited quantum resources for the implementation of the local channel $\Lambda^{B \rightarrow A'}$, so that it can only optimise over k -Schmidt number breaking and trace preserving maps $\mathcal{SB}_k - \mathcal{TP}$, for some $k \in \{1, \dots, d'\}$, $d' = \min\{d_A, d_B\}$ [1]. The figure of merit is similarly the fidelity between the final state and the maximally correlated state as $F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'})$. We are interested in maximising the figure of merit for resource-restricted state correlation games as:

$$\max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'}). \quad (5)$$

In Fig. 1 we illustrate this scenario. We are now ready to establish the first main result in this work.

2 Characterisation of resource-restricted state correlation games

Result 1. (*Optimal performance in resource-restricted state correlation games*) Consider a state correlation game where the player is asked to take the state ρ^{AB} as close as possible to the maximally correlated state $\phi_+^{AA'}$ by implementing actions on party B . We quantify the performance with the fidelity. For any bipartite quantum state ρ^{AB} , and any $k \in \{1, \dots, d'\}$, $d' := \{d_A, d_B\}$ we have:

$$\max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'}) = \frac{1}{d} \left[1 + R_{\text{IA}}^{\circ_k}(\rho^{AB}) \right], \quad (6)$$

with the maximisation over all k -Schmidt number breaking trace-preserving maps $\Lambda \equiv \Lambda^{B \rightarrow A'}$, the quantum state $\rho_{\Lambda}^{AA'} := (\mathbb{1}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$, and the noisy robustness measure with free cone IA (the cone of bipartite operators with identity in part A as $\mathbb{1}^A \otimes \tilde{\sigma}^B$, $\tilde{\sigma}^B \geq 0$), and the noise set given by the dual cone of the set of bipartite operators with Schmidt number at most k .

The proof of this statement relies on identifying that the optimisation in the left hand side can be written as a conic program, after which duality theory can be employed. The proof requires a couple of intermediate lemmas and so the full proof is provided in the main manuscript. We however provide a sketch of this below. *Proof.* (Sketch) We can rewrite:

$$\begin{aligned} & \max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} d F(\rho_{\Lambda}^{AA'}, \phi_{+}^{AA'}) \\ & \stackrel{1}{=} \max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} d \text{Tr}[(\mathbb{1}^A \otimes \Lambda)(\rho^{AB}) \phi_{+}^{AA'}] \end{aligned} \quad (7)$$

$$\stackrel{2}{=} \max_{\Lambda^{\dagger} \in \mathcal{SB}_k - \mathcal{U}} d \text{Tr}[\rho^{AB}(\mathbb{1}^A \otimes \Lambda^{\dagger})(\phi_{+}^{AA'})] \quad (8)$$

$$\stackrel{3}{=} \max_{d J_{\Lambda^{\dagger}}^{AB} \in \mathcal{S}_k, \text{Tr}_A[d J_{\Lambda^{\dagger}}^{AB}] = d_A \mathbb{1}^B} \text{Tr}[\rho^{AB}(d J_{\Lambda^{\dagger}}^{AB})]. \quad (9)$$

In the first line we use that the fidelity between a quantum state and a pure state reads $F(\rho, |\psi\rangle\langle\psi|) = \text{Tr}[\rho|\psi\rangle\langle\psi|]$, and replace $\rho_{\Lambda}^{AA'}$. In the second line we use that the dual of a $\mathcal{SB}_k - \mathcal{TP}$ (k -entanglement-breaking and trace-preserving) map is a $\mathcal{SB}_k - \mathcal{U}$ (k -entanglement breaking and unital) map. In the third line we introduce the Choi–Jamiołkowski (CJ) operator:

$$J_{\Lambda^{\dagger}}^{AB} := (\text{id}^A \otimes \Lambda^{\dagger})(\phi_{+}^{AA'}). \quad (10)$$

Taking into account that the map $\Lambda^{\dagger}$ is $\mathcal{SB}_k - \mathcal{U}$, in the full manuscript we show that its CJ-operator satisfies the two properties: i) $J_{\Lambda^{\dagger}}^{AB} \in \mathcal{S}_k$ (Schmidt number at most k), and ii) $\text{Tr}_A[J_{\Lambda^{\dagger}}^{AB}] = \frac{\mathbb{1}^B}{d_B}$, which implies $\text{Tr}_A[d J_{\Lambda^{\dagger}}^{AB}] = d_A \mathbb{1}^B$, $d = d_A d_B$. Consider now a QRT of bipartite states with free set $\overline{\text{IA}}$ given by states of the form $\sigma^{AB} = (\mathbb{1}^A/d_A) \otimes \sigma^B$, with σ^B a state. In the main manuscript we then use duality theory to show that:

$$\begin{aligned} & \max_{d J_{\Lambda^{\dagger}}^{AB} \in \mathcal{S}_k, \text{Tr}_A[d J_{\Lambda^{\dagger}}^{AB}] = d_A \mathbb{1}^B} \text{Tr}[\rho^{AB}(d J_{\Lambda^{\dagger}}^{AB})] = 1 + R_{\text{IA}}^{\mathcal{S}_k}(\rho^{AB}), \end{aligned}$$

thus achieving the claim.

We now analyse [Result 1](#). First, this result is a general statement that holds for all bipartite quantum states ρ^{AB} as well as for all integers $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$. To the best of our knowledge, only the case $k = d'$ has been reported before [\[1\]](#). In this latter particular case, the set of k -Schmidt breaking channels in the left hand side becomes the set of all completely positive maps $\mathcal{SB}_{d'} = \mathcal{CP}$, which naturally represents a situation where the player in question is a very capable agent who can implement *all* possible local channels. In this same case ($k = d'$), in the right hand side the noise set reduces to the set of positive semidefinite operators as

$\mathcal{S}_{d'}^{\circ} = \mathcal{L}_{+}^{\circ} = \mathcal{L}_{+}$, and consequently the *noisy* robustness measure becomes the *generalised* robustness $R_{\text{IA}}^{\mathcal{L}_{+}}(\rho^{AB})$, thus explicitly recovering the result by König, Renner, and Schaffner [\[1\]](#). We collect this in the following corollary.

Corollary 1. (Optimal performance in resource-unrestricted state correlation games [\[1\]](#)) Taking $k = d'$, for any bipartite quantum state ρ^{AB} we have:

$$\max_{\Lambda \in \mathcal{CP} - \mathcal{TP}} F(\rho_{\Lambda}^{AA'}, \phi_{+}^{AA'}) = \frac{1}{d} [1 + R_{\text{IA}}^{\mathcal{L}_{+}}(\rho^{AB})]. \quad (11)$$

We now continue with the analysis of [Result 1](#). In addition to $k = d'$, the statement holds for all $k \in \{1, \dots, d'\}$, and so we can analyse, in particular, the performance for different values of k . Let us fix two values of this parameter, say $k_1 < k_2$. Analysing first the left hand side, this represents a situation where the k_1 -player is less capable than the k_2 -player, as the second player can implement a larger set of local channels. This situation gets immediately translated to the right hand side since, due to the properties of the noisy robustness of resource, we have $R_{\text{IA}}^{\mathcal{S}_{k_1}}(\rho^{AB}) \leq R_{\text{IA}}^{\mathcal{S}_{k_2}}(\rho^{AB})$, thus telling us, as one can naturally expect, that having access to a larger pool of resources (local channels in this case) leads to a potentially larger performance. The two extremes at $k = 1$ and $k = d'$ thus represent the performance, respectively, of the least capable player (one that can only implement entanglement-breaking channels) and the most capable player (one that can implement *all* possible local channels).

In the main manuscript we furthermore introduce state *anti-correlation* games where the task is now to get as far as possible from a target maximally correlated state, and derive bounds for the optimal performance in such games. Moreover, we also introduce *measurement simulation* games, where the objective for the player is now to simulate ideal target measurements.

Conclusion.— [Result 1](#) establishes a general link between operational tasks in the form of *resource-restricted* correlation games and resource measures in the realm of quantum resource theories. Resource-restricted correlation games emerge as a physically motivated scenario where the player is allowed to have limited access to quantum resources, thus modelling realistic situations where players may have access only to noisy or imperfect devices. We show that, similarly to their unrestricted counterpart, that resource-restricted correlation games can also elegantly be characterised by resource measures, in this case by the *noisy* robustness of resource, thus establishing a solid theoretical bridge between resource-restricted operational tasks and resource measures. We believe that allowing players to be “resource-restricted” is an ubiquitous idea that can have further implications and ramifications on other tasks and areas within quantum information theory.

We introduce and characterise various new forms of correlation and simulation games to be played with quantum states and measurements, respectively, where the player may have limited access to quantum resources and is therefore considered resource-restricted. The state correlation game here considered refers to an operational task where the goal is to transform a bipartite state into a state close to the maximally correlated state, by implementing allowed transformations on only one part of the state, and with closeness being quantified by the fidelity. We derive the optimal performance that a resource-restricted player can achieve when playing state correlation games, and show that these resource-restricted scenarios are characterised by the *noisy* robustness of resource; a resource measure that depends both on a free set and a noise set. In particular, the free set relevant for the above scenario is the set of states with local maximally mixed state, whilst the noise set on the other hand is determined by the type of resources that the player is capable of implementing. Moreover, we introduce operational tasks for quantum measurements in the form of measurement simulation games, where the objective is to use a fixed bipartite measurement to simulate the maximally correlated measurement (Bell measurement), this, by means of local quantum pre-processing and classical post-processing. Similarly to the case for states, we prove that resource-restricted measurement simulation games are characterised by the *noisy* robustness of measurements, with the free set given by the set of local measurements, whilst the noise set being determined by the type of resources the player is capable of implementing.

I. INTRODUCTION

The theoretical framework of quantum resource theories (QRTs) has proven to be a fruitful approach for the development of quantum information science during the past few decades [1]. In this formalism, desirable properties of the mathematical constituents of the theory of quantum information are identified and classified as potential resources to be harnessed for the development of operational tasks and information-theoretic protocols [1]. There is a myriad of quantum objects of potential interest including: quantum states [2, 3], measurements [4–6], sets of measurements [7, 8], behaviours or boxes [9, 10], steering assemblages [11], teleportation assemblages [12], channels [13–16], amongst many others [1, 17–20]. Similarly, there are plenty of properties to be exploited as resources such as: entanglement [3], coherence [21], asymmetry [21], superposition [22], purity [23], magic [24], non-gaussianity [25], non-markovianity [26–30], measurement informativeness [31–33], non-projective measurement simulability [34], amongst many others [1].

There are several areas of active research within QRTs including: identification, classification, and quantification of quantum resources, as well as the identification and characterisation of operational tasks exploiting those resources, such as discrimination and exclusion

games, one-shot and asymptotic convertibility between resources, amongst several other tasks [1]. In particular, regarding the development of operational tasks and their characterisation in terms of resource measures, operational tasks based on the discrimination of quantum objects have been found to be linked to robustness-type resource measures. In a similar manner, exclusion-based operational tasks have been linked to a different family of resource measures known as weight-based resource measures. These connections have further been extended to include information-theoretic quantities such as mutual information measures, thus establishing important links between these a priori unrelated areas of research. In addition to discrimination and exclusion based operational tasks, there is also a family of tasks known as *correlation games* [35], which have also been found to be related to resource measures, and which are the main subject of study in this work.

The paradigmatic example of a correlation game, which we address here as a *state correlation game*, refers to an operational task where a player is asked to transform a bipartite state into a state as close as possible to the maximally correlated state, this, by implementing transformations on only one side of the state, and by quantifying closeness in terms of the quantum fidelity [35]. This operational task was first put forward, to the best of our knowledge, in 2009 in the work of König, Renner, and Schaffner [35], which furthermore provided a characterisation of the optimal performance that a player can achieve in terms of the resource measure known as the *generalised* robustness of resource which, in particu-

* andres.dg@ntu.edu.sg

† alejandro.aristizabal@correounivalle.edu.co

‡ john.reina@correounivalle.edu.co

lar, also allowed them to provide an operational interpretation to the min entropy. A first observation regarding this result is, that the resource measure in question is with respect to the free set of states with local maximally mixed state. A second observation and one which would constitute one of the main motivations behind this work, is that the player in this setup is assumed to be able to optimise over *all* possible local state transformations (local channels). In other words, that the player in question is a very capable agent who has access to *all* possible resources.

Taking into account these observations, one natural and physically-motivated question that emerges from the two above-mentioned scenario, concerns with the possibility of allowing situations where the player may now have limited access to resources. This is a physically relevant consideration to make, as the player in question may have only access to noisy or imperfect devices, and would consequently not be capable of implementing *all* possible game strategies that are in principle possible. In this work we follow this line of thought to introduce and characterise various new forms of correlation games which we coin as *resource restricted* correlation games, where the players are considered to have limited access to resources. We model this limited access to resources by invoking QRTs of entanglement in terms of states and measurements with Schmidt number at most k , as well as the QRT of k -Schmidt number breaking channels. QRTs involving the Schmidt number depend on an integer k , with $k = 1$ recovering the standard QRT of entangled states and measurements, as well as the QRT of entanglement breaking channels, thus representing a fine-grained treatment of QRTs of entanglement. These QRTs are particularly appealing for these correlation games because they naturally interpolate between the standard QRTs of entanglement (where the free set is the set of separable operators) and non-restricted scenarios (where the free set is trivially the set of all quantum states), thus modelling a wide range of resource-restricted agents, and consequently allowing for additional expressiveness in the models. The main general result that we provide in this manuscript is that these physically-motivated resource-restricted extended correlation games, similarly to their non-restricted counterparts, can also elegantly be characterised by suitable resource measures, in this case by a resource measure that depends both on a free set and a noise set, and which we here address here as the *noisy* robustness of resource. We succinctly summarise these findings as follows.

In the first part of this work we derive the optimal performance in resource-restricted *state correlation* games. We show that these resource-restricted scenarios are characterised by the *noisy* robustness of resource. In particular, the free set relevant for the above resource measure is the set of states with local maximally mixed state, whilst the noise set is determined by the types of resources that the player is capable of implementing. Moreover, we introduce a new variant of correlation games

which we coin *state anti-correlation* games, where the objective is now for the player to minimise (as opposed to maximise) the fidelity between a given state and the maximally correlated state. In this new regime, we similarly derive the optimal performance that resource-restricted agents can achieve, and show that it can be characterised by a measure we coin the *noisy* weight of resource, a resource measure that similarly depends on free and noise sets, and that recovers the usual weight of resource as an appropriate limit.

In the second part of this work, we introduce analogue operational tasks for quantum measurements in the form of measurement simulation and anti-simulation games, where the objective is now for the player to use a fixed bipartite measurement in order to simulate (anti-simulate) the maximally correlated measurement (Bell measurement), this, by using local quantum pre-processing together with classical post-processing strategies. Similarly to the case for states, we prove that the optimal performance in these *resource-restricted* measurement simulation (anti-simulation) games is characterised by the *noisy*-robustness (*noisy*-weight) of measurements, with the free set given by the set of local measurements, and the noise set being determined by the type of simulation resources that the player is capable of implementing.

This document is organised as follows. In [Section II](#) we start with resource measures for quantum states and describe state correlation and anti-correlation games. In [Section III](#) we derive the optimal performance achieved by resource-restricted players in state correlation and anti-correlation games. We then move on to quantum resource theories of measurements. In [Section IV](#) we address resource measures for measurements and introduce measurement simulation and anti-simulation games. In [Section V](#) we derive the optimal performance that resource-restricted players can achieve in measurement simulation and anti-simulation games. In [Section VI](#) we finish with conclusions and perspectives.

II. RESOURCE MEASURES AND CORRELATION GAMES FOR STATES

In this section we address some elements of quantum resource theories (QRTs) of states, resource measures, and introduce state correlation and anti-correlation games. Starting with QRTs of quantum states, consider a finite-dimensional complex Hilbert space $\mathcal{H}$, and let $\mathcal{L}(\mathcal{H})$, $\mathcal{L}_S(\mathcal{H})$, $\mathcal{L}_+(\mathcal{H})$, be the sets of all linear, self-adjoint (hermitian), and positive semi-definite operators, respectively. Given a cone $\mathcal{F} \subseteq \mathcal{L}_S$, we use the notation $\bar{\mathcal{F}} := \{O \in \mathcal{F} \mid \text{Tr}[O] = 1\}$, and so $\bar{\mathcal{L}}_+$ is the set of quantum states. For closed convex cones $\mathcal{N} \subseteq \mathcal{L}_S$ and $\mathcal{F} \subseteq \mathcal{L}_+$, we now consider the resource measure of $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness and the $\mathcal{N}$ -noisy $\mathcal{F}$ -weight of a

quantum state ρ as:

$$R_{\mathcal{F}}^{\mathcal{N}}(\rho) := \min_{\substack{r \geq 0 \\ \sigma^F \in \mathcal{F} \\ \sigma^N \in \mathcal{N}}} \left\{ r \mid \rho + r \sigma^N = (1+r) \sigma^F \right\}, \quad (1)$$

$$W_{\mathcal{F}}^{\mathcal{N}}(\rho) := \min_{\substack{w \geq 0 \\ \sigma^F \in \mathcal{F} \\ \sigma^N \in \mathcal{N}}} \left\{ r \mid \rho = (1-w) \sigma^F + w \sigma^N \right\}. \quad (2)$$

We note that taking $\mathcal{N} \rightarrow \mathcal{L}_+$ recovers the *generalised robustness* (also known as global robustness), whilst $\mathcal{N} \rightarrow \mathcal{F}$ recovers the *free robustness* (also known as standard robustness). We address $\mathcal{N}$ as the “noise set”, and $\mathcal{F}$ as the “free set”. We are now in particular interested in QRTs of entanglement. Let $\mathcal{S}_k$, $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$ be the set of bipartite operators with Schmidt number at most k :

$$\mathcal{S}_k := \{O^{AB} \in \mathcal{L}_+(\mathcal{H}) \mid SN(O^{AB}) \leq k\}, \quad (3)$$

with the Schmidt number of a bipartite operator as [36]:

$$SN(O^{AB}) := \min_{\{p_k, \psi_k^{AB}\}} \left\{ \max_k SR(\psi_k^{AB}) \right\}, \quad (4)$$

with the minimisation over all possible decompositions of O^{AB} into (unnormalised) pure states $O^{AB} = \sum_k p_k \psi_k^{AB}$, p_k a probability mass function (PMF), and the Schmidt rank of a pure (unnormalised) state as $SR(\psi^{AB}) = k$ whenever the Schmidt decomposition is given by $|\psi\rangle^{AB} = \sum_{i=1}^k \sqrt{\lambda_i} |a_i\rangle^A |b_i\rangle^B$, $\lambda_i \geq 0$, $\forall i$, $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$, with $\{|a_m\rangle_m^A\}$ and $\{|b_n\rangle_n^B\}$ orthonormal bases of $\mathcal{H}^A$, $\mathcal{H}^B$, respectively [37]. Having defined the cones of bipartite operators with Schmidt number at most k , it is also going to be useful to invoke sets of channels that break this type of entanglement. A k -Schmidt number breaking map Λ is a completely-positive map such that $(\text{id}_k \otimes \Lambda)(O^{SA}) \in \mathcal{S}_k$, $\forall O^{SA} \in \mathcal{L}_+(\mathcal{H}^{SA})$. We denote the set of k -Schmidt number breaking channels as $\mathcal{SB}_k$. We note that $k = 1$ recovers the standard set of entanglement-breaking maps. Finally, an important set later on is the cone of bipartite operators with identity on part A:

$$\text{IA} := \{\mathbb{1}^A \otimes \tilde{\sigma}^B \mid \tilde{\sigma}^B \in \mathcal{L}_+\}. \quad (5)$$

The Schmidt number has been explored as a QRT of states [38]. Entanglement breaking and more generally k -Schmidt number breaking channels have also been explored as a QRT of channels (or memories) [39–41]. We now move on to describe state correlation and anti-correlation games.

Definition 1. (*State correlation and anti-correlation games* [35]) A state correlation (anti-correlation) game is an operational task where a player is asked to take the bipartite state ρ^{AB} as close (far) as possible to (from) the maximally correlated state $\phi_+^{AA'} = |\phi_+\rangle\langle\phi_+|^{AA'}$,

$|\phi_+^{AA'}\rangle := (1/\sqrt{d_A}) \sum_{i=1}^{d_A} |ii\rangle^{AA'}$ by implementing actions on only one side of the state, say B, so that the accessible states are $\rho_{\Lambda}^{AA'} := (\text{id}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$, with $\Lambda \equiv \Lambda^{B \rightarrow A'}$ a CPTP map [35]. The figure of merit for this game is the fidelity between the final state and the maximally correlated state as $F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'})$. In a state correlation (anti-correlation) game the goal of the player is therefore to maximise (minimise) such fidelity.

State correlation games were first introduced by König, Renner, and Schaffner [35]. Anti-correlation games on the other hand, and up to the best of our knowledge, have not been explored in the literature. In particular, state correlation games were studied in [35] by allowing the player to optimise over all possible local channels. In this work we take one further step and consider *resource-restricted* state correlation games which we describe below.

Definition 2. (*Resource-restricted state correlation and anti-correlation games*) Similarly to their un-restricted counterparts, a resource-restricted state correlation (anti-correlation) game is an operational task where a player is asked to take the bipartite state ρ^{AB} as close (far) as possible to (from) the maximally correlated state $\phi_+^{AA'}$, by implementing actions on only one side of the state, say B, so that the accessible states are $\rho_{\Lambda}^{AA'} := (\text{id}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$. The main difference is that now the player is assumed to have limited quantum resources for the implementation of the local channel $\Lambda^{B \rightarrow A'}$, and so it is now considered a k -Schmidt number breaking and trace preserving map $\mathcal{SB}_k - \mathcal{TP}$ map, for some $k \in \{1, \dots, d'\}$, $d' = \min\{d_A, d_B\}$ [35]. The figure of merit is similarly considered as the fidelity between the final state and the maximally correlated state as $F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'})$. We are interested in maximising (minimising) the figure of merit for state correlation (anti-correlation) games, and so we are then interested in the quantities:

$$\max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'}), \quad \min_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'}). \quad (6)$$

In Fig. 1 we further describe and illustrate this game.

III. OPTIMAL PERFORMANCE IN RESOURCE-RESTRICTED CORRELATION AND ANTI-CORRELATION GAMES

In this section we start the main results in this work by quantifying the optimal performance achieved by resource-restricted players in state correlation and anti-correlation games.

Result 1. (*Optimal performance in resource-restricted state correlation games*) Consider a state correlation game where the player is asked to take the state ρ^{AB} as close as possible to the maximally correlated state $\phi_+^{AA'}$ by

FIG. 1. Resource-restricted quantum state correlation game. Single lines represent quantum information (quantum states). A referee asks a player to transform a fixed bipartite state ρ^{AB} into a state as close as possible to the maximally correlated state $\phi_+^{AA'}$, by means of local channels $\Lambda^{B \rightarrow A'}$. The states that the player can achieve are therefore of the form $\rho_\Lambda^{AA'} := (\text{id}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$. The player however has limited access to quantum resources and can only implement a subset of all possible local channels (CPTP maps) given by channels that can potentially degrade entanglement, and are therefore described by l -Schmidt number breaking and trace-preserving maps as $\Lambda^{B \rightarrow A'} \in \mathcal{EB}_l - \mathcal{TP}$. What is the optimal performance that this player can achieve in this task? in [Result 1](#) we provide an answer to this question.

implementing actions on party B . We quantify the performance with the fidelity. For any bipartite quantum state ρ^{AB} we have:

$$\max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} F(\rho_\Lambda^{AA'}, \phi_+^{AA'}) = \frac{1}{d} [1 + R_{\text{IA}}^{\mathcal{S}_k^\circ}(\rho^{AB})], \quad (7)$$

with the maximisation over all k -Schmidt number breaking trace-preserving maps $\Lambda \equiv \Lambda^{B \rightarrow A'}$, the quantum state $\rho_\Lambda^{AA'} := (\mathbb{1}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$, and the noisy robustness measure with free cone IA (the cone of bipartite operators with identity in part A as $\mathbb{1}^A \otimes \sigma^B$, $\sigma^B \geq 0$), and noise set given by the dual cone of bipartite operators with Schmidt number at most k .

The proof of this statement relies on identifying that the optimisation in the left hand side can be written as a conic program, after which duality theory can be employed. The proof requires a couple of intermediate lemmas and so the full proof is provided in [Appendix C](#). We now analyse this result. First, the result holds for all bipartite quantum states ρ^{AB} as well as for all integers $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$. To the best of our knowledge, only the case $k = d'$ had been reported before. In this particular case, the set of k -Schmidt breaking channels in the left hand side becomes the set of all completely positive maps $\mathcal{SB}_{d'} = \mathcal{CP}$, which naturally represents a situation where player in question is a very capable agent who can implement *all* possible local channels. In the right hand side, the noisy set reduces to the set of positive semidefinite operators $\mathcal{S}_{d'}^\circ = \mathcal{L}_+^\circ = \mathcal{L}_+$, and consequently the noisy robustness measure becomes the generalised robustness $R_{\text{MMA}}^{\mathcal{L}_+}(\rho^{AB})$, thus explicitly recovering the result by König, Renner, and Schaffner [\[35\]](#). We collect this in the following corollary.

Corollary 1. (Optimal performance in resource-unrestricted state correlation games [\[35\]](#)) Consider a state correlation game where the player is asked to take the state ρ^{AB} as close as possible to the maximally correlated state $\phi_+^{AA'}$ by implementing actions on party B . The player in question is a very capable agent that can implement all possible local channels. For any bipartite quantum state ρ^{AB} we have:

$$\max_{\Lambda \in \mathcal{CP} - \mathcal{TP}} F(\rho_\Lambda^{AA'}, \phi_+^{AA'}) = \frac{1}{d} [1 + R_{\text{IA}}^{\mathcal{L}_+}(\rho^{AB})], \quad (8)$$

with the maximisation over all completely-positive trace-preserving maps $\Lambda \equiv \Lambda^{B \rightarrow A'}$, the quantum state $\rho_\Lambda^{AA'} := (\mathbb{1}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$, and the generalised robustness measure with free cone IA (the cone of bipartite operators of the form $\mathbb{1}^A \otimes \tilde{\sigma}^B$, $\tilde{\sigma}^B \geq 0$).

We continue with the analysis of [Result 1](#). In addition to $k = d'$, the statement holds for all $k \in \{1, \dots, d'\}$, and so we can analyse, in particular, the performance for different values of k . Let us fix two values of this parameter, say $k_1 < k_2$. Analysing first the left hand side, this represents a situation of the k_1 -player being less capable than the k_2 -player, as the second player can implement a larger set of local channels. This situation gets immediately translated to the right hand side since, due to the properties of the noisy robustness of resource, we have $R_{\text{MMA}}^{\mathcal{S}_{k_1}^\circ}(\rho^{AB}) < R_{\text{MMA}}^{\mathcal{S}_{k_2}^\circ}(\rho^{AB})$, thus telling us, as one can naturally expect, that more having access to a larger pool of resources (local channels in this case) leads to a larger performance. The two extremes $k = 1$ and $k = d'$ thus represent the performance of the least capable player (can only implement entanglement-breaking channels) and the most capable player (as it can implement *all* local channels). We now move on to address state anti-correlation games.

Result 2. (Optimal performance in resource-restricted state anti-correlation games) Consider a state anti-correlation game where the player is asked to take the state ρ^{AB} as far as possible from the maximally correlated state $\phi_+^{AA'}$ by implementing actions on party B . We quantify the performance with the fidelity. For any bipartite quantum state ρ^{AB} we have:

$$\min_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} F(\rho_\Lambda^{AA'}, \phi_+^{AA'}) = \frac{1}{d} [1 - W_{\text{IA}}^{\mathcal{S}_k^\circ}(\rho^{AB})]. \quad (9)$$

with the minimisation over all k -Schmidt number breaking trace-preserving maps $\Lambda \equiv \Lambda^{B \rightarrow A'}$, the quantum state $\rho_\Lambda^{AA'} := (\mathbb{1}^A \otimes \Lambda^{B \rightarrow A'}) (\rho^{AB})$, and the noisy weight measure with free set MMA (the set of quantum states which are maximally mixed in part A as $(\mathbb{1}^A/d_A) \otimes \sigma^B$, σ^B a quantum state), and noise set given by the dual cone of bipartite operators with Schmidt number at most k .

The proof of this result relies on conic programming and some intermediate auxiliary lemmas. The full proof of this statement is provided in [??](#). Similar to result 1,

this result also holds very generally for all bipartite quantum states ρ^{AB} as well as all integers $k \in \{1, \dots, d'\}$. Unlike the case for correlation games however, and to the best of our knowledge, all the situations for values of k , even the case $k = d'$ are new. This latter case corresponds to a powerful player that can implement all possible local channels. We can also perform an analysis for different values of this parameters whilst keeping other things equal. In words, this translates to players that have access to a larger pool of local channels, can perform better at anti-correlation games, as one can also intuitively expect. It is worth noting that, despite anti-correlation games being a different task than standard correlation games, the optimal performance in this game can still elegantly be quantified by a resource measure, the noisy weight of resource in this case. This result however establishes an explicit quantitative achievable lower bound on the optimal performance achieve by the player, the more resourceful the ρ^{AB} is, the lower is the right hand size, and therefore the larger the advantage this player achieves. We can alternative phrase this result as maximising the infidelity, in which case it reads as follows.

Observation 1. (*Optimal performance in state anti-correlation games as infidelity maximisation games*) The minimum fidelity achievable in a correlation game, where the player acts on system B using a k -entanglement breaking and trace-preserving map, satisfies:

$$\max_{\Lambda \in \mathcal{EB}_k - \mathcal{TP}} I(\rho_{\Lambda}^{AA'}, \phi_{+}^{AA'}) = \frac{1}{d} [d - 1 + W_{\text{IA}}^{S_k^0}(\rho^{AB})]. \quad (10)$$

This finishes the quantification of the optimal performance in resource restricted correlation and anti-correlation games, and we now move on to explore resource measures and games for quantum measurements.

IV. RESOURCE MEASURES AND SIMULATION GAMES FOR MEASUREMENTS

In this section we address some elements of quantum resource theories (QRTs) of measurements, resource measures, and introduce measurement simulation and anti-simulation games. For QRTs of measurements we use the following notation. Consider the set of k -tuples of self-adjoint operators as $\mathcal{L}_S^{(k)} := \{\{O_a\}_{a=1}^k \mid O_a \in \mathcal{L}_S\}$. For any cone of k -tuples $\mathcal{F}^{(k)} \subseteq \mathcal{L}_S^{(k)}$ we use the notation $\overline{\mathcal{F}}^{(k)} := \{\{O_a\}_{a=1}^k \in \mathcal{F}^{(k)} \mid \sum_{a=1}^k O_a = \mathbb{1}\}$, and so $\overline{\mathcal{L}}_+^{(k)}$ is the set of all measurements with k outcomes. We interchangeably address a measurement $\{M_a\}$ as a positive operator-valued measure (POVM). For closed convex cones $\mathcal{N}^{(k)} \subseteq \mathcal{L}_S^{(k)}$ and $\mathcal{F}^{(k)} \subseteq \mathcal{L}_+^{(k)}$, we consider the resource measures of $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness and the

$\mathcal{N}$ -noisy $\mathcal{F}$ -weight of a POVM $\{M_a\}$ as:

$$R_{\mathcal{F}}^{\mathcal{N}}(\{M_a\}) := \min_{\substack{r \geq 0 \\ \{M_a^F\} \in \overline{\mathcal{F}} \\ \{M_a^N\} \in \mathcal{N}}} \left\{ r \mid M_a + r M_a^N = (1+r) M_a^F \right\}.$$

$$W_{\mathcal{F}}^{\mathcal{N}}(\{M_a\}) := \min_{\substack{w \geq 0 \\ \{M_a^F\} \in \overline{\mathcal{F}} \\ \{M_a^N\} \in \mathcal{N}}} \left\{ r \mid M_a = (1-w) M_a^F + w M_a^N \right\}.$$

Taking $\mathcal{N} \rightarrow \mathcal{L}_+^{(k)}$ recovers the *generalised robustness* (global robustness), whilst $\mathcal{N} \rightarrow \mathcal{F}$ recovers the *free robustness* (standard robustness). It is also going to be convenient to define the cone of local non-negative operators in party A as:

$$\text{LNA} := \{\{M_a^{AB} = G_a^A \otimes \mathbb{1}^B\}, \{G_a^A\} \in \mathcal{L}_+^{(k)}\}. \quad (11)$$

We are now ready to introduce measurement simulation and anti-simulation games.

Definition 3. (*Measurement simulation and anti-simulation games*) Consider a measurement simulation (anti-simulation) game where a player is asked to use a fixed POVM $\{M_a^{AB}\}$ to simulate a POVM $\{N_b^{AA'}\}$ that is as close (far) as possible to the maximally correlated POVM (Bell measurement) $\{\Phi_b^{AA'}\}$. The player is allowed to optimise over all local (say side B) quantum pre-processing (LQP) described by a local unital CPTP map $\Lambda^{B \rightarrow A'} \equiv \Lambda$, and all classical post-processing (CPP) described by conditional PMFs $p_{B|A}$. We denote the pair $\{\Lambda^{B \rightarrow A'}, p_{B|A}\}$ as the local quantum pre-processing and classical post-processing (LQP-CPP) strategy. The LQP is required to be a unital map so that the operators $\{N_b^{AA'}\}$ form a valid POVM. The simulated POVM $\{N_b^{AA'}\}$ has elements given by $N_b^{AA'} = \sum_a p(b|a) (\text{id}^A \otimes \Lambda^{B \rightarrow A'})(M_a^{AB})$, $\forall b$. How close the simulated POVM is to the maximally correlated POVM is here quantified by the measure known as the “degree of correlations” between two POVMs which is given by $\tau(\{N_a^{AB}\}, \{M_a^{AB}\}) := \sum_a \text{Tr}[N_a^{AB} M_a^{AB}]$.

This is measurement simulation and anti-simulation games. We now introduce a variant where the player has limited resources.

Definition 4. (*Resource-restricted measurement simulation and anti-simulation games*) Consider a measurement simulation game where the LQP that is available to the player is also allowed to be “resource-restricted”, meaning that the player has access to l -Schmidt number breaking trace-preserving maps $\Lambda \in \mathcal{SB}_l - \mathcal{TP}$, $l \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$. We write $\Lambda^{B \rightarrow A'} \in \text{LQP}_l$ to describe this. We are interested in the quantities:

$$\max_{\substack{\Lambda \in \text{LQP}_l \\ p_{B|A} \in \text{CPP}}} \tau(\{N_b^{AA'}\}, \{\Phi_b^{AA'}\}), \quad \min_{\substack{\Lambda \in \text{LQP}_l \\ p_{B|A} \in \text{CPP}}} \tau(\{N_b^{AA'}\}, \{\Phi_b^{AA'}\}).$$

In Fig. 2 we further describe and illustrate this game.

FIG. 2. Resource-restricted measurement simulation game. Single lines represent quantum information (quantum states) and double lines classical information (classical indexes). A referee asks a player to use a fixed measurement $\{M_a^{AB}\}$ to simulate the Bell measurement $\{\Phi_b^{AA'}\}$. The player can implement local quantum pre-processing (LQPreP) described by the local quantum channel $\mathcal{E} \equiv \mathcal{E}^{A' \rightarrow B}$ as well as classical post-processing (CPosP) described by the conditional PMF $p_{B|A}$. The measurements the player can simulate are therefore given by $\{N_b^{AA'}\}$ with $N_b^{AA'} = \sum_a p(b|a) (\text{id}^A \otimes \mathcal{E}^\dagger)(M_a^{AB})$, $\forall b$. The player however has limited access to quantum resources and can only implement a subset of all possible local channels given by l -Schmidt number breaking trace-preserving maps $\mathcal{E} \in \mathcal{SB}_l - \mathcal{TP}$. Taking into account these limitations, what is the optimal performance that the player can achieve in this task? In [Result 3](#) we provide an answer to this question.

V. OPTIMAL PERFORMANCE IN RESOURCE-RESTRICTED MEASUREMENT SIMULATION AND ANTI-SIMULATION GAMES

Result 3. (*Optimal performance in resource-restricted measurement simulation and anti-simulation games*) For any bipartite POVM $\{M_a^{AB}\}$ and for all integers $l \in \{1, \dots, d'\}$ we have:

$$\max_{\substack{\Lambda \in \text{LQP}_l \\ p_{B|A} \in \text{CPP}}} \tau(\{N_b^{AA'}\}, \{\Phi_b^{AA'}\}) = 1 + R_{\text{LNA}}^{S_l^\circ}(\{M_a^{AB}\}), \quad (12)$$

$$\min_{\substack{\Lambda \in \text{LQP}_l \\ p_{B|A} \in \text{CPP}}} \tau(\{N_b^{AA'}\}, \{\Phi_b^{AA'}\}) = 1 - W_{\text{LNA}}^{S_l^\circ}(\{M_a^{AB}\}). \quad (13)$$

In the RHS we have the $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness and the $\mathcal{N}$ -noisy $\mathcal{F}$ -weight of the POVM $\{M_a^{AB}\}$ with free set $\mathcal{F} = \text{LMA}$, the set of local measurements on party A, that is the set of bipartite POVMs $\{F_a^{AB}\}$ of the form $F_a^{AB} = G_a^A \otimes \mathbb{1}^B$, $\forall a$, with $\{G_a^A\}$ a POVM on party A, and noisy set $\mathcal{N} = S_l^\circ$ as the dual cone of the set of bipartite operators with Schmidt number at most l .

Similar to the case of the previous result, the proof of this result relies on conic programming, duality theory, and some intermediate steps to appropriately manipulate the quantities of interest. The full proof for measurement simulation games is provided in [Appendix E](#), and for anti-simulation games in [??](#). These statements hold very generally for all bipartite measurements $\{M_a^{AB}\}$ as well as for all integers $k \in \{1, \dots, d'\}$. Unlike the case for states, for measurement simulation games, all values of the integer k are new statements, even the case $k = d'$,

in which case one gets the generalised robustness of the measurement $\{M_a^{AB}\}$. This therefore provides a new operational interpretation of the *generalised* robustness for measurements. Similarly to the case for states, one can also make an analysis of the parameters k , with the least capable player being able to implement only entanglement breaking channels at $k = 1$ and a fully capable player being able to implement all possible local quantum pre-processing maps at $k = d'$, and with various degrees of agents in between. These cases then provide an operational interpretation to both the noisy robustness and the noisy weight of resource for arbitrary measurements.

VI. CONCLUSIONS

In this work we introduced and characterised various new forms of state correlation and anti-correlation games for QRTs of states as well as a simulation and anti-simulation games for QRTs of measurements where the player in question may have limited access to quantum resources and is therefore resource-restricted.

In the first part of this work we derived the optimal performance achieved by players in state correlation and anti-correlation games. First, we introduced *resource-restricted* state correlation games where the player has limited access to resources and is asked to take a bipartite state to a state as close as possible to the maximally correlated state. We showed that the optimal performance achieved by a resource-restricted player is characterised by the *noisy* robustness of resource of the fixed quantum state, and with the free set given by the set of states with maximally mixed marginal, whilst the noise set given by the dual of the set of bipartite operators with Schmidt number at most k . This then provides an operational interpretation to the noisy robustness of resource $R_{\text{LMA}}^{S_k^\circ}(\rho^{AB})$, for all $k \in \{1, \dots, d'\}$. In particular, the case $k = d'$ recovers the result by König, Renner, and Schaffner [\[35\]](#). The rest of cases are new, to the best of our knowledge.

In the second part of this work we introduced measurement simulation and anti-simulation games, where the player is asked to simulated a measurement close to (simulation) or far (anti-simulation) from the maximally correlated measurement (Bell measurement). Similarly to the case of states, we derived the optimal performance achieved by resource-restricted players and showed that this is given by the *noisy* robustness of resource of the given measurement, with the free set given by the set of local measurements, and noise set given by measurements with Schmidt number at most k . Similarly to the case for states, this provides an operational interpretation to the resource measure $R_{\text{LMA}}^{S_k^\circ}(\{M_a^{AB}\})$ for all $k \in \{1, \dots, d'\}$. Unlike the case for states however, this represents a new scenario for which all the values of k are new, including the particular case for $k = d'$, for which we have the generalised robustness of resource.

There are various directions which we believe are worth

further exploring for future research. First, more general resources beyond those related to the Schmidt number operators and k -Schmidt number breaking channels, perhaps s -shareability, and potentially general resources described by closed convex cones. Second, using the multi-object approach [42–44]. Third, for QRTs of non-convex resources [45–48]. Fifth, using expected utility theory [49, 50].

Appendix A: Mathematical preliminaries

We start with some elements of quantum information theory, conic programming, and we then address quantum resource theories, resource measures for states, measurements, some distance measures, and some useful sets of states and measurements.

Let $\mathcal{L}(\mathcal{H})$, $\mathcal{L}_S(\mathcal{H})$, $\mathcal{L}_+(\mathcal{H})$, be the sets of all linear, self-adjoint, and positive semi-definite operators, respectively, on a finite dimensional complex Hilbert space $\mathcal{H}$. Let us address some elements of conic programming [51–53]. First, a set $\mathcal{K} \subseteq \mathcal{L}_S(\mathcal{H})$ is a *cone* if $\lambda K \in \mathcal{K}$, $\forall K \in \mathcal{K}$ and $\forall \lambda \geq 0$. Second, a cone $\mathcal{K}$ is *convex* when $K_1 + K_2 \in \mathcal{K}$, $\forall K_1, K_2 \in \mathcal{K}$. Third, a *closed* set here is considered as being closed under some operator topology such as the trace norm [54, 55]. The *dual* of a cone $\mathcal{K}$ is the set $\mathcal{K}^\circ := \{O \in \mathcal{L}_S(\mathcal{H}) \mid \langle O, K \rangle_{\text{HS}} \geq 0, \forall K \in \mathcal{K}\}$, with the Hilbert-Schmidt inner product $\langle O, K \rangle_{\text{HS}} := \text{Tr}[O^\dagger K]$.

For any cone $\mathcal{K}$ we have $(\mathcal{K}^\circ)^\circ = \overline{\text{conv}(\mathcal{K})}$ (the closure of the convex hull), and so for any closed convex cone $\mathcal{K}$ we have $(\mathcal{K}^\circ)^\circ = \mathcal{K}$. A quantum *state*, or density operator, is a positive semi-definite operator with trace one. For any cone $\mathcal{F} \subseteq \mathcal{L}_S$ we also use the notation $\overline{\mathcal{F}} := \{O \in \mathcal{F} \mid \text{Tr}[O] = 1\}$. $\overline{\mathcal{L}}_+$ is the set of quantum states. The kernel and support of a linear operator $X \in \mathcal{L}$ are the subspaces $\ker(X) := \{|\psi\rangle \in \mathcal{H} \mid X|\psi\rangle = 0\}$ and $\text{supp}(X) := \ker(X)^\perp$. The nullity and rank of an operator X are the dimensions of these subspaces $\text{rank}(X) := \dim(\text{supp}(X))$ and $\text{nullity}(X) := \dim(\ker(X))$. The rank-nullity theorem establishes that $\text{rank}(X) + \text{nullity}(X) = \dim(\mathcal{H})$. A linear operator X is said to be *full rank* when $\text{rank}(X) = \dim(\mathcal{H})$ ($\text{nullity}(X) = 0$). Rank one quantum states ($\text{rank}(\rho) = 1$) are called *pure states*.

With these tools at hand, we now address conic programming. Conic programming (CP) is a sub-field of *convex optimisation* which includes other optimisation problems like *semidefinite programming*, *quadratic*, and *linear programming*. It is called *conic programming* because it deals with the optimisation of a convex function over the intersection of *closed convex cones* (CCC) and an *affine space*. This subsection follows Gärtner-Matoušek's book on general cone programs [51] and Johnston's PhD thesis [56].

Definition 5. (Conic program [56]) A conic program (CP) with two cones is a 5-tuple $(A, B, \mathcal{E}, \mathcal{K}, \mathcal{N})$, with $A \in \mathcal{L}_S(A)$, $B \in \mathcal{L}_S(B)$, $\mathcal{E} : \mathcal{N}(A) \rightarrow \mathcal{L}(B)$ a Hermiticity preserving linear map, and $\mathcal{K} \subseteq \mathcal{L}_S(A)$, $\mathcal{N} \subseteq \mathcal{L}_S(B)$ closed convex cones. Two optimisations associated to the 5-tuple $(A, B, \mathcal{E}, \mathcal{K}, \mathcal{N})$ are the primal conic program (primal CP) and the dual conic program (dual CP) given by:

Primal CP

$$\text{maximise: } \langle A|X \rangle_{\text{HS}} \quad (\text{A1a})$$

$$\text{subject to: } B - \mathcal{E}(X) \in \mathcal{N}, \quad (\text{A1b})$$

$$X \in \mathcal{K}. \quad (\text{A1c})$$

Dual CP

$$\text{minimise: } \langle B|Z \rangle_{\text{HS}} \quad (\text{A2a})$$

$$\text{subject to: } \mathcal{E}^\dagger(Z) - A \in \mathcal{K}^\circ, \quad (\text{A2b})$$

$$Z \in \mathcal{N}^\circ. \quad (\text{A2c})$$

We can alternatively write the objective functions as $\langle A|X \rangle_{\text{HS}} = \text{Tr}(A^\dagger X) = \text{Tr}(AX)$ and $\langle B|Z \rangle_{\text{HS}} = \text{Tr}(B^\dagger Z) = \text{Tr}(BY)$. The variable X is called a “primal variable” or “primal feasible”, and Z “dual variable” or “dual feasible”. X^* denotes the “optimal primal variable/solution”, and similarly Z^* as the “optimal dual variable/solution”. If there are no feasible solutions we set the values $-\infty$ and $+\infty$, respectively.

We define the *primal and dual feasible sets* as:

$$\mathcal{A} := \{X \in \mathcal{K} \mid B - \mathcal{E}(X) \in \mathcal{N}\}, \quad (\text{A3})$$

$$\mathcal{B} := \{Z \in \mathcal{N}^\circ \mid \mathcal{E}^\dagger(Z) - A \in \mathcal{K}^\circ\}. \quad (\text{A4})$$

Optimal primal and dual solutions are given by:

$$\alpha := \sup_{X \in \mathcal{A}} \{\text{Tr}(AX)\}, \quad \beta := \inf_{Y \in \mathcal{B}} \{\text{Tr}(BY)\}. \quad (\text{A5})$$

The primal CP and the dual CP are related as $\alpha \leq \beta$, which is called *weak duality*, and it represents the fact that for any conic program $(A, B, \mathcal{E}, \mathcal{K}, \mathcal{N})$ the primal CP is always less or equal than the dual CP. We can see that this is the case as follows. Consider a conic program described by the 5-tuple $(A, B, \mathcal{E}, \mathcal{K}, \mathcal{N})$, with dual variables $Y \in \mathcal{K}^\circ$ and $Z \in \mathcal{N}^\circ$. Consider now the Lagrangian:

$$\begin{aligned} \mathcal{L}(A, B, \mathcal{E}, \mathcal{K}, \mathcal{N}) \\ &:= \text{Tr}[AX] + \text{Tr}[XY] + \text{Tr}[(B - \mathcal{E}(X))Z] \end{aligned} \quad (\text{A6})$$

$$= \text{Tr}[X(A + Y - \mathcal{E}^\dagger(Z))] + \text{Tr}[BZ] \quad (\text{A7})$$

$$= \text{Tr}[BZ] \quad (\text{A8})$$

by construction we have $\text{Tr}[AX] \leq \mathcal{L}$, this is *weak duality*. We now impose the condition $A + Y - \mathcal{E}^\dagger(Z) = 0$, which is equivalent to $\mathcal{E}^\dagger(Z) - A \in \mathcal{K}^\circ$. Furthermore, it turns out that there are conditions, known as Slater-type conditions [51, 56], for the primal solution and the dual solution to be equal, and this is called *strong duality*.

Theorem 1. (Strong duality [56]) Consider a conic program (CP) described by the 5-tuple $(A, B, \mathcal{E}, \mathcal{K}, \mathcal{N})$, with $A \in \mathcal{L}_S(A)$, $B \in \mathcal{L}_S(B)$, $\mathcal{E} : \mathcal{N}(A) \rightarrow \mathcal{L}(B)$ a Hermiticity preserving linear map, and $\mathcal{K} \subseteq \mathcal{L}_S(A)$, $\mathcal{N} \subseteq \mathcal{L}_S(B)$ closed convex cones. Consider also their respective optimal primal and dual optimal solutions as α, β , respectively. We have the following two statements.

1. If β is finite and $\exists X \in \text{int}(\mathcal{K})$ such that $B - \mathcal{E}(X) \in \text{int}(\mathcal{N})$, then $\alpha = \beta$ and $\exists Y \in \mathcal{B}$ such that $\text{Tr}[BY] = \beta$.
2. If α is finite and $\exists Y \in \text{int}(\mathcal{N}^\circ)$ such that $\mathcal{E}^\dagger(Y) - A \in \text{int}(\mathcal{K}^\circ)$, then $\alpha = \beta$ and $\exists X \in \mathcal{A}$ such that $\text{Tr}[AX] = \alpha$.

These are also known as Slater-type conditions.

We now address some additional conditions implied by strong duality known as complementary slackness.

Lemma 1. (Strong duality implies complementary slackness conditions) Consider the primal and dual conic programs associated to a fixed 5-tuple $(A, B, \mathcal{E}, \mathcal{K}, \mathcal{N})$ with associated optimal primal and dual variables as X^* and Y^* , respectively. If strong duality holds, then the following conditions also hold:

$$\text{Tr}[X^*(\mathcal{E}^\dagger(Y^*) - A)] = 0, \quad (\text{A9})$$

$$\text{Tr}[Y^*(B - \mathcal{E}(X^*))] = 0. \quad (\text{A10})$$

These conditions are known as *complementary slackness conditions*, and can alternatively also be interpreted as *orthogonality conditions* between the optimal primal variables and their respective dual slacks. Explicitly, a first

relation between the optimal primal variable X^* and its dual slack $\mathcal{E}^\dagger(Y^*) - A$, and similarly a second relation between the optimal dual variable Y^* and its primal slack $B - \mathcal{E}(X^*)$.

Proof. Strong duality is assumed to hold and so $\text{Tr}[Y^*B] = \text{Tr}[X^*A]$. We can now add and subtract the quantity $\text{Tr}[X^*\mathcal{E}^\dagger(Y^*)] = \text{Tr}[Y^*\mathcal{E}(X^*)]$ and get:

$$0 = \text{Tr}[Y^*B] - \text{Tr}[X^*A] \quad (\text{A11})$$

$$= \text{Tr}[Y^*(B - \mathcal{E}(X^*))] + \text{Tr}[X^*(\mathcal{E}^\dagger(Y^*) - A)]. \quad (\text{A12})$$

Taking into account the conditions satisfied by the optimal variables $X^* \in \mathcal{K}$, $\mathcal{E}^\dagger(Y^*) - A \in \mathcal{K}^\circ$ as well as $Y^* \in \mathcal{N}^\circ$, $B - \mathcal{E}(X^*) \in \mathcal{N}$, the two terms are then both non-negative, and so they both have to be zero. $\square$

This finishes the description of conic programs, and we now move on to describe some cones of interest.

We start with some cones of bipartite operators $\mathcal{H} = \mathcal{H}^A \otimes \mathcal{H}^B$, $d_A := \dim(\mathcal{H}^A)$, $d_B := \dim(\mathcal{H}^B)$. Let $\mathcal{S}_k$, $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$ be the set of bipartite operators with Schmidt number at most k :

$$\mathcal{S}_k := \{O^{AB} \in \mathcal{L}_+(\mathcal{H}) | SN(O^{AB}) \leq k\}, \quad (\text{A13})$$

with the Schmidt number of a bipartite operator [36]:

$$SN(O^{AB}) := \min_{\{p_k, \psi_k^{AB}\}} \{\max_k SR(\psi_k^{AB})\}, \quad (\text{A14})$$

with the minimisation over all possible decompositions of O^{AB} into (unnormalised) pure states $O^{AB} = \sum_k p_k \psi_k^{AB}$, p_k a probability mass function (PMF), and the Schmidt rank of a pure (unnormalised) state as $SR(\psi^{AB}) = k$ whenever the Schmidt decomposition is given by $|\psi\rangle^{AB} = \sum_{i=1}^k \sqrt{\lambda_i} |a\rangle_i^A |b\rangle_i^B$, $\lambda_i \geq 0$, $\forall i$, $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$, with $\{|a\rangle_m^A\}$ and $\{|b\rangle_n^B\}$ orthonormal bases of $\mathcal{H}^A$, $\mathcal{H}^B$, respectively [37].

We now analyse some properties of $\mathcal{S}_k$. First, $\mathcal{S}_1$ is the set of separable bipartite operators, and so we write $\mathcal{S}_1 \equiv \mathcal{S}$. Second, $\mathcal{S}_{d'} = \mathcal{L}_+$, with $d' := \min\{d_A, d_B\}$. Third, $\mathcal{BP}_k := \mathcal{S}_k^\circ$ is known as the set of k -block positive operators. The set of 1-block positive operators is simply called the set of block positive operators and so we write $\mathcal{BP}_1 \equiv \mathcal{BP}$. Using that $\mathcal{L}_+^\circ = \mathcal{L}_+$, and that $\mathcal{K} \subseteq \mathcal{L}$ implies $\mathcal{L}^\circ \subseteq \mathcal{K}$, for any two cones $\mathcal{K}, \mathcal{L}$, we have the following nested cone structure:

$$\mathcal{S} \equiv \mathcal{S}_1 \subseteq \dots \subseteq \mathcal{S}_{d'} \equiv \mathcal{L}_+ \equiv \mathcal{BP}_{d'} \subseteq \dots \subseteq \mathcal{BP}_1 \equiv \mathcal{BP}. \quad (\text{A15})$$

In Fig. 3 we depict this nested cone structure for bipartite operators.

We now address some cones for maps. A map $\Lambda : \mathcal{L}(\mathcal{H}^A) \rightarrow \mathcal{L}(\mathcal{H}^B)$ is called: i) *positive* when $\Lambda(O) \in \mathcal{L}_+(\mathcal{H}^B)$, $\forall O \in \mathcal{L}_+(\mathcal{H}^A)$, ii) *k -positive*, when $(\text{id}_k \otimes \Lambda)(\cdot)$ is positive, $k \geq 1$, iii) *completely positive* (CP) when Λ is k -positive for all $k \geq 1$ (we note that if a map is d' -positive then it is completely positive), iv) *k -entanglement breaking* (or *k -superpositive*) when $(\text{id}_k \otimes \Lambda)(O^{SA}) \in \mathcal{S}_k$, $\forall O^{SA} \in \mathcal{L}_+(\mathcal{H}^{SA})$. We note that a d' -entanglement breaking map is completely positive, with

FIG. 3. Various families of cones of bipartite operators. We are interested in QRTs of bipartite states with Schmidt number at most k , $k \in \{1, \dots, d'\}$. That is, a QRT of states with free set $\mathcal{S}_k$. We recover the standard QRT of entangled states when $k = 1$, and a trivial QRT (a QRT where all bipartite quantum states are free) when $k = d'$. The QRT of Schmidt number at most k interpolates between being resource-restricted ($k = 1$) to no-restriction ($k = d'$), and therefore makes it appealing to explore the transition between a resource-restricted player and a non-restricted player.

$d' := \min\{d_A, d_B\}$. Denote the sets of k -entanglement breaking, completely positive, and k -positive maps, respectively, as $\mathcal{EB}_k$, $\mathcal{CP}$, $\mathcal{P}_k$. It is known that $\mathcal{EB}_k^\circ = \mathcal{P}_k$ [52]. We have the nested cone structure:

$$\mathcal{EB} \equiv \mathcal{EB}_1 \subseteq \dots \subseteq \mathcal{EB}_{d'} \equiv \mathcal{CP} \equiv \mathcal{P}_{d'} \subseteq \dots \subseteq \mathcal{P}_1 \equiv \mathcal{P}. \quad (\text{A16})$$

In Fig. 4 we depict this nested cone structure for bipartite operators.

FIG. 4. Various families of cones of maps. We are in particular interested in QRTs of quantum channels that are k -Schmidt number breaking, with $k \in \{1, \dots, d'\}$. That is, a QRT of channels with free set $\mathcal{SB}_k$. We recover the standard QRT of entangled breaking channels when $k = 1$, and a trivial QRT of channels (a QRT where all channels are free) when $k = d'$. The QRT of k -Schmidt number breaking channels is therefore an appealing QRT that interpolates between being resource-restricted ($k = 1$) to being no-restriction ($k = d'$).

Other useful properties and definitions are the following. A map $\Lambda : \mathcal{L}(\mathcal{H}^A) \rightarrow \mathcal{L}(\mathcal{H}^B)$ is called: iv) *trace preserving* (TP) when $\text{Tr}[\Lambda(O)] = \text{Tr}[O]$, $\forall O \in \mathcal{L}(\mathcal{H}^A)$, v) *trace non-increasing* (TNI) when $\text{Tr}[\Lambda(O)] \leq \text{Tr}[O]$, $\forall O \in \mathcal{L}(\mathcal{H}^A)$, vi) a *channel* when it is a CP-TP (CPTP) map, vii) a *sub-channel* when it is a CP-TNI (CPTNI) map, x) *unital* (U) when $\Lambda(\mathbb{1}^A) = \mathbb{1}^B$, xi) *sub-unital* (SU) when $\Lambda(\mathbb{1}^A) \leq \mathbb{1}^B$.

We now address two important dualities: i) a *map-map* duality and ii) a *map-operator* duality. Let us start with the *map-map* duality [35]. For any map $\Lambda : \mathcal{L}(\mathcal{H}^A) \rightarrow$

$\mathcal{L}(\mathcal{H}^B)$, consider the *dual map* $\Lambda^\dagger : \mathcal{L}(\mathcal{H}^B) \rightarrow \mathcal{L}(\mathcal{H}^A)$ as the map that satisfies:

$$\text{Tr}[\Lambda^\dagger(F^B)E^A] = \text{Tr}[F^B\Lambda(E^A)], \quad (\text{A17})$$

$\forall E^A \in \mathcal{L}(\mathcal{H}^A), \forall F^B \in \mathcal{L}(\mathcal{H}^B)$. The dual map satisfies the properties i) $(\Lambda^\dagger)^\dagger = \Lambda$, ii) $\text{id}^\dagger = \text{id}$, iii) $(\Lambda \otimes \Gamma)^\dagger = \Lambda^\dagger \otimes \Gamma^\dagger$. We can now ask about how properties of $\Lambda(\cdot)$ translate into properties of $\Lambda^\dagger(\cdot)$. We have the following dictionary [35].

Lemma 2. (Map-map duality properties, Lemma 2 in [35]) For any map $\Lambda : \mathcal{L}(\mathcal{H}^A) \rightarrow \mathcal{L}(\mathcal{H}^B)$: i) Λ is unital (sub-unital) iff $\Lambda^\dagger$ is TP (TNI), ii) Λ is CP iff $\Lambda^\dagger$ is CP, iii) Λ is l -Schmidt number breaking iff $\Lambda^\dagger$ is l -Schmidt number breaking.

We now address the *map-operator duality* [35]. For any map $\Lambda : \mathcal{L}(\mathcal{H}^{A'}) \rightarrow \mathcal{L}(\mathcal{H}^B)$, $\mathcal{H}^{A'} \cong \mathcal{H}^A$, consider the *Choi-Jamolkowski (CJ) operator* of Λ as the bipartite operator [57]:

$$J_\Lambda^{AB} := (\text{id}^A \otimes \Lambda^{A' \rightarrow B})(\phi_+^{AA'}), \quad (\text{A18})$$

$$|\phi_+^{AA'} := \frac{1}{\sqrt{d_A}} \sum_{i=1}^{d_A} |ii\rangle^{AA'}, \quad (\text{A19})$$

with $\phi_+^{AA'}$ the maximally correlated state. Similarly to the map-map duality, we can now ask about how properties of the map Λ translate into properties of its CJ operator and viceversa. We have the following characterisation [35, 52].

Lemma 3. (Map-operator duality properties part one, Lemma 3 in [35]) For any map $\Lambda : \mathcal{L}(\mathcal{H}^{A'}) \rightarrow \mathcal{L}(\mathcal{H}^B)$, its CJ-operator J_Λ^{AB} : i) Λ is unital (sub-unital) iff $\text{Tr}_A[J_\Lambda^{AB}] = \mathbb{1}^B/d_B$ ($\text{Tr}_A[J_\Lambda^{AB}] \leq \mathbb{1}^B/d_B$), ii) Λ is TP (TNI) iff $\text{Tr}_B[J_\Lambda^{AB}] = \mathbb{1}^A/d_A$ ($\text{Tr}_B[J_\Lambda^{AB}] \leq \mathbb{1}^A/d_A$).

Lemma 4. (Map-operator duality properties, part two) For any map $\Lambda : \mathcal{L}(\mathcal{H}^{A'}) \rightarrow \mathcal{L}(\mathcal{H}^B)$, its CJ-operator J_Λ^{AB} , and $k \in \{1, \dots, d'\}$, $d' := \min\{d_A, d_B\}$: i) Λ is k -positive iff J_Λ^{AB} is k -block-positive, ii) Λ is k -Schmidt number breaking iff J_Λ^{AB} has Schmidt number at most k .

Corollary 2. From the latter statements we get in particular that: iii) Λ is positive iff J_Λ^{AB} is block positive, iv) Λ is CP iff J_Λ^{AB} is positive semidefinite, v) Λ is entanglement breaking iff J_Λ^{AB} is separable.

We now move on to address the noisy robustness of resource for QRTs of states, measurements, and channels, as well as some distance measures and useful sets of states and measurements. For closed convex cones $\mathcal{N} \subseteq \mathcal{L}_S$ and $\mathcal{F} \subseteq \mathcal{L}_+$, consider the $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness of a quantum state ρ as:

$$R_{\mathcal{F}}^{\mathcal{N}}(\rho) := \min_{\substack{r \geq 0 \\ \sigma^F \in \overline{\mathcal{F}} \\ \sigma^N \in \overline{\mathcal{N}}}} \left\{ r \left| \rho + r \sigma^N = (1+r) \sigma^F \right. \right\}. \quad (\text{A20})$$

Taking $\mathcal{N} \rightarrow \mathcal{L}_+$ recovers the *generalised robustness*, whilst $\mathcal{N} \rightarrow \mathcal{F}$ recovers the *free robustness*. Finally, for QRTs of measurements we use the following notation. Consider the set of k -tuples of self-adjoint operators as $\mathcal{L}_S^{(k)} := \{\{O_a\}_{a=1}^k \mid O_a \in \mathcal{L}_S\}$. For any cone of k -tuples $\mathcal{F} \subseteq \mathcal{L}_S^{(k)}$ we use the notation $\overline{\mathcal{F}} := \{\{O_a\}_{a=1}^k \in \mathcal{F} \mid \sum_{a=1}^k O_a = \mathbb{1}\}$. $\overline{\mathcal{L}}_+^{(k)}$ is the set of all POVMs with k outcomes. For closed convex cones $\mathcal{N} \subseteq \mathcal{L}_S^{(k)}$ and $\mathcal{F} \subseteq \mathcal{L}_+^{(k)}$, consider the $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness of a POVM $\{M_a\}$ as:

$$R_{\mathcal{F}}^{\mathcal{N}}(\{M_a\}) = \min_{\substack{r \geq 0 \\ \{M_a^F\} \in \overline{\mathcal{F}} \\ \{M_a^N\} \in \overline{\mathcal{N}}}} \left\{ r \left| M_a + r M_a^N = (1+r) M_a^F \right. \right\}.$$

Taking $\mathcal{N} \rightarrow \mathcal{L}_+^{(k)}$ recovers the *generalised robustness*, whilst $\mathcal{N} \rightarrow \mathcal{F}$ recovers the *free robustness*. We also consider distance measures for states and measurements. Consider the fidelity between two states as $F(\rho, \sigma) := \|\sqrt{\rho}\sqrt{\sigma}\|_1^2$, with $\|X\|_1 := \text{Tr}[\sqrt{X^\dagger X}]$. Consider also the *degree of correlations* between two POVMs which is given by $\tau(\{N_a^{AB}\}, \{M_a^{AB}\}) := \sum_a \text{Tr}[N_a^{AB} M_a^{AB}]$.

Appendix B: Lemmas for robustness of states

Lemma 5. (Dual conic program of the $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness of a state) The $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness of a state ρ can be written as:

$$R_{\mathcal{F}}^{\mathcal{N}}(\rho) = \max_Z \text{Tr}[Z\rho] - 1, \quad (\text{B1a})$$

$$\text{s.t. } Z \in \mathcal{N}^\circ \quad (\text{B1b})$$

$$\mathbb{1} - Z \in \mathcal{F}^\circ. \quad (\text{B1c})$$

Proof. (of Lemma 5) Recall the noisy robustness:

$$R_{\mathcal{F}}^{\mathcal{N}}(\rho) := \min_{\substack{r \geq 0 \\ \sigma^F \in \overline{\mathcal{F}} \\ \sigma^N \in \overline{\mathcal{N}}}} \left\{ r \left| \rho + r \sigma^N = (1+r) \sigma^F \right. \right\}. \quad (\text{B2})$$

We can rewrite this quantity as:

$$1 + R_{\mathcal{F}}^{\mathcal{N}}(\rho) = \min_{O^F} \text{Tr}[O^F] \quad (\text{B3})$$

$$\text{s.t. } O^F \in \mathcal{F}, \quad (\text{B4})$$

$$O^F - \rho \in \mathcal{N}. \quad (\text{B5})$$

The constraints can equivalently be written as:

$$1 + R_{\mathcal{F}}^{\mathcal{N}}(\rho) = \min_{O^F} \text{Tr}[O^F] \quad (\text{B6})$$

$$\text{s.t. } \text{Tr}[O^F P] \geq 0, \quad \forall P \in \mathcal{F}^\circ \quad (\text{B7})$$

$$\text{Tr}[(O^F - \rho)Q] \geq 0, \quad \forall Q \in \mathcal{N}^\circ. \quad (\text{B8})$$

Let us now consider a Lagrangian as:

$$L(\rho, O^F, P, Q) := \text{Tr}[O^F] - \text{Tr}[O^F P] - \text{Tr}[(O^F - \rho)Q] \quad (\text{B9})$$

$$= \text{Tr}[O^F(\mathbb{1} - P - Q)] + \text{Tr}[Q\rho]. \quad (\text{B10})$$

By construction, $L(\rho, O^F, P, Q) \leq \text{Tr}[O^F]$, $\forall \rho, P, Q$. Maximising the Lagrangian over the dual variable Q whilst imposing the condition $\mathbb{1} - P - Q = 0$ (which is equivalent to $\mathbb{1} - Q \in \mathcal{F}^\circ$) together strong duality (which follows from Slater's condition) achieves:

$$1 + R_{\mathcal{F}}^{\mathcal{N}}(\rho) = \max_Q \text{Tr}[Q \rho] \quad (\text{B11})$$

$$\text{s.t. } Q \in \mathcal{N}^\circ \quad (\text{B12})$$

$$\mathbb{1} - Q \in \mathcal{F}^\circ, \quad (\text{B13})$$

thus completing the proof. $\square$

Lemma 6. (Dual conic program of IA) The robustness of resource of a state ρ^{AB} reads:

$$R_{\text{IA}}^{\mathcal{S}_k^\circ}(\rho^{AB}) = \max_{Z^{AB}} \text{Tr}[Z^{AB} \rho^{AB}] - 1, \quad (\text{B14a})$$

$$\text{s.t. } Z^{AB} \in \mathcal{S}_k, \quad (\text{B14b})$$

$$Z^B \leq d_A \mathbb{1}^B. \quad (\text{B14c})$$

Proof. Taking into account that $(\mathcal{S}_k^\circ)^\circ = \mathcal{S}_k$, it is enough to analyse the second condition. Let us first check that $d_A \mathbb{1}^B - Z^B > 0$ implies $\mathbb{1}^{AB} - Z^{AB} \in \text{IA}^\circ$. For any $\tilde{\sigma}^{AB} \in \text{IA}$, $\tilde{\sigma}^{AB} = \mathbb{1}^A \otimes \tilde{\sigma}^B$, $\tilde{\sigma}^B \geq 0$, we have:

$$\text{Tr}[(\mathbb{1}^{AB} - Z^{AB})\tilde{\sigma}^{AB}] \quad (\text{B15})$$

$$= \text{Tr}[(\mathbb{1}^{AB} - Z^{AB})(\mathbb{1}^A \otimes \tilde{\sigma}^B)] \quad (\text{B16})$$

$$= \text{Tr}_B[d_A \mathbb{1}^B \tilde{\sigma}^B] - \text{Tr}[Z^{AB}(\mathbb{1}^A \otimes \tilde{\sigma}^B)] \quad (\text{B17})$$

$$= \text{Tr}_B[d_A \mathbb{1}^B \tilde{\sigma}^B] - \text{Tr}_B[Z^B \tilde{\sigma}^B] \quad (\text{B18})$$

$$= \text{Tr}_B[(d_A \mathbb{1}^B - Z^B)\tilde{\sigma}^B] \quad (\text{B19})$$

$$\geq 0. \quad (\text{B20})$$

It then follows that $\mathbb{1}^{AB} - Z^{AB} \in \text{IA}^\circ$. For the other direction, assume that $\mathbb{1}^{AB} - Z^{AB} \in \text{IA}^\circ$ and let us prove that $Z^B \leq d_A \mathbb{1}^B$. We proceed by contradiction. Assume that $Z^B \not\leq d_A \mathbb{1}^B$, meaning that there exists at least one pure state, say $|\psi\rangle$, such that $\langle\psi| (d_A \mathbb{1}^B - Z^B) |\psi\rangle < 0$, or equivalently that $\langle\psi| d_A \mathbb{1}^B |\psi\rangle < \langle\psi| Z^B |\psi\rangle$. Take now $\sigma^B = \psi^B$, $\psi^B := |\psi\rangle\langle\psi|$, and so we get:

$$\text{Tr}[(\mathbb{1}^{AB} - Z^{AB})(\mathbb{1}^A \otimes \psi^B)] \quad (\text{B21})$$

$$= \text{Tr}_B[d_A \psi^B] - \text{Tr}[Z^{AB}(\mathbb{1}^A \otimes \psi^B)] \quad (\text{B22})$$

$$= \text{Tr}_B[d_A \mathbb{1}^B \psi^B] - \text{Tr}_B[Z^B \psi^B] \quad (\text{B23})$$

$$< 0. \quad (\text{B24})$$

This contradicts the assumption that $\mathbb{1}^{AB} - Z^{AB} \in \text{IA}^\circ$, and so $Z^B \leq d_A \mathbb{1}^B$ is false. $\square$

Lemma 7. (Dual conic program of IA) The generalised robustness of a state ρ^{AB} reads:

$$R_{\text{IA}}^{\mathcal{S}_k^\circ}(\rho^{AB}) = \max_{Z^{AB}} \text{Tr}[Z^{AB} \rho^{AB}] - 1, \quad (\text{B25a})$$

$$\text{s.t. } Z^{AB} \in \mathcal{S}_k, \quad (\text{B25b})$$

$$Z^B = d_A \mathbb{1}^B. \quad (\text{B25c})$$

Proof. First, it is clear that the first optimisation problem (OP) is greater or equal than the second OP, as the second constraint in the first OP is less restrictive, and it is a maximisation. We now check that the second OP is greater or equal than the first OP. Consider Z^{AB} the optimal variable satisfying the the first OP and so $Z^B \leq d_A \mathbb{1}^B$. We now construct a candidate dual variable for the second OP as $\tilde{Z}^{AB} := Z^{AB} + \sigma^A \otimes (d_A \mathbb{1}^B - Z^B)$, with σ^A a state. The operator $\tilde{Z}^{AB}$ constitutes a valid dual variable for the second OP because it satisfies the properties: i) $\tilde{Z}^{AB} \in \mathcal{S}_k$, and ii) $\text{Tr}_A[\tilde{Z}^{AB}] = Z^B + (d_A \mathbb{1}^B - Z^B) = d_A \mathbb{1}^B$. This new dual variable achieves $\text{Tr}[\tilde{Z}^{AB} \rho^{AB}] \geq \text{Tr}[Z^{AB} \rho^{AB}]$, and so the second OP is greater or equal than the first OP. Both optimisation problems are therefore equivalent. $\square$

Appendix C: Proof of Result 1

We want to prove that:

$$\max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'}) = \frac{1}{d} \left[1 + R_{\text{IA}}^{\mathcal{S}_k^\circ}(\rho^{AB}) \right],$$

Proof. Let us consider the quantity:

$$\begin{aligned} & \max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} d F(\rho_{\Lambda}^{AA'}, \phi_+^{AA'}) \\ & \stackrel{1}{=} \max_{\Lambda \in \mathcal{SB}_k - \mathcal{TP}} d \text{Tr}[(\mathbb{1}^A \otimes \Lambda)(\rho^{AB}) \phi_+^{AA'}] \end{aligned} \quad (\text{C1})$$

$$\stackrel{2}{=} \max_{\Lambda^\dagger \in \mathcal{SB}_k - \mathcal{U}} d \text{Tr}[\rho^{AB}(\mathbb{1}^A \otimes \Lambda^\dagger)(\phi_+^{AA'})] \quad (\text{C2})$$

$$\stackrel{3}{=} \max_{d J_{\Lambda^\dagger}^{AB} \in \mathcal{S}_k, \text{Tr}_A[d J_{\Lambda^\dagger}^{AB}] = d_A \mathbb{1}^B} \text{Tr}[\rho^{AB}(d J_{\Lambda^\dagger}^{AB})]. \quad (\text{C3})$$

In the first line we use that the fidelity between a quantum state and a pure state is $F(\rho, |\psi\rangle\langle\psi|) = \text{Tr}[\rho |\psi\rangle\langle\psi|]$, and replace $\rho_{\Lambda}^{AA'}$. In the second line we use Lemma 2; the dual of a $\mathcal{SB}_k - \mathcal{TP}$ (k -entanglement-breaking and trace-preserving) map is a $\mathcal{SB}_k - \mathcal{U}$ (k -entanglement breaking and unital) map. In the third line we introduce the CJ-operator:

$$J_{\Lambda^\dagger}^{AB} := (\text{id}^A \otimes \Lambda^\dagger)(\phi_+^{AA'}). \quad (\text{C4})$$

Taking into account that the map $\Lambda^\dagger$ is $\mathcal{SB}_k - \mathcal{U}$, Lemma 4 and Lemma 3 tell us that its CJ-operator satisfies the two properties: i) $J_{\Lambda^\dagger}^{AB} \in \mathcal{S}_k$ (Schmidt number at most k), and ii) $\text{Tr}_A[J_{\Lambda^\dagger}^{AB}] = \frac{\mathbb{1}^B}{d_B}$ which implies $\text{Tr}_A[d J_{\Lambda^\dagger}^{AB}] = d_A \mathbb{1}^B$, $d = d_A d_B$. Consider a quantum resource theory of bipartite states with free set MMA given by states of the form $\sigma^{AB} = (\mathbb{1}^A/d_A) \otimes \sigma^B$, with σ^B a state. Using Lemma 7 we have:

$$\begin{aligned} & \max_{d J_{\Lambda^\dagger}^{AB} \in \mathcal{S}_k} \text{Tr}[\rho^{AB}(d J_{\Lambda^\dagger}^{AB})] = 1 + R_{\text{IA}}^{\mathcal{S}_k^\circ}(\rho^{AB}), \\ & \text{Tr}_A[d J_{\Lambda^\dagger}^{AB}] = d_A \mathbb{1}^B \end{aligned}$$

thus achieving the claim. $\square$

Lemma 8. (Dual conic program of the $\mathcal{N}$ -noisy $\mathcal{F}$ -robustness with $\mathcal{F} = \text{LNA}$, and $\mathcal{N} = \mathcal{S}_l^\circ$) For any measurement $\{M_a^{AB}\}$, $a \in \{1, \dots, k\}$, consider the following conic program:

$$\max_{\{Z_a^{AB}\}} \sum_{a=1}^k \text{Tr}[Z_a^{AB} M_a^{AB}] - 1, \quad (\text{C5a})$$

$$\text{s.t. } \{Z_a^{AB} \in \mathcal{S}_l\}, \quad (\text{C5b})$$

$$Z_a^A \leq \frac{\mathbb{1}^A}{d_A}, \forall a \in \{1, \dots, k\}. \quad (\text{C5c})$$

The conic program above is equivalent to the following conic program:

$$\max_{\{Z_a^{AB}\}} \sum_{a=1}^k \text{Tr}[Z_a^{AB} M_a^{AB}] - 1, \quad (\text{C6a})$$

$$\text{s.t. } \{Z_a^{AB} \in \mathcal{S}_l\}, \quad (\text{C6b})$$

$$Z_a^A = \frac{\mathbb{1}^A}{d_A}, \forall a \in \{1, \dots, k\}. \quad (\text{C6c})$$

Proof. First, it is clear that the first optimisation problem (OP) is greater or equal than the second OP, as the second constraint in the first OP is less restrictive, and it is a maximisation. We now check that the second OP is greater or equal than the first OP. Consider the optimal dual variables satisfying the first OP as the k -tuple of operators $\{Z_a^{AB}\}_{a=1}^k$ and so $d_A Z_a^A \leq \mathbb{1}^A$, $\forall a \in \{1, \dots, k\}$. We now construct a candidate k -tuple of dual variables for the second OP $\{\tilde{Z}_a^{AB}\}_{a=1}^k$ as $\tilde{Z}_a^{AB} := Z_a^{AB} + (\frac{\mathbb{1}^A}{d_A} - Z_a^A) \otimes \sigma^B$, $\forall a$, with σ^B a quantum state. The k -tuple of operators $\{\tilde{Z}_a^{AB}\}_{a=1}^k$ constitutes a valid set of dual variables for the second OP because it satisfies the properties: i) $\tilde{Z}_a^{AB} \in \mathcal{S}_l$, $\forall a$ (this follows because $Z_a^{AB} \in \mathcal{S}_l$ and $(\frac{\mathbb{1}^A}{d_A} - Z_a^A) \otimes \sigma^B \in \mathcal{S}_1 \subseteq \mathcal{S}_l$), and ii) $d_A \tilde{Z}_a^A = d_A Z_a^A + d_A (\frac{\mathbb{1}^A}{d_A} - Z_a^A) = \mathbb{1}^A$, $\forall a$. This new set of dual variables achieves $\sum_a \text{Tr}[\tilde{Z}_a^{AB} M_a^{AB}] \geq \sum_a \text{Tr}[Z_a^{AB} M_a^{AB}]$, and so the second OP is greater or equal than the first OP. Both optimisation problems are therefore equivalent. $\square$

Lemma 9. Given a POVM $\{M_a^{AB}\}$, $a \in \{1, \dots, k\}$, consider the conic program:

$$\max_{\{Z_a^{AB}\}} \sum_{a=1}^k \text{Tr}[Z_a^{AB} M_a^{AB}] - 1, \quad (\text{C7a})$$

$$\text{s.t. } \{Z_a^{AB} \in \mathcal{S}_l\}, \quad (\text{C7b})$$

$$Z_a^A \leq \frac{\mathbb{1}^A}{d_A}, \forall a \in \{1, \dots, k\}. \quad (\text{C7c})$$

The dual of this conic program is the following conic program:

$$\begin{aligned} \min \quad & s, \\ \text{s.t. } \quad & \{s \geq 0, Y_a^A \in \mathcal{L}_+\} \\ & \{Y_a \otimes \mathbb{1}^B - M_a^{AB} \in \mathcal{S}_l^\circ\} \\ & \{\sum_a Y_a^A = s \mathbb{1}^A\}. \end{aligned} \quad (\text{C8})$$

Proof. Let us introduce dual variables for the constraints as $X_a^{AB} \in \mathcal{S}_l^\circ$, $\forall a$, and $Y_a^A \in \mathcal{L}_+$, $\forall a$, $\sum_a Y_a^A = s \mathbb{1}^A$, with $s \geq 0$. We can then construct a Lagrangian as:

$$\begin{aligned} \mathcal{L}(\{M_a^{AB}\}, \{Z_a^{AB}\}, \{Y_a^A\}) \\ &:= \sum_a \text{Tr}[M_a^{AB} Z_a^{AB}] + \text{Tr}[X_a^{AB} Z_a^{AB}] + \text{Tr}[Y_a^A (\frac{\mathbb{1}^A}{d_A} - Z_a^A)] \\ &= \sum_a \text{Tr}[Z_a^{AB} (M_a^{AB} + X_a^{AB} - Y_a^A \otimes \mathbb{1}^B)] + \frac{1}{d_A} \text{Tr}[Y_a^A], \\ &= \sum_a \text{Tr}[Z_a^{AB} (M_a^{AB} + X_a^{AB} - Y_a^A \otimes \mathbb{1}^B)] + s. \end{aligned} \quad (\text{C9})$$

By construction, the Lagrangian satisfies $\mathcal{L}(\{M_a^{AB}\}, \{Z_a^{AB}\}, \{Y_a^A\}) \geq \sum_a \text{Tr}[M_a^{AB} Z_a^{AB}]$. We now minimise the Lagrangian over the dual variables $\{Y_a^A\}$ whilst imposing the additional constraints $M_a^{AB} + X_a^{AB} - Y_a^A \otimes \mathbb{1}^B = 0$, $\forall a$. Using strong duality, which follows from Slater's condition, we obtain the dual conic program:

$$\min_{s \geq 0} s, \quad (\text{C10})$$

$$\text{s.t. } Y_a^A \in \mathcal{L}_+, \forall a, \quad (\text{C11})$$

$$Y_a^A \otimes \mathbb{1}^B - M_a^{AB} \in \mathcal{S}_l^\circ, \forall a, \quad (\text{C12})$$

$$\sum_a Y_a^A = s \mathbb{1}^A, \quad (\text{C13})$$

thus achieving the claim. $\square$

Appendix D: Some Lemmas for CJ-operators for maximally correlated states

In order to extend the standard duality lemmas (typically stated for the single state $\Phi_+^{AA'}$) to the entire set of maximally correlated states $\Phi_b^{AA'}$, we utilize the property that all such states are locally unitarily equivalent. Specifically, any maximally correlated state $\Phi_b^{AA'}$ can be generated from the standard state $\Phi_+^{AA'}$ via a local unitary operation on the system A' :

$$\Phi_b^{AA'} = (\text{id}^A \otimes \mathcal{U}_b^{A'}) (\Phi_+^{AA'}), \quad (\text{D1})$$

where $\mathcal{U}_b(\cdot) = U_b(\cdot) U_b^\dagger$ is a unitary channel corresponding to a generalized Pauli operator (Heisenberg-Weyl operator) U_b .

Lemma 10. (Extended Map-operator duality: Trace property) Let $\{\Phi_b^{AA'}\}$ be a set of maximally correlated states related by local unitaries as defined above. For any map $\Lambda : \mathcal{L}(\mathcal{H}^{A'}) \rightarrow \mathcal{L}(\mathcal{H}^B)$, the generalized CJ-operators $J_b^{AB} := (\text{id}^A \otimes \Lambda)(\Phi_b^{AA'})$ satisfy:

$$\Lambda \text{ is TP} \iff \text{Tr}_B[J_b^{AB}] = \frac{\mathbb{1}^A}{d_A}, \quad \forall b. \quad (\text{D2})$$

Proof. Using the unitary equivalence $\Phi_b^{AA'} = (\text{id}^A \otimes \mathcal{U}_b)(\Phi_+^{AA'})$, we can express the partial trace of the generalized CJ-operator as:

$$\begin{aligned} \text{Tr}_B[J_b^{AB}] &= \text{Tr}_B \left[(\text{id}^A \otimes \Lambda) \left((\text{id}^A \otimes \mathcal{U}_b)(\Phi_+^{AA'}) \right) \right] \\ &= \text{Tr}_B \left[(\text{id}^A \otimes (\Lambda \circ \mathcal{U}_b))(\Phi_+^{AA'}) \right]. \end{aligned} \quad (\text{D3})$$

Since Λ is trace-preserving (TP) and the unitary map $\mathcal{U}_b$ is also TP, their composition $\Lambda \circ \mathcal{U}_b$ is a TP map. Applying [Lemma 3](#) (standard duality for $\Phi_+^{AA'}$) to the composed map implies that the marginal of its Choi operator must be the maximally mixed state:

$$\text{Tr}_B[J_b^{AB}] = \frac{\mathbb{1}^A}{d_A}. \quad (\text{D4})$$

Conversely, if the marginal is fixed for all b (including the case $\mathcal{U}_b = \mathbb{1}$), the standard [Lemma 3](#) ensures Λ is TP. $\square$

Lemma 11. (*Extended Map-operator duality: Schmidt number*) For any map Λ and states $\{\Phi_b^{AA'}\}$ as defined above, let $J_b^{AB} := (\text{id}^A \otimes \Lambda)(\Phi_b^{AA'})$. For any $l \in \{1, \dots, d'\}$:

$$\Lambda \in \mathcal{EB}_l \iff J_b^{AB} \in \mathcal{S}_l, \quad \forall b. \quad (\text{D5})$$

Proof. We again use the structural relation of the CJ-operators. J_b^{AB} can be viewed as the standard Choi operator of a modified map $\tilde{\Lambda}_b := \Lambda \circ \mathcal{U}_b$:

$$J_b^{AB} = (\text{id}^A \otimes \tilde{\Lambda}_b)(\Phi_+^{AA'}). \quad (\text{D6})$$

The class of l -entanglement breaking maps $\mathcal{EB}_l$ is invariant under composition with unitary channels (since local unitaries do not change the Schmidt number of the output states). Therefore:

$$\Lambda \in \mathcal{EB}_l \iff \tilde{\Lambda}_b = \Lambda \circ \mathcal{U}_b \in \mathcal{EB}_l. \quad (\text{D7})$$

Now, applying the standard map-operator duality [Lemma 4](#) to the map $\tilde{\Lambda}_b$ and the standard state $\Phi_+^{AA'}$, we conclude:

$$\tilde{\Lambda}_b \in \mathcal{EB}_l \iff J_b^{AB} \in \mathcal{S}_l. \quad (\text{D8})$$

This holds for any b , completing the proof. $\square$

Appendix E: Proof of [Result 3](#) (Part I)

We want to prove that:

$$\max_{\substack{\Lambda \in \text{LQP}_l \\ p_{B|A} \in \text{CPTP}}} \tau(\{N_b^{AA'}\}, \{\Phi_b^{AA'}\}) = 1 + R_{\text{LNA}}^{S_l^\circ}(\{M_a^{AB}\}).$$

Proof. Consider the quantity:

$$\begin{aligned} &\max_{\substack{\Lambda \in \text{LQP}_l \\ p_{B|A} \in \text{CPTP}}} \tau(\{N_b^{AA'}\}, \{\Phi_b^{AA'}\}) \\ &\stackrel{1}{=} \max_{\substack{\Lambda \in \mathcal{EB}_l \\ p_{B|A}}} \sum_{b,a} p(b|a) \text{Tr}[(\text{id}^A \otimes \Lambda)(M_a^{AB}) \Phi_b^{AA'}] \end{aligned} \quad (\text{E1})$$

$$\stackrel{2}{=} \max_{\substack{\mathcal{E} \in \mathcal{EB}_l \\ \mathcal{E} \in \mathcal{TP}}} \sum_{b,a} p(b|a) \text{Tr}[M_a^{AB} (\text{id}^A \otimes \mathcal{E})(\Phi_b^{AA'})] \quad (\text{E2})$$

$$\stackrel{3}{=} \max_{\substack{\{Z_a^{AB} \in \mathcal{S}_l\} \\ \{d_A \text{Tr}_B[Z_a^{AB}] = \mathbb{1}^A\}}} \sum_a \text{Tr}[M_a^{AB} Z_a^{AB}], \quad (\text{E3})$$

In the first line we use the definition of the degree of correlations between two POVMs and replace the POVM $\{N_b^{AA'}\}$. In the second line we define $\mathcal{E} := \Lambda^\dagger$ and use that the dual map of a l -Schmidt number breaking unital map is a l -Schmidt number breaking trace-preserving map ([Lemma 2](#)). In the third line we introduce the CJ-operators:

$$Z_a^{AB} := \sum_b J_b^{AB} p(b|a), \quad (\text{E4})$$

$$J_b^{AB} := (\text{id}^A \otimes \mathcal{E})(\Phi_b^{AA'}). \quad (\text{E5})$$

Taking into account that the map $\mathcal{E}$ is l -Schmidt number breaking and trace-preserving ($\mathcal{E} \in \mathcal{EB}_l - \mathcal{TP}$), [Lemma 2](#), [Lemma 3](#), [Lemma 10](#), and [Lemma 11](#) tell us that the CJ-operators $\{J_b^{AB}\}$ satisfy the properties: i) $J_b^{AB} \in \mathcal{S}_l, \forall b$, and ii) $\text{Tr}_B[d_A J_b^{AB}] = \mathbb{1}^A, \forall b$. This in turn tells us that the operators $\{Z_a^{AB}\}$ satisfy the properties: i) $Z_a^{AB} \in \mathcal{S}_l, \forall a$, and ii) $\text{Tr}_B[d_A Z_a^{AB}] = \mathbb{1}^A, \forall a$. We now continue from the last equality:

$$\stackrel{4}{=} \max_{\substack{\{Z_a^{AB} \in \mathcal{S}_l\} \\ \{d_A \text{Tr}_B[Z_a^{AB}] \leq \mathbb{1}^A\}}} \sum_a \text{Tr}[M_a^{AB} Z_a^{AB}], \quad (\text{E6})$$

$$\stackrel{5}{=} \min_{\substack{s \\ \{s \geq 0, Y_a^A \in \mathcal{L}_+\} \\ \{Y_a \otimes \mathbb{1}^B - M_a^{AB} \in \mathcal{S}_l^\circ\} \\ \{\sum_a Y_a^A = s \mathbb{1}^A\}}} \sum_a \text{Tr}[M_a^{AB} Y_a^A] \quad (\text{E7})$$

$$\stackrel{6}{=} 1 + R_{\text{LNA}}^{S_l^\circ}(\{M_a^{AB}\}). \quad (\text{E8})$$

In the fourth line we use [Lemma 8](#). In the fifth line we use [Lemma 9](#). In the last line we identify the robustness measure with free cone given by operators $\{F_a^{AB}\}$ of the form $F_a^{AB} = G_a^A \otimes \mathbb{1}^B, \forall a, \{G_a^A\} \in \mathcal{L}_+^{(k)}$. $\square$

Complexity-theoretic goalposts for decoded quantum interferometry

Abstract. Decoded quantum interferometry (DQI) surpasses known classical algorithms for combinatorial optimization over finite fields on algebraically structured instances. We establish three benchmarks for these claims. First, on worst-case max-LINSAT(q, r), the random-assignment ratio r/q is an NP-hard wall. Second, for instances with bounded degree D , the optimal scaling is $r/q + \Theta(1/\sqrt{D})$, confining quantum advantage to a constant prefactor. Third, we prove an information-theoretic separation: DQI with classical decoders is limited to $1/\sqrt{D \log D}$, while quantum decoders may match the optimal $1/\sqrt{D}$. Thus, quantum decoding is key for saturating the complexity-theoretic ceiling using DQI.

Keywords: quantum algorithms, computational complexity, inapproximability, decoded quantum interferometry, constraint satisfaction problems, coding theory

This is based on the published work [KSE26b] and unpublished ongoing work [KSE26a], both attached.

1 Motivation

A central goal in the study of NP-hard optimization problems is to characterize the best approximation ratios achievable by polynomial-time algorithms. The approximability landscape depends crucially on the structure present in problem instances, and three qualitatively different regimes emerge. At one extreme, worst-case instances produced by PCP reductions possess no exploitable structure, and both quantum and classical algorithms face tight inapproximability walls—for instance, the random-assignment threshold $1/2$ for max- Ek -XORSAT with $k \geq 3$ [H01] and r/q for max-LINSAT(q, r) over finite fields [KSE26b]. At the other extreme, highly structured problems admit provable quantum–classical separations for combinatorial optimization tasks under standard complexity assumptions [PUW+24, Sze22, YZ24, BGM25]. The scientifically interesting regime lies between these extremes: instances with enough structure for algorithms to exploit, but where that structure arises naturally from the problem rather than being engineered to enable separation results.

Decoded quantum interferometry (DQI) [JSW+25] operates squarely in this intermediate regime. DQI reduces a linear constraint satisfaction problem over a finite field to a (quantum) decoding problem via a Fourier transform over the underlying field, an idea originating from Regev’s reduction [ATS03, Reg04, AR05, Reg09]. Its performance is characterized by the *semicircle law*: For a max-LINSAT instance over the finite field $\mathbb{F}_q$ with n variables, m constraints, acceptance-set size r , and decoding radius ℓ , DQI achieves an approximation ratio

$$\alpha_{\text{DQI}} = \left(\sqrt{\frac{\ell}{m} \left(1 - \frac{r}{q}\right)} + \sqrt{\frac{r}{q} \left(1 - \frac{\ell}{m}\right)} \right)^2 \quad (1)$$

for $r/q \leq 1 - \ell/m$ and 1 otherwise [JSW+25]. DQI’s performance depends critically on the structure present in the instance, as illustrated below:

Algebraic structure. The flagship application of DQI is *Optimal Polynomial Intersection* (OPI) [JSW+25], where the constraint matrix has Vandermonde structure arising from Reed–Solomon codes that are efficiently decodable up to their designed error radius. In this regime, DQI achieves approximation ratios far exceeding r/q and provides a super-polynomial speedup over *known classical algorithms*. Extensions to algebraic geometry codes via HOPI [GJ25] broaden this class further.

Bounded-degree instances. When each variable appears in at most D constraints, the random-assignment threshold is no longer a hard wall: algorithms can provably exceed it. On *random* (k, D) -regular max- Ek -XORSAT instances drawn from the Gallager ensemble, all known algorithms—DQI with various decoders, QAOA, and classical heuristics such as Turbo Prange—achieve approximation ratios of the form $1/2 + c/\sqrt{D}$, with algorithm-dependent constants c [SMR+26]. In the *worst-case*, Barak et al. [BMO+15] achieved $1/2 + e^{-\mathcal{O}(k)}/\sqrt{D}$ classically, and depth-1 QAOA achieves $1/2 + \Omega(1/(\sqrt{D} \log D))$ [FGG15]. The $1/\sqrt{D}$ scaling is optimal: Trevisan’s degree-reduction technique [Tre01], applied to Håstad’s inapproximability [H01], shows that $1/2 + \mathcal{O}(1/\sqrt{D})$ is NP-hard to exceed, matching Barak et al.’s upper bound up to the k -dependent constant.

These observations raise a fundamental question: what approximation ratios should we *reasonably expect* from efficient algorithms on max-XORSAT instances, and max-LINSAT instances more generally, and what ratios are *provably out of reach*? Without such complexity-theoretic guardrails, it remains unclear whether the ratios achieved by DQI and related quantum algorithms are close to optimal or whether substantially better algorithms might exist.

*m.kramer@fu-berlin.de

Figure 1: Approximability landscape for bounded-degree max-LINSAT(q, r). The $\ell/m = 0$ slice (worst-case) shows the $r/q + \mathcal{O}(1/\sqrt{D})$ scaling from Theorems 1–2. The dashed lines correspond to algorithmic scalings approaching this inapproximability result from below. For $\ell/m > 0$, DQI exploits decodable structure via the semicircle law. The interaction between bounded degree and decodable structure remains largely unexplored.

In our two works, we establish these goalposts in two complementary settings for max-LINSAT—at unbounded and bounded variable degree—showing that the random-assignment threshold r/q is a tight worst-case wall [KSE26b], that the $1/\sqrt{D}$ scaling is complexity-theoretically forced [KSE26a], and that quantum advantage in this bounded degree landscape is necessarily confined to constant prefactors and structured instances [KSE26a].

2 Setup

We study max-LINSAT(q, r) over a finite field $\mathbb{F}_q$: given a constraint matrix $B \in \mathbb{F}_q^{m \times n}$ and acceptance sets $F_i \subseteq \mathbb{F}_q$ with $|F_i| = r$, find $\mathbf{x} \in \mathbb{F}_q^n$ maximizing the number of constraints $\sum_j B_{i,j} x_j \in F_i$. A random assignment satisfies each constraint with probability r/q . The *degree* of variable x_j is the number of constraints in which it appears. When every variable has degree exactly D , and every constraint has arity exactly k , the instance is (k, D) -regular with $km = Dn$. Special cases include max-XORSAT ($q = 2, r = 1$) and max-Ek-XORSAT (arity exactly k over $\mathbb{F}_2$), which serve as the primary testbed for quantum optimization algorithms.

3 Results

The approximability landscape (Fig. 1) is governed by two parameters: the degree bound D and the decodable structure ℓ/m . Our results establish the tight worst-case boundary at $\ell/m = 0$.

3.1 Tight unbounded-degree inapproximability

In [KSE26b], we have proven the following tight inapproximability bound for max-LINSAT:

Theorem 1 *For every finite field $\mathbb{F}_q$, every $1 \leq r \leq q - 1$, and every $\varepsilon > 0$, it is NP-hard to distinguish max-LINSAT(q, r) instances with $\text{OPT} \geq (1 - \varepsilon)m$ from those with $\text{OPT} \leq (r/q + \varepsilon)m$.*

The proof proceeds by deterministic polynomial-time reduction from Håstad’s tight inapproximability of max-E3-LIN- q [H01]. Given a singleton-acceptance instance with constraint $L_i(\mathbf{x}) = b_i$, we replace each constraint by all $\binom{q-1}{r-1}$ acceptance sets of size r containing b_i . For an unsatisfied constraint evaluating to $c_i \neq b_i$, exactly $\binom{q-2}{r-2}$ of these derived constraints are satisfied, giving a per-constraint leakage ratio of $(r-1)/(q-1)$. An exact algebraic calculation then shows that the soundness maps $1/q + \varepsilon$ to $r/q + \varepsilon \cdot (q-r)/(q-1) \leq r/q + \varepsilon$, yielding the tight threshold.

This result is tight because a random assignment achieves r/q in expectation (derandomizable via conditional expectations). Assuming $P \neq NP$, no polynomial-time classical algorithm can consistently exceed r/q ; assuming $NP \not\subseteq BQP$, neither can any polynomial-time quantum algorithm. The hard instances produced by PCP reductions have $n/m = o(1)$ and unstructured constraint matrices—e.g., they lack the Vandermonde structure and constant n/m ratio characteristic of OPI. DQI’s advantage on structured instances is thus entirely consistent with this worst-case hardness.

3.2 Bounded-degree hardness and optimal degree scaling

In recent ongoing work [KSE26a], we address the regime most relevant to DQI and QAOA: instances in which each variable appears in at most D constraints.

When the degree is bounded, the picture changes qualitatively: both quantum and classical algorithms achieve ratios strictly above r/q (both in the *worst-case* [H00, FGG15, BMO⁺15] and in the *average-case* on instances drawn from the Gallager ensemble, see e.g. Ref. [SMR⁺26]). We show that a $1/\sqrt{D}$ scaling is complexity-theoretically forced in the worst case:

Theorem 2 *For every finite field $\mathbb{F}_q$, every $1 \leq r \leq q - 1$, and every degree bound D , it is NP-hard (under randomized reductions) to approximate max-LINSAT(q, r) on degree- D instances within $r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$.*

The proof composes three ingredients: (i) Håstad’s PCP-based hardness for max-E3-LIN- q [H01], which produces unbounded-degree instances; (ii) Trevisan’s randomized degree-reduction technique [Tre01], which converts these to bounded-degree instances at a $\mathcal{O}(1/\sqrt{D})$ cost to the gap via variable splitting, weighted replication, random sampling, and pruning; and (iii) the acceptance-set lifting from Theorem 1 (see Ref. [KSE26b]), which extends the result to max-LINSAT(q, r).

For max-Ek-XORSAT (i.e., max-LINSAT(2,1) with constraints on exactly k variables), combining this result with the algorithm of Barak et al. [BMO⁺15], which achieves $1/2 + \exp(-\mathcal{O}(k))/\sqrt{D}$ for max-Ek-XORSAT with odd k , pins down the optimal worst-case scaling:

Observation 3 For bounded-degree max-Ek-XORSAT with fixed odd k , the optimal worst-case approximation ratio scales as $1/2 + \Theta_k(1/\sqrt{D})$. Any improvement—classical or quantum—is confined to the k -dependent constant prefactor.

In the limit $D \rightarrow \infty$, the $\mathcal{O}_{q,r}(1/\sqrt{D})$ term vanishes and the bound collapses to the tight wall r/q of Theorem 1, unifying the bounded- and unbounded-degree settings into the continuous landscape $r/q + \Theta_{q,r}(1/\sqrt{D})$.

For $q > 2$, Theorem 2 establishes hardness at $r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$, but the algorithmic side lags behind: the best known worst-case algorithm remains Håstad’s greedy method [Hå00] at $r/q + \Omega(1/D)$ —a quadratic gap in D . The algorithm of Barak et al. [BMO⁺15] is inherently Boolean and does not straightforwardly extend to $\mathbb{F}_q$. Closing this gap is an important open problem; we discuss below how *DQI with quantum decoders* is information-theoretically compatible with saturating the ceiling, making it a candidate route to $r/q + \Omega(1/\sqrt{D})$ for $q > 2$ where no classical algorithm currently matches the hardness scaling.

3.3 Information-theoretic limits of DQI

Beyond complexity-theoretic hardness, we derive information-theoretic ceilings that constrain DQI itself, independently of computational assumptions. On (k, D) -regular instances with $n/m = k/D$, expanding the semicircle law for small ℓ/m gives $\alpha_{\text{DQI}} = r/q + \Theta(\sqrt{\ell/m})$, so the achievable advantage reduces to how large ℓ/m can be. DQI applies its decoder coherently in superposition, so the relevant capacity bound depends on the nature of the decoder as already observed in Ref. [JSW⁺25]: *classical decoders* are fundamentally limited by the *Shannon capacity* of the induced channel [Sha48], while *quantum decoders* are limited by the *Holevo capacity* [Hol73].

Classical decoders. Jordan et al. [JSW⁺25] observed for $q = 2$ that the Shannon capacity limits the decoding radius, constraining DQI with classical decoders on (k, D) -regular instances to $1/2 + \mathcal{O}(1/\sqrt{D \log D})$. We extend this to general q : the Shannon capacity $C_q(p) \sim \log_2 q - p \log_2((q-1)/p)$ for small p yields $\ell/m = \mathcal{O}((k/D)/\log(D/k))$ via the rate condition, giving $\alpha_{\text{DQI}}^{\text{cl}} \leq r/q + \mathcal{O}_{q,r}(1/\sqrt{D \log D})$ —better than Håstad’s greedy $r/q + \Omega(1/D)$ [Hå00] but a $\sqrt{\log D}$ factor short of the hardness ceiling.

Quantum decoders. Similarly, Jordan et al. [JSW⁺25] showed for $q = 2$ that coherent decoding accesses non-orthogonal quantum states rather than classical syndrome bits, and that the Holevo capacity of the induced channel satisfies $\chi(p) = 1 - \Theta(p)$ —linear rather than $p \log(1/p)$ —closing the $\sqrt{\log D}$ gap for (k, D) -regular instances. We again extend this analysis to general q : the natural q -ary classical-quantum channel has Holevo capacity $\chi_q(p) = \log_2 q - \Theta(p)$, yielding $\ell/m = \Theta(k/D)$ and thus $\alpha_{\text{DQI}}^{\text{q}} \leq r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$ for (k, D) -regular instances, matching the hardness ceiling of Theorem 2 for all (q, r) .

This extension to $q > 2$ is particularly compelling in light of the bounded-degree algorithmic landscape:

the best known worst-case algorithm for $q > 2$ remains Håstad’s greedy at $r/q + \Omega(1/D)$ [Hå00]—a quadratic gap below our hardness ceiling. DQI with quantum decoders is information-theoretically compatible with saturating this ceiling, making it a candidate for the first $r/q + \Omega(1/\sqrt{D})$ algorithm over $\mathbb{F}_q$. However, no efficient quantum decoder achieving this bound is currently known [Ren17, BMP22, BC25, CT24, MP26, SMR⁺26, PR25].

4 Implications for quantum advantage

Our results establish a rigorous complexity-theoretic landscape for evaluating DQI and related quantum optimizers, delineating precisely where advantage is possible and where it is provably foreclosed:

Worst-case barrier. On arbitrary max-LINSAT(q, r) instances, r/q is provably optimal—no efficient algorithm can beat random assignment. DQI’s demonstrated advantages on OPI and HOPI [JSW⁺25, GJ25] therefore rely essentially on instance structure absent from worst-case instances. The semicircle law recovers $\alpha_{\text{DQI}} \rightarrow r/q$ as $\ell/m \rightarrow 0$.

Bounded-degree goalpost. The universal $1/\sqrt{D}$ scaling observed across quantum and classical algorithms is complexity-theoretically forced. The question shifts from “Can quantum algorithms beat r/q ?” to the more refined “How large a constant prefactor can quantum algorithms achieve?” reframing of the question.

Quantum decoding as the path forward. The information-theoretic analysis reveals a qualitative separation: *DQI with classical decoders* is limited to $1/\sqrt{D \log D}$, while *DQI with quantum decoders* is compatible with the optimal $1/\sqrt{D}$. This is especially significant for $q > 2$, where the best classical algorithm achieves only $r/q + \Omega(1/D)$ [Hå00]. Constructing efficient quantum decoders that saturate the ceiling is perhaps the most important open problem in this area.

5 Relevance to AQIS

This work lies at the intersection of quantum algorithms and computational complexity—two core topics of AQIS. The tight inapproximability wall at r/q and the $r/q + \Theta(1/\sqrt{D})$ bounded-degree scaling establish provable benchmarks against which any quantum optimization algorithm must be evaluated, clarifying that quantum speedups must arise from instance structure rather than raw computational power. The bounded-degree regime connects naturally to the quantum information community: bounded-degree constraint matrices define LDPC codes, and the information-theoretic separation between classical and quantum decoders— $1/\sqrt{D \log D}$ versus $1/\sqrt{D}$ —provides a concrete target for quantum decoder design. Whether this information-theoretic compatibility can be realized by an efficient quantum decoder remains a compelling open problem at the interface of quantum algorithms and coding theory.

For general max- k -XORSAT with $k \geq 3$, no polynomial-time algorithm can do substantially better than random guessing on worst-case instances unless $P = NP$: approximating beyond the random-assignment value of $1/2$ is NP-hard. The picture changes when each variable appears in at most D constraints. In that bounded-degree setting, polynomial-time algorithms can provably beat the random baseline by an additive amount of order $1/\sqrt{D}$. For Boolean instances, this scaling is known to be optimal: the matching hardness result is due to Trevisan, while the corresponding algorithmic guarantee was established by Barak et al. Whether the same holds over general finite fields, and what it implies for quantum algorithms, has not been established. We make this connection explicit and extend the hardness to max-LINSAT(q, r) with bounded degree D and over arbitrary finite fields $\mathbb{F}_q$, proving that it is NP-hard to exceed $r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$. These results provide the complexity-theoretic benchmark for the bounded-degree instances targeted by decoded quantum interferometry (DQI), QAOA, and classical heuristics. Any quantum advantage on bounded-degree instances is therefore confined to the constant prefactor. We further show that in the context of DQI, this prefactor is sensitive to the nature of the decoder: DQI with classical decoders faces an information-theoretic $1/\sqrt{D \log D}$ barrier that prevents it from saturating the hardness ceiling, while DQI with quantum decoders is compatible with the optimal $1/\sqrt{D}$ scaling—identifying quantum decoding as the key ingredient for achieving the complexity-theoretic limit with DQI.

1 Introduction

A central goal in the study of NP-hard optimization problems is to characterize the best approximation ratios achievable by polynomial-time algorithms. Among such problems, sparse constraint satisfaction problems, and in particular max- k -XORSAT and related systems of linear constraints over finite fields, play a particularly important role. In max- k -XORSAT, one is given a system of parity constraints involving at most k Boolean variables each, and the goal is to find an assignment satisfying as many constraints as

Maximilian J. Kramer: m.kramer@fu-berlin.de

possible. This is a problem of substantial interest in its own right, but has also recently risen to prominence in the context of quantum algorithms for optimization, for which it is used as a testbed for achieving potential quantum advantages [1].

For general max- k -XORSAT with $k \geq 3$, the random-assignment threshold $1/2$ is a tight inapproximability wall: Håstad [2] has proven that no polynomial-time algorithm can exceed this threshold on worst-case instances, assuming $P \neq NP$. We have recently extended this inapproximability result to max-LINSAT(q, r) over arbitrary finite fields $\mathbb{F}_q$ and acceptance sets of size r with threshold r/q [3]. The instances produced by these PCP-reductions, however, have unbounded variable degree D and variables to clauses ratio $n/m = o(1)$.

To put this into perspective, it is important to state that PCP-based inapproximability [4, 5] does not tell the full story: the picture changes qualitatively when instances possess *exploitable structure*. In this case, both the approximability landscape and the question of quantum advantage change qualitatively. At one extreme, highly structured problems admit provable quantum-classical separations under standard complexity assumptions [6–9]. At the other extreme, worst-case PCP instances have no exploitable structure at all, and quantum algorithms face the same inapproximability walls as classical ones [3]. The scientifically interesting regime lies between these extremes: instances with enough structure for algorithms to exploit, but where that structure arises naturally from the problem rather than being engineered to enable separation results.

Decoded quantum interferometry (DQI) [1] and follow-up results [3, 10–29] operate squarely in this regime as a novel and compelling quantum approach for approximating max-XORSAT and max-LINSAT more generally. DQI reduces an optimization problem to a (quantum) decoding problem via a Fourier transform over the underlying finite field, an idea originating in Regev’s reduction [30–33]. Its performance is governed by the so-called semicircle law which is a function of the decodable structure present in the instance [1]. This makes DQI a compelling framework for exploring quantum advantage in approximation: it cannot help on structureless worst-case instances [3], but may outperform classical algorithms when sufficient decodable structure is present [1, 20]. This is a promising avenue toward quantum advantage for *practically relevant problems* [34–36].

Bounded-degree max- k -XORSAT-instances—where each variable appears in at most D constraints—occupy precisely this intermediate regime. On the worst-case side, polynomial-time algorithms are known to exceed the random-assignment threshold by $\Omega(1/D)$ [37], $\Omega(D^{-3/4})$ [38], and $\Omega(1/\sqrt{D})$ [39] on arbitrary bounded-degree instances. On the average-case side, Shutty et al. [28] recently undertook a systematic study on instances drawn from Gallager’s (k, D) -regular ensemble, showing that DQI/Regev with various decoders, QAOA [40], and classical heuristics such as Turbo Prange all achieve approximation ratios of the form $1/2 + c_k/\sqrt{D}$ with algorithm- and k -dependent constants c_k . Notably, even a relatively simple locally-quantum decoder (FGUM) combined with Regev’s reduction suffices to match the $1/\sqrt{D}$ scaling of the best classical heuristic [28], suggesting that quantum decoding is a promising route toward quantum advantage in this regime.

In the light of all this, a natural question is whether this shared $1/\sqrt{D}$ scaling is coincidental or fundamental, and whether any algorithm—quantum or classical—can do better. This is a crucial question: it provides the goalpost for bounded-degree algorithm design and determines the room for improvement by quantum or classical means. Understanding whether the $1/\sqrt{D}$ scaling is a hard ceiling or an artifact of current techniques is, therefore, important both for classical approximation theory and for assessing the potential of quantum approaches to combinatorial optimization.

In this work, we make three concrete technical contributions and interpret the implica-

tions. First, we make explicit a complexity-theoretic benchmark for worst-case bounded-degree max- k -XORSAT that follows from connecting two known results not previously brought into contact with the DQI literature: Trevisan’s randomized degree-reduction technique [41] and the algorithmic result of Barak et al. [39]. Together, these establish that the optimal worst-case approximation ratio is $1/2 + \Theta_k(1/\sqrt{D})$, which is tight for odd k up to constant factors between known algorithms and hardness. This, in turn, confines any potential quantum advantage on bounded-degree max- k -XORSAT to the constant prefactor. Second, we extend this bounded-degree hardness from max-XORSAT to max-LINSAT(q, r) over arbitrary finite fields $\mathbb{F}_q$ with acceptance sets of size r , proving that the threshold $r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$ is NP-hard to exceed. Third, we derive information-theoretic ceilings on DQI’s performance by extending the analysis of Ref. [1, Sections 13.1–13.2] to max-LINSAT(q, r), showing that quantum decoders are information-theoretically necessary for DQI to saturate the complexity-theoretic ceiling: DQI with classical decoders is limited to $r/q + \mathcal{O}_{q,r}(1/\sqrt{D \log D})$, while DQI with quantum decoders is compatible with the optimal $1/\sqrt{D}$ scaling.

We note that confinement of possible quantum advantage to the constant prefactor is not a limitation in practical settings: for all (q, r) , the approximation ratio lies in $[r/q, 1]$, so the constant directly determines the algorithmic advantage over random assignment. In this setting, a constant-factor improvement can be operationally significant.

2 Preliminaries

2.1 Problem definitions

We start by defining the optimization problems considered in this work, in particular focusing on the (bounded-degree) max-LINSAT-problem as defined in Ref. [1]. Throughout, we denote by OPT the maximum number of satisfiable constraints and define an approximation ratio α for a solution satisfying s out of m constraints to be $\alpha := s/m$.

Definition 1 (max-LINSAT over $\mathbb{F}_q$). *Let $\mathbb{F}_q$ be the finite field of order q and let $B \in \mathbb{F}_q^{m \times n}$. For each $i = 1, \dots, m$, let $F_i \subset \mathbb{F}_q$ be an arbitrary subset of $\mathbb{F}_q$, which yields a corresponding constraint $\sum_{j=1}^n B_{i,j} x_j \in F_i$. The max-LINSAT task is to find $\mathbf{x} \in \mathbb{F}_q^n$ satisfying as many as possible of these m constraints. The arity of constraint i is the number of nonzero entries in row i of B . The degree of variable x_j is the number of constraints in which it appears (i.e., the number of nonzero entries in column j of B). We say an instance has arity at most k if every constraint has arity at most k , and degree at most D if every variable has degree at most D .*

We assume that the acceptance sets F_i are given as an explicit list. In what follows, the arity is the number of variables participating in a single constraint.

Definition 2 (max-LINSAT(q, r) and variants). *We write max-LINSAT(q, r) for the restriction of max-LINSAT over $\mathbb{F}_q$ to instances in which $|F_i| = r$ for every i . The prefix “Ek-” restricts to instances of arity exactly k , while “k-” restricts to arity at most k . Thus:*

- max-LINSAT($q, 1$) consists of systems of linear equations $L_i(\mathbf{x}) = b_i$ over $\mathbb{F}_q$ (singleton acceptance sets);
- max-Ek-LIN- q is max-LINSAT($q, 1$) restricted to arity exactly k ;
- max-Ek-LINSAT(q, r) is max-LINSAT(q, r) restricted to arity exactly k ;

- $\text{max-XORSAT} = \text{max-LINSAT}(2, 1)$ is the special case over $\mathbb{F}_2$; and
- $\text{max-}k\text{-XORSAT}$ restricts max-XORSAT to arity at most k , with $\text{max-E}k\text{-XORSAT}$ denoting arity exactly k .

In particular, $\text{max-E}k\text{-XORSAT}$ and $\text{max-E}k\text{-LIN-2}$ are the same problem.

When every variable has degree exactly D , and every constraint has arity exactly k , the instance is called (k, D) -regular; its constraint–variable bipartite graph is then (k, D) -biregular and satisfies $km = Dn$. We will also need the following unrelated problem, whose bounded-degree inapproximability was established by Trevisan [41]:

Definition 3 ($\text{max-E}k\text{-SAT}$). *An instance of $\text{max-E}k\text{-SAT}$ consists of n Boolean variables $x_1, \dots, x_n \in \{0, 1\}$ and m clauses, each being a disjunction of exactly k literals (a literal is a variable x_j or its negation $\bar{x}_j$). The goal is to find an assignment maximizing the number of satisfied clauses. A random assignment satisfies each clause with probability $1 - 2^{-k}$, giving a baseline of $7/8$ for $k = 3$.*

We explicitly emphasize that max-E3-SAT and $\text{max-E3-LIN-2} = \text{max-E3-XORSAT}$ are distinct problems: in the former, each constraint is a disjunction of three literals (satisfiable by 7 out of 8 assignments), while in the latter each constraint is a linear equation over $\mathbb{F}_2$ (satisfiable by exactly half of all assignments). Trevisan’s degree-reduction technique [41] has originally been stated for max-E3-SAT but applies to any CSP; we exploit this generality in Theorem 6.

2.2 Inapproximability landscape

We now summarize the inapproximability landscape (i.e., PCP-hardness statements), proceeding from unbounded-degree to bounded-degree instances.

2.2.1 Unbounded degree

One of the building blocks of the proof we establish is the seminal work of Ref. [2]. Håstad [2, Theorem 5.9], building on the celebrated PCP theorem [4, 5], has proven that for every finite Abelian group Γ and every $\varepsilon > 0$, it is NP-hard to distinguish $\text{max-E}k\text{-LIN-}\Gamma$ instances with $\text{OPT} \geq (1 - \varepsilon)m$ from those with $\text{OPT} \leq (1/|\Gamma| + \varepsilon)m$. We recently generalized this in Ref. [3] to $\text{max-LINSAT}(q, r)$ with arbitrary-sized acceptance sets, yielding the following inapproximability theorem:

Theorem 4 (Inapproximability of $\text{max-LINSAT}(q, r)$ [3]). *For every finite field $\mathbb{F}_q$, every integer $1 \leq r \leq q - 1$, and every $\varepsilon > 0$, it is NP-hard to distinguish, given an instance of $\text{max-LINSAT}(q, r)$, between*

- (Y) *instances with $\text{OPT} \geq (1 - \varepsilon)m$ and*
- (N) *instances with $\text{OPT} \leq (r/q + \varepsilon)m$.*

This means it is NP-hard to approximate within a factor strictly better than $r/q + \varepsilon$ for every $\varepsilon > 0$.

Note that this inapproximability guarantee is *tight* since a uniformly chosen assignment $\mathbf{x} \in \mathbb{F}_q$ satisfies each constraint i with probability $|F_i|/q = r/q$ and thus gives an expected approximation ratio of r/q . The hard instances produced by these PCP reductions have unbounded variable degree and $n/m = o(1)$. When the degree is bounded, and hence when each variable appears in at most D constraints, the approximability landscape changes qualitatively.

2.2.2 Bounded degree

When the degree is bounded, the inapproximability landscape changes: the random-assignment threshold is no longer a hard wall, and algorithms can provably exceed it [37–39]. We will review these algorithms in detail in Section 4. On the hardness side, the relevant result on which we build here is due to Trevisan [41], who introduced a randomized degree-reduction technique (variable splitting, weighted replication, random sampling, and pruning) that converts arbitrary CSP instances into bounded-degree instances while incurring a $\mathcal{O}(1/\sqrt{D})$ loss in the approximation gap. Applied to Håstad’s optimal inapproximability of max-E3-SAT, this yields the following theorem.

Theorem 5 (Bounded-degree inapproximability of max-E3-SAT [41]). *For every degree bound D , it is NP-hard to approximate max-E3-SAT on instances where each variable appears in at most D clauses within $7/8 + \mathcal{O}(1/\sqrt{D})$.*

Since Trevisan’s reduction is randomized and succeeds with constant probability, the inapproximability with polynomial time classical algorithms holds under $\text{RP} \neq \text{NP}$ rather than $\text{P} \neq \text{NP}$; for quantum algorithms, the same conclusion holds under $\text{NP} \not\subseteq \text{BQP}$.

Although stated originally for max-E3-SAT, Trevisan’s reduction is purely combinatorial and applies to any CSP over a finite alphabet [41, 42]. Applying it instead to Håstad’s $(1-\varepsilon, 1/2+\varepsilon)$ -gap for max-E3-LIN-2 [2] yields hardness of approximating bounded-degree max-E3-XORSAT within $1/2 + \mathcal{O}(1/\sqrt{D})$ under the same assumptions. This appears to be folklore, though it has not been made explicit in the literature.¹ A central contribution of the present work is to extend this bounded-degree hardness from max-XORSAT to max-LINSAT(q, r) over arbitrary finite fields $\mathbb{F}_q$ with acceptance sets of size r , which we carry out in Section 3.

3 Inapproximability of bounded-degree max-LINSAT

The proof combines three ingredients:

1. Håstad’s $(1-\varepsilon, 1/q+\varepsilon)$ -inapproximability for max-E3-LIN- q [2], which produces hard instances with unbounded variable degree.
2. Trevisan’s randomized degree-reduction technique [41], which converts these into bounded-degree instances at the cost of a $\mathcal{O}(1/\sqrt{D})$ loss in the gap.
3. The deterministic reduction from max-LINSAT($q, 1$) to max-LINSAT(q, r) from Ref. [3], which lifts the result to arbitrary acceptance-set size r at the cost of a constant factor in the degree.

Composing these yields the following result.

Theorem 6 (Bounded-degree inapproximability of max-LINSAT(q, r)). *For every finite field $\mathbb{F}_q$, every integer $1 \leq r \leq q-1$, and every degree bound D , it is NP-hard under randomized reductions to approximate max-LINSAT(q, r) on instances where each variable appears in at most D constraints, within*

$$\frac{r}{q} + \mathcal{O}_{q,r}\left(\frac{1}{\sqrt{D}}\right). \quad (1)$$

In particular, this implies the same hardness for (k, D) -regular instances.

¹The composition is referenced informally in Refs. [38, 42]. It also follows as a special case of our Theorem 6.

Proof. We compose two reductions. The first reduction adapts Trevisan’s randomized degree-reduction technique [41]—stated for max-E3-SAT but applicable to any CSP over a finite alphabet [41, 42]—to convert Håstad’s unbounded-degree hard instances of max-E3-LIN- q [2] into bounded-degree instances. The second reduction applies the deterministic lifting from max-LINSAT($q, 1$) to max-LINSAT(q, r) from Ref. [3]; since this multiplies the degree by $\binom{q-1}{r-1}$, we choose the initial degree bound to $\tilde{D} = \lfloor D / \binom{q-1}{r-1} \rfloor$ so that the final degree after lifting is at most D .

Figure 1: Degree reduction $\phi \rightarrow \phi_w \rightarrow \phi_R \rightarrow \phi_{\tilde{D}}$ on an example with $n = 6$, $m = 5$, arity $k = 3$, with variable degree vector $(o_1, \dots, o_6) = (3, 3, 3, 2, 2, 2)$ and degree bound $\tilde{D} = 3$. Each panel transition represents a larger step of the construction. The first panel visualizes the input instance as a graph, showing which variables belong to which constraints. In the second panel, the weighted instance ϕ_w is shown: Each variable x_i is copied o_i times and each original constraint is expanded to a *constraint group*, such that each combination of copy-variables relating to the corresponding original constraint is covered by one element of the group. These group elements are also each weighted in inverse proportion to their group’s size. The third panel introduces the probabilistic step, where $\tilde{D}N/e^2$ constraints (rounded up) are chosen randomly in proportion to their weight. In the last panel, constraints are iteratively pruned as long as they contain variables that have more than $\tilde{D}$ appearances (marked orange). This is done by replacing them with trivial new constraints on new variables y_{*}^j , thus restoring the degree cap.

Degree reduction. We give the argument in full for arbitrary q , since the generalization from Boolean to $\mathbb{F}_q$ alphabets has not previously appeared in the literature; the key modification is in the union bound (which ranges over q^N rather than 2^N assignments) and the recovery step (which uses q -ary plurality rather than majority decoding). Let ϕ be a hard instance of max-E3-LIN- q with n variables over $\mathbb{F}_q$, m constraints, and gap $(1 - \varepsilon, 1/q + \varepsilon)$ as produced by Håstad’s PCP reduction [2]. Let o_i denote the number of constraints containing x_i and set $N = \sum_i o_i = 3m$. Following Trevisan [41], we construct a degree- $\tilde{D}$ instance $\phi_{\tilde{D}}$ by: (i) introducing, for each variable x_i , a set of o_i copy-variables $y_i^1, \dots, y_i^{o_i} \in \mathbb{F}_q$; (ii) building a weighted instance ϕ_w : for each original constraint involving variables $\{x_a, x_b, x_c\}$, we create all constraints obtained by substituting the original variables with their respective copies, i.e., we build each new constraint with $\{\{y_a^{j_1}, y_b^{j_2}, y_c^{j_3}\} \mid (j_1, j_2, j_3) \in [o_a] \times [o_b] \times [o_c]\}$

(carrying over their values); each of those new constraints is then weighted by $1/(o_a o_b o_c)$; (iii) sampling $(\tilde{D}/e^2) \cdot N$ constraints from ϕ_w proportionally to weight, yielding ϕ_R ; and (iv) pruning variables with more than $\tilde{D}$ occurrences by replacing excess constraints with trivially satisfiable ones on fresh variables, yielding $\phi_{\tilde{D}}$. An example of this construction is shown in Figure 1.

Completeness of the reduction is immediate: any assignment satisfying a $(1-\varepsilon)$ -fraction of ϕ extends to $\phi_{\tilde{D}}$ by setting all copies equal. We analyze soundness in two steps: First, we consider only ϕ_R , where concentration applies, then we account for the additional error introduced by pruning in the transition from ϕ_R to $\phi_{\tilde{D}}$. To begin, note that the sum of all weights in ϕ_w is m . We fix an assignment $\mathbf{a}$ to the copy-variables and let $\rho(\mathbf{a}) \in [0, 1]$ be the sum of weights of all constraints in ϕ_w that are satisfied by $\mathbf{a}$, divided by m . Each of the constraints in ϕ_R is drawn independently and proportionally to its weight so the indicator of whether $\mathbf{a}$ satisfies any one is i.i.d. Bernoulli($\rho(\mathbf{a})$). Applying Hoeffding's inequality to the total number S of those constraints satisfied by $\mathbf{a}$, we get

$$\Pr \left[\frac{S}{\tilde{D}N/e^2} \geq \rho(\mathbf{a}) + \varepsilon \right] \leq \exp(-2\varepsilon^2 \tilde{D}N/e^2). \quad (2)$$

Using the union bound over all possible assignments of the N copy-variables, we get

$$q^N \cdot \exp(-2\varepsilon^2 \tilde{D}N/e^2) < 1 \iff \varepsilon > e\sqrt{(\ln q)/(2\tilde{D})}, \quad (3)$$

so setting $\varepsilon = \Theta_q(1/\sqrt{\tilde{D}})$ ensures that simultaneously for all assignments $\mathbf{a}$, no assignment satisfies more than a $\rho(\mathbf{a}) + \varepsilon$ fraction of the constraints in ϕ_R (with high probability). We next argue that no dominant additional error is introduced in the pruning step. For each copy-variable y , let X_y count the constraints of ϕ_R that contain y ; as each sample contains y with probability $1/m$, we have $X_y \sim \text{Binomial}(\tilde{D}N/e^2, 1/m)$ with mean $\mu = 3\tilde{D}/e^2$ (using $N = 3m$) and variance $\sigma^2 \leq \mu$. Since $\max\{X_y - \tilde{D}, 0\}$, called *excess* of X_y , can be at most $\frac{(X_y - \mu)^2}{\tilde{D} - \mu}$ algebraically², the expected excess is $\sigma^2/(\tilde{D} - \mu) \leq \frac{1}{(e^2/3 - 1)}$. Summing over all copy-variables, the expected number R of pruned constraints satisfies $\mathbb{E}[R] \leq N/(\frac{e^2}{3} - 1)$. By Markov's inequality, $R \leq 4N/(\frac{e^2}{3} - 1)$ with probability at least $3/4$. The constraint replacements then contribute at most $\frac{R}{\tilde{D}N/e^2} = (4e^2/(\frac{e^2}{3} - 1))/\tilde{D} = \mathcal{O}(1/\tilde{D})$ to the satisfaction fraction.

To recover an assignment $\mathbf{x}(\mathbf{a}) \in \mathbb{F}_q^n$ from $\mathbf{a}$, set $x_i = v$ with probability $|\{j : y_i^j = v\}|/o_i$. For any constraint $x_a + x_b + x_c = b$, the satisfaction probability under this recovery equals exactly the weighted fraction W of its expansions satisfied by $\mathbf{a}$ in ϕ_w :

$$\Pr[x_a + x_b + x_c = b] = \sum_{v_1 + v_2 + v_3 = b} \frac{|\{j : y_a^j = v_1\}|}{o_a} \cdot \frac{|\{j : y_b^j = v_2\}|}{o_b} \cdot \frac{|\{j : y_c^j = v_3\}|}{o_c} = W. \quad (4)$$

This identity follows from the independence of the induced product distribution and holds for linear constraints over any finite Abelian group. Summing over all m constraints, the expected satisfaction is $m \cdot \rho(\mathbf{a})$, so an assignment achieving at least this exists. The degree reduction thus yields max-E3-LIN- q instances of degree at most $\tilde{D}$ with gap $(1 - \varepsilon, 1/q + \mathcal{O}_q(1/\sqrt{\tilde{D}}))$.

Lifting to max-LINSAT(q, r). The reduction from max-LINSAT($q, 1$) to max-LINSAT(q, r) in Ref. [3] replaces each constraint by $\binom{q-1}{r-1}$ constraints with r -element acceptance sets,

²For positive numbers $a = X_y - \tilde{D} > 0$ and $b = \tilde{D} - \mu > 0$: $(a + b)^2/b = a^2/b + 2a + b \geq a$.

multiplying the degree by $\binom{q-1}{r-1}$. With $\tilde{D} = \lfloor D/\binom{q-1}{r-1} \rfloor$, the output has degree at most D . The soundness maps $1/q + \delta$ to $r/q + \delta \cdot (q-r)/(q-1) \leq r/q + \delta$. Substituting $\delta = \mathcal{O}_q(1/\sqrt{\tilde{D}}) = \mathcal{O}_{q,r}(1/\sqrt{D})$ gives max-LINSAT(q, r) instances of degree at most D with gap $(1 - \varepsilon, r/q + \mathcal{O}_{q,r}(1/\sqrt{D}))$. $\square$

Remark 7 (Implications of the randomized reduction). *Since Trevisan’s degree reduction [41], and thus also our reduction, is randomized, the inapproximability from Theorem 6 holds under the assumption $\text{RP} \neq \text{NP}$ rather than $\text{P} \neq \text{NP}$. In particular, assuming $\text{RP} \neq \text{NP}$, no polynomial-time classical algorithm can approximate max-LINSAT(q, r) with bounded degree D beyond $r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$ on worst-case instances, and likewise no quantum algorithm can do so unless $\text{NP} \subseteq \text{BQP}$. The hard instances we construct have arity exactly 3; since max-E3-LINSAT(q, r) is a special case of max-LINSAT(q, r), this establishes hardness for the general problem.*

Remark 8 (Limiting cases of Theorem 6). *The hard instances produced by the reduction have arity exactly $k = 3$. Setting $q = 2$ and $r = 1$ recovers the claimed hardness for bounded-degree max-E3-XORSAT; hardness for $k > 3$ follows by padding each equation. In the limit $D \rightarrow \infty$, the $\mathcal{O}_{q,r}(1/\sqrt{D})$ term vanishes, and the bound collapses to the unbounded-degree wall r/q of Theorem 4, consistent with the fact that Håstad’s PCP reduction [2] produces instances with unbounded variable degree. Theorem 6 thus unifies the bounded- and unbounded-degree settings.*

4 Quantum and classical algorithms for bounded degree instances

The resulting landscape for max-LINSAT(q, r) is also graphically summarized in Fig. 2. We now complement the hardness results with the algorithmic landscape for bounded-degree max-LINSAT(q, r). The statements and algorithms for the special case of max-E k -XORSAT are summarized in Table 1.

Algorithm	Advantage over 1/2	Q/C
Worst-case guarantees		
Håstad greedy [37]	$\Omega(1/D)$	C
Depth-1 QAOA [38]	$c/(\sqrt{D} \ln D)$, $c = 1/101$	Q
Barak et al. [39] (odd k or triangle-free instances)	$\exp(-\mathcal{O}(k))/\sqrt{D}$	C
Complexity-theoretic limitations		
NP-hardness (cf. [41, 42] and Theorem 6)	optimal worst-case scaling: $\Theta_k(1/\sqrt{D})$ (up to constants)	–
Information-theoretic upper bound		
DQI with classical decoders (Section 4.3)	$\mathcal{O}(1/\sqrt{D \log D})$	Q
DQI with quantum decoders (Section 4.3)	$\mathcal{O}(1/\sqrt{D})$	Q

Table 1: Approximation landscape for bounded-degree max-E k -XORSAT at large degree D . The table summarizes worst-case algorithmic guarantees, complexity-theoretic hardness, and information-theoretic ceilings for DQI. The hardness results and the algorithm of Barak et al. together show that the optimal worst-case scaling in D is $\Theta(1/\sqrt{D})$ up to constant factors.

4.1 Bounded-degree max-E k -XORSAT

Worst-case algorithms and optimal scaling. Håstad [37] has shown first that bounded-degree CSP instances are not approximation-resistant: For any CSP with degree at most

Figure 2: Approximability landscape for bounded-degree max-LINSAT(q, r) as a function of $1/\sqrt{D}$ and normalized decoding radius ℓ/m of the dual code used in DQI [1]. The vertical axis is the approximation ratio. The plane interpolates between (i) worst-case bounded-degree instances with no decodable structure ($\ell/m = 0$) and (ii) structured instances with decoding gain ($\ell/m > 0$). For $\ell/m = 0$, the blue curve shows the worst-case hardness bound $r/q + \mathcal{O}(1/\sqrt{D})$ from Theorem 6, tight up to constants due to Barak et al. [39] (for $r = 1$ and $q = 2$). The orange and black curves indicate representative scalings of algorithms. For fixed D , the magenta curve shows the DQI semicircle law exploiting decodable structure. The hard instances produced by the reduction have $\ell/m = 0$, while the DQI regime reflects structured instances with $\ell/m > 0$. Characterizing the tight approximability across the full $(D, \ell/m)$ plane remains an important open problem.

D , a greedy algorithm achieves $\mu + \Omega(1/D)$ for μ being the random assignment threshold. For max-Ek-XORSAT this gives $1/2 + \Omega(1/D)$. Depth-1 QAOA improved the advantage to $\Omega(D^{-3/4})$ [38]. Barak et al. [39] (see also Ref. [43]) achieved the optimal scaling classically: for max-Ek-XORSAT with odd k and degree bound D , their algorithm finds an assignment satisfying at least a $1/2 + \exp(-\mathcal{O}(k))/\sqrt{D}$ fraction of constraints.³ Combining with the bounded-degree hardness from Theorems 5 and 6 pins down the optimal worst-case scaling:

Observation 9 (Optimal scaling for bounded-degree max-Ek-XORSAT). *For max-Ek-XORSAT with fixed odd k , degree at most D , and D large, the optimal polynomial-time approximation ratio on worst-case instances is $1/2 + \Theta_k(1/\sqrt{D})$: the hardness bound $1/2 + \mathcal{O}(1/\sqrt{D})$ follows from Theorem 6 (assuming $\text{RP} \neq \text{NP}$), and the matching algorithm achieving $1/2 + \exp(-\mathcal{O}(k))/\sqrt{D}$ is due to Barak et al. [39]. For even k , the algorithmic bound requires an additional triangle-freeness assumption.*

Despite extensive recent work on bounded-degree max- k -XORSAT via DQI and QAOA, this inapproximability landscape appears not to have been explicitly connected to these algorithms. In light of Theorem 6, any improvement—classical or quantum—is confined to the constant prefactor c_k in $1/2 + c_k/\sqrt{D}$. The worst-case constant $\exp(-\mathcal{O}(k))$ from Barak et al. is not computed explicitly and is likely very small for moderate k .

³A subsequent version of Ref. [38] independently obtained $1/2 + 1/(101\sqrt{D} \ln D)$ and $1/2 + \text{const}/\sqrt{D}$ on “typical” instances.

Average-case constants on Gallager instances. On random (k, D) -regular instances drawn from Gallager’s ensemble, a richer picture emerges; we summarize the landscape here, following the systematic catalog of Ref. [28]. Prange’s information-set decoding [44] solves a random $n \times n$ subsystem exactly and satisfies the residual constraints in expectation, giving $1/2 + k/(2D)$. All other average-case algorithms achieve the $1/\sqrt{D}$ improvement. Ref. [28] establishes that in the large D limit, both Regev/DQI with locally-quantum decoders (Regev+FGUM) and the classical Turbo Prange heuristic achieve $1/2 + 1/\sqrt{2\pi D}$, arising from the central limit theorem applied to binomial deviations. Remarkably, the relatively simple FGUM decoder thus already matches the $1/\sqrt{D}$ scaling and the exact constant $1/\sqrt{2\pi}$ of the best classical heuristic. Notably, the upgrade from Prange’s order $1/D$ -improvement to Turbo Prange’s order $1/\sqrt{D}$ -improvement comes from a single modification: a greedy local improvement step. QAOA at depth p achieves $1/2 + \nu_p^{[k]} \sqrt{k/(2(D-1))}$ with numerically calculated values $\nu_p^{[k]}$ for k up to 6 given in Ref. [45]. A systematic comparison of the constants achieved by these algorithms, including DQI with various decoders, QAOA at different depths, and classical heuristics, is provided in Ref. [28]. Additionally, Piveteau [46] computes the constants achieved by combining DQI with *belief propagation with quantum messages* (BPQM) [47–49] for different combinations of (k, D) .

In a closely related random regime— D -regular instances with random parities—Ref. [50] derives a closed-form expression for the approximation ratio of depth-1 QAOA, showing that it achieves $1/2 + c_k/\sqrt{D}$ with exactly computable constants c_k that rise monotonically with k . For random (k, D) -regular instances, they also establish a theoretical bound of the optimum concentrating around $1/2 + \Theta(\sqrt{k/D})$, which confirms that the $1/\sqrt{D}$ scaling reflects the structure of optimal solutions themselves and not just algorithmic limitations.

Summary. The worst-case scaling for bounded-degree max-Ek-XORSAT is understood up to k -dependent constants: current algorithms and hardness results together establish a $\Theta_k(1/\sqrt{D})$ scaling. It should be noted, however, that for large even k on instances containing triangles, the algorithmic picture remains incomplete as Barak et al.’s algorithm [39] requires odd k or triangle-freeness. The same $1/\sqrt{D}$ scaling also appears in average-case analyses of random Gallager instances, though no formal connection between worst-case hardness and average-case performance is known. Any quantum advantage for worst-case bounded-degree max-Ek-XORSAT in this setting must appear through the constant prefactor, not through the asymptotic dependence on the degree bound.

4.2 Bounded-degree max-LINSAT

For $q > 2$, the landscape is qualitatively different: the hardness side is established by Theorem 6 at $r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$, but the algorithmic side lags behind. The only worst-case guarantee for general alphabets remains Håstad’s greedy method [37] which extends routinely to CSPs over any fixed finite abelian group (in particular $\mathbb{F}_q$), achieving $r/q + \Omega(1/D)$ —a full quadratic factor weaker in D than the hardness ceiling.

The algorithm of Barak et al. [39] is inherently Boolean, relying on $\{\pm 1\}$ Fourier analysis and Bonami–Beckner hypercontractivity, and does not appear to extend in a straightforward way to $\mathbb{F}_q$ with $q > 2$. Extending it would require nontrivial generalizations of Boolean hypercontractive and invariance-based arguments. No $\mu + \Omega(1/\sqrt{D})$ (with μ being the random assignment threshold) algorithm for bounded-degree CSPs over non-Boolean alphabets is currently known. Whether any algorithm—classical or quantum—can match the $1/\sqrt{D}$ hardness scaling of Theorem 6 for $q > 2$ remains open (see Discussion, Question 4).

4.3 Information-theoretic limitations of DQI in the bounded-degree setting

The algorithmic gap for $q > 2$ identified in the previous subsection is particularly interesting from the perspective of DQI. Ref. [1, Sections 13.1–13.2] establishes information-theoretic ceilings on DQI’s performance for max-XORSAT under both classical and quantum decoding; we extend these to max-LINSAT(q, r) and derive their implications for bounded-degree instances.

The DQI semicircle law [1], combined with information-theoretic decoding limits, constrains DQI’s approximation ratio on bounded-degree instances independently of any complexity assumption. These bounds are complementary to the complexity-theoretic hardness results above: they constrain the DQI framework itself, regardless of computational efficiency. Consider a max-Ek-LINSAT(q, r) instance with constraint matrix $B \in \mathbb{F}_q^{m \times n}$ of row weight k and column weight at most D . The dual code $C^\perp = \ker(B^T) \subseteq \mathbb{F}_q^m$ has rate $R = 1 - \text{rank}(B)/m \geq 1 - n/m$ (with equality generically for full-column-rank instances). For (k, D) -regular instances, $km = Dn$ and hence $n/m = k/D$. Expanding the semicircle law [1] for small decoding radius ℓ/m gives

$$\alpha_{\text{DQI}} = \left(\sqrt{\frac{\ell}{m} \left(1 - \frac{r}{q}\right)} + \sqrt{\frac{r}{q} \left(1 - \frac{\ell}{m}\right)} \right)^2 = \frac{r}{q} + \frac{2\sqrt{r(q-r)}}{q} \sqrt{\frac{\ell}{m}} + \mathcal{O}\left(\frac{\ell}{m}\right), \quad (5)$$

if $r/q \leq 1 - \ell/m$, and $\alpha_{\text{DQI}} = 1$ otherwise. Here, ℓ denotes the asymptotic decoding radius under the induced channel model, i.e., the maximum number of random errors in $C^\perp$ that the decoder can reliably correct.

1. *Classical decoders.* For the binary case ($q = 2$), Jordan et al. [1, Theorem 13.2] show that DQI with classical decoders is bounded by

$$\alpha_{\text{DQI}}^{\text{cl}} \leq \frac{1}{2} + \sqrt{\frac{n/m}{\log(m/n)}}, \quad (6)$$

using the Shannon capacity of the binary symmetric channel [51, 52]. The $\log(m/n)$ denominator arises because $C_2(p) = 1 - H_2(p) \sim 1 - p \log_2(1/p)$ for small p [1], so inverting the rate condition $1 - n/m \leq C_2(\ell/m)$ yields $\ell/m = \mathcal{O}((n/m)/\log(m/n))$. For general q , the same argument applied to the q -ary symmetric channel [51, 52] gives $C_q(p) = \log_2 q - H_q(p)$ with $H_q(p) \sim p \log_2((q-1)/p)$ for small p , yielding

$$\alpha_{\text{DQI}}^{\text{cl}} \leq \frac{r}{q} + \mathcal{O}_{q,r} \left(\sqrt{\frac{n/m}{\log(m/n)}} \right), \quad (7)$$

which on (k, D) -regular instances specializes to $r/q + \mathcal{O}_{q,r}(1/\sqrt{D \log D})$. This would improve on Håstad’s $r/q + \Omega(1/D)$ [37] but falls short of the hardness ceiling $r/q + \mathcal{O}(1/\sqrt{D})$ from Theorem 6 by a $\sqrt{\log D}$ factor.

2. *Quantum decoders.* Quantum decoders may partially evade the classical $\log(1/p)$ entropy penalty, because coherent decoding accesses non-orthogonal quantum states rather than classical syndrome bits. For the binary case ($q = 2$), Jordan et al. [1, Section 13.2] model the coherent errors in DQI as a classical-quantum channel and show via the Holevo bound [53] that

$$\alpha_{\text{DQI}}^{\text{q}} \leq 1 - H_2^{-1} \left(1 - \frac{n}{m} \right). \quad (8)$$

For (k, D) -regular instances with $n/m = k/D$, the expansion $H_2(1/2 - \delta) = 1 - \Theta(\delta^2)$ near capacity gives $1/2 + \Theta(1/\sqrt{D})$, matching the hardness ceiling of Theorem 6. The key reason the $\sqrt{\log D}$ gap disappears is that the Holevo capacity of the induced channel satisfies $\chi(p) = 1 - \Theta(p)$ for small p [1], losing capacity linearly in p rather than as $p \log(1/p)$. For general q , the natural q -ary generalization maps each symbol $i \in \mathbb{F}_q$ to the state vector $|i_p\rangle = \sqrt{1-p}|i\rangle + \sqrt{p/(q-1)} \sum_{j \neq i} |j\rangle$ with $p = \ell/m$. Since the outputs are pure, the Holevo capacity equals the von Neumann entropy of the average state $\bar{\rho} = \frac{1}{q} \sum_i |i_p\rangle\langle i_p|$. A direct computation gives $\chi_q(p) = \log_2 q - 2p/\ln 2 + \mathcal{O}(p^{3/2})$, with the leading coefficient independent of q —again linear in p , without the logarithmic penalty. The rate condition then yields $\ell/m = \Theta(n/m)$, and via (5):

$$\alpha_{\text{DQI}}^q \leq \frac{r}{q} + \mathcal{O}_{q,r}\left(\frac{1}{\sqrt{D}}\right) \quad (9)$$

on (k, D) -regular instances, matching the hardness ceiling of Theorem 6 for all (q, r) .

Thus, *DQI with classical decoders* faces an information-theoretic $\sqrt{\log D}$ limitation on bounded-degree instances. By contrast, *DQI with quantum decoders* is information-theoretically compatible with the optimal $1/\sqrt{D}$ scaling: for $q = 2$ by following Ref. [1], and via the q -ary channel generalization above for $q > 2$.

This underscores the importance of quantum decoding as a direction for DQI: As observed in Ref. [28], quantum decoders significantly broaden the algorithmic toolbox for bounded degree instances, and our results show that this broadening is also justified from a complexity-theoretic and information-theoretic viewpoint. To the best of our knowledge, no efficient quantum decoder achieving the Holevo-capacity scaling for the codes arising in bounded-degree DQI instances is currently known, though several approaches toward *efficient quantum decoding* have been developed [10, 18, 28, 47–49, 54].

5 Discussion

In this work, we have explored and identified the best approximation ratios achievable by polynomial-time algorithms for an important family of optimization problems. The central message of this work is that the $1/\sqrt{D}$ scaling observed across all known algorithms for bounded-degree max- k -XORSAT is complexity-theoretically forced, and that the same scaling extends to max-LINSAT(q, r) over arbitrary finite fields. We conclude by highlighting several concrete questions that remain open in light of the bounded-degree inapproximability results established above.

1. **Optimal worst-case constant.** What is the tight worst-case constant $c^*(k)$ such that $1/2 + c^*(k)/\sqrt{D}$ is achievable but $1/2 + (c^*(k) + \varepsilon)/\sqrt{D}$ for any $\varepsilon > 0$ is NP-hard? The algorithm of Barak et al. [39] gives $c^*(k) \geq \exp(-\mathcal{O}(k))$, but the true constant could be much larger. Equivalently, is the $\exp(-\mathcal{O}(k))$ dependence necessary, or can it be improved to a polynomial in k ?
2. **Closing the gap for bounded-degree max-LINSAT(q, r) with $q > 2$.** Theorem 6 establishes hardness at $r/q + \mathcal{O}_{q,r}(1/\sqrt{D})$, but the best known worst-case algorithm for $q > 2$ remains Håstad’s greedy method [37] at $r/q + \Omega(1/D)$ —a quadratic gap in D . The algorithm of Barak et al. [39] is inherently Boolean, relying on $\{\pm 1\}$ Fourier analysis and Bonami–Beckner hypercontractivity. A classical route to closing the gap would be to extend their technique to $\mathbb{F}_q$. A more speculative, and potentially quantum, route is suggested by the information-theoretic arguments made in

Section 4.3 that suggest that DQI combined with a quantum decoding algorithm might feature the $r/q + \mathcal{O}(1/\sqrt{D})$ scaling for bounded-degree instances. However, no quantum decoding algorithms are currently known that match the information-theoretically achievable decoding limit, which would yield this performance. We note that worst-case bounded-degree instances can have dual codes with minimum distance $\mathcal{O}(1)$, in which case DQI reduces to random assignment regardless of decoder quality. The information-theoretic analysis of Section 4.3 shows that even on instances with good coding-theoretic properties, DQI with classical decoders is limited to $r/q + \mathcal{O}(1/\sqrt{D \log D})$.

3. **Quantum constant advantage for $k \geq 3$.** This raises the important question relevant for assessing potential quantum advantages [34–36]: Can any quantum algorithm achieve a strictly larger constant c than the best classical algorithm on bounded-degree max- k -XORSAT? On average-case bounded-degree max- k -XORSAT-instances drawn from the Gallager-ensemble, Ref. [28] shows that Regev+FGUM is exactly matched by the classical Turbo Prange for all (k, D) . QAOA achieves larger constants at moderate depth, but it is unknown whether this advantage persists against all classical algorithms. For the related but distinct problem of MaxCut ($k = 2$) on D -regular large-girth graphs, the constant-prefactor competition is more advanced: the best known assumption-free classical algorithms achieve $c = 2/\pi \approx 0.637$ [55], while QAOA at depth $p = 11$ provably exceeds this [45]. A conditional classical algorithm also exceeds $2/\pi$, but only assuming the *no overlap gap property* [56]. However, MaxCut is qualitatively different—the cost function is quadratic, and the classical benchmark arises from SDP rounding rather than the hypercontractivity-based methods relevant to $k \geq 3$ —so these results do not transfer directly. We stress that this competition over constants is not a second-order concern: since the approximation ratio lives in $[r/q, 1]$, the constant prefactor c is precisely what an algorithm buys over random assignment, so a quantum algorithm with a strictly larger constant c would constitute a genuine, operationally meaningful advantage on these instances.
4. **Average-case vs. worst-case.** The average-case constants on Gallager instances vastly exceed the worst-case constant $\exp(-\mathcal{O}(k))$. Does a complexity-theoretic explanation exist for why Gallager instances are easier, or is the gap an artifact of the analysis?

It is the hope that this work can stimulate the answer of some of those questions.

We establish tight inapproximability bounds for max-LINSAT, the problem of maximizing the number of satisfied linear constraints over the finite field $\mathbb{F}_q$, where each constraint accepts r values. Specifically, we prove by a direct reduction from Håstad’s theorem that no polynomial-time algorithm can exceed the random-assignment ratio r/q by any constant, assuming $P \neq NP$. This threshold coincides with the $\ell/m \rightarrow 0$ limit of the semicircle law governing decoded quantum interferometry (DQI), where ℓ is the decoding radius of the underlying code. Together, these observations delineate the boundary between worst-case hardness and potential quantum advantage, showing that any algorithm surpassing r/q must exploit instance structure beyond what is present in the hard instances produced by PCP reductions.

1 Introduction

Recent years have seen growing interest in quantum algorithms for combinatorial optimization [1], particularly for problems with strong worst-case classical hardness. Given the practical and industrial relevance of these problems across a wide range of scheduling and routing tasks, the design of corresponding quantum algorithms is of considerable importance. For such problems, one cannot expect a quantum computer to solve or approximate all instances of the combinatorial optimization problem in polynomial time. This does not mean that one cannot hope that quantum computers will have computational advantages over classical computers. Indeed, in such cases, potential super-polynomial quantum advantages are often investigated on restricted or structured families of instances [2–5]. One such example that has recently been given a lot of attention is the *decoded quantum interferometry* (DQI) algorithm introduced in Ref. [6]. DQI works by using the quantum Fourier transform to reduce the optimization problem to a decoding task, and then coherently applies an efficient decoding algorithm to amplify the quantum interference between satisfying assignments. The approximation ratio of DQI is characterized by a closed-form formula, coined the *semicircle law* [6].

DQI targets a generalized linear constraint satisfaction problem over finite fields, commonly referred to as max-LINSAT. The flagship application is the *optimal polynomial intersection* (OPI) problem, a structured max-LINSAT instance whose constraint matrix

Maximilian J. Kramer: m.kramer@fu-berlin.de

has Vandermonde structure arising from Reed–Solomon codes that are efficiently decodable up to their designed error radius. For OPI, in a certain parameter regime, DQI achieves a super-polynomial speed-up over *known* classical algorithms.

A growing body of follow-up work has developed around DQI [7–23]. Most relevant to our setting, the DQI advantage for OPI has been strengthened via soft decoding of Reed–Solomon codes [7, 21] and extended to algebraic geometry codes via a generalization called HOPI [17]. At the same time, several works have exposed DQI’s limitations [13, 14, 16].

A prerequisite for precisely interpreting the results surrounding DQI is a clear understanding of the *approximability limits* of the underlying optimization problem. For many well-studied constraint satisfaction problems, tight inapproximability thresholds are known, often matching the performance of a random assignment. For max-LINSAT in the formulation considered by DQI, which allows linear constraints with arbitrary acceptance sets over a finite field, no such worst-case guarantees have previously been established. Without such worst-case bounds, it is unclear whether the approximation ratios achieved by quantum or classical heuristics are close to being optimal, or whether substantially better polynomial-time algorithms might exist.

We address this gap in the present work by establishing *tight inapproximability results* for max-LINSAT over finite fields. We consider max-LINSAT instances over a finite field¹ $\mathbb{F}_q$ in which each constraint is satisfied whenever a linear form evaluates to one of r allowed values, with $1 \leq r \leq q - 1$. This class includes, as a special case, the linear constraint satisfaction problems studied in Ref. [6]. A random assignment satisfies each constraint with probability exactly r/q , yielding a natural baseline approximation ratio.

Our main result shows that this random baseline is *provably optimal in the worst case*. Specifically, for every finite field $\mathbb{F}_q$ of order q , every $1 \leq r \leq q - 1$, and every $\varepsilon > 0$, it is NP-hard to distinguish between instances in which almost all constraints are satisfiable and instances in which no assignment satisfies more than a $(r/q + \varepsilon)$ -fraction of constraints. Assuming $P \neq NP$, no polynomial-time classical algorithm can approximate max-LINSAT consistently beyond the random-assignment threshold, and likewise no polynomial-time quantum algorithm can do so unless $NP \subseteq BQP$. From the perspective of quantum optimization, this provides a *complexity-theoretic benchmark*. The threshold r/q is hence a hard wall for worst-case max-LINSAT(q, r): no efficient algorithm can consistently exceed it on arbitrary instances. This does not conflict with DQI’s demonstrated advantage on OPI, which operates in a qualitatively different regime with constant n/m , and instances derived from classical Reed–Solomon codes that exhibit specific Vandermonde structure. For such instances, both DQI and classical algorithms achieve approximation ratios exceeding the random assignment baseline, whereas the hard instances produced by PCP-reductions have $n/m = o(1)$. Rather, our result delineates a boundary: while structured instances may admit algorithms that beat the random-assignment threshold, no polynomial-time algorithm can do so on arbitrary max-LINSAT instances under reasonable complexity-theoretic assumptions.

Our proof builds on and generalizes an inapproximability result of Håstad for max-E3-LIN over finite Abelian groups, which establishes tight hardness for the case of single-valued acceptance sets [24]. We show how this hardness extends to max-LINSAT instances with uniform acceptance sets of size r , yielding a matching hardness threshold for the general problem. The resulting inapproximability bounds are tight.

¹Recall that the finite field $\mathbb{F}_q$ of order q exists whenever $q = p^\tau$ for some prime p and integer $\tau \geq 1$.

2 Preliminaries

We start by defining the optimization problems considered in this work, in particular focusing on the max-LINSAT-problem as defined in Ref. [6].

Definition 1 (max-LINSAT over $\mathbb{F}_q$). *Let $\mathbb{F}_q$ be the finite field of order q and let $B \in \mathbb{F}_q^{m \times n}$. For each $i = 1, \dots, m$, let $F_i \subset \mathbb{F}_q$ be an arbitrary subset of $\mathbb{F}_q$, which yields a corresponding constraint $\sum_{j=1}^n B_{i,j}x_j \in F_i$. The max-LINSAT task is to find $\mathbf{x} \in \mathbb{F}_q^n$ satisfying as many as possible of these m constraints. We denote by OPT the maximum number of satisfiable constraints and define an approximation ratio α for a solution satisfying s out of m constraints to be $\alpha := s/m$.*

We assume that the acceptance sets F_i are given as an explicit list.

Definition 2 (max-LINSAT(q, r)). *We write $\text{max-LINSAT}(q, r)$ for the restriction of max-LINSAT over $\mathbb{F}_q$ to instances in which $|F_i| = r$ for every i . The special case max-XORSAT is $\text{max-LINSAT}(2, 1)$: the field is $\mathbb{F}_2$ and every acceptance set is a singleton, so each constraint is a linear equation over $\mathbb{F}_2$.*

We will relate this problem to max-Ek-LIN- q for some integer k which has been studied more extensively in the literature.

Definition 3 (max-Ek-LIN- q). *Let $\mathbb{F}_q$ be the finite field of order q and let $k \geq 1$ be an integer. An instance of max-Ek-LIN- q consists of n variables $x_1, \dots, x_n \in \mathbb{F}_q$ and m linear equations*

$$\sum_{j \in S_i} x_j = b_i, \quad i = 1, \dots, m, \quad (1)$$

where for each i , $S_i \subseteq \{1, \dots, n\}$ satisfies $|S_i| = k$, and $b_i \in \mathbb{F}_q$. The goal is to find an assignment $\mathbf{x} \in \mathbb{F}_q^n$ that satisfies the maximum number of equations.

To establish worst-case limits on the approximation for max-LINSAT, we rely on a foundational result of Håstad [24, Theorem 5.9], which proves strong inapproximability for max-E3-LIN- Γ over finite Abelian groups. Håstad's result builds on the celebrated PCP theorem [25, 26], which characterizes NP in terms of probabilistically checkable proofs and underlies most modern inapproximability results. This result provides the base case from which we extend hardness to max-LINSAT instances with uniform acceptance sets of arbitrary size.

Theorem 4 (Inapproximability of max-E3-LIN- Γ). *For every finite Abelian group Γ and every $\varepsilon > 0$, it is NP-hard to approximate max-E3-LIN- Γ within a factor $|\Gamma| - \varepsilon$. Equivalently, max-E3-LIN- Γ is non-approximable beyond the random assignment threshold: it is NP-hard to distinguish, given an instance of max-E3-LIN- Γ , between*

(Y) *instances with $\text{OPT} \geq (1 - \varepsilon)m$ and*

(N) *instances with $\text{OPT} \leq (1/|\Gamma| + \varepsilon)m$.*

In particular, setting $\Gamma = (\mathbb{F}_q, +)$ for a finite field $\mathbb{F}_q$ yields the $(1 - \varepsilon, 1/q + \varepsilon)$ -hardness of max-E3-LIN- q .

The inapproximability guarantee in Theorem 4 is *tight*. Indeed, for max-E3-LIN- Γ over a finite Abelian group Γ , a random assignment satisfies each equation with probability exactly $1/|\Gamma|$. Therefore, any polynomial-time algorithm can trivially achieve an

approximation ratio of $1/|\Gamma|$. Håstad's theorem shows that it is NP-hard to exceed this baseline by more than an arbitrarily small constant ε , so the result matches the random-assignment threshold up to ε . No stronger worst-case hardness can hold under standard complexity assumptions, making the theorem optimal in this sense.

The inapproximability of $\text{max-LINSAT}(q, r)$ can also be situated within the broader theory of constraint satisfaction problems. Under the *unique games conjecture* (UGC) [27], Ref. [28] showed that for every *constraint satisfaction problem* (CSP), the optimal polynomial-time approximation ratio equals the integrality gap of a canonical *semi-definite programming* (SDP) relaxation; moreover, this ratio is achieved by an appropriate rounding of the SDP solution. More concretely, Ref. [29] has proven that any predicate whose satisfying assignments support a balanced pairwise-independent distribution is approximation resistant under the UGC. The $\text{max-LINSAT}(q, r)$ predicate for arity $k = 3$ and coefficients being one, i.e., checking whether $x_{i_1} + x_{i_2} + x_{i_3}$ falls in an r -element subset $S \subseteq \mathbb{F}_q$, satisfies this criterion (as does the analogous predicate for any fixed $k \geq 3$), so UGC-hardness of beating r/q follows immediately from their result. Our Theorem 5 establishes the same conclusion under the weaker assumption $P \neq NP$, via a direct reduction from Håstad's theorem [24]. This is notable because the UGC remains disputed. In a different direction, Ref. [30] proved unconditional ($P \neq NP$) approximation resistance for predicates whose satisfying assignments contain a pairwise-independent subgroup. For prime q , however, the only additive subgroups of $\mathbb{F}_q$ are $\{0\}$ and $\mathbb{F}_q$ itself, so acceptance sets of size $1 \leq r \leq q - 1$ are never subgroups, and this criterion does not apply to our setting. For prime power q , nontrivial additive subgroups do exist, but the criterion still does not cover generic acceptance sets of arbitrary size r . Ref. [31] extended Håstad's max-E3-LIN hardness from Abelian to all finite groups, and Ref. [32] recently transferred these inapproximability results to the setting of *promise constraint satisfaction problems*. These results may prove useful for establishing inapproximability bounds for potential DQI variants over more general finite groups.

3 Results

Theorem 5 (Inapproximability of $\text{max-LINSAT}(q, r)$). *For every finite field $\mathbb{F}_q$, every integer $1 \leq r \leq q - 1$, and every $\varepsilon > 0$, it is NP-hard to distinguish, given an instance of $\text{max-LINSAT}(q, r)$, between*

- (Y) *instances with $\text{OPT} \geq (1 - \varepsilon)m$ and*
- (N) *instances with $\text{OPT} \leq (r/q + \varepsilon)m$.*

This means it is NP-hard to approximate within a factor strictly better than $r/q + \varepsilon$ for every $\varepsilon > 0$.

Proof. The case $r = 1$ follows directly from Theorem 4, since every instance of $\text{max-E3-LIN-}q$ is syntactically an instance of $\text{max-LINSAT}(q, 1)$ with coefficients $B_{i,j}$ being one if and only if the variable is involved: each equation $\sum_{j \in S_i} x_j = b_i$ defines a constraint with $F_i = \{b_i\}$.

For general $r \geq 2$, we give a deterministic polynomial-time reduction from $\text{max-LINSAT}(q, 1)$ to $\text{max-LINSAT}(q, r)$. Let ϕ be an instance of $\text{max-LINSAT}(q, 1)$ with m constraints $L_i(\mathbf{x}) = b_i$ for $i = 1, \dots, m$, where each L_i is a linear form over $\mathbb{F}_q$. We construct an instance ϕ' of $\text{max-LINSAT}(q, r)$ on the same set of n variables as follows. For each constraint i , we enumerate all r -element subsets of $\mathbb{F}_q$ that contain b_i . There are exactly $\binom{q-1}{r-1}$ such subsets, since we choose the remaining $r - 1$ elements from $\mathbb{F}_q \setminus \{b_i\}$.

For each such subset S , we add the constraint $L_i(\mathbf{x}) \in S$ to ϕ' . The resulting instance ϕ' has $m' = m \cdot \binom{q-1}{r-1}$ constraints, each with acceptance set of size exactly r . Since q is a fixed constant, m' is polynomial in m .

Completeness. If $\mathbf{x}$ satisfies $L_i(\mathbf{x}) = b_i$, then $L_i(\mathbf{x}) \in S$ for every r -element subset S containing b_i , so all $\binom{q-1}{r-1}$ derived constraints from constraint i are satisfied. Therefore, $\text{OPT}(\phi') \geq \text{OPT}(\phi) \cdot \binom{q-1}{r-1}$. In the (Y)-case, $\text{OPT}(\phi) \geq (1 - \varepsilon)m$, so that

$$\text{OPT}(\phi') \geq (1 - \varepsilon)m'. \quad (2)$$

Soundness. Fix any assignment $\mathbf{x} \in \mathbb{F}_q^n$ and define

$$A(\mathbf{x}) = \{i : L_i(\mathbf{x}) = b_i\}, \quad (3)$$

$$\bar{A}(\mathbf{x}) = \{i : L_i(\mathbf{x}) \neq b_i\}. \quad (4)$$

For each $i \in A(\mathbf{x})$, all $\binom{q-1}{r-1}$ derived constraints are satisfied. For each $i \in \bar{A}(\mathbf{x})$, let $c_i = L_i(\mathbf{x}) \neq b_i$. The derived constraint $L_i(\mathbf{x}) \in S$ is satisfied if and only if $c_i \in S$. Since S must contain b_i , the number of r -element subsets of $\mathbb{F}_q$ containing both b_i and c_i is $\binom{q-2}{r-2}$ (choosing the remaining $r-2$ elements from $\mathbb{F}_q \setminus \{b_i, c_i\}$). Thus, for each $i \in \bar{A}(\mathbf{x})$, exactly $\binom{q-2}{r-2}$ out of $\binom{q-1}{r-1}$ derived constraints are satisfied. Consequently, the fraction of derived constraints satisfied per unsatisfied original constraint is

$$\frac{\binom{q-2}{r-2}}{\binom{q-1}{r-1}} = \frac{r-1}{q-1}. \quad (5)$$

Writing $\mu := |A(\mathbf{x})|/m$ for the fraction of original constraints satisfied exactly, the total fraction of constraints in ϕ' satisfied by $\mathbf{x}$ is

$$\mu \cdot 1 + (1 - \mu) \cdot \frac{r-1}{q-1} = \mu \cdot \frac{q-r}{q-1} + \frac{r-1}{q-1}. \quad (6)$$

In the (N)-case, Theorem 4 guarantees $\mu \leq 1/q + \varepsilon$ for every assignment. By substituting this and using the identity

$$\frac{1}{q} \cdot \frac{q-r}{q-1} + \frac{r-1}{q-1} = \frac{(q-r) + q(r-1)}{q(q-1)} = \frac{r}{q}, \quad (7)$$

we obtain

$$\mu \cdot \frac{q-r}{q-1} + \frac{r-1}{q-1} \leq \left(\frac{1}{q} + \varepsilon\right) \frac{q-r}{q-1} + \frac{r-1}{q-1} = \frac{r}{q} + \varepsilon \cdot \frac{q-r}{q-1}. \quad (8)$$

Since $(q-r)/(q-1) \leq 1$, this is at most $r/q + \varepsilon$. Therefore, $\text{OPT}(\phi') \leq (r/q + \varepsilon)m'$, completing the soundness analysis. $\square$

Remark 6 (Tightness of Theorem 5). *The threshold r/q in Theorem 5 is tight. Uniformly chosen assignments $\mathbf{x} \in \mathbb{F}_q^n$ satisfy each constraint i with probability exactly $|F_i|/q = r/q$, giving an expected approximation ratio of r/q . A deterministic polynomial-time algorithm achieving a ratio of at least r/q is obtained by the method of conditional expectations.*

Remark 7 (Coefficient-free hard instances). *The hard instances produced by the reduction have a particularly simple form: the constraint matrix B has entries in $\{0, 1\}$ only, with exactly three ones per row. This follows from the fact that Håstad's construction yields coefficient-free equations $x_{i_1} + x_{i_2} + x_{i_3} = b_i$. The inapproximability of $\text{max-LINSAT}(q, r)$ therefore already holds for this restricted class of instances, which is a stronger statement than hardness for general constraint matrices.*

Remark 8 (max-XORSAT). *Setting $q = 2$ and $r = 1$ in Theorem 5 recovers the result from Ref. [24] stating that max-XORSAT – equivalently, max-E3-LIN-2 – is NP-hard to approximate within $1/2 + \varepsilon$ for every $\varepsilon > 0$.*

4 Discussion

In this work, we have established tight inapproximability results for a family of optimization problems that feature strongly in the *decoded quantum interferometry* (DQI) algorithm [6], which has been proposed to offer a speedup over classical approaches. Theorem 5 establishes that no polynomial-time algorithm can approximate the problem $\text{max-LINSAT}(q, r)$ beyond the random assignment threshold r/q on worst-case instances, assuming $P \neq NP$, and likewise no polynomial-time quantum algorithm can do so unless $NP \subseteq BQP$. In light of the fact that this kind of problem is central to DQI, we now discuss the implications of this result for evaluating quantum optimization algorithms by resorting to DQI and beyond.

A key observation is that DQI’s quantum advantage claims are *not* for arbitrary max-LINSAT instances, but for *structured problems*, most notably *optimal polynomial intersection* (OPI), with constant n/m and a constraint matrix that has Vandermonde structure arising from classical Reed–Solomon codes, which DQI exploits via coherent implementation of the Berlekamp–Massey decoding algorithm [6]. For OPI with parameters $n/q = r/q = 1/2$, DQI achieves an approximation ratio of approximately 0.933 via the *semicircle law*, while the best known classical algorithm (Prange’s information set decoding [33]) achieves only ~ 0.55 [6]. These insights have recently been extended to algebraic geometry codes in Ref. [17], where a problem called HOPI is studied, which generalizes OPI. Therefore, DQI targets structured instances, not worst-case max-LINSAT .

Our worst-case inapproximability result is entirely consistent with these claims: Theorem 5 applies to worst-case $\text{max-LINSAT}(q, r)$ instances, whereas OPI operates in the structured regime described above. The hardness reduction from $\text{max-E3-LIN-}q$ produces instances with $n/m = o(1)$ and no such *exploitable* structure.

In DQI, the optimization problem is mapped to a decoding task for a classical error-correcting code. A central parameter governing the algorithm’s performance is the *decoding radius* ℓ , defined as the maximum number of errors that an efficient decoder can correct. If a max-LINSAT instance with m constraints gives rise to a dual code $C^\perp$ that can be decoded from up to ℓ errors, then DQI exploits this decodability to prepare a degree- ℓ polynomial enhancement of the objective function in superposition. The resulting approximation ratio is given by the *semicircle law* [6],

$$\alpha_{\text{DQI}} = \left(\sqrt{\frac{\ell}{m} \left(1 - \frac{r}{q}\right)} + \sqrt{\frac{r}{q} \left(1 - \frac{\ell}{m}\right)} \right)^2 \quad (9)$$

if $r/q \leq 1 - \ell/m$, and $\alpha_{\text{DQI}} = 1$ otherwise. This relationship is illustrated in Fig. 1. The ratio ℓ/m therefore quantifies the amount of decodable structure available to the algorithm. When ℓ/m is bounded away from zero, the decoder can correct a constant fraction of errors, and DQI achieves approximation ratios strictly above the random-assignment baseline r/q . In the limit $\ell/m \rightarrow 0$, the semicircle law yields $\alpha_{\text{DQI}} \rightarrow r/q$: without sufficient decoding capability, DQI reduces to a random assignment.

We note that on random $\text{max-LINSAT}(q, r)$ instances with n variables and m constraints, simple algorithms can exceed the r/q threshold. For example Prange’s information set decoding [33] solves an $n \times n$ subsystem exactly and achieves a total expected approximation ratio of $n/m + (1 - n/m) \cdot r/q$ for random instances. This does not conflict with Theorem 5: the formula is a heuristic expected-value analysis that assumes the residual $m - n$ constraints behave as random evaluations [6, Section 11.3], an assumption that fails on worst-case instances. Moreover, for any fixed $\varepsilon > 0$, the PCP-based reduction

Figure 1: Landscape of approximability for $\text{max-LINSAT}(q, r)$. The x-axis parametrizes the decodable structure ℓ/m , where ℓ is the decoding radius of the underlying error-correcting code and m is the number of constraints. For worst-case instances, by virtue of Theorem 5, approximation ratios within the blue-shaded region are unattainable. Importantly, this hardness statement does not depend on the parameter ℓ/m : the x-axis is only meaningful for structured instances arising from decoding problems (such as those targeted by DQI). The shading therefore illustrates a worst-case approximation barrier rather than a property that varies with ℓ/m . The pink curve depicts DQI's approximation ratio as given by the semicircle law [6], which surpasses the random-assignment bound r/q whenever $\ell/m > 0$ and saturates at $\alpha_{\text{DQI}} = 1$ for $\ell/m \geq 1 - r/q$. In the limit $\ell/m \rightarrow 0$, DQI's performance degrades to exactly r/q , matching the worst-case barrier.

produces instances in which n/m can be driven below ε , so Prange's advantage vanishes in exactly the regime where the hardness applies.

This observation is complemented by Theorem 5, which shows that on worst-case $\text{max-LINSAT}(q, r)$ instances, no polynomial-time algorithm can exceed the r/q threshold (assuming $P \neq NP$). While these two statements operate in different regimes – the semicircle law describes DQI's performance on code-derived instances as a function of the decoding radius, and Theorem 5 applies to adversarially constructed instances with no exploitable structure – they point to the same conclusion from different directions: r/q is the natural worst-case approximation barrier for max-LINSAT , and surpassing it requires both an algorithm capable of exploiting structure and instances that exhibit such structure. The codes for which DQI demonstrates an advantage over known classical algorithms, namely Reed–Solomon codes in OPI [6] and algebraic geometry codes in HOPI [17], satisfy these conditions.

It is suggestive to read this connection in coding-theoretic terms. For code families where efficient decoding beyond a vanishing fraction of errors is believed to be computationally hard – such as generic linear codes specified by arbitrary parity-check matrices, for which bounded-distance decoding is NP -complete [34] – one would expect the associated max-LINSAT instances to be similarly hard to approximate beyond r/q , since a sufficiently good approximate solution would be expected to reveal information about nearby codewords. Making this intuition precise by exhibiting a formal reduction from approximating code-derived max-LINSAT instances to decoding remains an interesting open question.

Recent work has further clarified that DQI's advantage, where it exists, depends critically on problem structure: Ref. [16] shows that for MaxCut instances where DQI achieves any nontrivial asymptotic approximation guarantee, the optimal solution can be found *exactly* in classical polynomial time. DQI consequently provides no advantage for MaxCut .

For unstructured max- k -XOR-SAT instances, Ref. [14] proves that DQI is obstructed by the overlap gap property, which is a topological barrier in the near-optimal solution space. Numerical evidence suggests that classical approximate message passing outperforms DQI on such instances. From the perspective of computational complexity, Ref. [13] places DQI in BPP^{NP} , thereby ruling out immediate quantum advantage via “supremacy”-style hardness arguments as they are used in quantum random sampling [35, 36]. There, it is $\#\text{P}$ -hard to compute individual output probabilities, and an efficient classical sampling algorithm up to a constant error in the total variation distance would lead to a collapse of the polynomial hierarchy to the third level. In contrast, DQI is already placed in a low level of the polynomial hierarchy. The hardness of DQI, if any, arises from locating elements in an exponentially large hidden subset without group structure and not from the hardness of simulating the quantum circuit itself, as here, in contrast to the situation in quantum random sampling, individual probabilities of outcomes can be efficiently computed.

Together with Theorem 5, these results rigorously establish that DQI is not a general-purpose quantum optimizer. Rather, any possible quantum advantage over (known) classical optimizers crucially depends on structures that are present in the instances. Several natural questions remain:

- **Inapproximability for OPI and HOPI:** Can inapproximability results be extended to settings studied in OPI [6]? The hard instances produced by our reduction have $n/m = o(1)$ and unstructured constraint matrices, so they do not directly address the Vandermonde-structured instances with constant n/m targeted by DQI. Since maximum-likelihood decoding of Reed–Solomon codes is NP -hard for certain parameters [37], it is natural to ask whether PCP-based methods can be adapted to establish worst-case inapproximability for OPI. The same question extends to the HOPI generalization of Ref. [17].
- **Average-case hardness:** Our result is worst-case. Establishing average-case inapproximability for natural distributions over max-LINSAT instances as they occur in DQI would provide stronger benchmarks for heuristic quantum algorithms.
- **Heterogeneous acceptance sets:** Throughout this work (and also in Ref. [6]) the acceptance sets satisfy $|F_i| = r$ uniformly. If the cardinalities $|F_i|$ are allowed to vary across constraints, a random assignment satisfies constraint i with probability $|F_i|/q$, so the natural baseline is no longer a single reference value but depends on the distribution of the $|F_i|$. In particular, instances with small acceptance sets ($|F_i| = 1$) are the most restrictive locally, yet mixtures of small and large sets may exhibit different global approximation behavior. What is a useful notion of a tight inapproximability threshold in this heterogeneous setting? Should it be governed by the minimum $|F_i|$, the average acceptance probability $\frac{1}{m} \sum_i |F_i|/q$, or a more refined structural parameter? Determining an optimal approximation guarantee as a function of the profile $(|F_i|)_{i=1}^m$ thus remains open.

Our Theorem 5 provides a complexity-theoretic benchmark for max-LINSAT, establishing r/q as the provable worst-case approximation limit and confirming that any improvement must arise from instance structure not present in the hard instances produced by PCP reductions. It is our hope that this result contributes to clarifying the landscape of quantum advantage for optimization problems of practical relevance [1, 38–40].

Acknowledgements

This work has been inspired by a recent Computer Science Stack Exchange post [41], which has motivated us to work out the inapproximability of max-LINSAT in full. The authors warmly thank Elies Gil-Fuster for helpful discussions and feedback on this work, and Noah Shatty for a string of highly helpful comments on an earlier version of this manuscript. Moreover, the authors acknowledge support by the BMFTR (PraktiQOM, QuSol, HYBRID++, PQ-CCA), the Munich Quantum Valley, Berlin Quantum, the Quantum Flagship (Millenion, PasQuans2), the DFG (CRC 183, SPP 2514), the Clusters of Excellence (MATH+, ML4Q), and the European Research Council (DebuQC).

Abstract. Quantum theory predicts intrinsically random measurement outcomes, but real devices introduce noise and imperfections that produce apparent, non-intrinsic randomness, making the quantification of true quantum randomness a fundamental problem. This amount is captured by the probability with which an adversary, Eve, with quantum side information about the device, can guess the outcomes. Building on [11], which defines the guessing probability for characterized but untrusted prepare-and-measure setups via a generalized Naimark dilation, we develop an SDP formulation to compute it. We illustrate our method on three setups and show that entanglement between the preparation and measurement boxes strictly increases Eve’s predictive power.

Keywords: quantum randomness, semidefinite programming, prepare-and-measure, quantum side information, device-dependent

1 Introduction

Quantum theory contains a form of randomness that is not the result of ignorance or any stochastic behaviour. For instance, according to the theory, the result of implementing a spin measurement along the x direction on a spin state pointing in the $+z$ direction is fully unpredictable. In real-life implementations, however, measurements are never projective and states are never pure. Noise and imperfections introduce an unavoidable element of *stochasticity* that produces an apparent randomness that is not intrinsic to quantum theory. Therefore, it is a fundamental problem to design the tools to estimate the correct amount of intrinsic quantum randomness produced in a quantum experiment. This question is of relevance from a quantum foundations viewpoint, but also for the proper design of QRNGs.

The amount of intrinsic randomness in the measurement’s outcomes is related to the maximum probability with which a potential adversary, Eve, can guess them given access to *side information* about the device. In this regard, previous works have typically considered either a trusted preparation or a trusted measurement. In other words, Eve was allowed to have side information about one of them, but not both. In [11], a general definition for guessing probability with characterized but untrusted devices was provided. Based on the model of quantum side information involving a *generalized* Naimark dilation of the user’s POVM introduced in [8], Eve is allowed to have a quantum system E correlated with the system being measured and with the ancillary system in the dilation. Unfortunately, the resulting definition involves a nonconvex optimization for which no general computational procedure is known.

In this work, based on the techniques from [9], we

construct an SDP formulation to compute the device-dependent guessing probability. We then provide three example applications. First, we show that the analytic lower bound derived in [5] for a device undergoing global depolarizing noise is optimal. Second, we tighten the bounds of the randomness generation scheme proposed by Berta and Brandão [2]. Third, we consider the source-device-independent scheme of [1], where a family of k -outcome POVMs allows, if trusted, unbounded randomness extraction from an uncharacterized qubit. While the unboundedness is unsurprisingly tied to the trusted-measurement assumption, we use our SDP to quantify the strength of this dependence. As our last result, we show that entanglement between the preparation and measurement boxes leads to a strictly higher guessing probability than if only classical correlations are allowed, already for the simplest setup of a binary measurement on a qubit.

2 Setting

We assume that an honest user, Alice, measures a known POVM $\{M_S^a\}_a$ on a system S in a known state ρ_S . The model from [8] considers that what Alice *sees* as a POVM on S is, in fact, a projective measurement (PVM) $\{\Pi_{SM}^a\}_a$ on the system S plus an ancillary system M . The state ρ_M of the ancilla together with the PVM $\{\Pi_{SM}^a\}_a$ form a so-called generalized Naimark dilation of $\{M_S^a\}_a$. Eve, who we assume has chosen the dilation, also holds a purification $|\psi\rangle_{SME}$ of the state ρ_{SM} of the system+ancilla.

This leads to the definition [11] of *Eve’s guessing probability* $P_{\text{guess}}(A|E, \rho_S, \{M_S^a\}_a)$ in Eq. (1). Notice that we allow ρ_{SM} to be any state whose marginal on S is ρ_S . In particular, there could be entanglement between S and M .

*raffaele.davino@icfo.eu

Figure 1: **Characterized but untrusted PM setup.** Alice holds a PM device that prepares a system S in some **known state** ρ_S . In the measurement box M , an unknown PVM $\{\Pi_{SM}^a\}_a$ is performed, whose outcome statistics are described by the **known POVM** $\{M_S^a\}_a$. Eve holds a purification $|\psi\rangle_{SME}$ of the joint state of the system S and the ancillary inside M .

Guessing probability

$$P_{\text{guess}}(A|E, \rho_S, \{M_S^a\}_a) := \max_{\{\Pi_{SM}^a\}_a, |\psi\rangle_{SME}, \{M_E^e\}_e} \sum_a \langle \psi | \Pi_{SM}^a \otimes M_E^a | \psi \rangle_{SME}$$

subject to

$$\begin{aligned} \text{Tr}_{ME}[|\psi\rangle\langle\psi|_{SME}] &= \rho_S, \\ \text{Tr}_M[\Pi_{SM}^a(\mathbb{1}_S \otimes \text{Tr}_{SE}[|\psi\rangle\langle\psi|_{SME}])] &= M_S^a \quad \forall a, \\ \langle \psi | \Pi_{SM}^a \otimes \mathbb{1}_E | \psi \rangle_{SME} &= \text{Tr}[M_S^a \rho_S] \quad \forall a. \end{aligned} \quad (1)$$

3 SDP formulation

The simple but key observation underlying our construction is that the projective measurement $\{\Pi_{SM}^a\}_a$ in any dilation of $\{M_S^a\}_a$ can be expressed in block form with respect to an orthonormal basis $\{|i\rangle\}_{i=0}^{d-1}$ of $\mathcal{H}_S$ as

$$\Pi_{SM}^a = \sum_{i,j=0}^{d-1} |i\rangle\langle j|_S \otimes K_M^{i,j|a} \quad \forall a, \quad (2)$$

where $\dim(\mathcal{H}_S) = d$ and $\{K_M^{i,j|a}\}_{i,j,a}$ are operators acting on the auxiliary system (of unrestricted dimension) M . With this, applying the techniques from [9], we can then consider the *generalized moment matrices*

$$\Gamma_e = \sum_{s,t \in \mathcal{O}} \sum_{i,j=0}^{d-1} |i\rangle\langle j| c_{s^\dagger t}^{i,j}(\tilde{\sigma}_{SM}^e) \otimes |s\rangle\langle t|, \quad (3)$$

with $c_{s^\dagger t}^{i,j}(\tilde{\sigma}_{SM}^e) = \text{Tr}[(|j\rangle\langle i| \otimes s^\dagger t) \tilde{\sigma}_{SM}^e]$ and where the outer sum runs over the finite set of operators $\mathcal{O} := \{\mathbb{1}\} \cup \{K_M^{i,j|a} : a = 1, \dots, k, i, j = 1, \dots, d\}$. Following [10], we have one matrix Γ_e for each of Eve's measurement outcomes e (corresponding to her *guess* for the result of Alice's measurement) occurring with associated probability $p(e)$.

Both the objective function and the constraints in Eq. (1) can then be expressed as linear functions of the coefficients of the matrices $\{\Gamma_e\}_e$. Adopting the shorthand $(K_M^{ij|a})^\dagger = K_M^{ji|a}$ for convenience, this provides the fol-

lowing *semidefinite relaxation*

$$\begin{aligned} P_{\text{guess}}(A|E, \rho_S, \{M_S^a\}_a) &= \max_{\{\Gamma_e\}_e} \sum_{a,i,j} \langle j | \langle \mathbb{1} | \Gamma_a | i \rangle | K_M^{i,j|a} \rangle \\ \text{subject to} \\ \Gamma_e &\succeq 0 \quad \forall e, \\ \sum_e \langle i | \langle \mathbb{1} | \Gamma_e | j \rangle | \mathbb{1} \rangle &= \langle i | \rho_S | j \rangle \quad \forall i, j, \\ \sum_{e,l} \langle l | \langle \mathbb{1} | \Gamma_e | l \rangle | K_M^{i,j|a} \rangle &= \langle i | M_S^a | j \rangle \quad \forall a, i, j, \\ \sum_{e,i,j} \langle j | \langle \mathbb{1} | \Gamma_e | i \rangle | K_M^{i,j|a} \rangle &= \text{Tr}[M_S^a \rho_S] \quad \forall a, \\ \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | s \rangle &= \langle m | \langle s^\dagger | \Gamma_e | n \rangle | \mathbb{1} \rangle \\ &\quad \forall s \in \mathcal{O} \quad \forall e, m, n, \\ \sum_a \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | K_M^{ij|a} \rangle &= \delta_{ij} \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | \mathbb{1} \rangle \\ &\quad \forall e, m, n, i, j, \\ \sum_l \langle m | \langle (K_M^{l,i|a})^\dagger | \Gamma_e | n \rangle | K_M^{l,j|b} \rangle &= \\ &\quad \delta_{ab} \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | K_M^{i,j|a} \rangle \quad \forall a, b, e, m, n, i, j. \end{aligned} \quad (4)$$

The second, third and fourth constraints are direct analogs of the ones in Eq. (1). The last three constraints, on the other hand, follow from the hermiticity, the completeness and projectivity of $\{\Pi_{SM}^a\}_a$ respectively.

Our main result, Theorem 1 below, shows that Eq. (4) is, in fact, a *characterization* of the device-dependent guessing probability.

Theorem 1 *Let $\{\Gamma_e\}_e$ be a feasible solution to Eq. (4) achieving some objective value c . Then, there exist a finite-dimensional Hilbert space $\mathcal{H}_M$, operators $K_M^{i,j|a}$ and (possibly subnormalized) states $\tilde{\sigma}_{SM}^e$ such that $\langle \{\sigma_{SM}^e\}_e, \{\Pi_{SM}^a\}_a \rangle$, with Π_{SM}^a as in Eq. (2), is a feasible solution to Eq. (1) achieving the same objective value c .*

4 Applications

We apply our SDP to three setups considered in the literature.

First, as shown in Fig. 2a, we match the analytical lower bound to Eq. (1) derived in [5] for a qubit S prepared in an eigenstate of σ_X and measured in the basis of σ_Z , while undergoing global (i.e. preparation- and measurement-affecting) depolarizing noise.

Next, we consider the scheme proposed in [2] for quantum randomness generation on quantum computers, comprising depolarized qubits $\rho_S(\delta) = \delta|+\rangle\langle+| + (1-\delta)\mathbb{1}/2$ and inefficient binary measurements $\mathcal{N}(\mu) = \{\mathbb{1} - \mu|1\rangle\langle 1|, \mu|1\rangle\langle 1|\}$. In [2], a lower bound to Eq. (1) was computed by fixing a particular dilation $\mathcal{D}$ of $\mathcal{N}(\mu)$. In Fig. 2b we plot the difference in randomness between using this fixed dilation and a generic one, showing that for a certain range of δ and μ this choice results in a (relatively slight) underestimation of Eve's predictive power.

Finally, we consider the source-device-independent scenario introduced in [1]. In this framework, no assumption is made on the prepared qubit state ρ_S , while the measurement is assumed to be fully characterized and trusted. Specifically, the measurement is described by an equiangular k -outcome POVM in the XZ plane of the Bloch sphere

$$M_S^a = \frac{1}{k} (\mathbb{1} + \vec{u}_a \cdot \vec{\sigma}), \quad (5)$$

with $\vec{u}_a = (\cos \theta_a, 0, \sin \theta_a)$ and $\theta_a = 2\pi a/k$. Under these assumptions, the authors show that the min-entropy diverges as k grows. Using our SDP formulation, we observe from Fig. 2c that, once the trusted-measurement assumption is dropped, this min-entropy significantly overestimates the actual amount of certifiable randomness for $k > 3$.

5 Entangled strategies increase Eve's predicting power

The global state ρ_{SM} of the system S and the ancilla M in Eq. (1) is unrestricted and, hence, potentially entangled. The rationale behind this decision is that Alice can only perform tomography on the S system. On the other hand, in a related work [6], the authors opted to restrict the global state to be product. Naturally, this raises the question of whether this restriction incurs in a loss of generality.

Let $P_{\text{guess}}^{\text{sep}}$ be as in Eq. (1) with the added restriction of a separable ρ_{SM} . Using the fact that if ρ_{SM} is separable then $\Gamma = \sum_e \Gamma_e$ has a positive partial transpose (PPT), we can upper bound $P_{\text{guess}}^{\text{sep}}$ with our SDP formulation by imposing a PPT constraint on Γ . Numerically, we find that there exists a qubit state ρ_S^* and a binary POVM M_S^* such that

$$P_{\text{guess}}(A|E, \rho_S^*, M_S^*) > P_{\text{guess}}^{\text{sep}}(A|E, \rho_S^*, M_S^*).$$

This consequence of entanglement-assistance for randomness generation in a prepare-and-measure setup has been previously observed under energy constraints [7, 4]. To our knowledge, the one we report here constitutes the first example of this phenomenon in the simplest scenario

possible: a single qubit preparation and a single binary measurement.

6 Future research directions

In this work, we have provided an SDP formulation for the quantification of the amount of intrinsic randomness generated in a characterized but untrusted prepare-and-measure scenario. More specifically, we introduced a semidefinite programming hierarchy for the conditional min-entropy in the presence of an adversary, Eve, holding quantum side information about the experimental setup. This solves the main open problem left in [11].

As for future directions, using the techniques from [3], we intend to apply our hierarchy to lower bound the von Neumann entropy $H(A|E)$ and study its consequences on the keyrates achievable in device-dependent QKD.

The fact that a quantum measurement's outcome will, in general, contain some amount of intrinsic randomness is a fundamental feature of quantum theory. However, except for a few restricted scenarios, up until now we lacked any computational procedure to quantify it, even in the most basic setting of a binary measurement on a qubit. In this work, we present a semidefinite programming (SDP) formulation of the maximum probability with which an adversary, Eve, can guess the outcomes of characterized but untrusted prepare-and-measure (PM) setups. We then present several applications of this construction. First, we apply our method to a variety of specific setups, allowing us both to benchmark the approach and, more importantly, to determine the exact amount of certifiable randomness in scenarios where previously only upper bounds were available, often relying on additional assumptions to make the conditional min-entropy computable. Finally, we show that the presence of entanglement between the PM boxes strictly increases Eve's predictive power, already in the most elementary setup of a qubit binary measurement. This constitutes, to our knowledge, the simplest example of the consequences of entanglement-assistance for randomness generation in PM setups.

I. Introduction

Randomness is a fundamental resource in both classical and quantum information processing, underpinning applications ranging from cryptography and numerical simulation to foundational tests of physical theories. Quantum mechanics provides a principled source of randomness: when a measurement is performed on a quantum system prepared in a state that is not an eigenstate of the measured observable, the outcome cannot be predicted with certainty, even in principle. This intrinsic unpredictability distinguishes quantum randomness from classical stochasticity and forms the basis of quantum random number generation [1–3].

One way of quantifying the amount of intrinsic randomness that a quantum device produces is via the maximum probability with which an adversary, Eve, can guess its outcomes given side information about it. In this work, we focus on characterized (or, device-dependent) prepare-and-measure (PM) setups. That is, we consider the situation in which a system is prepared in a known quantum state and a known positive operator-valued measure (POVM) is measured on it. In this regard, previous works have typically considered either a trusted preparation or a trusted measurement. In other words, Eve was allowed to have side information about one of them, but not both. In [4], a general definition for the guessing probability with characterized but untrusted devices was provided. Based on the model of quantum side information involving a *generalized* Naimark dilation of the considered POVM introduced in [5], Eve is assumed to hold a quantum system E purifying the joint state of the system S being measured and the ancillary M in the measurement device. Unfortunately, the re-

sulting definition involves a nonconvex optimization for which no general computational procedure is known.

In this work, leveraging the techniques from [6], we prove that the device-dependent guessing probability [4] can be expressed as a semidefinite program (SDP). Next, we provide three example applications of this new computational tool. First, we show that the analytic lower bound derived in [7] for the guessing probability of the outcomes of a device undergoing global depolarizing noise is optimal. Next, we improve the analysis of the amount of intrinsic randomness generated in a scheme targeting an implementation in quantum computers put forward by Berta and Brandão in [8], tightening the bounds provided therein. And, finally, we consider the source-device-independent randomness generation scheme introduced in [9]. Therein, the authors provide a family of k -outcome POVMs with which, if trusted, unbounded randomness can be extracted from an uncharacterized and untrusted qubit system. While it may be not surprising that this unboundedness is a consequence of the trusted-measurement assumption (it is well-known that no more than 2 bits of randomness can be extracted from a qubit in the untrusted setting), we use our SDP to properly quantify the strength of this dependence. In particular, we show that if the considered POVMs are not assumed trusted, the amount of randomness vanishes for $k = 4$.

In [10], a related framework for intrinsic randomness quantification in characterized but untrusted PM setups was introduced independently of [4]. While also based on the generalized Naimark dilations from [5], this framework deviates from [4] in assuming that: 1) the system being measured and the dilation's ancilla are in a product state; and 2) Eve holds independent purifications thereof which she cannot measure jointly. The results from [4,

FIG. 1: **Characterized but untrusted PM setup.** Alice holds a PM device that prepares a system S in some **known state** ρ_S . In the measurement box M , an unknown PVM $\{\Pi_{SM}^a\}_a$ is performed, whose outcome statistics are described by the **known POVM** $\{M_S^a\}_a$. Eve holds a purification $|\psi\rangle_{SME}$ of the joint state of the system S and the ancillary inside M .

Thms. 3 and 4] show that in a setting where 1) holds, assuming 2) incurs in a restriction to Eve's power. As our last result of this manuscript, we show that the presence of entanglement between the preparation and the measurement boxes leads to a strictly higher guessing probability than if only classical correlations are allowed, already for the simplest setup of a binary measurement on a qubit. To our knowledge, this is the simplest example of the consequences of entanglement-assistance on randomness certification in prepare-and-measure setups [11, 12].

The remainder of the manuscript is organized as follows. In Section II we introduce the PM scenario with characterized but untrusted devices and the guessing probability from [4]. In Section III, we present the SDP formulation used to compute this quantity. Section IV illustrates the method through three applications. Finally, in Section V we use our formulation to show that entanglement between the preparation and measurement devices can enhance Eve's predictive power.

II. The device-dependent guessing probability

We consider a scenario in which an honest user, Alice, holds a device that can prepare a d -dimensional quantum system S in some known state ρ_S and then perform a k -outcome measurement on it, described by a known positive operator-valued measure (POVM) $M_S = \{M_S^a\}_{1 \leq a \leq k}$. The goal is to determine how random the measurement's outcomes are from the point of view of an adversary, Eve, who holds quantum side-information E about Alice's device. To model Eve's side information, we follow the approach of [4] and consider that what Alice sees as the POVM M_S is, in fact, a projective measurement (PVM) $\{\Pi_{SM}^a\}_a$ on the system S plus an ancillary system M . The state ρ_M of the ancilla together with the PVM $\{\Pi_{SM}^a\}_a$ form a so-called generalized Naimark dilation of M_S [5]. See Fig. 1 for a schematic description of the scenario.

We assume that Alice only has tomographic access to

the system S . This implies that all the infinitely many dilations compatible with M_S are indistinguishable for her. Moreover, she can neither distinguish whether system S is correlated with system M or not. Therefore, we assume that the dilation has been chosen by Eve, who also holds a purification $|\psi\rangle_{SME}$ of the state ρ_{SM} of the system+ancilla. Eve may then perform an arbitrary measurement $\{M_E^a\}_a$ on her system to guess the outcome of the measurement on S . This leads to the definition [4] of *Eve's guessing probability* $P_{\text{guess}}(A|E, \rho_S, \{M_S^a\}_a)$ in Eq. (1)

$$P_{\text{guess}}(A | E, \rho_S, \{M_S^a\}_a) := \max_{\{\Pi_{SM}^a\}_a, \{M_E^a\}_e, |\psi\rangle_{SME}} \sum_a \langle \psi | \Pi_{SM}^a \otimes M_E^a | \psi \rangle_{SME}$$

subject to

$$\begin{aligned} \text{Tr}_{ME} [|\psi\rangle \langle \psi|_{SME}] &= \rho_S, \\ \text{Tr}_M [\Pi_{SM}^a (\mathbb{1}_S \otimes \text{Tr}_{SE} [|\psi\rangle \langle \psi|_{SME}])] &= M_S^a \quad \forall a, \\ \langle \psi | \Pi_{SM}^a \otimes \mathbb{1}_E | \psi \rangle &= \text{Tr}[M_S^a \rho_S] \quad \forall a. \end{aligned} \quad (1)$$

Eq. (1) can be reformulated by introducing subnormalized states of the system+ancilla conditioned on Eve's measurement outcomes,

$$\tilde{\sigma}_{SM}^a := \text{Tr}_E [(\mathbb{1}_{SM} \otimes M_E^a) |\psi\rangle \langle \psi|_{SME}]. \quad (2)$$

The guessing probability can then be expressed as

$$P_{\text{guess}}(A | E, \rho_S, \{M_S^a\}_a) = \max_{\{\Pi_{SM}^a\}_a, \{\tilde{\sigma}_{SM}^e\}_e} \sum_a \text{Tr}[\Pi_{SM}^a \tilde{\sigma}_{SM}^a]$$

subject to

$$\begin{aligned} \text{Tr}_M \left[\sum_e \tilde{\sigma}_{SM}^e \right] &= \rho_S, \\ \text{Tr}_M \left[\Pi_{SM}^a (\mathbb{1}_S \otimes \text{Tr}_S [\sum_e \tilde{\sigma}_{SM}^e]) \right] &= M_S^a, \quad \forall a, \\ \text{Tr} \left[\Pi_{SM}^a \sum_e \tilde{\sigma}_{SM}^e \right] &= \text{Tr}[M_S^a \rho_S], \quad \forall a. \end{aligned} \quad (3)$$

While this equivalent representation remains a non-commutative polynomial optimization problem, it provides a convenient starting point for the SDP construction presented in the next section.

III. SDP formulation

In this section, we describe our main contribution: an SDP formulation for Eq. (3). The simple but key observation underlying our construction is that the projective measurement $\{\Pi_{SM}^a\}_a$ in any dilation of $\{M_S^a\}_a$ can be expressed in block form with respect to an orthonormal basis $\{|i\rangle\}_{i=1}^d$ of $\mathcal{H}_S$ as

$$\Pi_{SM}^a = \sum_{i,j=1}^d |i\rangle \langle j|_S \otimes K_M^{i,j|a} \quad \forall a, \quad (4)$$

where $d = \dim(\mathcal{H}_S)$ and $\{K_M^{i,j|a}\}_{i,j,a}$ is a set of operators acting on the auxiliary system (of unrestricted dimension) M . This observation allows us to apply the techniques from [13] and consider the *generalized moment matrices*

$$\Gamma_e := \sum_{s,t \in \mathcal{O}} \sum_{i,j=1}^d c_e^{i,j}(s^\dagger t) |i\rangle \langle j| \otimes |s\rangle \langle t|, \quad (5)$$

with

$$c_e^{i,j}(s^\dagger t) = \text{Tr}[(|j\rangle \langle i| \otimes s^\dagger t) \tilde{\sigma}_{SM}^e]. \quad (6)$$

Here, the outer sum runs over the finite set of operators

$$\mathcal{O} := \{\mathbb{1}\} \cup \{K_M^{i,j|a} : a = 1, \dots, k, i, j = 1, \dots, d\}. \quad (7)$$

As described in [13], the matrices Γ_e can be seen as the result of the following mapping

$$\tilde{\sigma}_{SM}^e \longrightarrow \text{Tr}_M[(\mathbb{1}_S \otimes \Lambda) \tilde{\sigma}_{SM}^e (\mathbb{1}_S \otimes \Lambda^\dagger)] =: \Gamma_e, \quad (8)$$

with $\Lambda = \sum_s s^\dagger \otimes |s\rangle$. This, in particular, implies their positive-semidefiniteness. In Appendix A, we show that the objective function and the constraints in Eq. (3) can be expressed as linear functions of the coefficients of the matrices $\{\Gamma_e\}_e$. Adopting the shorthand $(K_M^{i,j|a})^\dagger = K_M^{j|i|a}$ for convenience, this provides the following *semidefinite relaxation*

$$\begin{aligned} P_{\text{guess}}(A | E, \rho_S, \{M_S^a\}_a) = & \max_{\{\Gamma_e\}_e} \sum_{a,i,j} \langle j | \langle \mathbb{1} | \Gamma_e | i \rangle | K_M^{i,j|a} \rangle \\ \text{subject to} & \\ \Gamma_e \succeq 0 \quad \forall e, & \\ \sum_e \langle i | \langle \mathbb{1} | \Gamma_e | j \rangle | \mathbb{1} \rangle = \langle i | \rho_S | j \rangle \quad \forall i, j, & \\ \sum_{e,l} \langle l | \langle \mathbb{1} | \Gamma_e | l \rangle | K_M^{i,j|a} \rangle = \langle i | M_S^a | j \rangle \quad \forall a, i, j, & \\ \sum_{e,i,j} \langle j | \langle \mathbb{1} | \Gamma_e | i \rangle | K_M^{i,j|a} \rangle = \text{Tr}[M_S^a \rho_S] \quad \forall a, & \\ \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | s \rangle = \langle m | \langle s^\dagger | \Gamma_e | n \rangle | \mathbb{1} \rangle & \\ \quad \forall s \in \mathcal{O} \quad \forall e, m, n, & \\ \sum_a \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | K_M^{i,j|a} \rangle = \delta_{ij} \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | \mathbb{1} \rangle & \\ \quad \forall e, m, n, i, j, & \\ \sum_l \langle m | \langle (K_M^{l,i|a})^\dagger | \Gamma_e | n \rangle | K_M^{l,j|b} \rangle = & \\ \delta_{ab} \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | K_M^{i,j|a} \rangle \quad \forall a, b, e, m, n, i, j. & \end{aligned} \quad (9)$$

The second, third and fourth constraints are direct analogs of the ones in Eq. (3). The last three constraints, on the other hand, follow from the hermiticity, the completeness and projectivity of $\{\Pi_{SM}^a\}_a$ respectively (see Appendix A).

Our main result, Theorem 1 below, shows that Eq. (9) is, in fact, a *characterization* of the device-dependent guessing probability.

Theorem 1. *Let $\{\Gamma_e\}_e$ be a feasible solution to Eq. (9) achieving some objective value c . Then, there exist a finite-dimensional Hilbert space $\mathcal{H}_M$, operators $K_M^{i,j|a}$ and (possibly subnormalized) states $\tilde{\sigma}_{SM}^e$ such that $\langle \{\sigma_{SM}^e\}_e, \{\Pi_{SM}^a\}_a \rangle$, with Π_{SM}^a as in Eq. (4), is a feasible solution to Eq. (3) achieving the same objective value c .*

The proof of this theorem is deferred to Appendix C.

IV. Application

In this section, we apply the SDP introduced in Section III on different setups.

A. Depolarized state and measurement

We first consider a setting that was studied in Ref. [7], where a lower bound to the guessing probability was derived analytically. Let the characterized state and POVM be, respectively,

$$\rho_S = (1 - \delta) |+\rangle \langle +| + \delta \frac{\mathbb{1}}{2}, \quad \text{and} \quad \{M_S^a\}_a = \{|0\rangle \langle 0|, |1\rangle \langle 1|\}. \quad (10)$$

where $\delta \in [0, 1]$ is the noisy parameter and $|+\rangle := 1/\sqrt{2}(|0\rangle + |1\rangle)$. Given that the measurement is projective, Eq. (1) in this case is known to reduce to an SDP [4]. Nevertheless, in Ref. [7], the authors derived an analytic expression for the optimum as a function of the noise parameter δ . In particular,

$$P_{\text{guess}}(A | E, \rho_S, \{M_S^a\}_a) = \frac{1}{2} \left(1 + \sqrt{\delta(2 - \delta)} \right). \quad (11)$$

The same work [7] also considers the case in which both the state and the measurement are equally affected by depolarizing noise. More formally, the state and the measurement are assumed to be

$$\begin{aligned} \rho_S &= \varepsilon |+\rangle \langle +| + (1 - \varepsilon) \mathbb{1}/2, \\ \{M_S^a\}_a &= \{\varepsilon |0\rangle \langle 0| + (1 - \varepsilon) \mathbb{1}/2, \\ &\quad \varepsilon |1\rangle \langle 1| + (1 - \varepsilon) \mathbb{1}/2\}, \end{aligned} \quad (12)$$

where $\varepsilon \in [0, 1]$ and $|+\rangle = (|0\rangle + |1\rangle)/\sqrt{2}$. The authors prove the following analytically lower bound to the guessing probability

$$P_{\text{guess}}(A | E, \rho_S, \{M_S^a\}_a) \geq \frac{1}{2} \left(1 + 2\sqrt{\delta(1 - \delta)} \right), \quad (13)$$

with $\varepsilon = 1 - \sqrt{1 - \delta}$. The relation between the noise parameters δ and ε is chosen so that the resulting measurement statistics are identical in the two scenarios.

In Fig. 2, we plot the upper bounds to conditional min-entropy

$$H_{\min}(A|E, \rho_S, \{M_S^a\}_a) := -\log_2 P_{\text{guess}}(A|E, \rho_S, \{M_S^a\}_a),$$

provided by Eq. (9) for these two situations. As can be seen, they match the analytic values obtained from Eqs. (11) and (13), establishing, in particular, the optimality of the latter.

FIG. 2: Lower bounds on $H_{\min}(A|E)$ obtained with our SDP for the setting in Eq. (10) (blue dots) and for the setting in Eq. (12) (orange dots). The solid lines represent the analytic results for the corresponding quantity.

B. Depolarized state and inefficient detector

In Ref. [8], the authors put forward a scheme for randomness generation with quantum computers. Specifically, they consider a setup preparing uniform superpositions $|+\rangle$ of computational basis states which are affected by depolarizing noise of strength δ . These qubits are later subject to a binary measurement parametrized by $\mu \in (0, 1)$, where smaller values of μ correspond to a stronger bias towards the read-out of the basis state $|0\rangle\langle 0|$. More formally, they consider the following state and measurement

$$\begin{aligned} \rho_S &= (1 - \delta) |+\rangle\langle +| + \delta \mathbb{1}/2, \\ \{M_S^a\}_a &= \{\mathbb{1} - \mu|1\rangle\langle 1|, \mu|1\rangle\langle 1|\}. \end{aligned} \quad (14)$$

To estimate the conditional min-entropy, following the prescription in [5], the authors fix a specific dilation $\mathcal{D}$ of the measurement $\{M_S^a\}_a$, given by

$$\begin{aligned} \{\Pi_{SM}^a\}_a &= \{|0\rangle\langle 0| \otimes |0\rangle\langle 0|, |0\rangle\langle 0| \otimes |1\rangle\langle 1| + \mathbb{1} \otimes |1\rangle\langle 1|\}, \\ \sigma_M &= (1 - \mu)|0\rangle\langle 0| + \mu|1\rangle\langle 1|. \end{aligned} \quad (15)$$

We compare the result obtained using this specific dilation with the unrestricted one using Eq. (9). In Fig. 3 we plot $H_{\min}(A|E, \mathcal{D}) - H_{\min}(A|E)$ as a function of the

parameters δ and μ . We observe that for many values of the parameters this quantity is positive, implying an overestimation (albeit small) of the amount of intrinsic randomness generated.

FIG. 3: Difference between the conditional min-entropy $H_{\min}(A|E)$ for the specific dilation in Eq. (15) and the upper bound obtained via our SDP over all possible dilations.

C. Uncharacterized state and equiangular planar measurement

As a final application, we consider the source-device-independent scenario introduced in Ref. [9]. In this framework, no assumption is made on the prepared qubit state ρ_S , while the measurement is assumed to be fully characterized and trusted. Specifically, it is described by an equiangular k -outcome POVM $\{M_S^a\}_{1 \leq a \leq k}$ defined on the XZ plane of the Bloch sphere, with elements

$$M_S^a = \frac{1}{k} (\mathbb{1} + \vec{u}_a \cdot \vec{\sigma}), \quad (16)$$

where $\vec{u}_a = (\cos \theta_a, 0, \sin \theta_a)$, with $\theta_a = 2\pi a/k$, are the vertices of a regular polygon in the XZ plane and $\vec{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ denotes the vector of Pauli operators.

Ref. [9] shows that, under these assumptions, the min-entropy diverges, suggesting that unbounded randomness can be certified even with qubit systems. In particular, the conditional min-entropy satisfies the lower bound

$$m_n \equiv \min_{\rho_S} H_{\min}(A|E) = \log_2(k) - 1, \quad (17)$$

which is represented by the continuous line in Fig. 4.

To assess whether these conclusions remain valid in a scenario with untrusted measurements, we consider a modified version of the SDP in Eq. (3). The only difference is that the input state ρ_S is no longer fixed, and

is instead included as an optimization variable. Accordingly, the maximization is extended to ρ_S , subject to the constraints $\rho_S \succeq 0$ and $\text{Tr}[\rho_S] = 1$.

The results reported in Fig. 4 show that, for $k > 3$, assuming a trusted measurement leads to a significant overestimation of the min-entropy.

FIG. 4: Conditional min-entropy $H_{\min}(A|E)$ as a function of the number of outcomes k for an equiangular POVM in the XZ plane of the Bloch sphere. The solid line represents the theoretical lower bound $m_n = \log_2(n) - 1$ assuming fully trusted measurements, while the points show the corresponding values obtained via our SDP formulation, without assuming trusted measurements. For $k > 3$, assuming trusted measurements significantly overestimates the min-entropy.

Extending our analysis, we take into account realistic depolarizing noise in the measurement, which further decreases the min-entropy values we observe. We model the measurement by replacing each POVM element M_S^a with

$$\tilde{M}_S^a = (1 - \delta)M_S^a + \delta \frac{\text{Tr}[M_S^a]}{d} \mathbb{1}_S, \quad (18)$$

where $\delta \in [0, 1]$ is the noisy parameter, with $\delta = 1$ corresponding to a fully depolarized measurement. For $k = 3$, Fig. 5 shows that the min-entropy already vanishes at $\delta \simeq 0.073$.

V. Entanglement-assistance increases Eve's predicting power

The global state ρ_{SM} of the measured system S and dilation's ancillary M in Eq. (1) is allowed to be correlated. As explained above, the rationale behind this decision follows from the fact that the honest user, Alice, is only assumed to have tomographic access to the system S , and is thus unable to detect correlations with M . This, however, contrasts with the assumption performed in the independently introduced randomness quantifica-

FIG. 5: Conditional min-entropy $H_{\min}(A|E)$ for $k = 3$ as a function of the depolarizing noise parameter δ of the measurement. The min-entropy decreases rapidly as the noise increases and vanishes around $\delta \simeq 0.073$.

tion framework from [10], where the system and the ancilla are restricted to be in a product state (see Eq. (32) therein). Naturally, this raises the question whether this restriction has any operational consequences.

Let $P_{\text{guess}}^{\text{sep}}$ be as in Eq. (1) but with the added constraint of a separable ρ_{SM} . In this section, we show that there exist states ρ_S^* and POVMs M_S^* for which

$$P_{\text{guess}}(A|E, \rho_S^*, M_S^*) > P_{\text{guess}}^{\text{sep}}(A|E, \rho_S^*, M_S^*).$$

We make use of the following lemma, whose proof we defer to Appendix B.

Lemma 2. *If the bipartite state ρ_{SM} is separable, then*

$$\Gamma^{T_S}(\rho_{SM}) \geq 0.$$

Here, T_S denotes the partial transposition with respect to subsystem S . Therefore, by constraining the sum $\Gamma = \sum_e \Gamma_e$ of the matrices defined in Eq. (5) to have a positive partial transpose (PPT), we obtain upper bounds to $P_{\text{guess}}^{\text{sep}}$.

As a concrete example, for the qubit state ρ_S and the binary measurement $M_S = \{M_S^0, \mathbb{1}_S - M_S^0\}$ given by

$$\rho_S = \begin{pmatrix} 0.2 & 0.3 \\ 0.3 & 0.8 \end{pmatrix}, \quad M_S^0 = \begin{pmatrix} 0.6 & re^{i\phi} \\ re^{-i\phi} & 0.1 \end{pmatrix}, \quad (19)$$

with $r = 0.24$, $\phi = 0.89$, we find that

$$P_{\text{guess}}^{\text{sep}} \leq 0.909672 < P_{\text{guess}} = 0.910376$$

In spite of the gap for this particular example being quite small, it suffices to show that, already in the simplest scenario given by a single qubit and a binary measurement, assuming no entanglement between the system S and the measurement register M can overestimate the amount of intrinsic randomness generated.

VI. Conclusion

In this work, we studied the amount of intrinsic randomness that can be generated in a characterized but untrusted prepare-and-measure scenario. In particular, we introduced a semidefinite programming formulation of the conditional min-entropy of Eve possessing quantum side information about the experimental setup.

We apply our method in three different scenarios. This allows us to benchmark our formulation and, more importantly, to determine the exact amount of certifiable randomness in settings where previously only upper bounds were known, often relying on additional assumptions to make the conditional min-entropy computable. Moreover, we used our framework to show that restricting the correlations between the preparation and measurement devices to be classical strictly reduces Eve's predictive power.

Our results provide a general tool for quantifying randomness in realistic, noise-affected quantum devices and

contribute to a more complete understanding of randomness generation in the presence of quantum side information.

APPENDIX

A. Moment matrix formulation

We now consider the optimisation problem in Eq. (3), which we rewrite here for convenience

$$P_{\text{guess}}^Q = \max_{\{\Pi_{SM}^a\}_a, \{\tilde{\sigma}_{SM}^e\}_e} \sum_{a=1}^k \text{Tr}[\Pi_{SM}^a \tilde{\sigma}_{SM}^a], \quad (\text{A1})$$

subject to

$$\begin{aligned} \text{Tr}_M \left[\sum_{e=1}^k \tilde{\sigma}_{SM}^e \right] &= \rho_S, \\ \text{Tr}_M \left[\Pi_{SM}^a \left(\mathbb{1}_S \otimes \text{Tr}_S \left[\sum_{e=1}^k \tilde{\sigma}_{SM}^e \right] \right) \right] &= M_S^a \quad \forall a \in \{1, \dots, k\}, \\ \text{Tr} \left[\Pi_{SM}^a \sum_{e=1}^k \tilde{\sigma}_{SM}^e \right] &= \text{Tr} [M_S^a \rho_S] \quad \forall a \in \{1, \dots, k\}. \end{aligned} \quad (\text{A2})$$

Following the approach in [13], we rewrite this optimisation in terms of moment matrices via the mapping

$$\tilde{\sigma}_{SM}^e \longrightarrow \text{Tr}_M [(\mathbb{1}_S \otimes \Lambda) \tilde{\sigma}_{SM}^e (\mathbb{1}_S \otimes \Lambda^\dagger)] := \Gamma_e, \quad (\text{A3})$$

where $\Lambda = \sum_{s \in \mathcal{O}} s^\dagger \otimes |s\rangle$, with $\mathcal{O} := \{1\} \cup \{K_M^{ij|a} : a = 1, \dots, k, i, j = 1, \dots, d\}$, and $e \in \{1, \dots, k\}$. Using this definition, the moment matrices $\{\Gamma_e\}_e$ can be written explicitly as

$$\begin{aligned} \Gamma_e &= \sum_{s, t \in \mathcal{O}} \text{Tr}_M [(\mathbb{1}_S \otimes s^\dagger \otimes |s\rangle) \tilde{\sigma}_{SM}^e (\mathbb{1}_S \otimes t \otimes \langle t|)] \\ &= \sum_{s, t \in \mathcal{O}} \text{Tr}_M \left[(\mathbb{1}_S \otimes s^\dagger \otimes |s\rangle) \left(\sum_{i, j, k, l} c_{i, j, k, l}^e |i\rangle \langle j| \otimes |k\rangle \langle l| \right) (\mathbb{1}_S \otimes t \otimes \langle t|) \right] \quad \forall e \in \{1, \dots, k\}. \\ &= \sum_{s, t \in \mathcal{O}} \sum_{i, j} |i\rangle \langle j| \text{Tr} [(|j\rangle \langle i| \otimes s^\dagger t) \tilde{\sigma}_{SM}^e] \otimes |s\rangle \langle t| \end{aligned} \quad (\text{A4})$$

Let's write the objective and the constraints in function of the matrices $\{\Gamma_e\}_e$.

• **Objective function.**

$$\begin{aligned} \sum_a \sum_{i, j} \langle j | \langle \mathbb{1} | \Gamma_a | i \rangle | K_M^{i, j|a} \rangle &= \sum_a \sum_{i, j} \text{Tr} [|i\rangle \langle j| \otimes K_M^{i, j|a} \tilde{\sigma}_{SM}^a] \\ &= \sum_a \text{Tr} [\Pi_{SM}^a \tilde{\sigma}_{SM}^a]. \end{aligned} \quad (\text{A5})$$

• **Constraint** $\text{Tr}_M [\sum_e \tilde{\sigma}_{SM}^e] = \rho_S$.

$$\begin{aligned} \sum_e \langle i | \langle \mathbb{1} | \Gamma_e | j \rangle | \mathbb{1} \rangle &= \sum_e \text{Tr} [(|j\rangle \langle i| \otimes \mathbb{1}) \tilde{\sigma}_{SM}^e] \\ &= \langle i | \rho_S | j \rangle \quad \forall i, j. \end{aligned} \quad (\text{A6})$$

• **Constraint** $\text{Tr}_M [\Pi_{SM}^a (\mathbb{1}_S \otimes \text{Tr}_S [\sum_e \tilde{\sigma}_{SM}^e])] = M_S^a$.

$$\begin{aligned} \sum_e \sum_l \langle l | \langle \mathbb{1} | \Gamma_e | l \rangle | K_M^{i, j|a} \rangle &= \sum_e \text{Tr} [(\mathbb{1} \otimes K_M^{i, j|a}) \tilde{\sigma}_{SM}^e] \\ &= \langle i | M_S^a | j \rangle \quad \forall a, i, j. \end{aligned} \quad (\text{A7})$$

This follows from the identity

$$\begin{aligned} M_S^a &= \text{Tr}_M \left[\Pi_{SM}^a (\mathbb{1}_S \otimes \text{Tr}_S [\sum_e \tilde{\sigma}_{SM}^e]) \right] \\ &= \sum_{i,j} |i\rangle \langle j| \text{Tr} \left[(\mathbb{1} \otimes K_M^{i,j|a}) \sum_e \tilde{\sigma}_{SM}^e \right]. \end{aligned} \quad (\text{A8})$$

• **Constraint** $\text{Tr}[\Pi_{SM}^a \sum_e \tilde{\sigma}_{SM}^e] = \text{Tr}[M_S^a \rho_S]$.

$$\sum_e \sum_{i,j} \langle j | \langle \mathbb{1} | \Gamma_e | i \rangle | K_M^{i,j|a} \rangle = \sum_e \text{Tr}[\Pi_{SM}^a \tilde{\sigma}_{SM}^e] \quad \forall a. \quad (\text{A9})$$

In addition to the constraints discussed above, further conditions must be imposed on the moment matrices to enforce the algebraic properties of the operators $\{\Pi_{SM}^a\}_a$. First, since $\{\Pi_{SM}^a\}_a$ are Hermitian, i.e. $(\Pi_{SM}^a)^\dagger = \Pi_{SM}^a \quad \forall a$, we require $(K_M^{i,j|a})^\dagger = K_M^{j,i|a} \quad \forall i, j, a$. In our formulation, this is enforced through

$$\langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | s \rangle = \langle m | \langle s^\dagger | \Gamma_e | n \rangle | \mathbb{1} \rangle \quad \forall s \in \mathcal{O} \quad \forall e, m, n. \quad (\text{A10})$$

Second, the completeness condition $\sum_a \Pi_{SM}^a = \mathbb{1}_{SM}$ implies

$${}_S \langle i | \sum_a \Pi_{SM}^a | j \rangle_S = \sum_a K_M^{i,j|a} = \delta_{i,j} \mathbb{1}_M. \quad (\text{A11})$$

At the level of the moments, this translates to

$$\begin{aligned} \sum_a \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | K_M^{i,j|a} \rangle &= \sum_a \text{Tr} \left[|m\rangle \langle n| \otimes K_M^{i,j|a} \tilde{\sigma}_{SM}^e \right] \\ &= \delta_{ij} \text{Tr} [|m\rangle \langle n| \otimes \mathbb{1}_M \tilde{\sigma}_{SM}^e] = \delta_{ij} \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | \mathbb{1} \rangle \quad \forall e, m, n, i, j. \end{aligned} \quad (\text{A12})$$

Finally, the projectivity condition $(\Pi_{SM}^a)^2 = \Pi_{SM}^a$ is equivalent to

$${}_S \langle i | (\Pi_{SM}^a)^2 | j \rangle_S = \sum_l K_M^{i,l|a} K_M^{l,j|a} = K_M^{i,j|a} = {}_S \langle i | \Pi_{SM}^a | j \rangle_S. \quad (\text{A13})$$

In terms of expectation values, we impose

$$\begin{aligned} \sum_l \langle m | \langle (K_M^{l,i|a})^\dagger | \Gamma_e | n \rangle | K_M^{l,j|b} \rangle &= \text{Tr} \left[\left(\sum_l |m\rangle \langle n| \otimes K_M^{l,i|a} K_M^{l,j|b} \right) \tilde{\sigma}_{SM}^e \right] \\ &= \delta_{ab} \text{Tr} \left[(|m\rangle \langle n| \otimes K_M^{i,j|a}) \tilde{\sigma}_{SM}^e \right] \\ &= \delta_{ab} \langle m | \langle \mathbb{1} | \Gamma_e | n \rangle | K_M^{i,j|a} \rangle \quad \forall a, b, e, m, n, i, j. \end{aligned} \quad (\text{A14})$$

B. Moment matrix separability lemma

Lemma 3. *Given a state ρ_{SM} separable then $\Gamma^{Ts}(\rho_{SM}) \geq 0$.*

Proof. Recall that

$$\Gamma(\rho_{SM}) = \sum_{i,j} |i\rangle \langle j| \otimes \sum_{s,t \in \mathcal{O}} c_{t^\dagger s}^{i,j}(\rho_{SM}) |s\rangle \langle t|,$$

with

$$c_s^{i,j}(\rho_{SM}) = \text{Tr} [|j\rangle \langle i| \otimes s \rho_{SM}].$$

Next, from the fact that

$$\mathrm{Tr}[(|i\rangle\langle j|_S \otimes s)\sigma_{SM}^{T_S}] = \mathrm{Tr}[(|j\rangle\langle i|_S \otimes s)\sigma_{SM}]$$

we have that

$$\begin{aligned}\Gamma(\rho_{SM})^{T_S} &= \sum_{i,j} |j\rangle\langle i| \otimes \sum_{s,t \in \mathcal{O}} c_{t^\dagger s}^{ij}(\rho_{SM}) |s\rangle\langle t| \\ &= \sum_{i,j} |j\rangle\langle i| \otimes \sum_{s,t \in \mathcal{O}} c_{t^\dagger s}^{ji}(\rho_{SM}^{T_S}) |s\rangle\langle t| \\ &= \Gamma(\rho_{SM}^{T_S}).\end{aligned}$$

The statement of the lemma then follows from the facts that $\rho_{SM}^{T_S} \geq 0$ for a separable ρ_{SM} and $\rho \geq 0 \implies \Gamma(\rho) \geq 0$. $\square$

C. Sufficiency of the SDP relaxation

This section is devoted to the proof of Theorem 1 from the main text. In fact, we will prove a somewhat stronger result, Proposition 4 below, from which the said theorem follows as a corollary.

In the following, we use the symbol $(K_M^{ij|a})^\dagger$ as a shorthand for $K_M^{ji|a}$. The goal of this section is to prove the following result.

Proposition 4. *For $e \in \{1, \dots, k\}$, let $\{c_e^{ij}(s) : i, j = 1, \dots, d, s \in \mathcal{O}^2\} \subset \mathbb{C}$ be such that*

$$\sum_{a=1}^k c_e^{mn}(K_M^{ij|a}) = \delta_{ij} c_e^{mn}(\mathbb{1}), \quad (C1)$$

$$\sum_{l=1}^d c_e^{mn}((K_M^{li|a})^\dagger K_M^{lj|b}) = \delta_{ab} c_e^{mn}(K_M^{ij|b}). \quad (C2)$$

and the matrix

$$\Gamma_e := \sum_{s,t \in \mathcal{O}} \sum_{i,j=1}^d c_e^{ij}(ts^\dagger) |i\rangle\langle j| \otimes |s\rangle\langle t| \quad (C3)$$

be positive semidefinite. Then, there exist a Hilbert space $\tilde{\mathcal{H}}$, non-normalized quantum states $\{\tilde{\sigma}_{SM}^e\}_e \subset B(\mathbb{C}^d) \otimes B(\tilde{\mathcal{H}})$ and operators $\{\tilde{K}_M^{ij|a}\} \subset B(\tilde{\mathcal{H}})$ such that

$$\tilde{\Pi}_{SM}^a := \sum_{i,j=1}^d |i\rangle\langle j| \otimes \tilde{K}_M^{ij|a}, \quad \forall a \in \{1, \dots, k\} \quad (C4)$$

defines a projective measurement and

$$\mathrm{tr}(|j\rangle\langle i| \otimes \tilde{t} \tilde{s}^\dagger \tilde{\sigma}_{SM}^e) = c_e^{ij}(ts^\dagger), \quad (C5)$$

for $s, t \in \mathcal{O}$.

To prove the proposition, we will make use of the following lemma.

Lemma 5. *Let $\{c^{ij}(s) : i, j = 1, \dots, d, s \in \mathcal{O}^2\} \subset \mathbb{C}$ satisfy the constraints*

$$\sum_{a=1}^k c^{mn}(K_M^{ij|a}) = \delta_{ij} c^{mn}(\mathbb{1}), \quad (C6)$$

$$\sum_{l=1}^d c^{mn}((K_M^{li|a})^\dagger K_M^{lj|b}) = \delta_{ab} c^{mn}(K_M^{ij|b}). \quad (C7)$$

Let the matrix

$$\Gamma = \sum_{s,t \in \mathcal{O}} \sum_{i,j=1}^d c^{ij}(ts^\dagger) |i\rangle \langle j| \otimes |s\rangle \langle t| \quad (\text{C8})$$

be positive semidefinite. Then, there exist a Hilbert space $\tilde{\mathcal{H}}$ of dimension $d|\mathcal{O}|$, a non-normalized quantum state $\tilde{\sigma} \in B(\mathbb{C}^d) \otimes B(\tilde{\mathcal{H}})$ and operators $\{\tilde{K}_M^{ij|a}\}_{i,j,a} \subset B(\tilde{\mathcal{H}})$ such that

$$\tilde{\Pi}_{SM}^a := \sum_{i,j=1}^d |i\rangle \langle j| \otimes \tilde{K}_M^{ij|a}, \quad \forall a \in \{1, \dots, k\} \quad (\text{C9})$$

defines a projective measurement and

$$\text{tr}(|j\rangle \langle i| \otimes \tilde{t} \tilde{s}^\dagger \tilde{\sigma}_{SM}) = c^{ij}(ts^\dagger), \quad (\text{C10})$$

for $s, t \in \mathcal{O}$.

The intuition of the proof of this lemma is that σ_{SM} can be chosen to be of the form $\sigma_{SM} = |\tilde{\psi}\rangle \langle \tilde{\psi}|$, with

$$|\psi\rangle = \sum_{m=1}^d |m\rangle |\tilde{\psi}_m\rangle. \quad (\text{C11})$$

If there exist projector operators of the form (C9) and relation (C10) is satisfied, then we have that:

$$c^{mn}(ts^\dagger) = \langle \tilde{\psi}_n | \tilde{t} \tilde{s}^\dagger | \tilde{\psi}_m \rangle. \quad (\text{C12})$$

In the proof, we will use a guess on $\{\tilde{s} |\psi_m\rangle : s \in \mathcal{O}\}$ to construct the projector operators $\{\tilde{\Pi}_{SM}^a\}_a$.

Proof. Since Γ is positive semidefinite, it admits a Gram decomposition, i.e., there exist vectors $\{|m, s\rangle : m = 1, \dots, d, s \in \mathcal{O}\} \subset \mathbb{C}^{d|\mathcal{O}|} =: \tilde{\mathcal{H}}$ such that

$$c^{mn}(ts^\dagger) = \langle m, s | n, t \rangle. \quad (\text{C13})$$

Comparing this expression with eq. (C12) suggests one to define the vectors

$$|\psi_m, s^\dagger\rangle := \overline{|m, s\rangle}, \quad (\text{C14})$$

which therefore satisfy

$$c^{mn}(t^\dagger s) = \langle \psi_n, t | \psi_m, s \rangle. \quad (\text{C15})$$

Intuitively, $|\psi_m, s\rangle$ would represent the vector $\tilde{s} |\tilde{\psi}_m\rangle$ alluded to above; accordingly, the vector

$$|\Phi_{m,a}^j\rangle := \sum_i |i\rangle |\psi_m, K_M^{ij|a}\rangle \quad (\text{C16})$$

would correspond to $\tilde{\Pi}_{SM}^a |j\rangle |\tilde{\psi}_m\rangle$. In this regard, note that

$$\begin{aligned} \langle \Phi_{m,a}^i | \Phi_{n,b}^j \rangle &= \sum_l \langle \psi_m, K_M^{li|a} | \psi_n, K_M^{lj|b} \rangle \\ &= \sum_l c^{nm} ((K_M^{li|a})^\dagger K_M^{lj|b}) \\ &= \delta_{ab} c^{nm} (K_M^{ij|b}); \end{aligned} \quad (\text{C17})$$

in particular, $|\Phi_{m,a}^i\rangle \perp |\Phi_{n,b}^j\rangle$ for $a \neq b$. For $a = 1, \dots, k$, the subspaces

$$H_a := \text{span}\{|\Phi_{m,a}^i\rangle : m, i\} \quad (\text{C18})$$

are therefore pair-wise orthogonal; this suggests defining the projectors

$$\tilde{\Pi}_{SM}^a := \text{proj}(H_a), \quad \forall a \in \{1, \dots, k\}. \quad (\text{C19})$$

The orthogonality relations between the subspaces $\{H_a\}_a$ guarantee that $\{\tilde{\Pi}_{SM}^a\}_a$ are either a complete or an under-complete set of projectors. In the latter case, we redefine $\tilde{\Pi}_{SM}^1 := \mathbb{1} - \sum_{a \neq 1} \tilde{\Pi}_{SM}^a$.

Now, consider the vector

$$|i\rangle |\psi_m, \mathbb{1}\rangle - \sum_a |\Phi_{m,a}^i\rangle. \quad (\text{C20})$$

This vector is null. Indeed, its norm squared is

$$\begin{aligned} & \langle \psi_m, \mathbb{1} | \psi_m, \mathbb{1} \rangle + \sum_a \langle \Phi_{m,a}^i | \Phi_{m,a}^i \rangle - \sum_a \langle i | \langle \psi_m, \mathbb{1} | \Phi_{m,a}^i \rangle - \sum_a \langle \Phi_{m,a}^i | i \rangle |\psi_m, \mathbb{1}\rangle \\ &= \langle \psi_m, \mathbb{1} | \psi_m, \mathbb{1} \rangle + \sum_a \sum_j \langle \psi_m, K_M^{ji|a} | \psi_m, K_M^{ji|a} \rangle - \sum_a \langle \psi_m, \mathbb{1} | \psi_m, K_M^{ii|a} \rangle - \sum_a \langle \psi_m, K_M^{ii|a} | \psi_m, \mathbb{1} \rangle \\ &= c^{mm}(\mathbb{1}) + \sum_a \sum_j c^{mm}((K_M^{ji|a})^\dagger K_M^{ji|a}) - \sum_a c^{mm}(K_M^{ii|a}) - \sum_a c^{mm}(K_M^{ii|a}) \\ &= c^{mm}(\mathbb{1}) + \sum_a c^{mm}(K_M^{ii|a}) - 2 \sum_a c^{mm}(K_M^{ii|a}) \\ &= c^{mm}(\mathbb{1}) - \sum_a c^{mm}(K_M^{ii|a}) = 0, \end{aligned} \quad (\text{C21})$$

where we made use of relations (C6), (C7). Thus, for all m, i , it holds that

$$|i\rangle |\psi_m, \mathbb{1}\rangle = \sum_a |\Phi_{m,a}^i\rangle. \quad (\text{C22})$$

By the orthogonality relations $\{H_a \perp H_b : a \neq b\}$, this implies that

$$\begin{aligned} \tilde{\Pi}_{SM}^a |i\rangle |\psi_m, \mathbb{1}\rangle &= \tilde{\Pi}_{SM}^a \sum_b |\Phi_{m,b}^i\rangle \\ &= |\Phi_{m,a}^i\rangle. \end{aligned} \quad (\text{C23})$$

Let $\{\tilde{K}_{SM}^{ij|a}\}_{a,i,j} \subset B(\tilde{\mathcal{H}})$ be such that

$$\tilde{\Pi}_{SM}^a = \sum_{i,j} |i\rangle \langle j| \otimes \tilde{K}_M^{ij|a}, \quad (\text{C24})$$

and define

$$|\tilde{\psi}\rangle := \sum_m |m\rangle |\psi_m, \mathbb{1}\rangle. \quad (\text{C25})$$

Then we have that

$$\begin{aligned} & \langle m | \otimes \tilde{K}_M^{jk|a} |\tilde{\psi}\rangle \\ &= (\langle j | \otimes \mathbb{1}) \tilde{\Pi}_{SM}^a (|k\rangle \langle m | \otimes \mathbb{1}) |\tilde{\psi}\rangle \\ &= (\langle j | \otimes \mathbb{1}) \tilde{\Pi}_{SM}^a |k\rangle |\psi_m, \mathbb{1}\rangle \\ &= (\langle j | \otimes \mathbb{1}) |\Phi_{m,a}^k\rangle \\ &= |\psi_m, K_M^{jk|a}\rangle, \end{aligned} \quad (\text{C26})$$

where we invoked eq. (C23) and the definition of $|\Phi_{a,m}^i\rangle$ in the last two lines.

Finally, define

$$\tilde{\sigma}_{SM} := |\tilde{\psi}\rangle\langle\tilde{\psi}|. \quad (\text{C27})$$

By eqs. (C15) and (C26), for all $s, t \in \mathcal{O}$ it holds that

$$\begin{aligned} & \text{tr}(|n\rangle\langle m| \otimes \tilde{t}\tilde{s}^\dagger \tilde{\sigma}_{SM}) \\ &= \langle\tilde{\psi}|(|n\rangle\langle m| \otimes \tilde{t})(\langle m| \otimes \tilde{s}^\dagger)|\tilde{\psi}\rangle \\ &= \langle\psi_n, \tilde{t}^\dagger|\psi_m, \tilde{s}^\dagger\rangle = c^{mn}(ts^\dagger). \end{aligned} \quad (\text{C28})$$

□

Now we are ready to prove the proposition.

Proof of Proposition 4. By Lemma 5, there exists a Hilbert space $\hat{\mathcal{H}}$ of dimension $d|\mathcal{O}|$ such that, for $e = 1, \dots, k$, there is a set of operators $\{\hat{s}(e) : s \in \mathcal{O}\} \subset B(\hat{\mathcal{H}})$ and a non-normalized state $\hat{\sigma}_{SM'}^e \subset B(\mathbb{C}^d \otimes \hat{\mathcal{H}})$ with the properties:

1. $\text{tr}(|j\rangle\langle i| \otimes \hat{t}(e)\hat{s}(e)^\dagger \hat{\sigma}_e) = c_e^{ij}(ts^\dagger) \quad \forall s, t \in \mathcal{O}.$
2. The operators

$$\tilde{\Pi}_{SM}^a := \sum_{i,j=1}^d |i\rangle\langle j| \otimes \tilde{K}_M^{ij|a}(e), \quad \forall a \in \{1, \dots, k\} \quad (\text{C29})$$

define a complete projective measurement.

We next integrate all the operators above in an extended Hilbert space $\tilde{\mathcal{H}} = \hat{\mathcal{H}} \otimes \mathbb{C}^k$, through the relation

$$\tilde{t} := \sum_{e=1}^k \hat{t}(e) \otimes |e\rangle\langle e|. \quad (\text{C30})$$

Similarly, we define the states

$$\tilde{\sigma}_{SM}^e := \hat{\sigma}_{SM'}^e \otimes |e\rangle\langle e|. \quad (\text{C31})$$

It can then be verified that the operators

$$\tilde{\Pi}_{SM}^a = \sum_{i,j} |i\rangle\langle j| \otimes \tilde{K}_M^{ij|a} = \sum_e \hat{\Pi}_{SM'}^a(e) \otimes |e\rangle\langle e| \quad (\text{C32})$$

form a complete system of projectors. Moreover, eq. (C5) holds, since, for all $t, s \in \mathcal{O}$,

$$\begin{aligned} & \text{tr}(|j\rangle\langle i| \otimes \tilde{t}\tilde{s}^\dagger \tilde{\sigma}_{SM}^e) \\ &= \text{tr}(|j\rangle\langle i| \otimes \hat{t}(e)\hat{s}^\dagger(e) \hat{\sigma}_{SM'}^e) = c_e^{ij}(ts^\dagger). \end{aligned} \quad (\text{C33})$$

□

Proof of Theorem 1. Let $\{\Gamma_e\}_e$, with

$$\Gamma_e := \sum_{s,t \in \mathcal{O}} \sum_{i,j=1}^d c_e^{ij}(ts^\dagger) |i\rangle\langle j| \otimes |s\rangle\langle t| \quad (\text{C34})$$

be a feasible solution to Eq. (9) achieving an objective value c . By identifying the coefficients $c_e^{i,j}(ts^\dagger) = \langle i|\langle s|\Gamma_e|j\rangle|t\rangle$, we can see that the constraints in the SDP formulation directly enforce the hypotheses of Proposition 4. Specifically

1. The completeness constraint $\sum_a \langle m|\langle \mathbb{1}|\Gamma_e|n\rangle|K_M^{ij|a}\rangle = \delta_{ij} \langle m|\langle \mathbb{1}|\Gamma_e|n\rangle|\mathbb{1}\rangle$ translates to (C1).
2. The projectivity constraint $\sum_l \langle m|\langle (K_M^{l,i|a})^\dagger|\Gamma_e|n\rangle|K_M^{l,j|b}\rangle = \delta_{ab} \langle m|\langle \mathbb{1}|\Gamma_e|n\rangle|K_M^{i,j|a}\rangle$ translates to (C2).

3. The constraint $\Gamma_e \succeq 0$ ensures the matrices are positive semidefinite.

Since all conditions of Proposition 4 are met, there exists a Hilbert space $\tilde{\mathcal{H}}$, subnormalized states $\{\tilde{\sigma}_{SM}^e\}_e$, and operators $\{\tilde{K}_M^{ij|a}\}_a$ forming a valid projective measurement $\tilde{\Pi}_{SM}^a = \sum_{i,j=1}^d |i\rangle\langle j| \otimes \tilde{K}_M^{ij|a}$ such that

$$\text{Tr}[(|j\rangle\langle i| \otimes \tilde{t}\tilde{s}^\dagger)\tilde{\sigma}_{SM}^e] = c_e^{ij}(ts^\dagger). \quad (\text{C35})$$

for $s, t \in \mathcal{O}$.

It directly follows from Equations (A5)-(A9), that these constructed states and measurements form a feasible solution to the original non-commutative polynomial optimization problem in Eq. (3) and that achieves the same optimal value c . $\square$

Simultaneous MCT Gate Decomposition for Reducing T-depth in Quantum Oracles

Abstract.

Quantum computation often relies on quantum oracles for evaluating Boolean functions. These oracles are typically constructed using Multiple-Controlled Toffoli (MCT) gates, which are further decomposed into Toffoli gates and ultimately into physically realizable Clifford+T gates. The T-depth, defined as the maximum number of sequential T-gate layers, is dominant in the overall execution cost. Since each Toffoli gate has a fixed T-depth, the overall T-depth is proportional to the number of Toffoli layers (the Toffoli depth), so minimizing the Toffoli depth minimizes the T-depth. Although previous studies have investigated the T-depth of MCT decompositions, existing methods process each MCT gate independently, which forces Toffoli gates from different MCT gates to execute sequentially even when they could overlap in time. We observe that decomposing multiple MCT gates together as a group allows their Toffoli sequences to be interleaved in time within a common execution window, reducing the overall Toffoli depth. The difficulty is that each MCT gate has freedom in choosing its control bits and ancillae, and poor choices cause Toffoli gates to clash on shared qubits and serialize. Based on this observation, we identify a set of non-trivial conditions on a candidate group under which interleaving succeeds with bounded depth overhead, and implement a heuristic algorithm to construct valid groups. Experimental results on quantum oracles for solving 3-SAT problems demonstrate that our method reduces T-depth by approximately 65% compared with existing decomposition methods.

Keywords: Multiple Controlled Toffoli (MCT) gates, Decomposition, T-depth

1 Introduction

For realizing quantum computation, we often need to design a *quantum oracle*, which calculates Boolean functions depending on each target problem [6]. Usually, we design such subcircuits using *Multiple Controlled Toffoli (MCT) gates* [4] at the logic design level. These MCT gates are decomposed into sequences of Toffoli gates, which are then decomposed into physically realizable gates. For fault-tolerant quantum computations, we often consider the *Clifford+T* gate set as one of the promising primitive gates.

The operation time of a T gate is considered to be dominant among the gates in the Clifford+T gate set, and so it is very important to reduce the *T-depth*, which is the longest sequence of T-gates that cannot be parallelized in a quantum circuit. Therefore, many MCT gate decomposition methods have been proposed to reduce the T-depth [1, 3, 5]. These existing decomposition methods require different numbers of ancillae (i.e., auxiliary qubits) and different T-depth; we can select the best decomposition method for *one* MCT gate from the existing methods.

Usually, many MCT gates are used in a quantum oracle circuit. However, as far as we know, almost no existing work specifically considers a decomposition method that treats multiple MCT gates simultaneously. In this paper, we show that it is not enough to consider the decomposition of each MCT gates one by one; we show

a motivational example and observation where the final T-depth of a circuit would be decreased if we consider multiple MCT gates appropriately at the same time for decomposing them.

Our method has the following features.

- We propose to decompose multiple MCT gates simultaneously rather than independently, formalizing the conditions under which the Toffoli sequences of different gates can be interleaved in time within a common execution window.
- We derive an upper bound on the per-group Toffoli depth under these conditions.
- We implement a heuristic algorithm to construct valid groups and validate the bound empirically.

We apply the proposed method to oracle circuits computing randomly generated 3-SAT formulas and demonstrate an average 65% T-depth reduction compared with applying an existing decomposition method to each MCT gate independently.

2 Decomposition of MCT gates

2.1 Toffoli Gate

The Toffoli gate is a three-qubit quantum gate consisting of two control bits and one target bit. The Toffoli gate inverts the value of the target bit when the values of all control bits are 1. To realize the operation of the Toffoli gate, it is necessary to decompose it into a group of Clifford+T gates. Figure 1 shows the Toffoli gate and an example of its decomposition [2].

In the decomposition example in Fig. 1, three layers of T gates that cannot be executed simultaneously appear.

Figure 1: Toffoli gate and decomposition example into Clifford+T [2]

Figure 2: An Example of decomposition of MCT gate into Toffoli gates

For this reason, the T-depth of the Toffoli gate in Fig. 1 is 3.

2.2 Multiple Controlled Toffoli (MCT) gate

A generalized Toffoli gate is called a Multiple Controlled Toffoli (MCT) gate [4]. An MCT gate consists of multiple control bits and one target bit. An MCT gate inverts the value of the target bit when the values of all control bits are 1. In the following, we denote the number of control bits of each MCT gate by n if the context is clear.

Figure 2 shows a naive decomposition of an MCT gate with four control bits into eight Toffoli gates [4]; each Toffoli gate is decomposed into a group of Clifford+T gates.

In Fig. 2, the MCT gate is decomposed into Toffoli gates using auxiliary qubits, a_0 and a_1 , which are called *dirty ancillae*; a dirty ancilla is an auxiliary qubit whose values are unknown when it is used. An MCT gate can be decomposed into $4(n-2)$ Toffoli gates using $n-2$ dirty ancillae [4].

More specifically, the $4(n-2)$ Toffoli gates in the decomposition follow a fixed pattern. The first Toffoli, denoted g_1 , is the only one that uses two of the original MCT gate's control bits as its inputs; each subsequent Toffoli uses one control bit and one or two ancilla bits. As discussed in the next section, this two-control-bit dependency of g_1 makes it the scheduling bottleneck when multiple MCT gates are decomposed together, and a smaller MCT gate with $n_i < n_{max}$ controls must start its g_1 no later than time-step $n_{max} - n_i$ (one time-step per Toffoli layer) to fit within the common window.

To improve over the naive decomposition, several methods have been explored [1, 3, 5] that reduce the T-depth of the MCT gate compared to Fig. 2. We call the method proposed in [1] the *existing method* in the following; it uses $n-2$ dirty ancillae and is built on top of the naive decomposition of Fig. 2.

2.3 Grouping MCT Gates to Reduce T-depth

When several MCT gates appear consecutively in a circuit, their Toffoli decompositions can in principle execute in an *interleaved* manner: while one MCT gate's Toffoli

sequence is using some qubits, another gate's Toffoli sequence can use disjoint qubits in parallel. Figures 3–5 illustrate this idea on a small example with two MCT gates, g_1 (red) and g_2 (blue), where each D_i marks the i -th time-step. Under existing decomposition (Fig. 4), the Toffoli sequences of the two gates execute in 7 time-steps. Under our proposed simultaneous decomposition (Fig. 5), the same gates complete in 4 time-steps by interleaving Toffoli sequences and sharing qubits across gates.

We show that if a set of MCT gates $\mathcal{G} = \{g_1, \dots, g_m\}$ satisfies the three conditions stated below, the entire group can be decomposed with a Toffoli depth bounded by $8(n_{max} - 2) - 3$, where $n_{max} = \max_i n_i$ is the largest control count in the group and n_i is the control count of g_i . This bound follows from a list-scheduling argument; we omit the full proof due to space constraints. We refer to this regime as *interleaved decomposition*, since the Toffoli sequences of different gates are scheduled to overlap in time rather than run sequentially.

For each gate g_i , let C_i , A_i , t_i denote its control-bit set, ancilla-bit set, and target bit, respectively. Let $\mathcal{N} = \bigcup_i C_i$, $A = \bigcup_i A_i$, $T = \{t_i\}_i$ be the union of these sets across the group. For each $q \in \mathcal{N}$, let $k_q = |\{i : q \in C_i\}|$ count how many gates use q as a control bit. The grouping conditions are as follows.

- **(C1) Resource isolation.** The sets $\mathcal{N}$, A , T are pairwise disjoint. This ensures that inter-gate conflicts can only arise on shared control bits.
- **(C2) Per-qubit capacity.** Each control bit is used as a control by at most $n_{max} - 2$ gates, i.e., $\forall q \in \mathcal{N}, k_q \leq n_{max} - 2$. Since each gate occupies a shared control bit for up to 4 time-steps and the window has length $4(n_{max} - 2)$, this keeps each qubit's total occupancy within the window.
- **(C3) Same-deadline compatibility.** Let $S_n = \{i : n_i = n\}$ denote the gates sharing the same deadline $n_{max} - n$. We require $|\bigcup_{i \in S_n} C_i| \geq 2|S_n|$ for each n , so that all gates at the same deadline have enough control bits to host their respective g_1 control-bit pairs.

The lower bound is $4(n_{max} - 2)$, achieved by the largest gate alone. The upper bound $8(n_{max} - 2) - 3$ refers to the total depth of the entire group, while serial (non-grouped) decomposition would require $\sum_i 4(n_i - 2)$ time-steps. When $|\mathcal{G}| \geq 2$ with n_i close to n_{max} , the grouped bound is strictly tighter than serial.

These three conditions are sufficient for the bound to hold. Our algorithm therefore partitions the MCT gates of a circuit into groups, each satisfying the conditions, and minimizes the number of such groups. To construct valid groups, we employ a two-layer heuristic. The first layer uses a constraint satisfaction problem (CSP) solver to place each gate's first Toffoli g_1 no later than its deadline. Once the first Toffolis are fixed, a greedy filling strategy schedules the remaining Toffoli gates of each decomposition sequence.

3 Experimental results

We use a computer with 64GB RAM and an AMD 7600X CPU to validate our method using oracle circuits constructed from randomly generated 3-SAT formulas, with comparative results shown in Table 1. Testing involves oracle circuits that calculate 100 randomly generated 3-SAT formulas for several configurations (i.e., different numbers of variables and clauses as shown in Table 1). We compare the T-depth after constructing full clauses between the existing method and our proposed method.

Figure 6 illustrates a quantum circuit $G_f = \{g_{f_1}, g_{f_2}, g_{f_3}\}$ that constructs clauses f_1 , f_2 , and f_3 within an oracle for the SAT formula $F = f_1 \wedge f_2 \wedge f_3 = (\neg q_0 \vee \neg q_1 \vee q_2) \wedge (q_2 \vee q_3 \vee \neg q_4) \wedge (q_3 \vee q_4 \vee \neg q_5)$, serving as a small illustration of the clause-construction circuits we evaluate. Our experiments target the clause-construction part of the oracle, which contains the MCT gates relevant to our method. Since the proposed method focuses on reducing T-depth, the positions of the X gates are marked during decomposition and inserted afterward to set the control-bit states.

Table 1 compares our proposed simultaneous decomposition method with the existing method. We restrict the available ancillae to the control-bit region (namely

q_0 to q_5 in Fig. 6), using no additional ancillae. The *var* indicates the number of variables, *clause* represents the number of clauses, *existing* shows results using post-control ancilla selection (choosing the first subsequent qubit as ancilla, or the preceding one when exceeding available qubits), while *proposed* demonstrates our proposed method results. The *depth* values represent average Toffoli depths across 100 circuit decompositions, *T-depth* shows the averaged maximum qubit T-depth, and *run time* shows the averaged run time observed in these decompositions.

The experimental results demonstrate that, compared to the existing method, our proposed method achieves significant reductions in both Toffoli depth and T-depth. Furthermore, the improvement ratio increases as the problem scale grows, as shown in Table 1.

4 Conclusion

This paper proposes a heuristic method that considers decomposing MCT gates simultaneously, aiming to reduce the overall circuit T-depth.

The experimental results show that, compared to the existing method, the proposed method reduces the overall circuit T-depth by an average of 65.59%.

For future work, we plan to investigate optimal grouping strategies, beyond the current heuristic, that minimize the total number of groups under the proposed conditions. Additionally, we will generalize the proposed method to arbitrary quantum circuits beyond 3-SAT oracles.

Fig. 1: Solving the BPSP on a Quantum Computer Using the ICC Encoding. This figure illustrates the process of solving the BPSP with the Initial-Car-Colour (ICC) encoding using QAOA and its variants. a) The process starts with a BPSP instance, which in this example consists of 6 cars of length 12 forming the sequence $C_5C_1C_1C_3C_2C_2C_5C_4C_3C_6C_6C_4$. b) Using the ICC encoding the BPSP instance with 6 cars is mapped to an Ising model with 6 spins. In the depicted graphs, orange edges symbolise an edge weight of $+1$, while green edges indicate an edge weight of -1 . c) The Ising model is then solved on quantum computer using QAOA or its variants. d) This is the ground state solution of the Ising model, where the colour of node (based on the spin) determines the colour of the first occurrence of the car; using this colour of the second occurrence of the car is painted the opposite colour. e) This is the solved BPSP instance with a total of 4 paint swaps.

The Binary Paint Shop Problem (BPSP) [5, 4, 6], a well-known APX-hard optimisation problem with significant applications in automotive manufacturing, aims to colour a sequence of $2n$ cars, where each of n unique cars appears exactly twice, using two colours such that each car receives both colours while minimising consecutive colour swaps. The paint swap ratio, defined as the average number of colour changes per car, serves as a key performance metric, with lower ratios enhancing production efficiency, reducing material waste, and increasing profitability. Recently, Streif et al. [8] demonstrated that the Quantum Approximate Optimisation Algorithm at $p = 7$ (QAOA₇) achieves an expected paint swap ratio of 0.393, outperforming the classical Recursive Greedy (RG) [2, 1] heuristic's ratio of 0.4. A newer classical heuristic, Recursive Star Greedy (RSG) [7], was conjectured to achieve a ratio of 0.361. In this study, we investigate two state-of-the-art QAOA—eXpressive QAOA (XQAOA) [9] and Recursive QAOA (RQAOA) [3]—and compare their performance against best known classical heuristics. We first establish a rigorous reduction of the BPSP sequence of $2n$ cars to a graph colouring problem on n vertices, which we term the Initial-Car-Colour (ICC) encoding. This reduction not only offers a novel structural perspective on the problem but also reduces the Hamiltonian size by a factor of two. Benchmarking XQAOA₁ and RQAOA₁ on BPSP instances with $N = 2^7$ to 2^{12} cars, we find that XQAOA₁ achieves an average paint swap ratio of 0.357, consistently surpassing RQAOA₁ and classical heuristics across nearly all instances, surpassing even the conjectured performance of RSG. Contrary to previous claims, we empirically estimate RSG's true average ratio to be closer to 0.371. Notably, RQAOA₁ exhibits diminishing performance as the problem size increases. Despite employing provably optimal QAOA₁ parameters at each recursive step, RQAOA₁ is outperformed by RSG on a majority of instances at $N = 2^{11}$ and on all instances at $N = 2^{12}$. To our knowledge, this work is the first to highlight RQAOA₁'s performance degradation at scale. In contrast, XQAOA₁ maintains robust performance with a paint swap ratio of 0.357, demonstrating strong potential to outperform all known heuristics in the asymptotic limit and offering a promising quantum approach to the BPSP.

The Binary Paint Shop Problem (BPSP) is an APX-hard optimisation problem in automotive manufacturing: given a sequence of $2n$ cars, comprising n distinct models each appearing twice, the task is to decide which of two colours to paint each car so that the two occurrences of each model are painted differently, while minimising consecutive colour swaps. The key performance metric is the paint swap ratio, the average number of colour changes per car, which directly impacts production efficiency and cost. Prior work showed that the Quantum Approximate Optimisation Algorithm (QAOA) at depth $p = 7$ achieves a paint swap ratio of 0.393, outperforming the classical Recursive Greedy (RG) heuristic with an expected ratio of 0.4 [Phys. Rev. A 104, 012403 (2021)]. More recently, the classical Recursive Star Greedy (RSG) heuristic was conjectured to achieve an expected ratio of 0.361. In this study, we develop the theoretical foundations for applying QAOA to BPSP through a formal reduction of BPSP to weighted MaxCut, and use this framework to benchmark two state-of-the-art low-depth QAOA variants—eXpressive QAOA (XQAOA) and Recursive QAOA (RQAOA)—at depth $p = 1$ (denoted XQAOA₁ and RQAOA₁) against the strongest classical heuristics known to date. Across instances ranging from 2^7 to 2^{12} cars, XQAOA₁ achieves an average ratio of 0.357, surpassing RQAOA₁ and all known classical heuristics, including the conjectured performance of RSG. Surprisingly, RQAOA₁ shows diminishing performance as the problem size increases: despite employing provably optimal QAOA₁ parameters at each recursive step, it is outperformed by RSG on most 2^{11} -car instances and on all 2^{12} -car instances. To our knowledge, this is the first study to report RQAOA₁'s performance degradation at scale. In contrast, XQAOA₁ stays robust across all sizes, indicating strong potential to asymptotically surpass all known heuristics.

I. INTRODUCTION

The advent of noisy intermediate-scale quantum (NISQ) devices [1–3] has opened new opportunities toward achieving near-term quantum advantage [4]. Although constrained by limited qubit connectivity, finite coherence times, and the absence of fault-tolerant quantum error correction, such devices can nevertheless execute relatively shallow quantum circuits with reasonable fidelity [5, 6]. These limitations have spurred the development of algorithms designed to maximise the utility of scarce quantum resources, most notably variational quantum algorithms (VQAs) [7–10], which combine quantum state preparation with classical parameter optimisation to adapt to device imperfections while tackling classically hard problems. A prominent example is the Quantum Approximate Optimisation Algorithm (QAOA) [9], which has been extensively studied for combinatorial optimisation [9, 11–21] through numerical benchmarks [22–24], theoretical analyses [25–29], and numerous algorithmic variants [30–39]. Beyond optimisation, QAOA is also computationally universal [40, 41]

and capable of generating distributions that are classically hard to sample from [42, 43].

One application of particular interest is the Binary Paint Shop Problem (BPSP) [44–46], an APX-hard optimisation problem arising in automotive manufacturing. The input is a sequence of $2n$ cars comprising n distinct models, each appearing twice. The objective is to paint each car in one of two colours such that the two occurrences of every model receive different colours, while minimising the number of colour transitions between consecutive cars. Performance is quantified by the paint swap ratio—defined as the average number of adjacent pairs of cars painted in different colours—which directly reflects production efficiency and material usage. Streif et al. [47] showed that QAOA at depth $p = 7$ (QAOA₇) achieves an expected paint swap ratio of 0.393, surpassing the Recursive Greedy (RG) algorithm [48, 49], which has a proven expected ratio of 0.4 and was, at the time, the best known classical heuristic for the BPSP. More recently, a new classical heuristic—the Recursive Star Greedy (RSG) heuristic [50]—was proposed, with a conjectured expected ratio of 0.361. While QAOA₇'s ability to outperform RG highlights the potential of quantum algorithms for solving complex real-world problems, matching or exceeding the conjectured performance of RSG would require quantum circuits far deeper than

* vjqntm@gmail.com

current devices can sustain. Indeed, noise accumulates rapidly with circuit depth [51–58], and while error mitigation can help [22, 59–65], its overhead often outweighs the modest performance gains [66, 67].

Motivated by the limitations of deep QAOA circuits, we investigate two state-of-the-art low-depth variants—eXpressive QAOA (XQAOA) [34] and Recursive QAOA (RQAOA) [30]—both of which have outperformed the best known classical algorithms for the maximum cut (MaxCut) problem at $p = 1$. We begin by establishing a formal reduction of BPSP to the weighted MaxCut problem and subsequently to an Ising spin model. Central to this reduction is the Initial Car Colour (ICC) encoding, which we formalise based on a technique introduced by Streif et al. [47], that halves the number of decision variables. We further derive exact interaction strengths from BPSP constraints and prove new structural properties of the resulting graphs, including a maximum degree bound and an explicit relation between total graph weight and paint swap cost. Together, these results provide a rigorous foundation for applying QAOA and its variants to BPSP and may be of independent interest for related optimisation problems.

We benchmark RQAOA₁ and XQAOA₁ on random BPSP instances with up to 2^{12} cars, comparing against the best known classical heuristics. Our simulations show that XQAOA₁ achieves an average swap ratio of 0.357, outperforming all tested classical heuristics—including the conjectured 0.361 performance of RSG—as well as RQAOA₁ on most instances. In contrast, RQAOA₁, despite employing provably optimal QAOA₁ parameters at each recursive step, exhibits diminishing performance with problem size, falling behind RSG for 2^{11} -car instances and larger. To our knowledge, this is the first report of RQAOA₁’s performance degradation at scale. The consistent robustness of XQAOA₁ across all tested sizes suggests strong potential to surpass all known heuristics in the asymptotic limit.

We note that, during the preparation of this manuscript, a related study by Mooney et al. [68] appeared on the arXiv, also applying RQAOA to the BPSP. Their approach differs from ours in that they avoid direct optimisation of QAOA parameters within each recursion. Instead, they leverage parameter concentration [69] and parameter transfer [70], setting QAOA parameters based on values optimised for other instances. Benchmarking RQAOA for $1 \leq p \leq 3$ on instances of up to 20 cars, they report no noticeable performance loss under parameter transfer. While these results indicate that transferred parameters can sustain RQAOA performance on small instances, our findings reveal that even with fully optimised parameters, RQAOA suffers diminishing returns as problem size increases. Beyond the shared application of RQAOA to the BPSP, the focus and conclusions of our works are distinct.

The remainder of this paper is organised as follows. Section II reviews the BPSP, classical heuristics, and relevant quantum optimisation algorithms. Section III de-

scribes the reduction of BPSP to MaxCut and its equivalent Ising formulation. Section IV reports our numerical benchmarking results, while section V analyses their implications and limitations. Finally, section VI concludes with a summary of insights and directions for future work.

II. PRELIMINARIES

A. The Binary Paint Shop Problem

The binary paint shop problem (BPSP) [44–46] is a combinatorial optimisation problem that arises in the paint shops of the automobile industry. A production line receives a fixed sequence of n distinct car models, each appearing exactly twice in the sequence. The order is predetermined by upstream and downstream factory stages—such as the body shop before the paint shop, and trim/chassis/assembly after it—and cannot be rearranged. Each car must be painted in two different colours (e.g., red and blue), but the order in which each car receives its two colours is left to be decided. This assignment, called a *colouring*, determines how colours are applied across the sequence. The objective is to choose a colouring that minimises the number of colour changes between consecutive cars, since every change requires additional setup time, increases paint waste, and reduces throughput.

Formally, given a set of n distinct cars $C = \{c_1, \dots, c_n\}$, and a sequence of car instances $w = (w_1, \dots, w_{2n})$ with $w_i \in C$ where each $c \in C$ appears exactly twice, the BPSP asks for a colouring $f = (f_1, \dots, f_{2n}) \in \{r, b\}^{2n}$ that minimises the total number of colour changes between consecutive cars, subject to the validity constraint that the two occurrences of each car receive opposite colours (i.e., if $w_i = w_j$ and $i \neq j$, then $f_i \neq f_j$). A convenient formulation is:

$$\begin{aligned} & \text{Minimize} && \sum_{i=1}^{2n-1} [f_i \neq f_{i+1}] \\ & \text{subject to} && f_i \in \{r, b\}, \quad \forall i \in \{1, \dots, 2n\} \\ & && f_i \neq f_j, \quad \forall i, j : w_i = w_j, i \neq j \end{aligned} \tag{1}$$

where $[\cdot]$ denotes the Iverson bracket which evaluates to 1 if its condition holds and 0 otherwise.

The BPSP is NP-complete in its decision form [45] and APX-hard in its optimisation form [44, 46]. In other words, unless $P = NP$, no polynomial-time classical algorithm can solve all instances exactly, nor approximate them arbitrarily well via a polynomial-time approximation scheme. Moreover, assuming the Unique Games Conjecture, BPSP is NP-hard to approximate within any constant factor [46]. This is in contrast to problems such as MaxCut, which admit polynomial-time classical algorithms that achieve constant-factor approximations [71].

Given these complexities, several heuristic approaches have been proposed for the BPSP, each producing solu-

FIG. 1: **Solving the BPSP on a Quantum Computer Using the ICC Encoding.** This figure illustrates the process of solving the BPSP with the Initial-Car-Colour (ICC) encoding using QAOA and its variants. a) The process starts with a BPSP instance, which in this example consists of 6 cars of length 12 forming the sequence $C_5C_1C_1C_3C_2C_2C_5C_4C_3C_6C_6C_4$. b) Using the ICC encoding the BPSP instance with 6 cars is mapped to an Ising model with 6 spins. In the depicted graphs, orange edges symbolise an edge weight of $+1$, while green edges indicate an edge weight of -1 . c) The Ising model is then solved on quantum computer using QAOA or its variants. d) This is the ground state solution of the Ising model, where the colour of node (based on the spin) determines the colour of the first occurrence of the car; using this colour the second occurrence of the car is painted the opposite colour. e) This is the solved BPSP instance with a total of 4 paint swaps.

tions with colour changes linear in n [48, 49, 72]. The simplest is the red-first algorithm [48], which colours the first occurrence of every car red and the second blue. The greedy algorithm [49, 72] improves on this by selecting at each step the colour that minimises immediate paint changes, switching only when necessary to satisfy the requirement that each car be painted in both colours. The recursive greedy (RG) algorithm [48, 49] offers a further improvement by recursively removing the last-occurring car from the sequence, optimally colouring the reduced instance, and then reinserting the removed pair in the best possible way. More recently, Hančl et al. [50] proposed the recursive star greedy (RSG) algorithm, a refinement of RG that introduces a temporary “undecided” colour (star) for car pairs that can be coloured either way without affecting the current swap count; during recursion, if placing a car next to a starred car would otherwise increase the swap count, both occurrences of that starred car are recoloured with binary colours to avoid the increase, and the final colouring is obtained by replacing any remaining stars with arbitrary legal binary assignments. Detailed explanations of these heuristics are provided in appendix B 2. The asymptotic performances of red-first, greedy, and RG are proven, with $\mathbb{E}_{\text{RF}}(\Delta_C) = 2n/3$, $\mathbb{E}_G(\Delta_C) = n/2$, and $\mathbb{E}_{\text{RG}}(\Delta_C) = 2n/5$; in contrast, RSG’s performance is unproven but conjectured to be $\mathbb{E}_{\text{RSG}}(\Delta_C) = 0.361n$, an improvement over RG. Despite these advances, numerical results indicate that the optimal number of colour

changes grows linearly in n , but with a much smaller constant factor than current heuristics achieve. A recent lower bound of $\mathbb{E}_{\text{OPT}}(\Delta_C) \geq 0.214n - o(n)$ by Hančl et al. [50] confirms that existing heuristics remain far from optimal in the asymptotic limit, leaving room for quantum algorithms to yield improvements.

Heuristic	Solution	# Swaps
Red-First	$C_5C_1C_1C_3C_2C_2C_5C_4C_3C_6C_6C_4$	7
Greedy	$C_5C_1C_1C_3C_2C_2C_5C_4C_3C_6C_6C_4$	6
RG	$C_5C_1C_1C_3C_2C_2C_5C_4C_3C_6C_6C_4$	5
RSG	$C_5C_1C_1C_3C_2C_2C_5C_4C_3C_6C_6C_4$	4

TABLE I: This table compares the paint sequences and corresponding number of colour swaps for a 6-car BPSP instance, showing the solutions obtained by the classical heuristics together with their swap counts. In this example, red-first produces the highest number of swaps, while RSG achieves the fewest and matches the optimal solution.

We conclude this subsection with an illustrative example of the BPSP, shown in fig. 1 with the corresponding results summarised in table I. The example compares the four classical heuristics described earlier on the same instance. As expected from their asymptotic behaviour, red-first produces the highest number of swaps, while RSG achieves the fewest and, in this case, matches the

optimal solution. It is worth noting that although RG generally outperforms the standard greedy algorithm—as it does in this example—there are instances where the greedy algorithm produces fewer paint swaps [49].

B. Quantum Approximate Optimisation Algorithm

The Quantum Approximate Optimisation Algorithm (QAOA) [9] is a variational quantum algorithm for approximating solutions to combinatorial optimisation problems. The problem is encoded into a problem Hamiltonian H_P , whose ground state represents the optimal solution. QAOA seeks to approximate this ground state by preparing a depth- p variational quantum circuit, parameterised by $2p$ real angles, and optimising them to minimise the expectation value $\langle H_P \rangle$. Measuring the resulting quantum state in the computational basis produces candidate bit strings, from which a low-cost solution is selected.

QAOA alternates between two parameterised unitaries: one generated by the problem Hamiltonian H_P , which encodes the cost function and biases the state toward low-energy configurations, and one by the mixing Hamiltonian H_M , which drives transitions between computational basis states. For an n -qubit instance, we take

$$H_P = \sum_{j=1}^n \sum_{k=1}^n J_{jk} Z_j Z_k, \quad H_M = \sum_{j=1}^n X_j, \quad (2)$$

where Z_j and X_j are Pauli operators acting on qubit j , and J_{jk} are problem-specific couplings.

The corresponding parameterised unitaries are

$$U(H_P, \gamma) = e^{-i\gamma H_P} = \prod_{j,k} e^{-i\gamma J_{jk} Z_j Z_k}, \quad (3)$$

$$U(H_M, \beta) = e^{-i\beta H_M} = \prod_{j=1}^n e^{-i\beta X_j}, \quad (4)$$

with $\gamma \in \mathbb{R}$ and $\beta \in [0, \pi]$.

Starting from the uniform superposition $|+\rangle^{\otimes n}$, the level- p QAOA (QAOA _{p}) is

$$|\psi(\beta, \gamma)\rangle = \prod_{l=1}^p U(H_M, \beta_l) U(H_P, \gamma_l) |+\rangle^{\otimes n}. \quad (5)$$

The parameters (β, γ) are optimised classically to obtain

$$(\beta^*, \gamma^*) = \underset{\beta, \gamma}{\operatorname{argmin}} \langle \psi(\beta, \gamma) | H_P | \psi(\beta, \gamma) \rangle. \quad (6)$$

The optimised state $|\psi(\beta^*, \gamma^*)\rangle$ is then prepared on a quantum computer, measured repeatedly in the computational basis, and the lowest-cost bit string obtained is reported as the solution.

C. Expressive QAOA

The Expressive QAOA (XQAOA) [34] is an overparameterised extension of standard QAOA, designed to increase ansatz expressiveness at shallow circuit depths. While standard QAOA uses a single γ for all terms in H_P and a single β for all terms in H_M , XQAOA assigns independent parameters to each term of both Hamiltonians. This allows different qubits and couplings to be rotated by distinct angles, enabling a richer exploration of the solution space.

XQAOA further augments the standard mixer by introducing an additional α -dependent unitary acting on Pauli- Y operators. Let $\mathbf{A} = (A_j)_{j=1}^n$ denote the collection of single-qubit Pauli- Y operators with $A_j = Y_j$, and let $\mathbf{B} = (B_j)_{j=1}^n$ denote the corresponding Pauli- X operators with $B_j = X_j$. For the problem Hamiltonian, we write $\mathbf{C} = (H_{P_{jk}})_{(j,k) \in E}$, where each $H_{P_{jk}} = J_{jk} Z_j Z_k$ corresponds to the Ising interaction on edge (j, k) .

The mixing unitaries with parameter vectors $\alpha = (\alpha_1, \dots, \alpha_n)$ and $\beta = (\beta_1, \dots, \beta_n)$ are defined as

$$U(\mathbf{A}, \alpha) = e^{-i \sum_{j=1}^n \alpha_j A_j} = \prod_{j=1}^n e^{-i \alpha_j Y_j}, \quad (7)$$

$$U(\mathbf{B}, \beta) = e^{-i \sum_{j=1}^n \beta_j B_j} = \prod_{j=1}^n e^{-i \beta_j X_j}, \quad (8)$$

where $\alpha_j, \beta_j \in [0, \pi]$ are independent angles acting locally on each qubit. The problem unitary is likewise parameterised per interaction term as

$$U(\mathbf{C}, \gamma) = \prod_{j,k} e^{-i \gamma_{jk} J_{jk} Z_j Z_k}, \quad (9)$$

where $\gamma_{jk} \in \mathbb{R}$ are the parameters associated with each $Z_j Z_k$ term in the problem Hamiltonian H_P .

At $p = 1$, XQAOA prepares the state

$$\begin{aligned} |\psi(\alpha, \beta, \gamma)\rangle &= U(\mathbf{A}, \alpha) U(\mathbf{B}, \beta) U(\mathbf{C}, \gamma) |+\rangle^{\otimes n} \\ &= \prod_j e^{-i \alpha_j Y_j} e^{-i \beta_j X_j} \prod_{j,k} e^{-i \gamma_{jk} J_{jk} Z_j Z_k} |+\rangle^{\otimes n}. \end{aligned} \quad (10)$$

The XQAOA ansatz admits four notable configurations, distinguished by the constraints placed on the mixing unitary angles. The Multi-Angle QAOA (MA-QAOA) [33] is obtained by setting all $\alpha_j = 0$, yielding a multi-angle extension of the standard X-only QAOA mixer. The XY mixer is the most general form, allowing independent α_j and β_j for each qubit. The Y mixer restricts the ansatz to Y -rotations by setting all $\beta_j = 0$, while the X=Y mixer applies both X and Y rotations with a shared angle on each qubit, enforcing $\alpha_j = \beta_j$. Numerical results indicate that the X=Y mixer outperforms the other three configurations; therefore, all references to XQAOA in this work pertain to the X=Y mixer.

D. Recursive QAOA

The Recursive QAOA (RQAOA) [30] is a non-local variant of the QAOA designed to enhance QAOA's performance, especially at shallow circuit depths. RQAOA leverages QAOA as a subroutine to recursively reduce the problem size until it becomes tractable for brute-force methods. Specifically, RQAOA₁—RQAOA that uses QAOA₁ as its subroutine—has been shown to outperform state-of-the-art classical algorithms for MaxCut and similar problems [30, 73, 74]. Additionally, RQAOA₁ provides performance guarantees for particular graph structures [30, 75, 76] and has been successfully applied to small-scale, real-world problems [77, 78].

11 Solve  $C_0$  by backtracking through constraints
12 return Approximate ground state of  $C_0$ 

```

At each recursive step, RQAOA executes QAOA on the current problem Hamiltonian H_P , calculating the correlation metrics $M_{ij} = \langle Z_i Z_j \rangle$ for all pairs of qubits $\{i, j\}$. The pair with the highest absolute correlation, identified as $\{u, v\} = \underset{\{i, j\}}{\operatorname{argmax}} |M_{ij}|$, is selected. If $M_{uv} > 0$, the qubits u and v are positively correlated, and the constraint $Z_v = Z_u$ is imposed. Conversely, if $M_{uv} < 0$, the qubits are anti-correlated, leading to the constraint $Z_v = -Z_u$. These constraints effectively eliminate one qubit by expressing its state in terms of the other, thereby reducing the problem size. This process is iteratively applied to the updated Hamiltonian until the problem size is sufficiently small to be solved exactly using brute-force methods. The solution to the reduced instance is then propagated back through the imposed constraints to derive the solution to the original problem. The detailed steps of RQAOA are outlined in algorithm 1.

III. RECASTING BPSP AS AN ISING MODEL

We now present a complete and provably equivalent mapping of the BPSP to an Ising model suitable for quantum optimisation. Our approach formalises the Initial-Car-Colour (ICC) encoding, inspired by Streif et al. [47], which reduces the number of decision variables by half. Using this encoding we construct, for any BPSP instance, a weighted graph whose MaxCut value directly corresponds to the optimal paint swap cost. In particular, we establish a polynomial-time reduction from BPSP to weighted MaxCut, which in turn, provides an exact Ising Hamiltonian whose ground state encodes the optimal solution. The full technical development, with proofs and derivations, is given in the appendix; here we present only the essential ingredients needed for the remainder of the paper.

A. Initial Car Colour Encoding

A BPSP instance is a sequence $x \in (1, \dots, n)^{2n}$ in which every symbol occurs exactly twice. A colouring of x is given by a string $f \in \{r, b\}^{2n}$, where r (red) and b (blue) denote the two paint colours. The colouring f is valid if, whenever two positions i and j in the sequence correspond to the same car (i.e. $x_i = x_j$), the assigned colours differ ($f_i \neq f_j$). This direct encoding, however, contains redundant information: once the colour of the first occurrence of each car is fixed, the second occurrence must necessarily take the opposite colour. In other words, if the first appearance of car j is assigned colour f_i , then its second appearance is automatically $\neg f_i$, where $\neg$ flips red to blue and vice versa. This motivates the Initial-Car-Colour (ICC) encoding, which records only the colours of the first occurrences. Thus, every valid colouring can be described succinctly by an n -bit string instead of a $2n$ -bit one. For a rigorous treatment of this encoding, we refer the reader to appendix C 1.

To formalise this compression, we define the expansion map $\mathcal{E}_n$. Given a BPSP instance x and an ICC colouring $z \in \{r, b\}^n$, the corresponding full colouring is defined as $f = \mathcal{E}_n(x, z) \in \{r, b\}^{2n}$, with entries

$$\mathcal{E}_n(x, z)_i = \neg^{[x_i \in \{x_1, \dots, x_{i-1}\}]} z_{x_i} \quad \forall i \in [2n], \quad (11)$$

where $[\cdot]$ denotes the Iverson bracket which evaluates to 1 if its condition holds and 0 otherwise. In words, $\mathcal{E}_n$ assigns to each position the colour of that car's first occurrence, flipped if the car has already appeared earlier in the sequence. For example, for the BPSP instance $x = (1, 2, 1, 3, 3, 2)$ and an ICC string $z = rrb$, the expansion $\mathcal{E}_3(x, z)$ yields the valid BPSP colouring $rrbrbb$. The mapping from ICC strings to valid colourings is bijective (see proposition 4), ensuring no information is lost.

With the ICC encoding and the expansion map $\mathcal{E}_n$, the BPSP objective can be expressed directly in terms of ICC variables $z \in \{r, b\}^n$ (see proposition 5). Given a

BPSP instance x and an ICC colouring z , the number of paint swaps is

$$\tilde{\xi}_n(x, z) = \sum_{i=1}^{2n-1} \left[-\eta(x, i) z_{x_i} \neq z_{x_{i+1}} \right], \quad (12)$$

where the auxiliary function $\eta(x, i)$ determines whether the pair (x_i, x_{i+1}) contributes a “same-colour” or “opposite-colour” preference. It is defined by

$$\eta(x, i) = [x_{i+1} \in \{x_1, \dots, x_i\}] \oplus [x_i \in \{x_1, \dots, x_{i-1}\}], \quad (13)$$

with $\oplus$ denoting the exclusive-or operation. In words, $\eta(x, i) = 1$ when the boundary (x_i, x_{i+1}) consists of one first occurrence and one second occurrence, and $\eta(x, i) = 0$ when both are of the same type. Thus, η encodes the local parity between neighbours, enabling the swap count to be expressed as a quadratic form in the ICC variables and setting the stage for the graph and Ising formulations.

B. BPSP Graph Construction

We associate each BPSP instance with a corresponding BPSP graph whose vertices correspond to cars, edges connect cars that appear consecutively in the sequence, and weights reflect the cost preference for colour assignments.

Given a BPSP instance $x = (x_1, x_2, \dots, x_{2n})$, we associate to it a weighted graph $G_x = (V_x, E_x, W_x)$. The vertex set is $V_x = \{1, \dots, n\}$, corresponding to the cars in the alphabet $[n]$. An edge $\{u, v\}$ is included in E_x whenever the symbols u and v appear consecutively somewhere in the word x , provided that $u \neq v$ and the resulting weight is nonzero. The weight of an edge $e \in E_x$ aggregates the contributions of all such adjacencies in the word and is defined as

$$W_x(e) = - \sum_{k=1}^{2n-1} (-1)^{\eta(x, k)} \delta_{e, \{x_k, x_{k+1}\}}, \quad (14)$$

where $\delta_{e, \{x_k, x_{k+1}\}}$ equals 1 if the boundary (x_k, x_{k+1}) corresponds to the unordered pair e and 0 otherwise. In this way, each edge weight records how many times the pair of cars appears as neighbours in the sequence, corrected by the parity term $(-1)^{\eta(x, k)}$ that enforces whether equal or opposite colours are favoured.

The BPSP graph has two particularly useful structural properties. First, we show in proposition 8 that its maximum degree is bounded by four, since each car can be adjacent to at most two distinct neighbours across its two occurrences. Second, as shown by Streif et al. [47], the edge weights take values in $\{\pm 1, -2\}$. As $n \rightarrow \infty$, edges of weight -2 vanish in probability, while the remaining couplings occur with limiting probabilities: -1 with probability 2/3 and +1 with probability 1/3.

Beyond local structure, we also identify global properties of the BPSP graph. In proposition 9 we show that

its total weight can be expressed compactly in terms of the η -function and the number of double letters. Corollary 10 then relates this quantity directly to the cost of the red-first colouring, revealing that even this simple heuristic is governed by a global invariant of the graph.

Together, these local and global properties establish the BPSP graph as the central combinatorial object underlying the problem. In the next subsection, we exploit this structure to obtain an exact reduction of BPSP to weighted MaxCut.

C. Reduction to Weighted MaxCut

Once the BPSP graph is defined, the connection to MaxCut becomes clear. MaxCut asks for a partition of the vertices of a weighted graph into two sets such that the total weight of the edges between them is maximised. For a given instance x , each ICC assignment $z \in \{r, b\}^n$ induces such a partition of the vertices of G_x : two vertices lie on opposite sides of the cut whenever their ICC colours differ. The weight of this cut is obtained by summing the weights of the edges it separates, making the cut value a direct function of the ICC assignment.

In corollary 11 we show that for a BPSP instance x with graph G_x , the cut weight induced by an ICC assignment z can be expressed as

$$\text{wt}_{G_x}(z) = - \sum_{k=1}^{2n-1} (-1)^{\eta(x, k)} [z_{x_k} \neq z_{x_{k+1}}]. \quad (15)$$

Building on this, corollary 13 establishes a direct link between cut weight and paint swaps:

$$\tilde{\xi}_n(x, z) = \xi_n(\sigma_{\text{RF}}(x)) - \text{wt}_{G_x}(z), \quad (16)$$

where σ_{RF} denotes the red-first colouring $f \in \{r, b\}^{2n}$ and ξ_n counts the number of swaps in such colouring. Thus, the BPSP cost can be written as the red-first baseline minus the cut weight achieved by z . Using corollary 10, this relation can also be expressed in terms of global graph invariants such as the number of double letters and the total weight, though we omit the details here for brevity.

This reformulation shows that minimising $\tilde{\xi}_n(x, z)$ is exactly equivalent to maximising $\text{wt}_{G_x}(z)$, i.e. solving weighted MaxCut on the BPSP graph. In corollary 15 we rigorously prove this equivalence and, in algorithm 2, present the polynomial-time reduction from BPSP to weighted MaxCut problem.

D. Ising Model Formulation

The weighted MaxCut objective can be naturally reformulated as the ground-state energy of an Ising Hamiltonian. Using spin variables $z \in \{-1, 1\}^n$, the cut weight

of the BPSP graph can be written as

$$\text{wt}_{G_x}(z) = \frac{-1}{2} \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} (1 - z_{x_k} z_{x_{k+1}}). \quad (17)$$

Substituting this expression into eq. (16) and replacing the spin variables by Pauli-Z operators yields a quantum Ising Hamiltonian whose ground state encodes the optimal BPSP colouring.

While this already provides a valid mapping, it is possible to obtain a more direct formulation that avoids referencing the red-first cost. By working directly with the ICC objective defined in eq. (12), proposition 17 shows that for a BPSP instance x and ICC assignment $z \in \{-1, 1\}^n$, the number of paint swaps can be expressed as

$$\tilde{\xi}_n(x, z) = n - \frac{1}{2} - \frac{1}{2} \sum_{i=1}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}}. \quad (18)$$

In corollary 18 we further show that the ground state of this Hamiltonian corresponds exactly to the optimal BPSP colouring, i.e., the colouring with the minimal number of paint swaps.

Hence, solving BPSP with quantum heuristics such as QAOA amounts to preparing the ground state of the quantum Ising Hamiltonian

$$H_P(x) = n - \frac{1}{2} - \frac{1}{2} \sum_{i=1}^{2n-1} (-1)^{\eta(x,i)} Z_{x_i} Z_{x_{i+1}}. \quad (19)$$

where the spin variables have been promoted to Pauli-Z operators.

IV. NUMERICAL RESULTS

In this section, we benchmark the performance of XQAOA₁ and RQAOA₁ on the Binary Paint Shop Problem, comparing them against the known classical heuristics: Red-First, Greedy, Recursive Greedy, and Recursive-Star Greedy. All BPSP instances were generated randomly using a quantum random number generator [79, 80]. Since both XQAOA₁ and QAOA₁ admit closed-form expressions for their expectation values—given respectively by Theorem 3, Eq. (22), and Theorem 1, Eq. (13) of [34]—all benchmarks were performed entirely on a classical computer, without the use of quantum hardware. For XQAOA₁, the large number of parameters motivated the use of the JAX framework for efficient gradient computation via backpropagation, with optimisation carried out using the Limited-Memory Broyden–Fletcher–Goldfarb–Shanno (LBFGS) algorithm [81]. To address the highly non-convex optimisation landscape, each instance was run with 100 random initialisations. For RQAOA₁, the pairwise expectation values required at each recursion step were computed

analytically as functions of (β, γ) , and the variational parameters were set using the provably near-optimal values obtained by the method of Vijendran et al. [82]¹, eliminating the need for multiple restarts; hence, each instance was simulated only once. The deterministic classical heuristics were likewise run once per instance.

We consider two benchmark sets. The first comprises 200 random instances for each $n \in \{5, 10, \dots, 120\}$, probing how the number of paint swaps scales with problem size. The second consists of 50 random instances for each $n \in \{128, 256, 512, 1024, 2048, 4096\}$, used to compare expected swap ratios $\mathbb{E}(\Delta_C/n)$ on larger instances. Results are summarised in fig. 2 and fig. 3. In reporting results for XQAOA₁, we show the best solution from 100 restarts, except in fig. 2b and fig. 3b, where the distribution across all restarts is presented.

Figure 2a shows the average number of paint swaps on smaller instances. Among classical heuristics, Red-First scales the worst, while Recursive-Star Greedy is the most effective. Both quantum heuristics outperform the classical heuristics, with XQAOA₁ consistently below RQAOA₁ and showing the most favourable scaling. The widening separation between methods as n increases highlights how even small improvements in swap ratio compound into large advantages in the asymptotic regime.

Figure 2b compares paint-swap ratios for larger instances. The classical heuristics behave in line with theoretical expectations: Red-First, Greedy, and Recursive Greedy converge to asymptotic averages near 0.66, 0.5, and 0.4 respectively, while the Recursive-Star Greedy achieves an average of 0.37, slightly higher than its conjectured value of 0.361. XQAOA₁ attains an average ratio of about 0.357, outperforming all classical heuristics. In contrast, RQAOA₁ exhibits size-dependent performance: it is competitive on smaller instances, but its average ratio rises steadily with n , eventually falling behind both XQAOA₁ and Recursive-Star Greedy. This deterioration is evident in fig. 3, where the mean of the RQAOA₁ distributions drifts steadily rightward, increasing from 0.322 at $n = 128$ to 0.335 at $n = 256$, 0.346 at $n = 512$, and 0.362 at $n = 1024$, already worse than the stable XQAOA₁ average of 0.357; by $n = 2048$ the mean reaches 0.375, exceeding the Recursive-Star Greedy benchmark of 0.37, and at $n = 4096$ it rises further to 0.390, with the right tail extending to 0.4, matching the performance of Recursive Greedy. Despite relying on provably near-optimal parameters for QAOA₁ at every recursive step, RQAOA₁ deteriorates consistently with system size. In contrast, XQAOA₁ remains strikingly stable, with its distributions sharply peaked around 0.357

¹ In brief, this method applies to Ising models with arbitrary rational weights, reducing the two-dimensional optimisation over (β, γ) to a one-dimensional search in γ , using the Nyquist–Shannon theorem to set the sampling resolution, and a subdivision algorithm to locate the optimal angle in linear time.

FIG. 2: Benchmarking Classical and Quantum Heuristics on BPSP Instances. (a) Line plot showing the number of paint swaps produced by different heuristics on 200 random problems for each $n \in \{5, 10, \dots, 120\}$. Each point represents the average over all instances, with XQAOA₁ evaluated from the best of 100 random restarts per problem. Among the classical heuristics, Red-First performs the worst, while RSG performs the best. Both quantum heuristics achieve lower swap counts, with XQAOA₁ consistently outperforming RQAOA₁. (b) Boxplot showing the distribution of paint swap ratios for larger instances comprising 50 random problems for each $n \in \{128, 256, 512, 1024, 2048, 4096\}$. For XQAOA₁, the boxplots include all solutions from 100 restarts per instance. RSG achieves the best classical performance with an average ratio of about 0.37, yet it is consistently surpassed by XQAOA₁, which attains an average ratio of roughly 0.357. RQAOA₁ performs well for smaller n , but its advantage diminishes after $n = 512$. The best solutions from XQAOA₁, visible as outliers below the whiskers, consistently outperform those of RQAOA₁. (c-e) Scatterplots comparing the relative performance of RSG, RQAOA₁, and XQAOA₁. Each plot places one algorithm on each axis, with the $y = x$ diagonal as reference: points above the diagonal indicate superior performance of the x -axis algorithm, while points below indicate the y -axis algorithm performs better. Panel (c) shows RQAOA₁ outperforming RSG on most instances up to $n = 1024$, after which RSG dominates, particularly for $n \geq 2048$. Panel (d) shows XQAOA₁ consistently outperforming RSG by a wide margin across all sizes. Panel (e) shows XQAOA₁ outperforming RQAOA₁ in nearly all cases, with only a few exceptions.

across all tested sizes, strongly supporting convergence to this value in the large- n limit.

Returning to fig. 2, the boxplots in fig. 2b compress as variance shrinks with increasing size, making it difficult to distinguish the relative performance of Recursive-Star Greedy, RQAOA₁, and XQAOA₁. To address this, figs. 2c to 2e present pairwise scatter plots, where each

point compares the swap ratios of two algorithms and the diagonal $y = x$ line is shown for reference. Points lying above the diagonal indicate that the algorithm on the x -axis achieves a lower swap ratio, while points below the diagonal indicate that the y -axis algorithm performs better. In fig. 2c, RQAOA₁ outperforms Recursive-Star Greedy up to $n = 1024$, but its advantage disappears at

FIG. 3: Distribution of Paint Swap Ratios for RQAOA₁ and XQAOA₁. This figure shows KDE plots of paint-swap ratio distributions for larger instances comprising 50 random problems for each $n \in \{128, 256, 512, 1024, 2048, 4096\}$. Panel (a) presents RQAOA₁ and panel (b) XQAOA₁, with the latter including all solutions from 100 restarts per instance. For RQAOA₁, the mean of each distribution shifts steadily right as n increases, indicating deteriorating performance: rising from 0.322 at $n = 128$ to 0.362 at $n = 1024$, where it already falls behind XQAOA₁'s average of 0.357. At $n = 2048$, the mean increases further to 0.375, worse than RSG's 0.37, and by $n = 4096$ it reaches 0.39, with the right tail extending to 0.4, matching the performance of RG. In contrast, XQAOA₁ exhibits stable behaviour across all sizes, with means consistently near 0.357. As n grows, its distributions sharpen and concentrate around this value, strongly suggesting that XQAOA₁ outputs solutions with an average swap ratio of about 0.357 in the large limit.

$n = 2048$ and reverses completely by $n = 4096$, where Recursive-Star Greedy dominates all instances. By contrast, fig. 2d shows that XQAOA₁ consistently surpasses Recursive-Star Greedy at every size, typically by a substantial margin. Finally, fig. 2e reveals that XQAOA₁ also dominates RQAOA₁ across nearly all instances, with only a handful of small- n cases lying close to the diagonal. Taken together, these comparisons reinforce the trend that XQAOA₁ maintains robust performance at scale, while RQAOA₁ progressively deteriorates and is ultimately overtaken by classical heuristics.

Across all simulations, Recursive-Star Greedy averages about 0.37, above its conjectured 0.361; RQAOA₁ shows diminishing returns with size, drifting toward Recursive Greedy despite near-optimal QAOA₁ parameters; and XQAOA₁ remains stable around 0.357, consistently outperforming both classical heuristics and RQAOA₁. Together, these results indicate that XQAOA₁ sustains competitiveness at scale, whereas RQAOA₁ does not.

V. DISCUSSIONS

In this section we discuss the key patterns that emerge from our benchmarks. We highlight the diminishing returns observed for RQAOA as problem size increases,

contrast this with the stable performance of XQAOA around a paint-swap ratio of roughly 0.357, and consider what these findings imply for scalability and the choice of algorithms.

A. Diminishing Returns of Level-1 RQAOA

Our large-scale benchmarks reveal a surprising and previously unreported trend: the performance of RQAOA₁ deteriorates with problem size even when the QAOA₁ subroutine is run with provably near-optimal parameters [82]. This stands in sharp contrast to prior guarantees showing that RQAOA₁ can exactly solve unweighted cycles [30], complete graphs [75], and weighted bipartite graphs [76], as well as large-scale simulations on MaxCut and Ising models without external fields, which reported stable behaviour up to hundreds of qubits with no indication of degradation [30, 82]. Empirically, however, our kernel density estimates in fig. 3a shift monotonically toward higher paint-swap ratios as n grows, providing the first clear evidence of RQAOA₁ deteriorating at scale. Related work [82] also noted instability on Ising models with external fields, where RQAOA₁ could perform extremely well on some instances but poorly on others.

This degradation could be detected largely because of our choice of metric. The paint-swap ratio $\mathbb{E}[\Delta_C/n]$ is scale-normalised and requires no oracle access to the optimum, enabling consistent evaluation at arbitrarily large n . In contrast, the approximation ratio for MaxCut requires the exact optimum, which is infeasible at scale and can mask size-dependent pathologies. While one might object that these are distinct metrics, our formal reduction of BPSP to MaxCut, together with the expression of BPSP cost in terms of MaxCut cost, suggests that degradation in BPSP implies analogous deterioration in MaxCut, and consequently in general Ising models as system size increases.

B. Performance of Level-1 XQAOA as $n \rightarrow \infty$

In contrast to the deteriorating performance of RQAOA₁, XQAOA₁ remains stable and consistent across all tested sizes. As shown in figs. 2b and 3b, its distributions are sharply peaked and essentially stationary, with empirical means concentrated near ≈ 0.357 throughout the full range of n . This behaviour parallels that of the Red-First, Greedy, and Recursive Greedy heuristics, whose distributions are similarly stationary around their respective proven constants. Motivated by this consistency, we state the following conjecture on the asymptotic performance of XQAOA₁.

Conjecture 1. *For Binary Paint Shop Problem instances encoded as Ising models, the level-1 XQAOA ansatz with parameters optimised by gradient-based methods achieves a limiting paint-swap ratio of approximately 0.357, i.e.*

$$\lim_{n \rightarrow \infty} \mathbb{E} \left[\frac{\Delta_C}{n} \right] \approx 0.357.$$

Although a formal proof remains out of reach—owing to the high dimensionality of the parameter space and the non convexity of the optimisation landscape—the conjectured value is strongly supported by numerical evidence and, being lower than the empirical 0.37 ratio of Recursive-Star Greedy, constitutes a meaningful improvement in the BPSP literature.

C. Beyond the Benchmarked Algorithms

In this work we restricted our benchmarks to classical heuristics with known guarantees for BPSP and shallow-depth QAOA variants previously shown to outperform the best classical algorithms on MaxCut. Other algorithms, while lacking proven performance for BPSP, could in principle achieve lower empirical paint-swap ratios. A natural candidate is the Goemans–Williamson (GW) algorithm [71]: since BPSP reduces to a weighted MaxCut instance, GW can be applied directly. However, two caveats arise. First, the presence of negative edge

weights prevents the constant-factor approximation guarantee from carrying over. Second, GW requires solving a large semidefinite program whose memory demands grow rapidly with system size, often exceeding the capacity of standard hardware. For this reason we did not include GW in our large-scale comparisons; preliminary tests on small instances suggest that it can perform marginally better than XQAOA₁, though its scalability is limited.

Beyond this, there exist many untested heuristics that could achieve lower empirical ratios on specific instances, including simple meta-heuristics such as randomised local search, albeit without provable guarantees. Finally, we emphasise that there is still considerable room between the conjectured asymptotic performance of XQAOA₁, $\mathbb{E}_{\text{XQAOA}}[\Delta_C] \approx 0.357n$, and the recently established lower bound on the optimal solution, $\mathbb{E}_{\text{OPT}}[\Delta_C] \geq 0.214n - o(n)$ [50]. This gap suggests that further algorithmic improvements—classical, quantum, or hybrid—remain possible.

VI. CONCLUSION

We studied the Binary Paint Shop Problem through a formal reduction to a weighted MaxCut instance and then to an Ising model, enabled by an Initial Car Colour encoding that halves the number of decision variables and yields exact interaction strengths together with structural graph properties. These reductions provide a rigorous foundation for applying QAOA-type quantum heuristics to BPSP.

Building on this foundation, we benchmarked two state-of-the-art QAOA variants, XQAOA₁ and RQAOA₁, against classical heuristics with proven or conjectured performance guarantees, including Red-First, Greedy, Recursive-Greedy, and Recursive-Star Greedy. Our large-scale simulations reveal three key findings. First, XQAOA₁ consistently outperforms all classical heuristics and RQAOA₁, with outcomes tightly concentrated around a stable paint-swap ratio of ≈ 0.357 . Second, RQAOA₁ exhibits clear diminishing returns: its average ratio drifts steadily upward from 0.322 at $n = 128$ to 0.390 at $n = 4096$, eventually being surpassed by Recursive-Star Greedy and approaching Recursive-Greedy. Third, our benchmarks revise the empirical performance of Recursive-Star Greedy on upward to ≈ 0.370 , above its conjectured value of 0.361.

The remarkable stationarity of XQAOA₁’s distributions motivates the conjecture that it converges to a limiting swap ratio of ≈ 0.357 under our Ising encoding with gradient-based parameter optimisation. Taken together, these results establish XQAOA₁ as the most robust method we tested at scale, while providing the first clear numerical evidence that RQAOA₁ deteriorates on large BPSP instances. More broadly, these findings hint that expressiveness may be a more influential factor than non-locality in shaping the performance of QAOA-type heuristics for general Ising models, though further study

is required to confirm this. Extending this line of work to higher-depth variants, multi-colour paint shop problems, and other industrially motivated combinatorial tasks remains an important direction for future research.

Appendices

In the following appendices, we delve into the necessary mathematical ingredients needed to formulate BPSP in a framework compatible with implementation using QAOA and its variants. Furthermore, we elucidate the relationship between BPSP and the weighted maximum cut (MaxCut) problem, examining key properties exhibited by the associated MaxCut graph.

Appendix A: BPSP Formulation

We begin by introducing some notation. Throughout the appendix, we fix $n \in \mathbb{Z}^+$ to be a positive integer that denotes the number of distinct symbols. Additionally, we let r and b be formal symbols representing the colours *red* and *blue*, respectively.

BPSP instances: The instances of BPSP are *double-occurrence* words, defined as even-length words over an alphabet $[n] = \{1, \dots, n\}$ where each symbol $i \in [n]$ occurs exactly twice in each word. Each BPSP word of length $2n$ can be thought of as representing a sequence comprising n cars, with each car appearing precisely twice within the sequence. Formally, we denote the set of such words of length $2n$ by

$$\Gamma_n = \{(x_1, x_2, \dots, x_{2n}) \in [n]^{2n} : \forall i \in [n], |\{j \in [2n] : x_j = i\}| = 2\}. \quad (\text{A1})$$

Note that the length of any word $x \in \Gamma_n$ is $|x| = 2n$. The set of double-occurrence words, regardless of their length, is then the union of the sets in (A1):

$$\Gamma = \bigcup_{n \in \mathbb{Z}^+} \Gamma_n. \quad (\text{A2})$$

An example of an $n = 3$ BPSP instance is

$$t = (1, 2, 1, 3, 3, 2) \in \Gamma_3. \quad (\text{A3})$$

BPSP colourings: A valid BPSP colouring of a BPSP instance $x \in \Gamma$ is one that colours the symbols of x using two different colours in such a way that pairs of identical symbols are coloured differently. We let Ξ denote the function that maps an instance $x \in \Gamma$ to the set of its valid colourings, i.e.,

$$\Xi(x) = \left\{ f \in \{r, b\}^{|x|} : \forall i \neq j \in [|x|], x_i = x_j \implies f_i \neq f_j \right\}. \quad (\text{A4})$$

We denote the restriction of Ξ to the domain Γ_n by $\Xi_n = \Xi|_{\Gamma_n}$, i.e. if $x \in \Gamma_n$, we write $\Xi(x) = \Xi_n(x)$. For example,

$$rrbrbb, rbbbrb \in \Xi_3(t) \quad (\text{A5})$$

are valid BPSP colourings of the BPSP instance in (A3).

BPSP cost function: The BPSP cost function ξ measures the number of colour swaps in a given colouring of a BPSP instance. More formally, let $f \in \Xi(x)$ be a valid BPSP colouring of a BPSP instance $x \in \Gamma_n$. The BPSP cost ξ of f is given by

$$\xi(f) = \sum_{i=1}^{2n-1} [f_i \neq f_{i+1}], \quad (\text{A6})$$

where $[\cdot]$ denotes the Iverson bracket which evaluates to 1 if its argument is true and 0 otherwise. When restricted to inputs of length $2n$, we write $\xi = \xi_n$, i.e. $\xi(f) = \xi_n(f)$ if $f \in \{r, b\}^{2n}$. For the valid BPSP colourings in our example (A5), we have

$$\xi(rrbrbb) = 3, \quad \xi(rbbbrb) = 2. \quad (\text{A7})$$

BPSP problem: With the above definitions, the BPSP problem (1) can formally be expressed as follows:

Problem 1. BINARY PAINT SHOP PROBLEM (BPSP)

Input: a BPSP instance $x \in \Gamma$.

Output: minimise $\xi(f)$, as defined in eq. (A6)
subject to $f \in \Xi(x)$, where $\Xi(x)$ is defined in eq. (A4).

For $x \in \Gamma$, we denote the optimal cost and the set of optimal solutions of Problem 1, respectively, as follows:

$$\text{BPSP}(x) = \min_{f \in \Xi(x)} \xi(f), \quad (\text{A8})$$

$$\text{BPSP}^*(x) = \arg \min_{f \in \Xi(x)} \xi(f). \quad (\text{A9})$$

In the context of our example presented in eq. (A3), with some effort, one could demonstrate that $\text{BPSP}(t) = 2$ and $\text{BPSP}^*(t) \ni rbbrrr$.

Appendix B: Fundamentals

1. Eta Function

We begin this section by introducing the *eta function*, a useful function that recurs throughout many subsequent expressions. The *eta function* $\eta : \Gamma_n \times [2n - 1] \rightarrow \{0, 1\}$ is defined as follows:

$$\eta(x, i) = [x_{i+1} \in \{x_1, \dots, x_i\}] \oplus [x_i \in \{x_1, \dots, x_{i-1}\}], \quad (\text{B1})$$

where $\oplus$ is the *exclusive or* operation defined by $a \oplus b = 0$ if $(a, b) = (0, 0)$ or $(1, 1)$, and $a \oplus b = 1$ otherwise. Equivalently,

$$\eta(x, i) = \begin{cases} 0, & \text{if } (x_{i+1} \in \{x_1, \dots, x_i\} \wedge x_i \in \{x_1, \dots, x_{i-1}\}) \text{ or } (x_{i+1} \notin \{x_1, \dots, x_i\} \wedge x_i \notin \{x_1, \dots, x_{i-1}\}) \\ 1, & \text{if } (x_{i+1} \in \{x_1, \dots, x_i\} \wedge x_i \notin \{x_1, \dots, x_{i-1}\}) \text{ or } (x_{i+1} \notin \{x_1, \dots, x_i\} \wedge x_i \in \{x_1, \dots, x_{i-1}\}). \end{cases} \quad (\text{B2})$$

For our example word $t = (1, 2, 1, 3, 3, 2)$ in eq. (A3), we have

$$\eta(t, 1) = \eta(t, 5) = 0 \text{ and } \eta(t, 2) = \eta(t, 3) = \eta(t, 4) = 1. \quad (\text{B3})$$

We next establish a useful property of the eta function: if a BPSP instance denoted by $x \in \Gamma$ exhibits consecutive occurrences of the same symbol, with the initial occurrence positioned at index i , it follows that $\eta(x, i) = 1$.

Lemma 2. *Let $x \in \Gamma_n$ and $i \in [2n - 1]$. If $x_i = x_{i+1}$, then $\eta(x, i) = 1$.*

Proof. If $x \in \Gamma_n$ and $x_i = x_{i+1}$, then $x_{i+1} \in \{x_1, \dots, x_i\}$ and $x_i \notin \{x_1, \dots, x_{i-1}\}$ since the symbol x_i occurs at most twice. Hence, $\eta(x, i) = 1$. $\square$

2. Colouring Schemes

A *colouring scheme* refers to an algorithm designed to assign colours to a BPSP word in accordance with a valid BPSP colouring. These schemes can be categorised as either deterministic or probabilistic. In this section, we focus on deterministic colouring schemes, which can be formally characterised by functions $\sigma : \Gamma_n \rightarrow \{r, b\}^{2n}$ satisfying $\sigma(x) \in \Xi_n(x)$. To exemplify our definition, we discuss two deterministic colouring schemes:

1. The *red-first colouring scheme* is the function $\sigma_{\text{RF}} : \Gamma_n \rightarrow \{r, b\}^{2n}$, where $\forall x \in \Gamma_n$ and $i \in [2n]$,

$$\sigma_{\text{RF}}(x)_i = \begin{cases} r, & x_i \notin \{x_1, \dots, x_{i-1}\} \\ b, & \text{otherwise.} \end{cases} \quad (\text{B4})$$

In words, this scheme colours the initial instance of each symbol red and the subsequent occurrence of each symbol blue.

2. The *greedy colouring scheme* is the function $\sigma_{\text{G}} : \Gamma_n \rightarrow \{r, b\}^{2n}$, where $\forall x \in \Gamma_n$, $g = \sigma_{\text{G}}(x) \in \{r, b\}^{2n}$ is defined recursively by

$$g_1 = r \quad (\text{B5})$$

$$g_i = \begin{cases} g_{i-1}, & x_i \notin \{x_1, \dots, x_{i-1}\}, \\ \neg g_{\min\{j : x_j = x_i\}}, & \text{otherwise,} \end{cases} \quad (\text{B6})$$

for $i \geq 2$. In essence, this scheme employs a greedy approach to colour symbols in x from left to right, switching colours only when maintaining the current colour would violate the validity of the BPSP colouring.

3. The *recursive greedy colouring scheme* is a map $\sigma_{\text{RG}} : \Gamma_n \rightarrow \{r, b\}^{2n}$ that assigns to every BPSP instance x a feasible colouring $\sigma_{\text{RG}}(x) \in \Xi_n(x)$ of its $2n$ car occurrences. Write the input as $x^{(n)} = (x_1^{(n)}, \dots, x_{2n}^{(n)})$, where the superscript records the number of distinct cars. The construction proceeds in two stages. *Reduction* iteratively removes, from right to left, the last car in the current sequence together with its earlier partner, recording the partner's index and thereby producing a chain of shorter instances $x^{(n)} \rightarrow x^{(n-1)} \rightarrow \dots \rightarrow x^{(1)}$. *Reconstruction* then rebuilds the colouring from length 2 up to $2n$: at each step it copies all already fixed colours into the longer sequence and assigns colours to the two reinserted cars using only local information. We now formalise the two stages, beginning with the reduction step.

Reduction: Starting from $x^{(n)}$, peel off pairs from right to left; at each step note where the partner of the last car sits so the pair can be reinserted in the correct gap later. Formally, for $j = n - 1, n - 2, \dots, 1$:

- (a) Let $m_{j+1} \in \{1, 2, \dots, 2j + 1\}$ be the position of the earlier occurrence of the last car of $x^{(j+1)}$, i.e. $x_{m_{j+1}}^{(j+1)} = x_{2j+2}^{(j+1)}$.
- (b) Delete both occurrences to obtain $x^{(j)} \in \Gamma_j$:

$$x_k^{(j)} = \begin{cases} x_k^{(j+1)}, & k = 1, 2, \dots, m_{j+1} - 1, \\ x_{k+1}^{(j+1)}, & k = m_{j+1}, m_{j+1} + 1, \dots, 2j. \end{cases}$$

Reconstruction: Begin from the unique length-two colouring and, at each extension, reinsert the pair at the recorded gap, copy all previously fixed colours unchanged, and choose the two new colours so as not to introduce avoidable swaps. Concretely:

- (a) *Base Case.* Set $g^{(1)} = (r, b) \in \Xi_1(x^{(1)})$.
- (b) *Recursive Step.* For $j = 2, 3, \dots, n$:
- i. *Embed the previously assigned colours* by copying the colouring from the shorter instance into $x^{(j)}$ at all positions except the two reinserted occurrences, which occupy indices m_j and $2j$:

$$g_k^{(j)} = \begin{cases} g_k^{(j-1)}, & k = 1, 2, \dots, m_j - 1, \\ g_{k-1}^{(j-1)}, & k = m_j + 1, m_j + 2, \dots, 2j - 1. \end{cases}$$

- ii. *Colour the two reinserted cars*—the first occurrence placed at index m_j and the second occurrence placed at index $2j$. Let $L := g_{m_j-1}^{(j)}$ and $R := g_{m_j+1}^{(j)}$ denote the colours of the cars immediately to the left and right of the gap (when they exist), and let $T := g_{2j-1}^{(j)}$ be the colour of the last pre-existing car. Set

$$\begin{array}{ll} \text{if } m_j = 1 : & g_{m_j}^{(j)} = R, \quad g_{2j}^{(j)} = \neg R; \\ \text{if } m_j = 2j - 1 : & g_{m_j}^{(j)} = L, \quad g_{2j}^{(j)} = \neg L; \\ \text{if } 1 < m_j < 2j - 1 \text{ and } L = R : & g_{m_j}^{(j)} = L, \quad g_{2j}^{(j)} = \neg L; \\ \text{if } 1 < m_j < 2j - 1 \text{ and } L \neq R : & g_{m_j}^{(j)} = T, \quad g_{2j}^{(j)} = \neg T. \end{array}$$

This recursion yields a unique colouring $g^{(n)}$, ensuring that the two occurrences of each car receive opposite colours (so $g^{(n)} \in \Xi_n(x^{(n)})$), and does not introduce additional colour changes beyond those that are unavoidable. We set $\sigma_{\text{RG}}(x^{(n)}) := g^{(n)}$.

4. The *recursive star greedy* colouring is a map $\sigma_{\text{RSG}} : \Gamma_n \rightarrow \{r, b\}^{2n}$ that returns, for every BPSP instance x , a feasible colouring $\sigma_{\text{RSG}}(x) \in \Xi_n(x)$. It augments the recursive greedy scheme by allowing a temporary symbol $*$ (“star”) during the construction to mark a car whose colour choice does not affect the current number of paint swaps. Stars are used only as placeholders: a finalisation step replaces each $*$ by r or b without changing the swap count and while preserving the opposite-colour constraint for the two occurrences of every car. Write the input as $x^{(n)} = (x_1^{(n)}, \dots, x_{2n}^{(n)})$. The algorithm has two stages. *Reduction* removes, from left to right, the first car of the current sequence together with its later partner, records the partner's index, and thereby produces a chain of shorter instances $x^{(n)} \rightarrow x^{(n-1)} \rightarrow \dots \rightarrow x^{(1)}$. *Reconstruction* then rebuilds the colouring from length 2 up to $2n$ by copying previously fixed colours and assigning colours—or, when locally indifferent, stars—to the

previously reinserted cars using only local information. We now formalise these two stages, beginning with the reduction step.

Reduction: Starting from $x^{(n)}$, peel off pairs from left to right; at each step note where the partner of the first car sits so the pair can be reinserted in the correct gap later. Formally, for $j = n - 1, n - 2, \dots, 1$:

- (a) Let $m_j \in \{2, 3, \dots, 2j + 2\}$ be the position of the partner of the first car of $x^{(j+1)}$, i.e. $x_1^{(j+1)} = x_{m_j}^{(j+1)}$.
- (b) Delete positions 1 and m_j to obtain $x^{(j)} \in \Gamma_j$:

$$x_k^{(j)} = \begin{cases} x_{k+1}^{(j+1)}, & k = 1, 2, \dots, m_j - 2, \\ x_{k+2}^{(j+1)}, & k = m_j - 1, m_j, \dots, 2j, \end{cases}$$

and record m_j (the future insertion position of the second occurrence).

Reconstruction: Start from the unique length-two colouring; at each extension, reinsert the recorded pair, copy all previously fixed colours unchanged, and assign colours to the two new cars so as to avoid any unnecessary swaps. When a local tie occurs—i.e., both assignments give the same swap count—mark the indifferent choice with a star *. After the final step, replace every remaining * arbitrarily by r or b , choosing the replacements so that the two occurrences of each car have opposite colours and the swap count is unchanged. Concretely:

- (a) *Base Case.* Set $h^{(1)} = (r, b) \in \Xi_1(x^{(1)})$.
- (b) *Recursive Step.* For $j = 2, 3, \dots, n$:
 - i. *Embed the previously assigned symbols* by copying the colouring from the shorter instance into $x^{(j)}$ at all positions except the two reinserted occurrences, which occupy indices 1 and m_{j-1} :

$$h_k^{(j)} = \begin{cases} h_{k-1}^{(j-1)}, & k = 2, 3, \dots, m_{j-1} - 1, \\ h_{k-2}^{(j-1)}, & k = m_{j-1} + 1, \dots, 2j. \end{cases}$$

- ii. *Colour the two reinserted cars*—the first occurrence at index 1 and the second at index m_{j-1} . Let $L := h_{m_{j-1}-1}^{(j)}$ and $R := h_{m_{j-1}+1}^{(j)}$ be the colours immediately to the left and right of the car at m_{j-1} (when they exist), and let $N := h_2^{(j)}$ be the colour of the second car. If exactly one of L or R is a star, write $s \in \{-1, +1\}$ for the side of that star (so $h_{m_{j-1}+s}^{(j)} = *$) and set $U := h_{m_{j-1}-s}^{(j)}$ for its second (non-starred) neighbour. Apply the following local rules:

- if $m_{j-1} = 2$: $h_{m_{j-1}}^{(j)} = R, \quad h_1^{(j)} = \neg R;$
- if $m_{j-1} = 2j$: $h_{m_{j-1}}^{(j)} = b, \quad h_1^{(j)} = r;$
- if $2 < m_{j-1} < 2j$ and $L = R$: $h_{m_{j-1}}^{(j)} = L, \quad h_1^{(j)} = \neg L;$
- if $2 < m_{j-1} < 2j$ and $L \neq R$: $h_1^{(j)} = N, \quad h_{m_{j-1}}^{(j)} = \neg N;$
- if $2 < m_{j-1} < 2j$ and exactly one of $\{L, R\}$ is * and $U \neq N$: $h_1^{(j)} = N, \quad h_{m_{j-1}}^{(j)} = \neg N;$
- if $2 < m_{j-1} < 2j$ and exactly one of $\{L, R\}$ is * and $U = N$: $h_1^{(j)} = N, \quad h_{m_{j-1}}^{(j)} = h_{m_{j-1}+s}^{(j)} = \neg N.$

- iii. *Star Creation.* Let b be the index of the second occurrence of the second car in the sequence $x^{(j)}$. Define the adjacent colours as follows:

$$L_1 := h_1^{(j)}, \quad R_1 := h_3^{(j)}, \quad L_2 := h_{b-1}^{(j)}, \quad R_2 := h_{b+1}^{(j)}.$$

Apply the following rules:

- if $L_1 = R_1$ and $L_2 = R_2$: $h_2^{(j)} = h_b^{(j)} = *;$
- if $L_1 \neq R_1$ and $L_2 \neq R_2$: $h_2^{(j)} = h_b^{(j)} = *.$

- (c) *Breaking Ties.* After all pairs have been reinserted, replace each remaining * arbitrarily with r or b , subject to the opposite-colour constraint: the two occurrences of any car must receive different colours. This choice does not affect the total number of paint swaps.

The recursion together with the star finalisation step determines a colouring $h^{(n)}$. It is feasible, so $h^{(n)} \in \Xi_n(x^{(n)})$, and by construction no additional paint swaps are created unless they are forced by the local neighbourhood. We set $\sigma_{\text{RSG}}(x^{(n)}) := h^{(n)}$. The recursive star greedy method is a local strategy: resolving ties with stars and committing based only on current information can block better future choices. Consequently, there are instances where recursive star greedy performs worse than recursive greedy, and in some cases even worse than the basic greedy heuristic.

Note that in all colouring schemes, we consistently follow the convention of colouring the first symbol of x in red.

3. BPSP Costs of Red-First colouring

In this section, we focus on the red-first colouring scheme and show that the BPSP cost of this colouring can be expressed in terms of the eta function.

Proposition 3. *Let $x \in \Gamma_n$. Then the BPSP cost of the red-first colouring of x is*

$$\xi_n(\sigma_{\text{RF}}(x)) = \sum_{i=1}^{2n-1} \eta(x, i) = n - \frac{1}{2} - \frac{1}{2} \sum_{i=1}^{2n-1} (-1)^{\eta(x, i)}. \quad (\text{B7})$$

Proof. We start by proving the first equality. Let $f = \sigma_{\text{RF}}(x)$. Then, we have that

$$f_i = \begin{cases} r, & x_i \notin \{x_1, \dots, x_{i-1}\} \\ b, & x_i \in \{x_1, \dots, x_{i-1}\} \end{cases} \quad (\text{B8})$$

$$\text{and } f_{i+1} = \begin{cases} r, & x_{i+1} \notin \{x_1, \dots, x_i\} \\ b, & x_{i+1} \in \{x_1, \dots, x_i\}. \end{cases} \quad (\text{B9})$$

Hence, it follows that:

$$\begin{aligned} f_i \neq f_{i+1} &\iff (f_i = r \wedge f_{i+1} = b) \vee (f_i = b \wedge f_{i+1} = r) \\ &\iff (x_i \notin \{x_1, \dots, x_{i-1}\} \wedge x_{i+1} \in \{x_1, \dots, x_i\}) \vee (x_i \in \{x_1, \dots, x_{i-1}\} \wedge x_{i+1} \notin \{x_1, \dots, x_i\}) \\ &\iff [x_{i+1} \in \{x_1, \dots, x_i\}] \oplus [x_i \in \{x_1, \dots, x_{i-1}\}] = 1 \\ &\iff \eta(x, i) = 1. \end{aligned} \quad (\text{B10})$$

Therefore, the sum $\xi_n(f)$ can be calculated as:

$$\xi_n(f) = \sum_{i=1}^{2n-1} [f_i \neq f_{i+1}] \quad (\text{B11})$$

$$= \sum_{i=1}^{2n-1} [\eta(x_i, i) = 1] \quad (\text{B12})$$

$$= \sum_{i=1}^{2n-1} \eta(x_i, i), \quad \text{since } \eta(x_i) \in \{0, 1\}. \quad (\text{B13})$$

To prove the second equality, we use the fact that if $z \in \{0, 1\}$, then $z = \frac{1 - (-1)^z}{2}$. This allows us to rewrite the above expression as follows:

$$\xi_n(f) = \sum_{i=1}^{2n-1} \eta(x, i) = \sum_{i=1}^{2n-1} \frac{1 - (-1)^{\eta(x, i)}}{2} = n - \frac{1}{2} - \frac{1}{2} \sum_{i=1}^{2n-1} (-1)^{\eta(x, i)}.$$

□

Appendix C: Initial-Car-Colour (ICC) Encoding

1. ICC Encoding Scheme

In eq. (A4), we defined a valid BPSP colouring of a BPSP instance $x \in \Gamma_n$ using a $2n$ -bit string $f \in \{r, b\}^{2n}$. However, this representation carries excess information. Merely indicating the colouring of the initial occurrence of each symbol in x is adequate for reconstructing the valid colouring. In other words, a succinct description of the colouring requires only n bits. To formally express the relationship between these two representations, we introduce the function $\mathcal{E}_n: \Gamma_n \times \{r, b\}^n \rightarrow \{r, b\}^{2n}$ defined as:

$$\mathcal{E}_n(x, z)_i = \neg^{[x_i \in \{x_1, \dots, x_{i-1}\}]} z_{x_i} \quad (C1)$$

$$= \begin{cases} z_{x_i}, & \text{if } x_i \notin \{x_1, \dots, x_{i-1}\}, \\ \bar{z}_{x_i}, & \text{if } x_i \in \{x_1, \dots, x_{i-1}\}, \end{cases} \quad \text{for } i \in [2n]. \quad (C2)$$

In words, $\mathcal{E}_n$ takes as input a BPSP instance and the succinct n -bit description of a BPSP colouring and outputs the $2n$ -bit description used in (A4). Also, we define $\mathcal{E} = \bigcup_{n \in \mathbb{N}} \mathcal{E}_n$ to be the union of the functions $\mathcal{E}_n$ (viewed as a binary relation), i.e., $\mathcal{E}(x, z) = \mathcal{E}_n(x, z)$ if $x \in \Gamma_n$ and $z \in \{r, b\}^n$. For convenience, we shall refer to the elements $f \in \Xi(x)$ defined in eq. (A4) as BPSP colourings in the *standard encoding* and refer to the succinct colouring $\mathcal{E}(x, z)$ as BPSP colourings in the *ICC encoding*.

Now, note that if we fix the first argument of $\mathcal{E}_n$, we get a function $\{r, b\}^n \rightarrow \{r, b\}^{2n}$ that maps the succinct n -bit description to the original $2n$ -bit description. Formally, this may be described by the *currying* function, which gives:

$$\text{curry}(\mathcal{E}_n): \Gamma_n \rightarrow (\{r, b\}^n \rightarrow \{r, b\}^{2n}), \quad (C3)$$

where

$$\text{curry}(\mathcal{E}_n)(x)(z) = \mathcal{E}_n(x, z). \quad (C4)$$

Note that for $x \in \Gamma_n$, the function $\text{curry}(\mathcal{E}_n)(x): \{r, b\}^n \rightarrow \{r, b\}^{2n}$ is not surjective, since not all $2n$ -bit colourings are valid BPSP colourings. For simplicity, we will henceforth restrict the codomain of $\text{curry}(\mathcal{E}_n)(x)$ to its range. Our next proposition establishes this notion and confirms that the range of $\text{curry}(\mathcal{E}_n)(x)$ is $\Xi_n(x)$.

Proposition 4. *Let $x \in \Gamma_n$. Then, the function*

$$\text{curry}(\mathcal{E}_n)(x): \{r, b\}^n \rightarrow \Xi_n(x) \quad (C5)$$

is invertible, with the inverse given by

$$\text{curry}(\mathcal{E}_n)(x)^{-1}: \Xi_n(x) \rightarrow \{r, b\}^n, \quad (C6)$$

where

$$\text{curry}(\mathcal{E}_n)(x)^{-1}(f)_t = f_{\min\{k | x_k = t\}}, \quad \text{for } t \in [n]. \quad (C7)$$

In other words, for all $x \in \Gamma_n$, we have the following:

(i) *For all $z \in \{r, b\}^n$, $\mathcal{E}_n(x, z) = \text{curry}(\mathcal{E}_n)(x)(z) \in \Xi_n(x)$,*

(ii) *Let $f \in \Xi_n(x)$ and $z = (f_{\min\{k | x_k = t\}})_{t=1}^n$. Then*

$$\mathcal{E}_n(x, z) := \text{curry}(\mathcal{E}_n)(x)(z) = f, \quad (C8)$$

That is, one could write

$$\Xi_n(x) = \{\mathcal{E}_n(x, z) \mid z \in \{r, b\}^n\}. \quad (C9)$$

Proof. We prove the two statements (i) and (ii) of the proposition separately:

- (i) Let $x \in \Gamma_n$ and $z \in \{r, b\}^n$. Choose distinct indices $i < j \in [2n]$ such that $x_i = x_j$. In order to demonstrate that $\mathcal{E}_n(x, z) \in \Xi_n(x)$, we employ a proof by contradiction. Suppose that $\mathcal{E}_n(x, z)_i = \mathcal{E}_n(x, z)_j$. Then, the following implications hold

$$\begin{aligned}
& \neg[x_i \in \{x_1, \dots, x_{i-1}\}] z_{x_i} = \neg[x_j \in \{x_1, \dots, x_{j-1}\}] z_{x_j} \\
& \implies \neg[t \in \{x_1, \dots, x_{i-1}\}] z_t = \neg[t \in \{x_1, \dots, x_{j-1}\}] z_t \\
& \implies [t \in \{x_1, \dots, x_{i-1}\}] = [t \in \{x_1, \dots, x_{j-1}\}] \\
& \implies \underbrace{t \in \{x_1, \dots, x_{i-1}\} \wedge t \in \{x_1, \dots, x_{j-1}\}}_{\textcircled{1}} \quad \text{or} \quad \underbrace{t \notin \{x_1, \dots, x_{i-1}\} \wedge t \notin \{x_1, \dots, x_{j-1}\}}_{\textcircled{2}}.
\end{aligned}$$

Now, case $\textcircled{1}$ implies that there exists $k \in \{1, \dots, i-1\}$ such that $t = x_k$. But this would then mean that $x_k = x_i = x_j = t$ for distinct $k < i < j$, which then implies that $|\{j : x_j = t\}| \geq 3$, which contradicts our assumption that $x \in \Gamma_n$. On the other hand, case $\textcircled{2}$ implies that $t \notin \{x_1, \dots, x_{j-1}\}$. But since $i < j$, we have $\{x_1, \dots, x_{j-1}\} \ni x_i = t$, which contradicts $\textcircled{2}$.

Since both cases lead to a contradiction, $\mathcal{E}_n(x, z)_i = \mathcal{E}_n(x, z)_j$, which contradicts our supposition. Therefore, $\mathcal{E}_n(x, z) \in \Xi_n(x)$.

- (ii) Let $x \in \Gamma_n$ represent a BPSP instance, and let $f \in \Xi_n(x)$ denote a valid BPSP colouring. For $t \in [n]$, define $z_t = f_{\min\{k: x_k = t\}}$.

We aim to show that $\mathcal{E}_n(x, z) = f$. To establish this, we note that for $i \in [2n]$,

$$\mathcal{E}_n(x, z)_i = \neg[x_i \in \{x_1, \dots, x_{i-1}\}] z_{x_i} \tag{C10}$$

$$= \neg[x_i \in \{x_1, \dots, x_{i-1}\}] f_{\min\{k: x_k = x_i\}}. \tag{C11}$$

Since $x \in \Gamma_n$ we have that $|\{k : x_k = x_i\}| = 2$. Hence, let l be the unique element in $\{k : x_k = x_i\}$ that is not i . In other words, $\{k : x_k = x_i\} = \{i, l\}$, where $l \neq i$. We now consider the following two cases.

Case 1: $i < l$. In this case, we have $x_i \notin \{x_1, \dots, x_{i-1}\}$ (otherwise $\exists k < i : x_k = x_i$), and $\min\{k : x_k = x_i\} = i$.

Hence, by eq. (C11) it follows that

$$\mathcal{E}_n(x, z)_i = \neg^0 f_i = f_i. \tag{C12}$$

Case 2: $i > l$. In this case, $x_i \in \{x_1, \dots, x_l, \dots, x_{i-1}\}$ since $l \in \{1, \dots, i-1\}$. Furthermore, $\min\{k : x_k = x_i\} = l$. Hence, by eq. (C11) we have that

$$\mathcal{E}_n(x, z)_i = \neg f_l = f_i. \tag{C13}$$

Since $\mathcal{E}_n(x, z)_i = f_i$ for all $i \in [2n]$, it follows that $\mathcal{E}_n(x, z) = f$.

This completes our proof of the proposition. $\square$

2. BPSP Cost in ICC Encoding

In eq. (A6), we expressed the BPSP cost function ξ as a function of the BPSP colouring $f \in \Xi(x)$. With the introduction of the ICC encoding scheme in appendix C1, our objective in this section is to express the BPSP cost function directly in terms of the ICC-encoded colouring $\mathcal{E}(x, z)$. To this end, we define the function $\tilde{\xi}_n : \Gamma_n \times \{r, b\}^n \rightarrow \mathbb{N}$ as

$$\tilde{\xi}_n = \xi_n \circ \mathcal{E}_n \tag{C14}$$

and $\tilde{\xi} = \bigcup_{n \in \mathbb{N}} \tilde{\xi}_n$. Expressed in words, $\tilde{\xi}_n(x, z)$ denotes the tally of colour swaps when the BPSP instance x is coloured using the colouring specified by z . The proof of the following proposition derives an explicit expression for $\tilde{\xi}_n(x, z)$.

Proposition 5. *Let $z \in \{r, b\}^n$ and $x \in \Gamma_n$. Then,*

$$\tilde{\xi}_n(x, z) = \sum_{i=1}^{2n-1} \left[\neg^{\eta(x, i)} z_{x_i} \neq z_{x_{i+1}} \right]. \tag{C15}$$

Proof. Through a straightforward calculation, we determine:

$$\begin{aligned}
\tilde{\xi}_n(x, z) &= \xi_n(\mathcal{E}_n(x, z)) \\
&= \sum_{i=1}^{2n-1} [\mathcal{E}_n(x, z)_i \neq \mathcal{E}_n(x, z)_{i+1}] \\
&= \sum_{i=1}^{2n-1} \left[\neg[x_i \in \{x_1, \dots, x_{i-1}\}] z_{x_i} \neq \neg[x_{i+1} \in \{x_1, \dots, x_i\}] z_{x_{i+1}} \right] \\
&= \sum_{i=1}^{2n-1} \left[\neg[x_{i+1} \in \{x_1, \dots, x_i\}] \oplus [x_i \in \{x_1, \dots, x_{i-1}\}] z_{x_i} \neq z_{x_{i+1}} \right] \\
&= \sum_{i=1}^{2n-1} \left[\neg \eta(x, i) z_{x_i} \neq z_{x_{i+1}} \right],
\end{aligned}$$

where the first line is derived from eq. (C14), the second line from eq. (A6), the third line from eq. (C1), and the fifth line from the definition of the eta function as specified in eq. (B1). The fourth line follows from the properties $\neg^a \neg^b = \neg^{a \oplus b}$ and $\neg^0 = I$. This completes the proof of the proposition. $\square$

3. BPSP in ICC Encoding

We now formulate the BPSP problem, as defined in Problem 1, using the ICC encoding. We begin by observing the equivalence $\{\tilde{\xi}_n(x, z) : z \in \{r, b\}^n\} = \{\xi_n(f) : f \in \Xi_n(x)\}$, which implies that for any BPSP instance $x \in \Gamma_n$,

$$\min_{f \in \Xi_n(x)} \xi_n(f) = \min_{z \in \{r, b\}^n} \tilde{\xi}_n(x, z). \quad (\text{C16})$$

Hence, in parallel to the formulation presented in Problem 1, the *ICC formulation* of the BPSP problem can be expressed as

$$\begin{aligned}
&\text{Input: } x \in \Gamma \\
&\text{Output: Minimize } \tilde{\xi}(x, z) \\
&\quad \text{subject to } z \in \{r, b\}^{|x|/2}.
\end{aligned} \quad (\text{C17})$$

Also, eq. (A8) can be written as

$$\text{BPSP}(x) = \min_{f \in \Xi(\omega)} \xi(f) = \min_{z \in \{r, b\}^{|x|/2}} \tilde{\xi}(x, z). \quad (\text{C18})$$

Similarly to eq. (A9), we define $\widetilde{\text{BPSP}^*}(x)$ as

$$\widetilde{\text{BPSP}^*}(x) := \arg \min_{z \in \{r, b\}^{|x|/2}} \tilde{\xi}(x, z) \subseteq \{r, b\}^{|x|/2}. \quad (\text{C19})$$

4. ICC Encoding of Colouring Schemes

Our next objective is to reformulate the results of appendix B2 for colouring schemes using the ICC encoding. This can be achieved as follows: Let $\sigma : \Gamma_n \rightarrow \{r, b\}^{2n}$ be a BPSP colouring scheme. We define the *ICC encoding* of σ as $\text{ICC}(\sigma) : \Gamma_n \rightarrow \{r, b\}^n$, where

$$\text{ICC}(\sigma)(x) = (\text{curry}(\mathcal{E}_n)(x))^{-1}(\sigma(x)), \quad \text{for } x \in \Gamma_n. \quad (\text{C20})$$

Equivalently,

$$\sigma(x) = \text{curry}(\mathcal{E}_n)(x) (\text{ICC}(\sigma)(x)) = \mathcal{E}_n(x, \text{ICC}(\sigma)(x)). \quad (\text{C21})$$

Therefore,

$$\xi(\sigma(x)) = \tilde{\xi}(x, \text{ICC}(\sigma)(x)). \quad (\text{C22})$$

Our next proposition demonstrates that the ICC encoding of the red-first colouring scheme maps any length- n BPSP instance to r^n , aligning with the prescribed rule of colouring the initial occurrence of each symbol in red.

Proposition 6. *Let $x \in \Gamma_n$. The ICC encoding of the red-first colouring $\text{RF}(x)$ of x is*

$$\text{ICC}(\sigma_{\text{RF}})(x) = r^n. \quad (\text{C23})$$

Proof. For $t \in [n]$, we have

$$\begin{aligned} \text{ICC}(\sigma_{\text{RF}})(x)_t &= \text{curry}(\mathcal{E}_n)(x)^{-1}(\sigma_{\text{RF}}(x))_t \\ &= \sigma_{\text{RF}}(x)_{\min\{k : x_k = t\}}. \end{aligned} \quad (\text{C24})$$

Now, let $i = \min\{k : x_k = t\}$. Then, $x_j = x_i \Rightarrow j > i$, which implies that

$$\begin{aligned} &x_i \notin \{x_1, \dots, x_{i-1}\} \\ \Rightarrow &\sigma_{\text{RF}}(x_i) = r \\ \Rightarrow &\text{ICC}(\sigma_{\text{RF}})(x)_t = r \quad \forall t \in [n] \\ \Rightarrow &\text{ICC}(\sigma_{\text{RF}})(x) = r^n, \end{aligned}$$

completing the proof of the proposition. $\square$

Appendix D: BPSP Graph

In this appendix, we will demonstrate how every BPSP instance x can be associated with a graph G_x , referred to as the BPSP graph. Through this association, we will establish that computing $\text{BPSP}(x)$ from x can be efficiently reduced to finding the maximum cut of G_x .

1. BPSP Graph: Definition

We begin by establishing some notation. For the BPSP instance $x = (x_1, x_2, \dots, x_{2n}) \in \Gamma_n$, we define the function $\theta_x : 2^{[n]} \rightarrow \mathbb{R}$, which maps subsets of $[n]$ to real numbers as follows:

$$\theta_x(e) = - \sum_{i=1}^{2n-1} (-1)^{\eta(x,i)} \delta_{e, \{x_i, x_{i+1}\}}, \quad (\text{D1})$$

where $2^{[n]}$ denotes the power set of $[n]$ and δ denotes the Kronecker delta. Now, we define the BPSP graph.

Definition 7 (BPSP graph). Let $x = (x_1, x_2, \dots, x_{2n}) \in \Gamma_n \subseteq [n]^{2n}$ be a BPSP instance. The *BPSP graph* of x is the weighted graph $G_x = (V_x, E_x, W_x)$, where

- $V_x = [n]$ are the vertices,
- $E_x = \{ \{x_i, x_{i+1}\} : i \in [2n-1], x_i \neq x_{i+1}, \theta_x(\{x_i, x_{i+1}\}) \neq 0 \}$ are the edges,
- $W_x = \theta_x|_{E_x} : E_x \rightarrow \mathbb{R}$ is the weight function assigning edges to real numbers.

In essence, the BPSP graph associated with a length- $2n$ BPSP instance x is constructed with vertices representing the symbols of the alphabet $[n]$. In this graph, edges connect symbols that are adjacent in x , with the exception of consecutive identical symbols and the zeroes of the θ_x function. According to Definition 7 and eq. (D1), the weight of an edge $e \in E_x \subset [n]$ in the graph is given by

$$W_x(e) = - \sum_{i=1}^{2n-1} (-1)^{\eta(x,i)} \delta_{e, \{x_i, x_{i+1}\}}. \quad (\text{D2})$$

2. Properties of BPSP Graph

a. Possible degrees of BPSP graph

We begin by establishing some properties of BPSP graphs. To initiate, we show that the vertex degrees of a BPSP graph cannot exceed 4. Denoting the degree of a vertex v in G by

$$\deg_G(v) = |\{u \in V : \{u, v\} \in E\}|, \quad (\text{D3})$$

we prove the following proposition.

Proposition 8. *Let $x \in \Gamma_n$ be a BPSP instance. Then, for all vertices $v \in V_x$ in the BPSP graph of x ,*

$$\deg_{G_x}(v) \leq 4. \quad (\text{D4})$$

Proof. Consider $v \in V_x = [2n]$. Given that $x \in \Gamma_n$, it follows that the set of indices $\{j \in [2n] : x_j = v\}$ contains precisely two elements, which we denote by α and β . By construction, $\alpha \neq \beta$, $x_\alpha = x_\beta = v$, and for any γ such that $x_\gamma = v$, we have $\gamma \in \{\alpha, \beta\}$.

Let $u \in V$ satisfy $\{u, v\} \in E$, i.e. u and v are neighbours in the BPSP graph. Then we have that

$$\begin{aligned} & \{u, x_\alpha\} \in E \quad \text{or} \quad \{u, x_\beta\} \in E \\ \implies & u = x_{\alpha-1} \quad \text{or} \quad u = x_{\alpha+1} \quad \text{or} \quad u = x_{\beta-1} \quad \text{or} \quad u = x_{\beta+1} \\ \implies & u \in \{x_{\alpha-1}, x_{\alpha+1}, x_{\beta-1}, x_{\beta+1}\}. \end{aligned} \quad (\text{D5})$$

Hence, $\{u \in V : \{u, v\} \in E\} \subseteq \{x_{\alpha-1}, x_{\alpha+1}, x_{\beta-1}, x_{\beta+1}\}$, which implies that

$$\begin{aligned} \deg_{G_x}(v) &= |\{u \in V : \{u, v\} \in E\}| \\ &\leq |\{x_{\alpha-1}, x_{\alpha+1}, x_{\beta-1}, x_{\beta+1}\}| \\ &\leq 4, \end{aligned} \quad (\text{D6})$$

which completes the proof of the proposition. $\square$

b. Total weight of BPSP graph

Next, for any weighted graph $G = (V, E, W)$ (where V is the set of vertices, E is the set of edges, and $W : E \rightarrow \mathbb{R}$ is a weight function), we define the total weight of G as the sum of the weights of all its edges:

$$W_{\text{tot}}(G) = \sum_{\{i, j\} \in E} W(\{i, j\}). \quad (\text{D7})$$

Additionally, we introduce the concept of the *double letter count* of a BPSP instance $x = (x_1, x_2, \dots, x_{2n}) \in \Gamma_n \subseteq [n]^{2n}$, which is defined as the number of consecutive identical symbols in x , denoted as:

$$\#\text{dl}(x) = |\{i \in [2n-1] : x_i = x_{i+1}\}|. \quad (\text{D8})$$

Our next proposition expresses the total weight of a BPSP graph G_x using eq. (D8) and the eta function defined in eq. (B1).

Proposition 9. *Given a BPSP instance $x \in \Gamma_n$, the total weight of the BPSP graph $G_x = (V_x, E_x, W_x)$ associated with x is given by*

$$W_{\text{tot}}(G_x) = - \sum_{\substack{k=1 \\ x_k \neq x_{k+1}}}^{2n-1} (-1)^{\eta(x, k)} = -\#\text{dl}(x) - \sum_{k=1}^{2n-1} (-1)^{\eta(x, k)}. \quad (\text{D9})$$

Proof. To establish the first equality presented in eq. (D9), we proceed with the following calculation:

$$\begin{aligned}
W_{\text{tot}}(G_x) &= \sum_{\{a,b\} \in E_x} W_x(\{a,b\}) \\
&= \sum_{\{a,b\} \in E_x} \theta_x(\{a,b\}) \\
&= \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1} \\ \theta_x(\{x_i, x_{i+1}\}) \neq 0}} \frac{\theta_x(\{x_i, x_{i+1}\})}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \\
&= \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1}}} \frac{\theta_x(\{x_i, x_{i+1}\})}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \\
&= \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1}}} \frac{-\sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}}}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \\
&= -\sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1}}} \frac{\delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}}}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \\
&= -\sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \sum_{i \in [2n-1]} [x_i \neq x_{i+1}] \frac{\delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}}}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \\
&= -\sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \frac{[x_k \neq x_{k+1}]}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_k, x_{k+1}\}\}|} \sum_{i \in [2n-1]} \delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}} \\
&= -\sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \frac{[x_k \neq x_{k+1}]}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_k, x_{k+1}\}\}|} |\{i \in [2n+1] : \{x_i, x_{i+1}\} = \{x_k, x_{k+1}\}\}| \\
&= -\sum_{\substack{k=1 \\ x_k \neq x_{k+1}}}^{2n-1} (-1)^{\eta(x,k)}. \tag{D10}
\end{aligned}$$

The first line above follows directly from the definition of total weight given in eq. (D7). The second line stems from the relationship $W_x = \theta_x|_{E_x}$, as defined in Definition 7. The third line follows from the observation that if a finite set $T = \{a_i : i \in M\}$ (where M is also a finite set) contains elements a_i , with the possibility of some elements being identical, then for any function $f : T \rightarrow \mathbb{R}$:

$$\sum_{t \in T} f(t) = \sum_{i \in M} \frac{f(a_i)}{|\{j : a_i = a_j\}|}. \tag{D11}$$

This indicates that when summing over a set with potentially repeated elements, each distinct element contributes its value divided by the number of times it appears in the set. The fourth line arises from the observation that the summand in the expression vanishes whenever $\theta_x(\{x_i, x_{i+1}\}) = 0$. The fifth line follows from the definition of θ_x provided in eq. (D1). The sixth line is attained by rearranging the terms presented on the fifth line. The seventh line ensues from the property that if $S \subseteq T$ are any two indexing sets, then the following sums are equivalent:

$$\sum_{i \in S} (\cdot) = \sum_{i \in T} [i \in S] (\cdot). \tag{D12}$$

This enables us to represent the sum over the potentially smaller set S as the sum over its superset T by incorporating an indicator function. The eighth line follows from the observation that the sum in the expression vanishes whenever the sets $\{x_i, x_{i+1}\}$ and $\{x_k, x_{k+1}\}$ are not equal. The ninth line stems from the property that

$$\sum_i \delta_{a_i a_j} f(a_j) = f(a_j) |\{i : a_i = a_j\}|.$$

Finally, the tenth line is derived by applying eq. (D12) once more. This concludes the proof of the first equality.

To show the second equality of eq. (D9), consider:

$$\begin{aligned}
\sum_{\substack{k=1 \\ x_k \neq x_{k+1}}}^{2n-1} (-1)^{\eta(x,k)} &= \left(\sum_{k=1}^{2n-1} - \sum_{\substack{k=1 \\ x_k = x_{k+1}}}^{2n-1} \right) (-1)^{\eta(x,k)} \\
&= \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} - \sum_{\substack{k=1 \\ x_k = x_{k+1}}}^{2n-1} (-1)^{\eta(x,k)} \\
&= \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} + |\{i \in [2n-1] : x_i = x_{i+1}\}| \\
&= \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} + \#_{\text{dl}}(x).
\end{aligned} \tag{D13}$$

Negating the equalities in eq. (D13) yields the second equality in eq. (D9).

The first line above arises from the observation that the indices k satisfying $x_k = x_{k+1}$ and those satisfying $x_k \neq x_{k+1}$ form a partition of the index set $[2n-1]$. The second line follows from the distributive property. The third line is deduced from the observation that the second summation is exclusively over terms where $x_k = x_{k+1}$, thereby implying $\eta(x,k) = 1$, as shown by Lemma 2. Finally, the fourth line follows from the definition of the double letter count as defined by eq. (D8). $\square$

c. Relating total weight of BPSP graph to BPSP cost of red-first colouring

Our next corollary expresses the BPSP cost of the red-first colouring, calculated in eq. (B7), in terms of the double letter count as defined in eq. (D8) and the total weight of the BPSP graph defined in eq. (D7).

Corollary 10. *Let $x \in \Gamma_n$. Then the BPSP cost of the red-first colouring of x is*

$$\xi_n(\sigma_{\text{RF}}(x)) = n - \frac{1}{2} + \frac{1}{2}\#_{\text{dl}}(x) + \frac{1}{2}W_{\text{tot}}(G_x). \tag{D14}$$

Proof. From eq. (B7), we derive the BPSP cost of the red-first colouring of x as follows:

$$\begin{aligned}
\xi_n(\sigma_{\text{RF}}(x)) &= n - \frac{1}{2} - \frac{1}{2} \underbrace{\sum_{i=1}^{2n-1} (-1)^{\eta(x,i)}}_{=-\#_{\text{dl}}(x) - W_{\text{tot}}(G_x)} = n - \frac{1}{2} + \frac{1}{2}\#_{\text{dl}}(x) + \frac{1}{2}W_{\text{tot}}(G_x),
\end{aligned}$$

where the equality within the underbraces above is obtained from eq. (D9). $\square$

3. Reducing BPSP to Weighted MaxCut

In this section, we present a polynomial-time reduction from the BPSP problem to the weighted maximum cut (MaxCut) problem. We begin by introducing the necessary terminology for defining the MaxCut problem: Consider a weighted graph $G = (V, E, W)$, where $V = [n]$ for simplicity and $W : E \rightarrow \mathbb{R}$ represents the edge weights. A *cut* of G is defined as a binary string $z \in \{r, b\}^n$. The *weight* of a cut $z \in \{r, b\}^n$ in G is defined as

$$\text{wt}_G(z) = \sum_{\{i,j\} \in E} W(\{i,j\})[z_i \neq z_j]. \tag{D15}$$

The MaxCut problem, whose goal is to identify the cut that maximises the total weight of the cut edges in the graph, can be expressed as follows:

Problem 2. WEIGHTED MAXIMUM CUT (MAXCUT)

Input: a weighted graph $G = (V, E, W)$, where $V = [n]$ and $W : E \rightarrow \mathbb{R}$.

Output: maximize $\text{wt}_G(z)$, as defined in eq. (D15)
subject to $z \in \{r, b\}^n$.

Also, we denote the optimal cost and the set of optimal solutions of Problem 2, respectively, as follows:

$$\text{MAXCUT}(G) = \max_{z \in \{r, b\}^n} \text{wt}_G(z) \quad (\text{D16})$$

$$\text{MAXCUT}^*(G) = \arg \max_{z \in \{r, b\}^n} \text{wt}_G(z). \quad (\text{D17})$$

Our next proposition provides a formula for computing the weight of a cut of a BPSP graph G_x for a given BPSP instance x , expressed in terms of the eta function.

Corollary 11. *Let $x \in \Gamma_n$ be a BPSP instance, and denote its BPSP graph as $G_x = (V_x, E_x, W_x)$. For a cut $z \in \{r, b\}^n$ of G_x , the weight of z in G_x is*

$$\text{wt}_{G_x}(z) = - \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} [z_{x_k} \neq z_{x_{k+1}}]. \quad (\text{D18})$$

Proof. To begin, we note the similarity between the formulae for the weight of a cut specified in eq. (D15) and the total weight of a graph given in eq. (D7), where the sole difference is the presence of the indicator function $[z_i \neq z_j]$ in each term of the sum in the former formula. Accordingly, our proof parallels that of Proposition 9:

$$\begin{aligned} \text{wt}_{G_x}(z) &= \sum_{\{a,b\} \in E_x} W_x(\{a,b\}) [z_a \neq z_b] \\ &= \sum_{\{a,b\} \in E_x} \theta_x(\{a,b\}) [z_a \neq z_b] \\ &= \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1} \\ \theta_x(\{x_i, x_{i+1}\}) \neq 0}} \frac{\theta_x(\{x_i, x_{i+1}\}) [z_{x_i} \neq z_{x_{i+1}}]}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \\ &= \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1}}} \frac{\theta_x(\{x_i, x_{i+1}\}) [z_{x_i} \neq z_{x_{i+1}}]}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \\ &= \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1}}} \frac{1}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} \left\{ - \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}} \right\} [z_{x_i} \neq z_{x_{i+1}}] \\ &= - \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \sum_{\substack{i \in [2n-1] \\ x_i \neq x_{i+1}}} \frac{\delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}}}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} [z_{x_i} \neq z_{x_{i+1}}] \\ &= - \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \sum_{i \in [2n-1]} \frac{[x_i \neq x_{i+1}] \delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}}}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_i, x_{i+1}\}\}|} [z_{x_i} \neq z_{x_{i+1}}] \\ &= - \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \frac{[x_k \neq x_{k+1}] [z_{x_k} \neq z_{x_{k+1}}]}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_k, x_{k+1}\}\}|} \sum_{i \in [2n-1]} \delta_{\{x_i, x_{i+1}\}, \{x_k, x_{k+1}\}} \\ &= - \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} \frac{[x_k \neq x_{k+1}] [z_{x_k} \neq z_{x_{k+1}}]}{|\{j \in [2n-1] : \{x_j, x_{j+1}\} = \{x_k, x_{k+1}\}\}|} |\{i \in [2n-1] : \{x_i, x_{i+1}\} = \{x_k, x_{k+1}\}\}| \\ &= - \sum_{\substack{k=1 \\ x_k \neq x_{k+1}}}^{2n-1} (-1)^{\eta(x,k)} [z_{x_k} \neq z_{x_{k+1}}] \end{aligned}$$

$$= - \sum_{k=1}^{2n-1} (-1)^{\eta(x,k)} [z_{x_k} \neq z_{x_{k+1}}].$$

The first line above stems from the definition of the weight of a cut, as provided in eq. (D15). Subsequent lines 2 through 7, and 9 through 10, are derived from the same line of reasoning as the chain of equalities presented in eq. (D10).

To show that the eighth line follows from the seventh, it suffices to prove that if

$$\{x_i, x_{i+1}\} = \{x_k, x_{k+1}\}, \quad (\text{D19})$$

then

$$[x_i \neq x_{i+1}][z_{x_i} \neq z_{x_{i+1}}] = [x_k \neq x_{k+1}][z_{x_k} \neq z_{x_{k+1}}]. \quad (\text{D20})$$

To prove this, let us assume that eq. (D19) holds. Then the ordered pair (x_i, x_{i+1}) is equal to either (x_k, x_{k+1}) or (x_{k+1}, x_k) . In either case, $x_i = x_{i+1}$ holds if and only if $x_k = x_{k+1}$ holds. Hence,

$$[x_i \neq x_{i+1}] = [x_k \neq x_{k+1}]. \quad (\text{D21})$$

Similarly, eq. (D19) implies that the ordered pair $(z_{x_i}, z_{x_{i+1}})$ is equal to either $(z_{x_k}, z_{x_{k+1}})$ or $(z_{x_{k+1}}, z_{x_k})$. In either case, $z_{x_i} \neq z_{x_{i+1}}$ holds if and only if $z_{x_k} \neq z_{x_{k+1}}$ holds. Hence,

$$[z_{x_i} \neq z_{x_{i+1}}] = [z_{x_k} \neq z_{x_{k+1}}]. \quad (\text{D22})$$

Combining eq. (D21) and eq. (D22) yields eq. (D20). This concludes our proof that eq. (D19) implies eq. (D20), thereby completing the derivation of the eighth line.

Finally, the derivation of the eleventh line follows from the following observation: when $x_k = x_{k+1}$, it follows that $z_{x_k} = z_{x_{k+1}}$, yielding $[z_{x_k} \neq z_{x_{k+1}}] = 0$. This implies that the terms where $x_k \neq x_{k+1}$ make no contribution to the sum. Consequently, whether these terms are included or not has no bearing on the sum, affirming the equivalence of the tenth and eleventh lines. $\square$

Our next objective is to establish a formula that connects $\tilde{\xi}_n(x, z)$ —the measure of colour swaps required in colouring the BPSP instance x with the colouring z , defined in eq. (C14)—to the weight of the cut z in the BPSP graph G_x . To achieve this, we note that the expression for $\tilde{\xi}_n(x, z)$ that was derived in eq. (C15) contains terms of the form $[\neg^a u \neq v]$. To simplify these terms, our subsequent lemma establishes an identity that re-expresses them in a more useful form:

Lemma 12. *For any $u, v \in \{r, b\}$ and $a \in \{0, 1\}$, the following equality holds:*

$$[\neg^a u \neq v] = a + (-1)^a [u \neq v]. \quad (\text{D23})$$

Proof. We analyse the cases $a = 0$ and $a = 1$ separately, establishing the equivalence between the expressions on the left-hand side (LHS) and the right-hand side (RHS) of eq. (D23): When $a = 0$,

$$\text{RHS} = 0 + (-1)^0 [u \neq v] = [u \neq v] = \text{LHS}. \quad (\text{D24})$$

When $a = 1$,

$$\text{RHS} = 1 + (-1)[u \neq v] = 1 - [u \neq v] = [u = v] = [\neg u \neq v] = \text{LHS}. \quad (\text{D25})$$

In both cases, we observe that the RHS equals the LHS, thus establishing the validity of the lemma. $\square$

We are now poised to leverage Lemma 12 to express the number of colour swaps $\tilde{\xi}_n(x, z)$ in terms of the cut weight $\text{wt}_{G_x}(z)$. Strikingly, we find that $\xi_n(z, x)$ is precisely the difference between $\xi_n(\sigma_{\text{RF}}(x))$ —the number of colour swaps in the red-first encoding—and the cut weight $\text{wt}_{G_x}(z)$:

Proposition 13. *For any $z \in \{r, b\}^n$ and $x \in \Gamma_n$,*

$$\tilde{\xi}_n(x, z) = \xi_n(\sigma_{\text{RF}}(x)) - \text{wt}_{G_x}(z). \quad (\text{D26})$$

Proof. To prove the proposition, we carry out the following calculation:

$$\begin{aligned}
\tilde{\xi}_n(x, z) &= \sum_{i=1}^{2n-1} \left[-\eta(x, i) z_{x_i} \neq z_{x_{i+1}} \right] \\
&= \sum_{i=1}^{2n-1} \left\{ \eta(x, i) + (-1)^{\eta(x, i)} [z_{x_i} \neq z_{x_{i+1}}] \right\} \\
&= \sum_{i=1}^{2n-1} \eta(x, i) + \sum_{i=1}^{2n-1} (-1)^{\eta(x, i)} [z_{x_i} \neq z_{x_{i+1}}] \\
&= \xi_n(\sigma_{\text{RF}}(x)) - \text{wt}_{G_x}(z).
\end{aligned}$$

The first line above corresponds to eq. (C15). The second line follows from utilising Lemma 12 to rewrite the indicator function as a sum of two terms. The third line rearranges the second line into a sum of two terms, ensuring that the first term equals $\xi_n(\sigma_{\text{RF}}(x))$ by eq. (B7), and the second term equals $-\text{wt}_{G_x}(z)$ by eq. (D18). From this rearrangement, we observe that the fourth line ensues. $\square$

Next, note that eq. (D14) provides an equivalent expression for the number of colour swaps $\xi_n(\sigma_{\text{RF}}(x))$ in the red-first encoding. By substituting eq. (D14) into eq. (D26), we obtain the following corollary:

Corollary 14. *For any $z \in \{r, b\}^n$ and $x \in \Gamma_n$,*

$$\tilde{\xi}_n(x, z) = n - \frac{1}{2} + \frac{1}{2} \#_{\text{dl}}(x) + \frac{1}{2} W_{\text{tot}}(G_x) - \text{wt}_{G_x}(z). \quad (\text{D27})$$

The above equation expresses the number of colour swaps involved when x is coloured with z in terms of the double-letter count of x , the total weight of the BPSP graph G_x , and the weight of the cut z in G_x .

Next, by optimising eq. (D27) over the cuts $z \in \{r, b\}^n$, we obtain the following corollary:

Corollary 15. *Let $x \in \Gamma_n$. Then, we have that*

$$\text{BPSP}(x) = \xi_n(\sigma_{\text{RF}}(x)) - \text{MAXCUT}(G_x) = n - \frac{1}{2} + \frac{1}{2} \#_{\text{dl}}(x) + \frac{1}{2} W_{\text{tot}}(G_x) - \text{MAXCUT}(G_x), \quad (\text{D28})$$

$$\widetilde{\text{BPSP}}^*(x) = \text{MAXCUT}^*(G_x). \quad (\text{D29})$$

Proof. Let $x \in \Gamma_n \subset \Gamma$. Then eq. (D28) holds because

$$\begin{aligned}
\text{BPSP}(x) &= \min_{z \in \{r, b\}^n} \tilde{\xi}_n(x, z) = \min_{z \in \{r, b\}^n} [\xi_n(\sigma_{\text{RF}}(x)) - \text{wt}_{G_x}(z)] \\
&= \xi_n(\sigma_{\text{RF}}(x)) - \max_{z \in \{r, b\}^n} \text{wt}_{G_x}(z) \\
&= \xi_n(\sigma_{\text{RF}}(x)) - \text{MAXCUT}(G_x) = n - \frac{1}{2} + \frac{1}{2} \#_{\text{dl}}(x) + \frac{1}{2} W_{\text{tot}}(G_x) - \text{MAXCUT}(G_x),
\end{aligned}$$

where the last equality follows from eq. (D14). Similarly, eq. (D29) holds because

$$\begin{aligned}
\widetilde{\text{BPSP}}^*(x) &= \arg \min_{z \in \{r, b\}^n} \tilde{\xi}_n(x, z) = \arg \min_{z \in \{r, b\}^n} [\xi_n(\sigma_{\text{RF}}(x)) - \text{wt}_{G_x}(z)] \\
&= \arg \min_{z \in \{r, b\}^n} (-\text{wt}_{G_x}(z)) = \arg \max_{z \in \{r, b\}^n} (\text{wt}_{G_x}(z)) = \text{MAXCUT}^*(G_x).
\end{aligned}$$

This completes the proof of the corollary. $\square$

Finally, we note that Corollary 15 provides us with a polynomial-time reduction from the BPSP problem stated in Problem 1 to the weighted MaxCut problem presented in Problem 2. Specifically, one use of an oracle for Problem 2 enables us to solve Problem 1 in polynomial time, as we demonstrate in Algorithm 2.

Algorithm 2: Polynomial-time reduction from BPSP (Problem 1) to MAXCUT (Problem 2)

Input: $x \in \Gamma$ **Output:** BPSP(x) and BPSP*(x)

- 1 Construct G_x , the BPSP graph of x , utilising Definition 7.
 - 2 Execute the weighted MAXCUT oracle for Problem 2 on G_x to obtain MAXCUT(G_x) and $z^* \in \text{MAXCUT}^*(G_x)$.
 - 3 Compute $\xi_n(\sigma_{\text{RF}}(x))$ using eq. (D14).
 - 4 Compute $f^* = \mathcal{E}(x, z^*)$ using eq. (C1).
 - 5 **return** BPSP(x) = $\xi_n(\sigma_{\text{RF}}(x)) - \text{MAXCUT}(G_x)$ and BPSP*(x) = f^* .
-

Appendix E: Ising Formulation of BPSP

In the Ising formulation, we assign numerical values to the formal symbols r and b :

$$r \equiv 1, \quad b \equiv -1. \quad (\text{E1})$$

In the following lemma, we present several identities that will prove useful for translating formulas in appendix D into an algebraic form:

Lemma 16. *Let $y, z \in \{r, b\}$, where $r = 1$ and $b = -1$, and $a \in \{0, 1\}$. Then, we have:*

- (i) $\neg z = -z$.
- (ii) $\neg^a z = (-1)^a z$.
- (iii) $[y = z] = \frac{1}{2}(1 + yz)$.
- (iv) $[y \neq z] = \frac{1}{2}(1 - yz)$.
- (v) $[\neg^a z \neq y] = \frac{1}{2} - \frac{1}{2}(-1)^a zy$.

Proof. To prove these identities, it suffices to check that equality holds for each of the possible discrete binary values of y , z , and a . Indeed, (i) holds since $\neg r = b = -1 = -r$ and $\neg b = r = 1 = -b$. (ii) holds because $a = 0$ implies that $\neg^a z = z = (-1)^0 z$ and $a = 1$ implies that $\neg^a z = \neg z = -z = (-1)^1 z$. (iii) holds because

$$yz = \begin{cases} 1, & y = z \\ -1, & y \neq z \end{cases} \implies \frac{1}{2}(1 + yz) = \begin{cases} 1, & y = z \\ 0, & y \neq z \end{cases} = [y = z]. \quad (\text{E2})$$

(iv) holds since $[y \neq z] = 1 - [y = z] = 1 - \frac{1}{2}(1 + yz) = \frac{1}{2}(1 - yz)$. Finally, (v) holds because $[\neg^a z \neq y] = [(-1)^a z \neq y] = \frac{1}{2}(1 - (-1)^a zy) = \frac{1}{2} - \frac{1}{2}(-1)^a zy$. $\square$

1. Ising Expressions for BPSP Cost Function

We now present a formula for the colour swap tally $\tilde{\xi}_n(x, z)$ from eq. (C15) in terms of the Ising formulation.

Proposition 17. *Consider $z \in \{-1, 1\}^n$ and $x \in \Gamma_n$. Then, we can express the number of colour swaps required when x is coloured with z as*

$$\tilde{\xi}_n(x, z) = n - \frac{1}{2} - \frac{1}{2} \sum_{i=1}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \quad (\text{E3})$$

$$= n - \frac{1}{2} + \frac{1}{2} \#_{\text{dl}}(x) - \frac{1}{2} \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}}. \quad (\text{E4})$$

Proof. By applying Lemma 16(v) to eq. (C15) and simplifying, we obtain:

$$\tilde{\xi}_n(x, z) = \sum_{i=1}^{2n-1} \left[\neg^{\eta(x,i)} z_{x_i} \neq z_{x_{i+1}} \right]$$

$$\begin{aligned}
&= \sum_{i=1}^{2n-1} \frac{1}{2} \left(1 - (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \right) \\
&= n - \frac{1}{2} - \frac{1}{2} \sum_{i=1}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \\
&= n - \frac{1}{2} - \frac{1}{2} \left(\sum_{\substack{i=1 \\ x_i = x_{i+1}}}^{2n-1} + \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{2n-1} \right) (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \\
&= n - \frac{1}{2} - \frac{1}{2} \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} - \frac{1}{2} \sum_{\substack{i=1 \\ x_i = x_{i+1}}}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \\
&= n - \frac{1}{2} - \frac{1}{2} \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} + \frac{1}{2} |\{i \in [2n-1] : x_i = x_{i+1}\}| \\
&= n - \frac{1}{2} - \frac{1}{2} \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} + \frac{1}{2} \#_{\text{dl}}(x),
\end{aligned}$$

where the sixth line follows from the observation that when $x_i = x_{i+1}$, we have $\eta(x, i) = 1$ (by Lemma 2) and $z_{x_i} z_{x_{i+1}} = z_{x_i}^2 = 1$. The third and last lines provide the desired expressions eq. (E3) and eq. (E4), respectively. $\square$

Finally, through optimisation of eq. (E3) and eq. (E4) over the cuts $z \in \{-1, 1\}^n$, and noting that for $n = |x|/2$ for $x \in \Gamma_n$, we arrive at the following corollary:

Corollary 18. *Let $x \in \Gamma$ be a BPSP instance. Then the optimal cost and the set of optimal solutions of the BPSP problem are, respectively,*

$$\text{BPSP}(x) = \frac{1}{2} \left\{ |x| - 1 - \max_{z \in \{-1, 1\}^{|x|/2}} \sum_{i=1}^{|x|-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \right\} \quad (\text{E5})$$

$$= \frac{1}{2} \left\{ |x| - 1 + \#_{\text{dl}}(x) - \max_{z \in \{-1, 1\}^{|x|/2}} \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{|x|-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \right\} \quad (\text{E6})$$

$$\widetilde{\text{BPSP}}^*(x) = \arg \max_{z \in \{-1, 1\}^{|x|/2}} \sum_{i=1}^{|x|-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}} \quad (\text{E7})$$

$$= \arg \max_{z \in \{-1, 1\}^{|x|/2}} \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{|x|-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}}. \quad (\text{E8})$$

In essence, these expressions unveil the underlying connection between solving the BPSP and finding the ground state energy of the associated Ising Hamiltonian:

$$H(z_1, \dots, z_n) = - \sum_{\substack{i=1 \\ x_i \neq x_{i+1}}}^{2n-1} (-1)^{\eta(x,i)} z_{x_i} z_{x_{i+1}}. \quad (\text{E9})$$

Coherent-State Propagation: A Computational Framework for Simulating Bosonic Quantum Systems

Full version: <https://arxiv.org/abs/2604.19625>

Abstract. We develop *coherent-state propagation*, a computational framework for simulating bosonic systems. We focus on bosonic circuits composed of displaced linear optics augmented by Kerr nonlinearities, a universal model of bosonic quantum computation that is also physically motivated by driven Bose–Hubbard dynamics. The method works in the Schrödinger picture representing the evolving state as a sparse superposition of coherent states. We develop approximation strategies that keep the simulation cost tractable in physically relevant regimes, notably when the number of Kerr gates is small or the Kerr nonlinearities are weak, and prove rigorous guarantees for both observable estimation and sampling. In particular, bosonic circuits with logarithmically many Kerr gates admit quasi-polynomial-time classical simulation at exponentially small error in trace distance. We further identify a weak-nonlinearity regime in which the runtime is polynomial for arbitrarily small constant precision. We complement these results with numerical benchmarks on the Bose–Hubbard model with all-to-all connectivity.

Keywords: coherent-state propagation, bosonic simulation, Kerr nonlinearity, continuous variables

Bosonic degrees of freedom are native to many physical systems, including phonons, photonic and cavity lattices, superconducting resonators, and ultracold gases. In these platforms, bosonic models describe nonlinear response, coherent transport, Josephson dynamics, and driven Bose–Hubbard physics. Practical methods for simulating interacting bosons are therefore of broad relevance: they enable quantitative modelling across a wide range of experimental platforms, while also providing a natural arena in which to delineate the boundary between classical and quantum computational power.

Resource-sensitive classical simulation asks what dynamical features control the cost of representing, propagating, and measuring a quantum state. For qubits, stabilizer dynamics give an efficiently simulable baseline, while simulation overhead is often tied to non-Clifford structure [1–3]. Propagation-based methods give a complementary viewpoint: Pauli propagation tracks observables through a circuit and truncates the growing Pauli expansion when it remains sparse [4, 5], with related Majorana-propagation ideas for fermions [6, 7]. These approaches suggest a useful principle: choose a representation adapted to a tractable baseline, propagate in that representation, and quantify when the generated nonclassical structure remains controlled.

For continuous-variable bosonic systems, Gaussian states, Gaussian operations, and Gaussian measurements are efficiently simulable [8], while non-Gaussianity is required for universal continuous-variable computation. Existing classical methods approaching non-Gaussianity include quasiprobability techniques, and displacement propagation in noisy circuits [9–11]. By contrast, methods for noiseless bosonic circuits with dynamically generated non-Gaussianity remain less developed. This raises the key question: **how much dynamically generated bosonic non-Gaussianity can be tolerated while retaining controlled classical simulation?**

We study circuits built from displaced passive linear optics and local Kerr nonlinearities $K_\kappa = e^{i\kappa\hat{n}^2}$, as shown

in Fig. 1. This architecture is universal for continuous-variable computation in the energy-cutoff sense [12, 13]. Displaced passive linear optics map coherent states to coherent states, while Kerr gates are the only operations that branch the coherent-state representation, making the model well suited for isolating the simulation cost of non-Gaussianity.

We develop **coherent-state propagation**, a Schrödinger-picture framework that represents the evolving state as a sparse superposition of multimode coherent-product states. The method updates coherent amplitudes exactly under displaced passive linear optics and approximates Kerr branching through controlled coherent-state reconstructions.

Main results:

- **Framework:** we develop an end-to-end coherent-state propagation framework for DPLO+Kerr circuits.
- **Theoretical guarantees:** in regimes with few Kerr gates or weak non-Gaussianity we provide polynomial (quasi-polynomial) complexity simulation guarantees.
- **Readout:** we derive readout costs for observables estimation and quadrature sampling.
- **Numerics:** the theoretical guarantees are further supported by numerical benchmarks on driven Bose–Hubbard dynamics against MPS and dense Fock simulation.

1 Algorithm

We now describe the simulation data and update rules. Coherent-state propagation follows the wavefunction in a moving phase-space expansion that branches at nonlinear Kerr updates.

For a single bosonic mode, a coherent state is

$$|\alpha\rangle = D(\alpha)|0\rangle, \quad D(\alpha) = \exp(\alpha\hat{a}^\dagger - \alpha^*\hat{a}). \quad (1)$$

Fig. 1: Circuit architecture. The input is a finite superposition of multimode coherent-product states. Each layer applies a displaced passive linear-optical unitary followed by a local Kerr gate $K_\kappa = e^{i\kappa\hat{n}^2}$, which branches the coherent-state representation. A final Gaussian unitary maps the propagated branches to Gaussian components; swaps inside DPLO layers can route the Kerr gate to any mode.

Fig. 2: Benchmark. Six-mode all-to-all driven Bose-Hubbard model, with $\hat{X}_j$ the position quadrature. (a) $\langle \hat{X}_0 \hat{X}_1 \rangle$ trajectory and absolute error for branch cutoff $\mathcal{S} = 2^{12}$ and finite-Fourier order $M = 3$. (b) Relative error of $\langle \hat{X}_0^2 \rangle$ at $T = 1$ versus $\mathcal{S}$, for different M . (c) Same for $\langle \hat{X}_0 \hat{X}_1 \rangle$. Here M is the finite-Fourier Kerr parameter: one local Kerr update uses $2M$ phase-orbit coherent states before truncation, see Eq. (12).

For an m -mode amplitude vector $\alpha_k = (\alpha_k^{(1)}, \dots, \alpha_k^{(m)})$, we use the product coherent state

$$|\alpha_k\rangle := \bigotimes_{j=1}^m |\alpha_k^{(j)}\rangle. \quad (2)$$

Coherent-state propagation stores the state as

$$|\psi\rangle = \sum_{k=1}^N C_k |\alpha_k\rangle, \quad (3)$$

where the simulation data are the coefficients C_k and amplitudes α_k . The main bookkeeping variable is the number N of branches: if N remains moderate, overlaps, observables, and sampling distributions can be evaluated from coherent- or Gaussian-state matrix elements.

A circuit layer consists of a displaced passive linear-optical unitary followed by a local Kerr gate, as in Fig. 1. The displaced linear step maps each amplitude vector by an affine update

$$\alpha_k \mapsto e^{-iKt} \alpha_k + \gamma(t), \quad (4)$$

so the coherent-product form is preserved. The Kerr gate

$$K_\kappa = \exp(i\kappa\hat{n}^2) \quad (5)$$

is the only step that changes a single incoming coherent component into a superposition. For arbitrary Kerr strength, its action on a coherent state is reconstructed

on a phase orbit,

$$K_\kappa |\alpha\rangle \approx \sum_{r=0}^{N_F} c_r |\alpha \omega_r\rangle, \quad \omega_r = \exp\left(2\pi i \frac{r}{N_F + 1}\right), \quad (6)$$

with coefficients obtained from a discrete Fourier transform of the Kerr phases. The required local reconstruction size scales as

$$N_F = |\alpha|^2 + \mathcal{O}(\log(1/\varepsilon_{\text{Kerr}})). \quad (7)$$

General Kerr update. For the true Kerr gate, the elementary update is compactly described as follows. First expand the incoming coherent state in the Fock basis,

$$|\alpha\rangle = e^{-|\alpha|^2/2} \sum_{n=0}^{\infty} \frac{\alpha^n}{\sqrt{n!}} |n\rangle; \quad (8)$$

then apply the exact phase $e^{i\kappa n^2}$, truncate at N_F using the Poisson tail of mean $|\alpha|^2$, and transform the truncated Kerr state back to the coherent phase orbit with coefficients

$$c_r = C_\alpha \sum_{n=0}^{N_F} \exp\left(i\kappa n^2 - 2\pi i \frac{nr}{N_F + 1}\right). \quad (9)$$

This is the general-Kerr propagation rule before any weak-nonlinearity simplification.

The full algorithm propagates a list of coherent branches through the circuit

$$U = U_G \prod_{\ell=1}^L U^{(\ell)} := U_G \prod_{\ell=1}^L U_{\text{Kerr}}^{(\ell)} U_{\text{DPLO}}^{(\ell)}, \quad (10)$$

after which the final Gaussian unitary maps each surviving coherent branch to a Gaussian component.

In the **weak-Kerr numerical update**, we use a finite-Fourier phase-orbit approximation. For an integer $M \geq 1$, define

$$\tilde{\omega}_r = \exp\left(i\pi \frac{r}{M}\right), \quad r = 0, \dots, 2M-1. \quad (11)$$

Then one local Kerr action is approximated by

$$K_\kappa |\alpha\rangle \approx \sum_{r=0}^{2M-1} c_r^{(M)} |\alpha \tilde{\omega}_r\rangle. \quad (12)$$

Thus M fixes the local Kerr reconstruction grid: larger M uses more phase-orbit coherent states before truncation. For the theoretical weak-nonlinearity guarantee, we use the two-branch small-angle picture

$$K_\kappa |\alpha\rangle \approx \cos \vartheta |\alpha\rangle - i \sin \vartheta |\alpha - \alpha\rangle, \quad (13)$$

where the second branch is small when the Kerr angle is small. Retaining only branches that accumulate at most s sines gives

$$N_L \leq N_0 \sum_{q=0}^s \binom{L}{q} = O(N_0 L^s). \quad (14)$$

2 Main Guarantees

The cost is governed by the number of retained coherent branches and by the local coherent amplitudes before Kerr updates. The next two theorems formalize two regimes: arbitrary Kerr strength with few nonlinear layers, and weak Kerr strength with branch truncation.

Let

$$\lambda := \max_{\ell} \max_{k \in [N_\ell]} |\alpha_{k,\ell}^{(1)}|^2. \quad (15)$$

This is the largest local mean photon number on the Kerr mode among the coherent branches encountered during propagation.

Theorem 1 (Circuits with few Kerr layers) Let $|\psi_0\rangle$ be a superposition of $N_0 = \text{poly}(m)$ coherent states and let $|\psi\rangle = U|\psi_0\rangle$, where U is the circuit defined in Eq. (10). For any $\varepsilon > 0$, coherent-state propagation outputs a state $|\tilde{\psi}\rangle$ such that

$$\| |\psi\rangle - |\tilde{\psi}\rangle \|_2 \leq \varepsilon \quad (16)$$

in time

$$\mathcal{O}\left(Lm^3 + m^2(\lambda + \log(L/\varepsilon))^L\right). \quad (17)$$

Consequently, for circuits with $L = \mathcal{O}(\log m)$ layers:

1. if $\lambda = \text{poly}(m)$ and $\varepsilon = \exp(-\mathcal{O}(m))$, then the simulation runs in quasi-polynomial time,

$$m^{\mathcal{O}(\log m)}; \quad (18)$$

2. if $\lambda = \mathcal{O}(\log m)$ and $\varepsilon = 1/\text{poly}(m)$, then the simulation runs in almost-polynomial time,

$$m^{\mathcal{O}(\log \log m)}. \quad (19)$$

This result gives the general resource scaling: at fixed coherent energy scale, the overhead is controlled by the number of nonlinear branch-generating layers and by the local accuracy required at each Kerr reconstruction.

Theorem 2 (Circuits with small nonlinearity)

Let $|\psi_0\rangle$ be a superposition of $N_0 = \text{poly}(m)$ coherent states and let $|\psi\rangle = U|\psi_0\rangle$, where U is the circuit defined in Eq. (10). Assume the strength of the Kerr gates is upper bounded by

$$\kappa \leq \frac{\delta}{L(1 + \lambda^2)}, \quad (20)$$

for a sufficiently small constant δ .

Then, for every $\varepsilon \in (0, 1)$, coherent-state propagation with a small-angle truncation scheme outputs a state $|\tilde{\psi}\rangle$ such that

$$\| |\psi\rangle - |\tilde{\psi}\rangle \|_2 \leq \mathcal{O}(\delta) + \varepsilon, \quad (21)$$

with runtime

$$t = \mathcal{O}\left(Lm^3 + m^2 L^{1+\mathcal{O}(\log(1/\varepsilon))}\right). \quad (22)$$

In particular, for constant ε , the runtime is polynomial in m and L .

The weak-nonlinearity guarantee is closely aligned with short-time Trotterized dynamics. The small branch in the two-term Kerr approximation can be pruned systematically, replacing a binary tree by $O(N_0 L^s)$ retained terms for fixed s , analogous in spirit to small-angle qubit simulation [14].

After the final Gaussian layer, the **output** has the form $|\psi_{\text{out}}\rangle = \sum_j C_j |G_j\rangle$. The readout guarantees cover polynomial quadrature observables

$$\hat{O} = \sum_{r=1}^{\eta} \left(o_r \hat{\mathbf{X}}^{\mathbf{q}^{(r)}} \hat{\mathbf{P}}^{\mathbf{s}^{(r)}} + o_r^* \hat{\mathbf{P}}^{\mathbf{s}^{(r)}} \hat{\mathbf{X}}^{\mathbf{q}^{(r)}} \right), \quad (23)$$

with cost $\mathcal{O}(N^2(m^3 + \eta m^2))$. We can also sample rotated quadratures

$$\hat{X}_\theta = \hat{X} \cos \theta + \hat{P} \sin \theta. \quad (24)$$

Sampling N_{shot} outcomes costs $\mathcal{O}(N^2 m^2 \log(1/\varepsilon) + N_{\text{shot}} N m^2)$.

3 Numerical Experiments

We validate coherent-state propagation on the driven Bose-Hubbard model in the rotating frame,

$$\begin{aligned} \hat{H}_{\text{rot}} = & -J \sum_{\langle i,j \rangle} \left(\hat{a}_i^\dagger \hat{a}_j + \hat{a}_j^\dagger \hat{a}_i \right) - \Delta \sum_i \hat{n}_i \\ & + \frac{U}{2} \sum_i \hat{n}_i^2 + \sum_i \left(\Omega_i \hat{a}_i^\dagger + \Omega_i^* \hat{a}_i \right). \end{aligned} \quad (25)$$

The hopping, detuning, and drive terms form the DPLO part, while the onsite interaction gives local Kerr evolution [15–18]. For the six-mode all-to-all system in Fig. 2, we compare against matrix-product-state reference data [19, 20]. The agreement and cutoff trends support the central picture: coherent-state propagation is effective when weak Kerr steps generate an organized, tunable coherent-state expansion.

A Quantum Algorithm for the Radical of a Lie Algebra with Applications to Symmetries and Decoupling

Yibin Wang¹ *

Abstract. A closed quantum system's strictly conserved quantities occupy the center of its dynamical Lie algebra, formally the radical of the Levi–Malcev decomposition. We give the first general quantum algorithm that recovers this radical from the algebra's structure constants. Recognizing the radical as an operator kernel, the method projects onto it by quantum singular value transformation, so the dense Killing form that classical methods must build explicitly is never assembled. Reused across several Hamiltonians, it yields up to a cubic speedup over a structure-aware classical benchmark. The speedup follows one basis-independent conditioning law, staying polynomial for Pauli-based algebras and diverging only as a new conserved quantity emerges. A speedup and a nontrivial center coincide only for the single particle-number charge, so the algorithm is most reliable as a certificate that the conserved structure contains no hidden charge.

Keywords: quantum algorithms; dynamical Lie algebra; radical; QSVT; dynamical decoupling; conserved quantities

1 Introduction

The Levi–Malcev theorem places a unique maximal solvable ideal, the radical $\mathfrak{r}$, inside every finite-dimensional Lie algebra $\mathfrak{g}$ over a field of characteristic zero, leaving a semisimple Levi factor $\mathfrak{s}$ as the complement in the semidirect product $\mathfrak{g} = \mathfrak{s} \ltimes \mathfrak{r}$ [13]. For the dynamical Lie algebra (DLA) of a closed quantum system this structure carries direct physical content. The DLA $\mathfrak{g} = \text{Lie}(\{iH_k\})$ generated by a system's Hamiltonians is skew-Hermitian, so it lies inside the compact algebra $\mathfrak{u}(N)$ with $N = 2^n$ for n qubits, and compactness collapses the general decomposition to a direct sum $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$ with $[\mathfrak{s}, \mathfrak{z}] = 0$ [8]. The radical is then the center $\mathfrak{z}$, the operators that commute with the entire dynamics.

Those central operators are the system's strictly conserved quantities. Their joint eigenspaces block-diagonalize the Hilbert space into superselection sectors, and identifying them is the standard construction of decoherence-free subspaces [15]. Because $[\mathfrak{s}, \mathfrak{z}] = 0$, any Hamiltonian $H = H_s + H_z$ factorizes its evolution exactly, $U(t) = e^{-iH_s t} e^{-iH_z t}$, with zero Trotter error between the two sectors.

Classically the obstruction is dimension. The DLA dimension d reaches $O(4^n)$ [17], and the dense implementations in GAP [16] and Magma [1] that follow the de Graaf line [5, 6] cost $O(d^4)$. A structure-aware optimization lowers the classical cost to $O(d s_{adj} s_{int} + d^3)$ in two sparsity param-

eters defined below, and for Pauli-spanned algebras the symplectic geometry over $\mathbb{F}_2^{2n}$ reduces it further to $\tilde{O}(d)$ [12]. We adopt both bounds as classical benchmarks for the quantum algorithm.

The problem remains distinct from two adjacent uses of Lie-algebraic structure in quantum computing. One line treats the DLA dimension as a predictor of variational-circuit trainability and barren plateaus [14, 19]; a second uses that structure to simulate dynamics classically, and a recent dichotomy argues that the absence of barren plateaus often renders the dynamics classically simulable [3, 11]. The deliverable here is the algebraic structure itself, which a Heisenberg-picture simulation of an observable never returns, so the advantage window remains narrow but open.

2 The Quantum Algorithm

A consequence of Cartan's criterion turns the decomposition into linear algebra. The radical is the Killing-orthogonal complement of the derived algebra, $\mathfrak{r} = ([\mathfrak{g}, \mathfrak{g}])^{\perp_K}$, where K denotes the Killing form [13]. In a basis $\{e_i\}$ the structure constants are fixed by $[e_i, e_j] = \sum_k f_{ijk} e_k$; writing them into the $d \times d^2$ commutator matrix C , whose columns span $[\mathfrak{g}, \mathfrak{g}]$, turns membership in the radical into the kernel condition $C^T K x = 0$ for $x \in \mathfrak{g}$. The target operator is therefore $A_{opt} = C^T K$, and the radical is its kernel. For a compact DLA the Killing form already vanishes on the center, so $\mathfrak{r} = \ker K$ and the

*yibinw0210@gmail.com

C^T factor is removed.

A direct block encoding of K is inefficient, since the Killing form is generically dense. The matrix elements $K_{ij} = \sum_{k,m} f_{ikm} f_{jmk}$ factor as $K = A^T B$ with $A_{(k,m),i} = f_{ikm}$ and $B_{(k,m),j} = f_{jmk}$, two matrices of size $d^2 \times d$ that inherit the sparsity of the structure constants. The saving is not in the query count but in the block-encoding subnormalization α . A sparse-access block encoding already reaches its target in a constant number of queries [10], so encoding the dense K directly would only inflate α to $O(d)$, whereas the sparse factors hold it near $O(\sqrt{s_{adj} s_{int}})$.

Four numbers read from the tensor f_{ijk} govern the cost. The magnitude $F = \max_{i,j,k} |f_{ijk}|$ sets the scale, the adjoint sparsity s_{adj} counts the bracket couplings of a single basis element, the interaction sparsity s_{int} measures how tightly a fixed output and one input fix the remaining index, and the balance β tracks how evenly the squared structure-constant norms spread across the basis. The Pauli basis gives $F = 2$ and $s_{int} = O(1)$, whereas generic bases reach $s_{int} = O(d)$.

For Pauli-spanned algebras the structure constants are a computable rule and not stored data. Membership and sign follow from the symplectic form on $\mathbb{F}_2^{2n}$ together with the $\mathbb{Z}_4$ -valued Pauli phase law [12, 7], so a depth- $O(\log n)$ arithmetic circuit replaces the QRAM Prepare and Select oracles and reduces the classical setup from $O(d^3)$ to $\tilde{O}(1)$.

Quantum singular value transformation applies a spectral filter to the singular values of a block-encoded operator [10]. Filtering onto the zero singular value of A_{opt} builds a block encoding of the projector P_τ onto its kernel, hence onto the radical, at polynomial degree $D = O(\kappa \log(1/\epsilon))$ for target precision ϵ , set by the condition number κ of the normalized operator. A singular-value estimation step fixes κ beforehand at the same asymptotic cost, so the projector is the algorithm's output.

3 Main Results

The runtime reduces to the subnormalization α_{opt} of the block encoding of A_{opt} and to the conditioning of that operator.

Theorem 1 (Query complexity) *The algorithm produces a block encoding of P_τ with query complexity*

$$T_Q = \tilde{O}(\alpha_{opt}/\sigma_{\min}(A_{opt})),$$

$$\alpha_{opt} = O\left(F^3 \sqrt{\beta} s_{adj}^{3/2} \sqrt{s_{int}}\right),$$

tight in the Pauli frame to $T_Q = \tilde{O}(\kappa(A_{opt}))$. For a compact algebra the target is K , giving $T_Q = \tilde{O}(\kappa(K|_{\mathfrak{s}}))$.

Theorem 2 (Classical benchmark) *Given sparse access to the structure constants, the optimized classical radical algorithm runs in time*

$$T_{C-Opt} = O(d s_{adj} s_{int} + d^3),$$

which collapses to $O(d^3)$ in the dense regime and to $\tilde{O}(d)$ for Pauli-spanned algebras through elimination over $\mathbb{F}_2^{2n}$.

No published classical algorithm computes the radical faster, and Theorem 2 is a deliberately conservative optimization of the de Graaf line [5, 6], so the advantage below is measured against a strengthened classical baseline.

The condition number that drives the runtime is tightly constrained. It obeys a single identity that holds before any basis is fixed.

Theorem 3 (Conditioning law) *Write $\mathfrak{s} = \bigoplus_l \mathfrak{s}_l$ for the splitting of the semisimple part into simple ideals of dimension d_l , and take a basis orthonormal for an invariant inner product and adapted to that splitting together with the center. Total antisymmetry of the structure constants then gives $CC^T = -K$, so*

$$\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}.$$

Each simple ideal carries a block-scalar Killing form $K|_{\mathfrak{s}_l} = -N_l I_{d_l}$ with $N_l = 2h_l^\vee \nu_l$, where $h_l^\vee$ is the dual Coxeter number of the Cartan type of $\mathfrak{s}_l$ and ν_l the squared basic length shared by its generators, so that

$$\kappa(A_{opt}) = \left(\frac{\max_l N_l}{\min_l N_l} \right)^{3/2}.$$

The exponent 3/2 is the same for every compact simple type and every such frame.

Theorem 3 is the paper's central theoretical result. It collapses the entire runtime dependence on conditioning to a ratio of simple-ideal scales, and it locates the obstruction in a mismatch of scale, not of dimension count. Conditioning stays bounded exactly when the block scalars are comparable, and a scale mismatch across summands raises κ to $\text{poly}(d)$. The Pauli basis is one such invariant-orthonormal frame, and there the growth is bounded.

Table 1: Performance summary under a standardized basis ($F = O(1)$, $s_{adj} = O(d)$), derived from Theorems 1–4. The Speedup column is the per-call ratio of the classical baseline to the quantum T_Q ; “None” marks the rows where the two match. The QRAM rows amortize the one-time $O(d^3)$ setup over $M \geq 2$ shared Hamiltonians, so their classical baseline quotes the structure-dependent term. [†]The $\tilde{O}(1)$ -query Pauli projector is absorbed by the $\tilde{O}(d)$ dense state preparation, which matches the symplectic benchmark. [‡]The worst-case Pauli row already meets or exceeds the $\tilde{O}(d)$ benchmark.

Basis and conditioning	s_{int}	κ	Setup	Quantum T_Q	vs. Classical	Speedup
Pauli, well-conditioned ($\mathfrak{su}(2^n)$)	$O(1)$	$O(1)$	$\tilde{O}(1)$	$\tilde{O}(1)$	vs. $\tilde{O}(d)$	None [†]
Pauli, worst-case ($\kappa(K _{\mathfrak{s}})$ at ceiling)	$O(1)$	$O(d^{3/2})$	$\tilde{O}(1)$	$\tilde{O}(d^{3/2})$	vs. $\tilde{O}(d)$	None [†]
Gell-Mann basis of $\mathfrak{su}(N)$, well-conditioned	$\Theta(\sqrt{d})$	$O(1)$	$O(d^3)$	$\tilde{O}(d^{0.75})$	vs. $O(d^{2.5})$	$\tilde{O}(d^{1.75})$
Generic dense, well-conditioned (QRAM)	$O(d)$	$O(1)$	$O(d^3)$	$\tilde{O}(d)$	vs. $O(d^3)$	$\tilde{O}(d^2)$
Continuous symmetry-adapted, near-critical	$O(d)$	$O(d)$	$O(d^3)$	$\tilde{O}(d^2)$	vs. $O(d^3)$	$\tilde{O}(d)$

Theorem 4 (Pauli polynomial conditioning)

For any algebra spanned by skew-Hermitian Pauli operators, the Killing form is integer and diagonal with $\kappa(K|_{\mathfrak{s}}) \leq d$, so that $\kappa(A_{opt}) \leq O(d^{3/2})$. Exponential ill-conditioning, the usual failure mode of singular-value methods, is excluded.

Pairing the query cost against the classical benchmark regime by regime gives Table 1.

A structural speedup and a nontrivial center rarely coexist. A rich center conflicts with the comparable-scale condition of Theorem 3. An $SU(2)$ -symmetric subalgebra, for instance, splits under Schur–Weyl duality into blocks $\mathfrak{su}(m_J)$ whose multiplicities m_J are mismatched, and degrades to the worst case. Only in the number-conserving regime, where the center is the single particle-number charge, do a structural speedup and a nontrivial center meet. The algorithm is then most reliable as a negative certificate, ruling out any hidden charge beyond the expected symmetries.

4 Applications

Beyond the structural readout, the projector serves as a computational primitive. Applied to a state $|H\rangle$ that encodes a Hamiltonian $H \in \mathfrak{g}$, the QSVT circuit prepares the coherent split

$$|0\rangle \otimes P_{\mathfrak{t}} |H\rangle + |1\rangle \otimes (I - P_{\mathfrak{t}}) |H\rangle,$$

and a measurement on the ancilla returns either the central component H_z or the semisimple component H_s [10]. Because the two components commute, the evolution factorizes as $e^{-iHt} = e^{-iH_s t} e^{-iH_z t}$ with no Trotter error, which realizes an exact dynamical decoupling for control and simulation [4]. One application costs $T_{prep} + T_Q$ for state preparation T_{prep} , and amplitude amplification raises the targeted component to unit weight [2]; the algebraic advantage survives whenever H is sparse enough that $T_{prep} \ll T_Q$.

The same output certifies symmetry. The center returns the strictly conserved charges and the superselection sectors, while the derived algebra supplies the unique Levi factor of a compact DLA. A finer split of the semisimple part into simple ideals follows from a hybrid step, in which quantum subspace tomography on the image of $I - P_{\mathfrak{t}}$ passes a classical description of the quotient $\mathfrak{g}/\mathfrak{t} \cong \mathfrak{s}$ to a standard structural solver [6]. The tomography overhead $O((\dim \mathfrak{s})^2)$ [18] stays low precisely when the center dominates, so a small center makes the full decomposition efficient and the symmetry certificate cheap to produce.

5 Outlook: A Necessary Signature of Criticality

The condition number acquires physical meaning through the Algebraic Adjoint Gap $\Delta_{ad}(\mathfrak{g}) := \sigma_{\min}(K|_{\mathfrak{s}})$, the smallest singular value of the Killing form on the semisimple part. A structural-stability bound ties this gap to geometry. The gap obeys $\sigma_{\min}(K) \leq C_1 d^{3/2}(F + \delta)\delta$ with an absolute constant $C_1 = 3$, where δ is the Frobenius distance from the algebra to the non-semisimple variety $\mathcal{V}_{\text{deg}}$.

Along a one-parameter family in the QRAM regime, a soft mode of the adjoint action migrates into the center as a new conserved quantity emerges, forcing $\Delta_{ad} \rightarrow 0$ and $\kappa \rightarrow \infty$ at the transition. A diverging runtime is therefore a necessary, though not sufficient, signature of a symmetry-emergent quantum phase transition [9]. The integer rigidity of Theorem 4 forbids a continuous gap closure, so the divergence is a QRAM-regime effect. Extracting a critical exponent from the runtime rests on a scaling hypothesis and is left to future numerical work.

Abstract

A closed quantum system's evolution is governed by its dynamical Lie algebra, and the center of that algebra holds its strictly conserved quantities. Recovering this center, formally the radical of the algebra's Levi–Malcev decomposition, reveals its superselection sectors and yields an exact dynamical decoupling. Classically the task is intractable, because the algebra's dimension can grow exponentially with the qubit count.

We give the first general quantum algorithm for this radical, working from the algebra's structure alone. The algorithm recognizes the radical as an operator's kernel and projects onto it by quantum singular value transformation, so the dense Killing form that stalls classical methods is never built. When the structure is reused across several Hamiltonians, this yields a speedup over a structure-aware classical benchmark, up to cubic when well-conditioned.

The speedup's magnitude depends on the conditioning of the algebra's structure, which follows a single basis-independent law and stays bounded when its simple parts are comparable in scale. For Pauli-based algebras it remains polynomial, ruling out exponential ill-conditioning; in the general case it can diverge as a new conserved quantity emerges, a necessary but not sufficient signature of a quantum phase transition. A speedup and a nontrivial center coincide only when that center is a single particle-number charge, so the algorithm works best as a certificate that the conserved structure hides no extra charge.

1 Introduction

Lie groups and Lie algebras give the language for the continuous symmetries and the dynamical evolution of quantum systems [29, 22]. The Levi–Malcev theorem [32, 34] lies at the base of that theory. It states that any finite-dimensional Lie algebra $\mathfrak{g}$ over a field of characteristic zero splits as a semidirect product $\mathfrak{g} = \mathfrak{s} \ltimes \mathfrak{r}$ into a semisimple Levi factor $\mathfrak{s}$ and the unique maximal solvable ideal $\mathfrak{r}$, the radical. Identifying these two components is the entry point to any structural or dynamical analysis of $\mathfrak{g}$.

The decomposition splits into two tasks, identifying the unique radical $\mathfrak{r}$ and identifying a Levi factor $\mathfrak{s}$. This paper focuses on the first task, the efficient identification of the radical using quantum computation, with a specific emphasis on its application to the analysis of quantum dynamics.

1.1 The Central Role of the Radical in Quantum Dynamics

The radical takes on direct physical content here. The Dynamical Lie Algebra (DLA) of a closed quantum system inherits constraints from the unitarity of time evolution, and under those constraints the general Levi–Malcev decomposition collapses to a simpler form in which the radical becomes a concrete physical object [15, 14].

In quantum mechanics, we analyze the DLA $\mathfrak{g} = \text{Lie}(\{iH_k\})$ generated by a set of Hamiltonians $\{H_k\}$, for example, control Hamiltonians. Since these generators are skew-Hermitian matrices (iH_k), the DLA is a subalgebra of the unitary algebra $\mathfrak{u}(N)$, where $N = 2^n$ for n qubits. The unitary group $U(N)$ is compact. Consequently, the DLA of any finite-dimensional closed quantum system is a compact Lie algebra. Compactness specializes the Levi–Malcev structure. Any compact Lie algebra $\mathfrak{g}$ is a direct sum of its center $\mathfrak{z}$ and a semisimple subalgebra $\mathfrak{s} = [\mathfrak{g}, \mathfrak{g}]$ [32]:

$$\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}. \quad (1)$$

The radical equals the Abelian center $\mathfrak{z}$, and $[\mathfrak{s}, \mathfrak{z}] = 0$. For any $H = H_s + H_z \in \mathfrak{g}$, where $H_s \in \mathfrak{s}$ and $H_z \in \mathfrak{z}$, the components commute, so the time evolution operator factorizes exactly:

$$U(t) = e^{-iHt} = e^{-iH_s t} e^{-iH_z t}. \quad (2)$$

The factorization incurs zero Trotter error between $\mathfrak{s}$ and $\mathfrak{z}$, unlike the general Levi–Malcev case where $[\mathfrak{s}, \mathfrak{r}] \neq 0$ forces Trotter–Suzuki formulas [53, 51]. The central evolution $e^{-iH_z t}$ is trivial since $\mathfrak{z}$ is Abelian, so all dynamical complexity sits in H_s . Identifying the radical thus yields an exact dynamical decoupling for quantum control and simulation [13].

Beyond identifying exact symmetries, we introduce a quantitative metric on the DLA’s spectrum, which we term the Algebraic Adjoint Gap, to probe the system’s proximity to a structural instability.

Definition 1.1 (Algebraic Adjoint Gap). *For a compact Lie algebra $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$, the Algebraic Adjoint Gap $\Delta_{ad}(\mathfrak{g})$ is the smallest singular value of the Killing form matrix K , represented in an orthonormal basis and restricted to the semisimple component $\mathfrak{s}$:*

$$\Delta_{ad}(\mathfrak{g}) := \sigma_{\min}(K|_{\mathfrak{s}}). \quad (3)$$

The physical meaning of Δ_{ad} and its connection to quantum phase transitions are discussed in Section 5.4.

The center $\mathfrak{z}$ consists of operators that commute with all elements of the DLA. Physically, these elements correspond directly to the system’s conserved quantities or global symmetries. Their common eigenvalues block-diagonalize the Hilbert space into superselection sectors that confine the dynamics. In quantum information, identifying the center is the standard method for finding Decoherence-Free Subspaces (DFS) [39].

1.2 Classical Algorithms and Their Limits

For an n -qubit system the DLA dimension can reach $d = O(4^n)$ [45]. That scaling puts a structural analysis out of classical reach on all but small systems.

Classical algorithms for radical computation implement the structural identity $\mathfrak{r} = [\mathfrak{g}, \mathfrak{g}]^{\perp\kappa}$ (Theorem 3.1) and follow the line developed by de Graaf and collaborators [17, 28, 16]. Dense implementations cost $O(d^4)$, dominated by explicit construction of the Killing form, and are the route taken by widely deployed systems such as GAP [40] and Magma [6]. In Section 4.3 we show that sparse data structures keyed to s_{adj} and s_{int} (Definitions 2.5 and 2.6), together with the bilinear factorization $K = A^T B$ (Section 3.2), reduce the optimized benchmark to $T_{C-Opt} = O(d \cdot s_{adj} \cdot s_{int} + d^3)$. For generic structure ($s_{int} = O(d)$) the benchmark is $O(d^3)$, while in the Pauli basis ($s_{int} = O(1)$) the symplectic logic over $\mathbb{F}_2^{2n}$ collapses the radical problem to $\tilde{O}(d)$. These are the two benchmarks against which the quantum runtimes of Section 4 are measured.

1.3 A Quantum Algorithm via Direct Projection

Our algorithm implements the Cartan criterion identity directly as a kernel projection on a quantum block encoding; it never assembles the Killing form or runs Gaussian elimination, and so sidesteps the $O(d^3)$ classical bottleneck for the well-conditioned Pauli case.

The starting point is the Cartan-criterion identity $\mathfrak{r} = ([\mathfrak{g}, \mathfrak{g}])^{\perp\kappa}$ (Theorem 3.1). The identity converts radical finding into a single linear algebraic question: compute the kernel of a composite operator built from the structure constants (Section 3.1). The Quantum Singular Value Transformation (QSVT) [23] applies arbitrary spectral filters to a block-encoded operator. Filtering on the zero singular value isolates the kernel, with no explicit Killing form K . The Killing form is dense, so a direct $d \times d$ block encoding is wasteful. Our main technical move is to factor it as $K = A^T B$ from the structure constants (Section 3.2). Every speedup reported below depends on this factorization.

1.4 Related Works and Assumptions

Earlier quantum algorithms for algebraic problems mostly worked on sharply structured inputs, the hidden subgroup problem being the canonical example [41]. Quantum linear algebra methods, such as HHL [30] and QSVT [23], broadened that scope to dense problems. The Lie algebra decomposition we treat here is dense and high-dimensional, and the speedup we extract rides on specific physical structure; generic sparsity plays no role.

1.4.1 Distinction from Related Research Areas

Lie algebras enter quantum computing in several adjacent regimes the present work does not address. One line studies the DLA as a predictor of Variational Quantum Algorithm trainability: the dimension of the DLA controls the variance of cost gradients and the onset of barren plateaus [38, 47], separately from the locality of the cost function [10]. A second line uses Lie-algebraic structure to speed up *classical* simulation of quantum dynamics [57]. We instead run a quantum computer to extract the algebraic structure itself.

The radical problem sits closer to a third body of work, where Lie-algebraic data is itself the object being computed. On the classical side, identifying a Lie algebra from its structure constants, including its Levi factor and nilradical, goes back to Rand, Winternitz and Zassenhaus [48] and the computer-algebra algorithms of de Graaf and collaborators [17, 28]. On the quantum side the dynamical Lie algebra of a fixed ansatz has been worked out by hand, as Allcock and coworkers do for the QAOA cycle-graph DLA [2], while Cartan (KAK) methods compile a single unitary into fixed-depth circuits without ever computing the algebra’s radical [37]. A separate task learns conserved quantities of unknown dynamics from measured data alone [58]. Against this backdrop the present algorithm occupies an unclaimed place. To our knowledge it is the first general quantum procedure that computes the radical and the Levi structure of a compact DLA directly from its structure constants. The Pauli-oracle regime frees that computation from QRAM and from classical dequantization, since the structure constants are generated on demand from the symplectic form.

Whether a quantum advantage for such problems survives the recent simulability dichotomy is a separate and pressing question, taken up in Section 6.4.

1.4.2 The DLA Generation Problem and Input/Output Model

Physical systems are typically defined by a small set of generating Hamiltonians. The algorithm presented here assumes access via Quantum Random Access Memory (QRAM) to the structure constants of the entire Dynamical Lie Algebra.

This paper focuses exclusively on solving the structural algebraic problem given access to the algebraic description. We analyze two distinct regimes based on the nature of the DLA basis: an algorithmic regime (Pauli basis, arithmetic oracles, setup $\tilde{O}(1)$) and a QRAM regime (generic basis, setup $O(d^3)$, amortized over $M \geq 2$ Hamiltonians). Full parameter dependence is laid out in Section 4.4.

Whether the algorithm is reached in practice turns on how the structure-constant array is produced. Three bands cover the physically relevant inputs. The cheapest is the implicit Pauli rule. When the algebra is spanned by Pauli strings, every constant is fixed by the symplectic form on $\mathbb{F}_2^{2n}$ and is returned on demand by the depth- $O(\log n)$ oracle of Section 3.3, so nothing is generated or stored and the setup stays $\tilde{O}(1)$. This band holds $\mathfrak{su}(2^n)$, the free-fermion $\mathfrak{so}(2n)$ under Jordan–Wigner, and the k -local Heisenberg and Hubbard families whose closure lands in one of them (Section 5.2). A middle band covers algebras of a recognized simple type given in a closed-form basis, such as the generalized Gell-Mann basis of $\mathfrak{su}(N)$: the constants are known analytically, so generation is polynomial, but with no symplectic oracle they must still be loaded, which fixes the generic $O(d^3)$ QRAM setup. Generation dominates only in the third band, a DLA presented through a few k -local generators with no recognized structure, where closing the algebra by iterated brackets, the *DLA generation problem* tied to controllability analysis, can take time exponential in n [49] before any quantum step begins. The headline figures of Section 4.4 apply in full to the first two bands and are reached in the third only once its generation cost is paid.

The algorithm does not return a classical basis of the radical $\mathfrak{r}$. Its output is a quantum circuit $U_{P_{\mathfrak{r}}}$ implementing a block encoding of the orthogonal projector $P_{\mathfrak{r}}$, normalized to unity since $\|P_{\mathfrak{r}}\| = 1$. A classical basis would require quantum subspace tomography of the

projected image, with overhead scaling quadratically in $\dim \mathfrak{r}$ [46], an overhead capable of erasing the quantum advantage on its own. The application side of this input-output contract, including state-preparation cost, the coherent radical/semisimple splitting, and the amplitude-amplification budget, is treated in Section 7.1.

1.5 Summary of Contributions

The paper makes two contributions, plus a boundary on where they apply and an outlook.

1. **Algorithm and complexity.** A single-stage quantum algorithm returns the radical of a compact DLA by projecting onto the kernel of $A_{opt} = C^T K$, which identifies the center, i.e. the continuous symmetries, and enables exact dynamical decoupling. The dense Killing form is never built: its bilinear factorization $K = A^T B$ (Section 3.2) block-encodes two sparse factors in its place. The magnitude F , the adjoint sparsity s_{adj} , the interaction sparsity s_{int} , and the balance β drive the runtime. Theorem 4.1 gives the query complexity $T_Q = \tilde{O}(\alpha_{opt}/\sigma_{\min}(A_{opt}))$ with subnormalization $\alpha_{opt} = O(F^3 \sqrt{\beta} s_{adj}^{3/2} \sqrt{s_{int}})$, tight in the Pauli frame to $\tilde{O}(\kappa(A_{opt}))$, against the optimized classical bound $T_{C-Opt} = O(d \cdot s_{adj} \cdot s_{int} + d^3)$ of Theorem 4.12. Data access has two modes. A generic basis loads the constants through QRAM at an $O(d^3)$ setup. The Pauli case needs no QRAM at all, since the symplectic form on $\mathbb{F}_2^{2n}$ yields the structure constants through a depth- $O(\log n)$ arithmetic oracle at $\tilde{O}(1)$ setup (Section 3.3). On the $\mathfrak{su}(2^n)$ benchmark dense state preparation then holds the end-to-end cost at $\tilde{O}(d)$, level with the classical symplectic bound (Remark 4.3).
2. **A basis-independent conditioning law, whose dimensional obstruction over the simple types is the central theoretical result.** The runtime factor κ reduces to one invariant identity. On any basis orthonormal for an invariant inner product and adapted to the refined splitting into simple ideals and center, $CC^T = -K$, so $\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}$, and a semisimple part $\mathfrak{s} = \bigoplus_l \mathfrak{s}_l$ carries a block-scalar Killing form $K|_{\mathfrak{s}_l} = -N_l I$ with $N_l = 2h_l^\vee \nu_l$ (Theorem 4.6). The exponent $3/2$ is the same for every compact simple type and every such frame; only the law tying N_l to d_l moves with the type and the normalization. Conditioning stays bounded exactly when the block scalars are comparable, and a dimension mismatch across simple summands pushes κ to $\text{poly}(d)$, capped in the Pauli regime at $\kappa \leq O(d^{3/2})$ so that exponential ill-conditioning is ruled out there (Theorem 4.10). The $SU(2)$ -symmetric isotypic case (Theorem 4.9) and the free-fermion and Bogoliubov–de Gennes types (Section 5.3) are further frames of the one law. The balance factor obeys $\beta = \beta_{\mathfrak{s}} \cdot (d/r)$, so only a center-dominated algebra forces $\beta = O(d)$.
3. **Outlook: a necessary signature of criticality.** The Adjoint Gap $\Delta_{ad}(\mathfrak{g}) := \sigma_{\min}(K|_{\mathfrak{s}})$ is bounded above by the Frobenius distance from $\mathfrak{g}$ to the non-semisimple variety $\mathcal{V}_{\text{deg}}$ (Theorem 5.1), and in the QRAM regime its closure forces $\kappa \rightarrow \infty$ at criticality (Theorem 5.5). A diverging runtime is therefore a necessary, not sufficient, signature of a symmetry-emergent quantum phase transition; extracting a critical exponent from the runtime rests on Hypothesis 5.7 and is left to future numerical work.

A structural caveat fixes where the speedup exists. A rich center works against the comparable-scalar condition of Theorem 4.6: the $SU(2)$ -symmetric subalgebra splits into mismatched $\mathfrak{su}(m, j)$ blocks and falls to the worst case (Theorem 4.9). Only in the number-conserving regime, where the center is the single particle-number charge, do a structural speedup and a nontrivial center meet. The algorithm is then most reliable as a negative certificate, ruling out any hidden charge beyond the expected symmetries; Section 5.3 splits this conclusion across the three conditioning regimes.

2 Notation and Background

This section fixes the notation, structural parameters, and one structural fact used throughout. We assume working with finite-dimensional Lie algebras over $\mathbb{R}$ or $\mathbb{C}$; standard references are [32, 34, 22].

2.1 Lie Algebras and Structure Constants

Throughout this paper, $\mathfrak{g}$ denotes a finite-dimensional Lie algebra of dimension d with Lie bracket $[\cdot, \cdot] : \mathfrak{g} \times \mathfrak{g} \rightarrow \mathfrak{g}$. The Levi-Malcev decomposition $\mathfrak{g} = \mathfrak{s} \ltimes \mathfrak{r}$ separates $\mathfrak{g}$ into a semisimple Levi part $\mathfrak{s}$ and the solvable radical $\mathfrak{r}$ [42]. Given a basis $\{B_i\}_{i=1}^d$ for $\mathfrak{g}$, the structure constants $f_{ijk} \in \mathbb{F}$ are determined by

$$[B_i, B_j] = \sum_{k=1}^d f_{ijk} B_k. \quad (4)$$

These d^3 values are the fundamental input to the algorithm.

For any $x \in \mathfrak{g}$ the linear map $\text{ad}(x) : \mathfrak{g} \rightarrow \mathfrak{g}$, $\text{ad}(x)(y) := [x, y]$, has matrix elements in the basis $\{B_i\}$ given by

$$(\text{ad}(B_i))_{kj} = f_{ijk}. \quad (5)$$

The Killing form $\mathcal{K}(x, y) := \text{Tr}(\text{ad}(x)\text{ad}(y))$ is bilinear, and its matrix elements expand to

$$K_{ij} = \sum_{k=1}^d \sum_{m=1}^d f_{ikm} f_{jmk}. \quad (6)$$

This double-sum form is the target of the bilinear factorization $K = A^T B$ developed in Section 3.2 and exploited by both the quantum algorithm and the structure-aware classical benchmark.

Definition 2.1 (Standard Pauli Basis (Skew-Hermitian)). *For an n -qubit system ($N = 2^n$), the standard Pauli operators $\{P_k\}$ are the $N \times N$ Hermitian matrices formed by tensor products of the single-qubit Pauli matrices $\{I, X, Y, Z\}$. We define the Skew-Hermitian Pauli Basis $\{B_k\}$ for the unitary algebra $\mathfrak{u}(N)$ by multiplying the standard Pauli operators by the imaginary unit i : $B_k = iP_k$.*

This convention keeps the basis elements skew-Hermitian (consistent with the generators of unitary evolution).

Lemma 2.2 (Reality and Integrality of Structure Constants). *In the Skew-Hermitian Pauli Basis, the structure constants f_{ijk} are real integers belonging to $\{0, \pm 2\}$.*

Proof. The commutator of two standard Pauli operators P_i, P_j satisfies $[P_i, P_j] = 2i \sum_k \epsilon_{ijk} P_k$ if they anti-commute and form a triplet (e.g., X, Y, Z), or $[P_i, P_j] = 0$ if they commute. The tensor ϵ_{ijk} takes values in $\{0, \pm 1\}$.

We examine the commutator in the Skew-Hermitian basis:

$$[B_i, B_j] = [iP_i, iP_j] = -[P_i, P_j] = -\left(2i \sum_k \epsilon_{ijk} P_k\right).$$

Rearranging the terms:

$$[B_i, B_j] = -2 \sum_k \epsilon_{ijk} (iP_k) = -2 \sum_k \epsilon_{ijk} B_k.$$

The structure constants are therefore $f_{ijk} = -2\epsilon_{ijk}$. Since $\epsilon_{ijk} \in \{0, \pm 1\}$, the structure constants f_{ijk} are real integers in $\{0, \pm 2\}$. $\square$

2.2 Complexity Parameters and Basis Properties

Both the quantum runtime and the structure-aware classical benchmark are controlled by four parameters drawn from the f_{ijk} tensor.

Definition 2.3 (Maximum Structure Constant Magnitude (F)). *The magnitude F is defined as the maximum absolute value of the structure constants in the given basis:*

$$F = \|f\|_{\max} = \max_{i,j,k} |f_{ijk}|. \quad (7)$$

For the Pauli basis, Lemma 2.2 establishes $F = 2$.

Definition 2.4 (Standardized Basis). *A basis is standardized when $F = O(1)$.*

We now define parameters that characterize the sparsity of the algebraic interactions. These parameters control both the quantum block encoding normalization factors and the optimized classical Sparse Matrix Multiplication (SpMM).

Definition 2.5 (Adjoint Sparsity (s_{adj})). *The adjoint sparsity s_{adj} is defined as the maximum number of non-zero structure constants associated with any single basis element acting as the first argument of the commutator:*

$$s_{adj} = \max_i |\{(j, k) : f_{ijk} \neq 0\}|. \quad (8)$$

This parameter corresponds to the maximum sparsity of the adjoint representation matrices, see Equation (5).

An algebra is said to have *adjoint-linear sparsity* when $s_{adj} = O(d)$; this scaling is characteristic of dense physical structures, including DLAs in the Pauli basis. A second sparsity parameter captures the structure of the Killing form factorization.

Definition 2.6 (Interaction Sparsity (s_{int})). *The interaction sparsity s_{int} is defined as the maximum number of basis elements B_i that can combine with a fixed basis element B_k (as the second argument) to produce a component along a fixed basis element B_m (as the result),*

$$s_{int} = \max_{k,m} |\{i : f_{ikm} \neq 0\}|. \quad (9)$$

At $s_{int} = O(1)$, fixing the output B_m and one input B_k leaves only $O(1)$ possibilities for the other input B_i . This parameter determines the sparsity of the matrix A in the Killing form factorization $K = A^T B$ (Section 3.2), which is distinct from the sparsity of B (governed by s_{adj}). The Pauli basis achieves $s_{int} = O(1)$ (as shown in Section 4.4), whereas generic bases typically have $s_{int} = O(d)$.

Finally, we introduce a definition to characterize the distribution of the magnitudes of the structure constants across the basis.

Definition 2.7 (β -Balance). *Let $N_k = \sum_{i,j} |f_{ijk}|^2$ be the squared L_2 norm of the structure constants associated with the output basis element B_k . The average squared norm is $\bar{N} = (1/d) \sum_k N_k$. The balance parameter is defined as $\beta = (\max_k N_k) / \bar{N}$. We call the representation β -balanced.*

A basis is *balanced* when $\beta = O(1)$, so the algebraic interactions spread roughly uniformly across basis elements. The dependence of β on subalgebra structure is treated in Section 4.2.

2.3 The Quantum Linear Algebra Toolkit

Block Encoding from QRAM Data Structures A unitary U on $a+n$ qubits is an (α, a, ϵ) -block encoding of an n -qubit operator A when $\|A - \alpha(|0\rangle^{\otimes a} \otimes I_n)U(|0\rangle^{\otimes a} \otimes I_n)\| \leq \epsilon$, with normalization $\alpha \geq \|A\|$. An (α, a, ϵ_A) -encoding of A and a (β, b, ϵ_B) -encoding of B yield an $(\alpha\beta, a+b, \alpha\epsilon_B + \beta\epsilon_A)$ -encoding of AB . The normalization factor α_M for a matrix M is typically optimized based on the maximum L_2 norms of its columns or rows, and is the optimization target of the analysis in Section 4. The $O(d^3)$ structure constants are assumed loaded in a standard QRAM data structure [23] that supports $O(\text{polylog } d)$ Prepare/Select queries after an $O(d^3)$ classical setup; this reliance is a strong but standard assumption, justified in Section 6.2. It is standard because the architecture and its circuit realizations are well developed [24, 5], and strong because the fault-tolerant cost remains contested [1, 19].

Quantum Singular Value Transformation (QSVT) for Kernel Projection. QSVT [23] applies a degree- D polynomial P to the singular values of a block-encoded matrix $A = \sum_i \sigma_i |w_i\rangle \langle v_i|$ via D alternating queries to U_A and $U_A^\dagger$, producing a block encoding of $\sum_i P(\sigma_i) |w_i\rangle \langle v_i|$. The required polynomial degree D necessary to achieve a precision ϵ scales as $D = O(\kappa \log(1/\epsilon))$ [23]. Consequently, the QSVT circuit requires $O(\kappa \log(1/\epsilon))$ queries to the block encoding U_A .

The application we use is the construction of projectors onto the kernel of a matrix via polynomial approximation of a threshold function. We seek a polynomial $P_{\ker}(x)$ approximating the indicator function for $x = 0$.

Let δ be the gap between the zero singular value and the smallest non-zero singular value of the normalized matrix A/α . We require a polynomial $P_{\ker}(x)$ such that $P_{\ker}(x) \approx 1$ for $x \approx 0$ and $P_{\ker}(x) \approx 0$ for $x \in [\delta, 1]$.

Definition 2.8 (Condition Number κ). *For the operator A_{opt} (state in Section 3.1), let α_{opt} be its normalization factor $\|A_{\text{opt}}\|_2$. If δ is the smallest non-zero singular value of $A_{\text{opt}}/\alpha_{\text{opt}}$, then the condition number is $\kappa = 1/\delta = \alpha_{\text{opt}}/\sigma_{\min}(A_{\text{opt}})$. When the block encoding is tight ($\alpha_{\text{opt}} = \sigma_{\max}$, as in the Pauli frame) this coincides with the spectral condition number $\sigma_{\max}/\sigma_{\min} = \kappa(A_{\text{opt}})$ analyzed in Section 4.2; otherwise it exceeds it by the block-encoding overhead $\alpha_{\text{opt}}/\sigma_{\max}$.*

Section 4.2 analyzes κ for the operator A_{opt} built from the Killing form.

3 Quantum Algorithm for Radical Identification

The algorithm rests on the following standard structural fact, which converts the algebraic decomposition problem into a linear-algebraic kernel problem.

Theorem 3.1 (Radical as Killing-orthogonal complement). *Let $\mathfrak{g}$ be a finite dimensional Lie algebra over a field of characteristic zero. The radical $\mathfrak{r} = \text{Rad}(\mathfrak{g})$ is the orthogonal complement of the derived algebra $\mathfrak{g}^{(1)} = [\mathfrak{g}, \mathfrak{g}]$ with respect to the Killing form $\mathcal{K}$,*

$$\mathfrak{r} = ([\mathfrak{g}, \mathfrak{g}])^{\perp_{\mathcal{K}}}. \quad (10)$$

This is a standard consequence of Cartan's criteria [32]. We exploit it to reformulate radical identification as a kernel-finding task; the remainder of this section details the construction of the target operator, the bilinear factorization of the Killing form, and the QSVT-based kernel projection.

3.1 The Radical as an Operator Kernel

The core requirement for an element $x \in \mathfrak{g}$ to be in the radical $\mathfrak{r}$ is that it must be $\mathcal{K}$ -orthogonal to every element y in the derived algebra $[\mathfrak{g}, \mathfrak{g}]$. To translate this into linear algebra, we first characterize the derived algebra as the image of a specific linear operator.

We define the commutator matrix C as a $d \times d^2$ matrix whose columns span the derived algebra. The rows are indexed by k , and the columns are indexed by the pair (i, j) . The entries of C are the structure constants, indexed such that $C_{k,(i,j)} = f_{ijk}$. The image of C , $\text{Im}(C)$, is precisely the vector subspace $[\mathfrak{g}, \mathfrak{g}]$.

The Killing form $\mathcal{K}$ is symmetric and bilinear, and the standard orthogonality for such a form, even over the complex field $\mathbb{C}$, is defined via the transpose, without complex conjugation:

$$x^T K y = 0 \quad \forall y \in \text{Im}(C). \quad (11)$$

Equation 11 makes the vector $x^T K$ orthogonal to all columns of C , so $x^T K C = 0$. Transposing yields $C^T K^T x = 0$, and the symmetry $K^T = K$ of the Killing form reduces this to $C^T K x = 0$. Thus our target operator is $A_{\text{opt}} = C^T K$; the task is to find the kernel of A_{opt} .

3.2 Algorithmic Workflow and Unitary Construction

The algorithm proceeds through the following distinct stages.

Step 1: Input assumptions and pre-processing. The algorithm accepts the structure constants f_{ijk} in any basis, with performance depending on $F, \beta, s_{\text{int}}, s_{\text{adj}}$ (Theorem 4.1). Producing favorable (standardized and balanced) basis from an arbitrary input is generally intractable, it is a rank-3 tensor optimization related to NP-hard problems [31], and standard linear algebra techniques do not guarantee it. The favorable basis assumption is nontrivial but physically realistic in key cases, such as DLAs in the Pauli basis and the Chevalley basis for simple Lie algebras. The f_{ijk} data and the column norms required for Prepare oracles are loaded into QRAM at classical setup cost $O(d^3)$.

Step 2: Quantum unitary construction. The core of the quantum computation builds block encodings of the components of $A_{\text{opt}} = C^T K$.

Killing Form Factorization. A direct construction of the Killing form matrix K is inefficient. To enable efficient quantum block encoding, we employ the bilinear factorization tailored to the expression $K_{ij} = \sum_{k,m} f_{ikm} f_{jmk}$ (Equation 6). This factorization is also central to the optimized classical algorithm.

We define two auxiliary matrices $A, B \in \mathbb{F}^{d^2 \times d}$ (where $\mathbb{F}$ is the underlying field, $\mathbb{R}$ or $\mathbb{C}$). The rows of these matrices are indexed by the pair (k, m) , corresponding to the summation indices in Equation 6. The columns are indexed by a single index i or j . We define the elements of A and B as follows:

$$A_{(k,m),i} := f_{ikm} \quad \text{and} \quad B_{(k,m),j} := f_{jmk}. \quad (12)$$

With these definitions, the Killing form matrix is precisely realized as the product $K = A^T B$. We verify this by examining the (i, j) -th element:

$$(A^T B)_{ij} = \sum_{k,m} (A^T)_{i,(k,m)} B_{(k,m),j} = \sum_{k,m} A_{(k,m),i} B_{(k,m),j}.$$

Substituting the definitions from Equation 12:

$$(A^T B)_{ij} = \sum_{k,m} f_{ikm} f_{jmk} = K_{ij}.$$

The task of block encoding the dense matrix K is reduced to the task of block encoding the potentially sparser matrices A^T and B , and then composing them. The efficiency depends on the sparsity of A and B , captured by s_{int} and s_{adj} , respectively. The saving here is not in

the query count. A standard sparse-access block encoding [23] already reaches its target with a constant number of oracle queries, but its subnormalization is fixed by the sparsity and the entry magnitudes of the matrix it encodes. Block encoding the dense Killing form directly would inflate that subnormalization, so we encode the sparse factors A^T and B instead of K .

Constituent Unitaries and Transpose Implementation The block encodings U_B , U_{A^T} , and U_{C^T} are constructed from QRAM access to the f_{ijk} data. This requires a specific assumption about the capabilities of the QRAM infrastructure.

We assume the QRAM stores both the f_{ijk} values and the pre-computed L_2 norms of the tensor slices required for the B , A^T , and C^T Prepare oracles; this is standard for QRAM models handling multi-dimensional data, and the marginals are computed as part of the $O(d^3)$ classical setup, so Prepare oracles remain $O(\text{polylog } d)$.

Constituent block encodings. The three block encodings U_B , U_{A^T} , U_{C^T} all factor through QRAM as Prepare/Select pairs. For a generic source matrix $M \in \{B, A^T, C^T\}$ with column index c , row index r , and precomputed column L_2 norm α_{M_c} , the Prepare oracle takes the form

$$\text{Prep}_M |c\rangle |0\rangle = \frac{1}{\alpha_{M_c}} \sum_r M_{r,c} |c\rangle |r\rangle,$$

and the Select oracle fetches the matrix entries from QRAM. Three index conventions instantiate the formula above:

$$\begin{aligned} B : c = j, r = (k, m), M_{r,c} &= f_{jmk}; \\ A^T : c = (k, m), r = i, M_{r,c} &= f_{ikm}; \\ C^T : c = k, r = (i, j), M_{r,c} &= f_{ijk}. \end{aligned}$$

Final Operator A_{opt} : The block encodings are composed sequentially to create the unitary $U_{A_{opt}}$ for the target operator $A_{opt} = C^T K = C^T A^T B$. The total normalization factor α_{opt} of the composite operator is bounded by the product of the individual normalization factors: $\alpha_{opt} \leq \alpha_{C^T} \cdot \alpha_{A^T} \cdot \alpha_B$.

Step 3: Quantum Singular Value Estimation (QSVE). The condition number κ of A_{opt} (more precisely, of the normalized operator A_{opt}/α_{opt}) is generally unknown a priori, and the QSVT projection cost is linear in it. A Quantum Singular Value Estimation (QSVE) subroutine is therefore applied to $U_{A_{opt}}$ to fix the QSVT parameters.

QSVE is a phase estimation procedure applied to the singular values encoded within the QSVT routine [23, 11]. It allows for the efficient estimation of the normalized gap δ , thereby providing $\kappa = 1/\delta$. The runtime is $\tilde{O}(1/\delta) = \tilde{O}(\alpha_{opt}/\sigma_{\min}(A_{opt}))$, which matches the final projection cost, so estimating κ does not add a dominant overhead.

The estimate of κ obtained from QSVE is then used to determine the required polynomial degree D and the corresponding phase angles for the final QSVT step.

Step 4: QSVT kernel projection. Using the estimated condition number κ , the QSVT algorithm is applied to the block encoding $U_{A_{opt}}$. The phase angles are classically computed to implement the kernel finding polynomial $P_{ker}(x)$ of degree $D = O(\kappa \log(1/\epsilon))$. The result of this procedure is a unitary circuit that acts as a high fidelity block encoding of the projector $P_{\mathfrak{r}}$ onto the kernel of A_{opt} , which is precisely the radical $\mathfrak{r}$.

3.3 Efficient Block Encoding via Arithmetic Oracles (Pauli Basis)

For the physically ubiquitous case of the Pauli basis, the reliance on QRAM is unnecessary. The structure constants of the Pauli group are not arbitrary data; they are strictly determined

by the symplectic structure of the binary strings representing the operators. We exploit this algorithmic computability to construct the block encodings for B , A^T , and C^T using Arithmetic Oracles, thereby eliminating the $O(d^3)$ data-loading bottleneck.

Algorithmic structure. Let the basis elements B_j correspond to Pauli strings iP_j , indexed by symplectic vectors $v_j = (x_j, z_j) \in \mathbb{F}_2^{2n}$ whose halves $x_j, z_j \in \mathbb{F}_2^n$ record the X - and Z -supports of P_j [27]. The commutator $[B_j, B_k]$ vanishes precisely when the symplectic inner product $\omega(v_j, v_k) = x_j \cdot z_k + z_j \cdot x_k \pmod{2}$ is zero. On the anticommuting branch the bracket lands on a single Pauli B_m with $v_m = v_j \oplus v_k$, and the sign of the resulting structure constant is set by the phase law discussed below.

Oracle construction. We replace the QRAM *Prepare* and *Select* oracles with coherent arithmetic circuits that exploit the isomorphism between the Pauli group and the vector space $\mathbb{F}_2^{2n}$. The indices j, k are represented by $2n$ -bit symplectic vectors.

We implement a coherent oracle O_B that computes structure constants on-the-fly. The oracle first evaluates the symplectic inner product $\omega(v_j, v_k)$ to identify anti-commuting pairs. To determine the sign ± 2 as well as the support, the circuit also evaluates the phase indicator $\phi(v_j, v_k)$ dictated by the Pauli product law $P_j P_k = i^{\phi(j,k)} P_{j+k}$.

The explicit coherent phase logic of Dehaene and De Moor [18] computes $\phi(j, k)$ via a depth- $O(\log n)$ circuit evaluating a $\mathbb{Z}_4$ -valued quadratic form over the symplectic vectors. Transversal logic produces the bitwise terms $x_j \cdot z_k + z_j \cdot x_k$ together with the overlap corrections they require. A binary tree accumulates the resulting mod-4 phase sum. A final controlled rotation writes ± 1 or $\pm i$ into the amplitude. Memory lookup is no longer needed; the $O(d^3)$ QRAM bottleneck disappears and the implicit basis algorithmic regime settles into $\tilde{O}(1)$ setup cost.

The $\tilde{O}(1)$ setup applies strictly to the implicit case, where membership in $\mathfrak{g}$ is decided by a rule. The benchmark $\mathfrak{g} = \mathfrak{su}(2^n)$ and the k -local Hamiltonian families of Section 5.2 both qualify. An explicit list of d Pauli strings still costs $O(d)$ to fix the basis, matched by the classical symplectic algorithm of Section 4.3.

4 Complexity and Performance Analysis

This section derives the algorithm's complexity from the structural parameters $F, s_{adj}, s_{int}, \beta$, traces the dependence of β and κ on algebraic structure, and compares the result against the optimized classical benchmark derived under the same assumptions.

4.1 Quantum Complexity Analysis

We first derive the main quantum complexity result, using the factorization $A_{opt} = C^T A^T B$.

Theorem 4.1 (Quantum Query Complexity). *Given QRAM access to the structure constants of a d -dimensional Lie Algebra $\mathfrak{g}$ in an arbitrary basis, the query complexity to compute a block encoding of the projector onto the radical $\mathfrak{r}$ is*

$$T_Q = \tilde{O}\left(\frac{\alpha_{opt}}{\sigma_{\min}(A_{opt})}\right) = \tilde{O}\left(\frac{\alpha_{opt}}{\sigma_{\max}(A_{opt})} \kappa(A_{opt})\right), \quad \alpha_{opt} = O\left(F^3 \sqrt{\beta} s_{adj}^{3/2} \sqrt{s_{int}}\right). \quad (13)$$

When the constituent block encodings are tight, so that $\alpha_{opt} = \Theta(\sigma_{\max}(A_{opt}))$ as in the Pauli frame, this reduces to $T_Q = \tilde{O}(\kappa(A_{opt}))$; for compact algebras the target is $A'_{opt} = K$ and $T_Q = \tilde{O}(\kappa(K|_{\mathfrak{s}}))$.

The proof rests on bounding the normalization factor α_{opt} of the composite block encoding $U_{A_{opt}}$. The constituent factors satisfy $\alpha_B = O(F\sqrt{s_{adj}})$, $\alpha_{A^T} = O(F\sqrt{s_{adj} s_{int}})$, and $\alpha_{C^T} =$

$O(F\sqrt{\beta s_{adj}})$; full derivations are given in Appendix A, where the sparse-access form of α_{AT} (row and column sparsities s_{adj} and s_{int}) replaces the column-norm-only estimate. Combining these factors yields the generalized bound for α_{opt} :

$$\alpha_{opt} \leq \alpha_{CT} \cdot \alpha_{AT} \cdot \alpha_B = O(F\sqrt{\beta \cdot s_{adj}}) \cdot O(F\sqrt{s_{adj} \cdot s_{int}}) \cdot O(F\sqrt{s_{adj}}) = O(F^3 \cdot \sqrt{\beta} \cdot s_{adj}^{3/2} \sqrt{s_{int}}). \quad (14)$$

The total quantum query complexity is dominated by the QSVE subroutine (Section 3.2) and the final QSVT projection step, both of which resolve the smallest nonzero singular value of A_{opt} . In the normalized operator A_{opt}/α_{opt} that gap equals $\sigma_{\min}(A_{opt})/\alpha_{opt}$, so the QSVT polynomial degree, and with it the query count, is set by its reciprocal [23]:

$$T_Q = O\left(\frac{\alpha_{opt}}{\sigma_{\min}(A_{opt})} \cdot \log(1/\epsilon) \cdot \text{poly}(\log d)\right).$$

Because every block encoding obeys $\alpha_{opt} \geq \sigma_{\max}(A_{opt})$, this equals $O((\alpha_{opt}/\sigma_{\max}) \kappa(A_{opt}) \log(1/\epsilon) \text{poly}(\log d))$ with the spectral condition number $\kappa(A_{opt}) = \sigma_{\max}/\sigma_{\min}$; a looser estimate of the form $\alpha_{opt} \cdot \kappa(A_{opt})$ over-counts by the factor $\sigma_{\max}$ and is not used. In the Pauli frame the constituent encodings are tight, so $\alpha_{opt}/\sigma_{\max} = \Theta(1)$, the runtime gap $1/\delta$ coincides with $\kappa(A_{opt})$, and the bound recovers $T_Q = \tilde{O}(\kappa(A_{opt}))$ as stated in Theorem 4.1. The $\tilde{O}$ notation absorbs $\log(1/\epsilon)$ and $\text{poly}(\log d)$.

Optimization for compact algebras. For the specific but physically dominant case of Compact DLAs ($\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$), identifying the radical is equivalent to identifying the kernel of the Killing form itself: $x \in \mathfrak{z} \iff x \in \ker(K)$.

Corollary 4.2 (Optimized Complexity for Compact Algebras). *For a compact Lie algebra, the target operator becomes $A'_{opt} = K = A^T B$. The substitution removes the C^T block encoding and with it the dependency on the balance parameter β . It also reduces the scaling with respect to the magnitude F from cubic (F^3) to quadratic (F^2), since $\alpha_{CT} \propto F$ is removed; the new normalization factor is $\alpha'_{opt} \leq \alpha_{AT} \cdot \alpha_B = O(F^2 s_{adj} \sqrt{s_{int}})$. A further gain is spectral. With $A'_{opt} = K$ the runtime conditioning drops to $\kappa(K|_{\mathfrak{s}})$ from the $\kappa(K|_{\mathfrak{s}})^{3/2}$ of $C^T K$, since the cube in $G = -K^3$ no longer enters (Lemma C.1). Because $A'_{opt} = K$ is tight in the Pauli frame ($\alpha'_{opt} = \Theta(\sigma_{\max}(K))$), the projection cost there is $T_Q = \tilde{O}(\kappa(K|_{\mathfrak{s}}))$.*

Remark 4.3 (End-to-End Latency and State Preparation). *The speedups derived in this work apply strictly to the algebraic structural analysis (T_Q). The end-to-end simulation time is lower-bounded by the state preparation cost T_{prep} for the Hamiltonian vector $|H\rangle$. For dense Hamiltonians where $T_{prep} \approx O(d)$, the total runtime scales as $O(d)$. In the Pauli rows of Table 2, if T_{prep} dominates, the quantum runtime matches the classical symplectic benchmark $\tilde{O}(d)$ and the algebraic advantage is absorbed by state preparation. In the well-conditioned QRAM row, where the classical barrier is $O(d^3)$, the quantum scaling of $O(d)$ leaves a cubic speedup regardless of linear state preparation costs.*

4.2 Structural Dependencies: Balance and Conditioning in the Pauli Basis

The quantum complexity is linear in the balance β and the condition number κ . The Pauli basis already gives $F = O(1)$ and $s_{int} = O(1)$, but it does not by itself force arbitrary Pauli-spanned DLAs to be balanced ($\beta = O(1)$) or well-conditioned ($\kappa = O(1)$). We trace both parameters to the global structure of the DLA below. Table 1 lists the four runtime parameters and the two conditioning factors, and what fixes each.

This analysis focuses on real compact DLAs, where $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$ and $r := \dim(\mathfrak{s})$. The input basis for $\mathfrak{g}$ is assumed to be a subset of the standard Skew-Hermitian Pauli operators, i.e. $\mathfrak{g}$ is Pauli-spanned. The restriction buys two facts the analysis below leans on: the structure constants f_{ijk} are real, and the deterministic Pauli product law of Section 4.2.2 applies.

Table 1: The four runtime parameters $(F, s_{adj}, s_{int}, \beta)$ and the two factors of the conditioning, with the algebra feature that sets each. The runtime is linear in β and κ (Theorem 4.1); the last row gives $\kappa(A_{opt})$ on any invariant-orthonormal frame adapted to $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$.

Symbol	Set by, and role in κ
F	$O(1)$ in the Pauli basis; not a factor of κ
s_{adj}	$O(d)$ generically; not a factor of κ
s_{int}	$O(1)$ in the Pauli basis; not a factor of κ
β	sets $\kappa(D _{\mathfrak{s}}) = \sqrt{\max_k N_k / \min_k N_k}$
$\kappa(K _{\mathfrak{s}})$	block-scalar ratio $\max_l N_l / \min_l N_l$
$\kappa(A_{opt})$	$\kappa(K _{\mathfrak{s}})^{3/2}$, or $\kappa(K _{\mathfrak{s}})$ with $A'_{opt} = K$

4.2.1 Analysis of Balance β

The balance parameter β measures the uniformity of the structure constant distribution across the basis. We demonstrate that imbalance can arise structurally if the DLA is dominated by its center.

Theorem 4.4 (Structural Dependence of β). *For a compact DLA $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$ with $\dim(\mathfrak{s}) = r$ and $\dim(\mathfrak{g}) = d$, the balance parameter β satisfies:*

$$\beta = \beta_{\mathfrak{s}} \cdot \frac{d}{r}, \quad (15)$$

where $\beta_{\mathfrak{s}}$ is the intrinsic balance of the semisimple part $\mathfrak{s}$ (calculated using the norms N_k restricted to $k \in \mathfrak{s}$ and the average norm $\bar{N}_{\mathfrak{s}}$ within $\mathfrak{s}$).

Proof sketch. The derived algebra $[\mathfrak{g}, \mathfrak{g}] = \mathfrak{s}$ implies $f_{ijk} = 0$ whenever $B_k \in \mathfrak{z}$, so the total squared norm $S = \sum_k N_k$ concentrates on $\mathfrak{s}$. Comparing the average norm $\bar{N} = S/d$ over $\mathfrak{g}$ to $\bar{N}_{\mathfrak{s}} = S/r$ over $\mathfrak{s}$ yields $\beta = \beta_{\mathfrak{s}} \cdot d/r$. The full proof is in Appendix B. $\square$

Implications for β Scaling. Imbalance ($\beta \gg 1$) enters through either factor: an intrinsically unbalanced semisimple core ($\beta_{\mathfrak{s}} \gg 1$), or center domination, a small interacting core with $r \ll d$ driving $d/r \gg 1$.

Example 4.5 (Structural Imbalance $O(d)$ in the Pauli Basis). *Consider the compact DLA $\mathfrak{g} = \mathfrak{su}(2) \oplus \mathfrak{u}(1)^{\oplus m}$. This algebra can be represented entirely within the Pauli basis. Here, $\mathfrak{s} = \mathfrak{su}(2)$ and $\mathfrak{z} = \mathfrak{u}(1)^{\oplus m}$. The dimensions are $r = 3$ and $d = 3 + m$. The semisimple part $\mathfrak{su}(2)$ is intrinsically balanced in the Pauli basis ($\beta_{\mathfrak{s}} = 1$).*

Applying Theorem 4.4:

$$\beta = 1 \cdot \frac{3 + m}{3}.$$

If the number of central elements is proportional to the total dimension, $m = O(d)$, then $\beta = O(d)$. This scenario corresponds to a system with a small interacting core and a large number of conserved quantities.

4.2.2 Analysis of Conditioning κ

We turn to the condition number κ of $A_{opt} = C^T K$. One law fixes it before any choice of basis. Whenever the generators are orthonormal for an invariant inner product and adapted to the splitting $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$, total antisymmetry of the structure constants forces $CC^T = -K$, and hence

$$\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}.$$

Lemma C.1 of Appendix C proves this with no appeal to the Pauli product law or to Schur–Weyl, and Theorem 4.6 below reads the right-hand side off the dimensions of the simple ideals.

The Pauli basis is one such invariant-orthonormal frame, and there the identity is concrete and computable: CC^T is equal to $-K$ and diagonal as well, which is what lets us write κ in closed form.

That Pauli specialization is made explicit in Appendix B, where diagonality of CC^T (Lemma B.1) puts the condition number in the closed form of Theorem B.2. The reduction's consequence for the dimensions of the simple ideals is the following.

Theorem 4.6 (General dimensional obstruction). *Let $\mathfrak{g}$ be a compact DLA with Levi decomposition $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$ and semisimple part $\mathfrak{s} = \bigoplus_l \mathfrak{s}_l$ a sum of simple ideals of dimension d_l , and let $\{B_k\}$ be orthonormal for an invariant inner product and adapted to the refined splitting $\mathfrak{g} = \bigoplus_l \mathfrak{s}_l \oplus \mathfrak{z}$. Let $h_l^\vee$ be the dual Coxeter number of the Cartan type of $\mathfrak{s}_l$ and ν_l the squared basic-length shared by its generators. Then the Killing form is block-scalar,*

$$K|_{\mathfrak{s}_l} = -N_l I_{d_l}, \quad N_l = 2h_l^\vee \nu_l,$$

and the conditioning of $A_{opt} = C^T K$ is

$$\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2} = \left(\frac{\max_l N_l}{\min_l N_l} \right)^{3/2}.$$

The exponent $3/2$ is fixed by the reduction alone, the same for every combination of simple types and every invariant-orthonormal frame adapted to the refined splitting. What moves with the type and the normalization is the law tying N_l to d_l .

Proof. Appendix C supplies the three statements for the proof. Lemma C.1 turns invariance of the inner product into total antisymmetry of the structure constants, hence $CC^T = -K$ and $\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}$. Corollary C.2 uses simplicity of each $\mathfrak{s}_l$ to collapse $K|_{\mathfrak{s}_l}$ to a single scalar $-N_l$, so $\kappa(K|_{\mathfrak{s}}) = \max_l N_l / \min_l N_l$. Proposition C.4 reads that scalar off the type, $N_l = 2h_l^\vee \nu_l$, the adjoint Casimir in the chosen normalization. Composing the three statements gives the claim. $\square$

The normalizations that recur through the paper now fall out as corollaries, set apart only by how each frame presents its generators; nothing internal to $\mathfrak{g}$ distinguishes them.

Corollary 4.7 (Pauli frame, type-A family). *Suppose each $\mathfrak{s}_l$ is Pauli-spanned and isomorphic to $\mathfrak{su}(2^{n_l})$, so its symplectic indices fill a $2n_l$ -dimensional non-degenerate symplectic subspace of $\mathbb{F}_2^{2n}$ and $d_l = 4^{n_l} - 1$. In the Pauli basis*

$$N_k = 2(d_l + 1) \text{ for } k \in \mathfrak{s}_l, \quad K|_{\mathfrak{s}_l} = -2(d_l + 1) I_{d_l},$$

and the two conditioning factors are

$$\kappa(D|_{\mathfrak{s}}) = \sqrt{\frac{d_{\max}+1}{d_{\min}+1}} = \Theta(\sqrt{d_{\max}/d_{\min}}), \quad \kappa(A_{opt}) = \left(\frac{d_{\max}+1}{d_{\min}+1} \right)^{3/2} = \Theta((d_{\max}/d_{\min})^{3/2}).$$

So $\kappa(A_{opt}) = O(1)$ forces every simple summand to share one dimension up to a constant, and the saturating case $d_{\min} = O(1)$, $d_{\max} = \Theta(d)$, realized by $\mathfrak{s} = \mathfrak{su}(2) \oplus \mathfrak{su}(2^k)$, attains the Pauli ceiling $\kappa(A_{opt}) = \Theta(d^{3/2})$.

Proof. The type is $A_{2^{n_l}-1}$, whose dual Coxeter number is $h_l^\vee = 2^{n_l}$ (Table 3). The skew-Hermitian Pauli generators are the full-rank, unit-operator-norm frame of Remark C.5, with squared basic-length $\nu_l = 2^{n_l} = \sqrt{d_l+1}$, so Proposition C.4 gives $N_l = 2h_l^\vee \nu_l = 2 \cdot 4^{n_l} = 2(d_l+1)$; the direct count of anti-commuting Pauli pairs over $\mathbb{F}_2^{2n_l}$ in Appendix B reaches the same constant. The conditioning then follows from Theorem 4.6. In the Pauli basis $CC^T = D^2 = -K$, so $\kappa(D|_{\mathfrak{s}}) = \kappa(K|_{\mathfrak{s}})^{1/2}$ is the square root of the same ratio. $\square$

Remark 4.8 (Isotypic decompositions and scope). *Continuous symmetries of type $SU(2)$ or $U(1)$ induce an isotypic decomposition of the symmetric subalgebra into simple ideals indexed by irreducible-representation labels; for an n -qubit $SU(2)$ -symmetric system the spin- J multiplicities range from $m_{n/2} = 1$ at the highest spin to $\Theta(2^n/\sqrt{n})$ near $J \approx 0$, so the summand dimensions $d_l = m_J^2 - 1$ span a window of order $\Theta(d)$. The Pauli count of Corollary 4.7 does not reach this case as it stands, since m_J is generally not a power of two and the symplectic count behind it has no immediate analogue. Theorem 4.9 below fixes the isotypic conditioning through the invariant dictionary.*

Feeding the Schur–Weyl multiplicities of an $SU(2)$ -symmetric algebra into the same dictionary gives the following worked instance; a bounded normalization instead lowers the exponent to three quarters across any type- A semisimple part, recorded as Corollary C.6 in Appendix C.

Theorem 4.9 (Isotypic obstruction under $SU(2)$ symmetry). *Let $\mathfrak{g} \subseteq \mathfrak{su}(2^n)^{SU(2)}$ be a compact DLA commuting with a global $SU(2)$ action. Schur–Weyl duality decomposes the Hilbert space as $(\mathbb{C}^2)^{\otimes n} = \bigoplus_J V_J \otimes M_J$, with $\dim V_J = 2J + 1$ and multiplicity*

$$m_J = \dim M_J = \binom{n}{n/2 - J} - \binom{n}{n/2 - J - 1}.$$

The symmetric subalgebra is $\mathfrak{su}(2^n)^{SU(2)} \cong \bigoplus_J \mathfrak{u}(m_J)$. Its semisimple part is $\mathfrak{s} = \bigoplus_{J: m_J \geq 2} \mathfrak{su}(m_J)$, the J -th ideal acting as $I_{V_J} \otimes \mathfrak{su}(m_J)$ on the factor $V_J \otimes M_J$, and its center $\mathfrak{z} = \bigoplus_J \mathfrak{u}(1)$ carries the sector projectors. Each ideal is simple of Cartan type A_{m_J-1} with dual Coxeter number $h^\vee = m_J$ and dimension $d_J = m_J^2 - 1$. For a basis orthonormal under an invariant inner product and adapted to the refined splitting $\mathfrak{g} = \bigoplus_J \mathfrak{su}(m_J) \oplus \mathfrak{z}$, Proposition C.4 fixes the block scalar of Corollary C.2 at

$$N_J = 2m_J \nu_J, \quad \nu_J = \text{tr}_{M_J}(\lambda_k^2),$$

the trace of the squared generator on the multiplicity space. The conditioning of $A_{\text{opt}} = C^T K$ is therefore

$$\kappa(A_{\text{opt}}) = \left(\frac{\max_J m_J \nu_J}{\min_J m_J \nu_J} \right)^{3/2}. \quad (16)$$

Appendix C carries the proof.

Two frames bracket the exponent. A full-rank frame of unit operator norm gives $\nu_J = m_J$ and the $3/2$ power, while the Hilbert–Schmidt frame gives $\nu_J = 2$ and the three-quarters power. The split between $3/2$ and $3/4$ records in N_J ; neither power is privileged. The Hilbert–Schmidt frame here is the $SU(2)$ instance of Corollary C.6.

4.2.3 Bounds on $\kappa(D|_{\mathfrak{s}})$ and $\kappa(K|_{\mathfrak{s}})$

In the Pauli frame the reduction of Appendix B makes the conditioning concrete. It is fixed by the Killing form K together with the norm distribution matrix D on the semisimple part $\mathfrak{s}$, and bounded by the product of the factor condition numbers:

$$\kappa(A_{\text{opt}}) \leq \kappa(K|_{\mathfrak{s}}) \kappa(D|_{\mathfrak{s}}). \quad (17)$$

Bounds on $\kappa(D|_{\mathfrak{s}})$. The condition number of D restricted to $\mathfrak{s}$ is related to the intrinsic balance $\beta_{\mathfrak{s}}$.

$$\kappa(D|_{\mathfrak{s}}) = \sqrt{\frac{\max_{k \in \mathfrak{s}} N_k}{\min_{k \in \mathfrak{s}} N_k}}.$$

If the semisimple core is balanced ($\beta_{\mathfrak{s}} = O(1)$), then $\kappa(D|_{\mathfrak{s}}) = O(1)$. A naive worst case admits $N_{\max} = O(d^2)$ and $N_{\min} = O(1)$, which bounds $\kappa(D|_{\mathfrak{s}})$ only by $O(d)$. The Pauli regime is

tighter. At fixed i and k the Pauli product law admits at most one j with $B_i B_j \propto B_k$, so $N_k = \sum_{i,j} f_{ijk}^2 \leq d \cdot 4 = 4d$. Each $B_k \in \mathfrak{s}$ receives a non-zero contribution from at least one pair, so $N_k \geq 4$ on $\mathfrak{s}$. Combining the two bounds yields

$$\kappa(D|_{\mathfrak{s}}) \leq \sqrt{\frac{4d}{4}} = O(\sqrt{d}) \quad \text{for any Pauli-spanned } \mathfrak{g}.$$

The generic $O(d)$ envelope is therefore not saturable inside the Pauli regime. This $O(\sqrt{d})$ tightening is itself sharp: Corollary 4.7 attains it on the family $\mathfrak{s} = \mathfrak{su}(2) \oplus \mathfrak{su}(2^k)$.

Bounds on $\kappa(K|_{\mathfrak{s}})$. For simple $\mathfrak{s}$, Schur’s Lemma forces $K \propto \text{Trace form}$; in the Pauli basis (Trace-form orthonormal) this gives $K|_{\mathfrak{s}} \propto I$ and $\kappa(K|_{\mathfrak{s}}) = O(1)$. The general Pauli-spanned case is tighter than continuous bases.

Theorem 4.10 (Polynomial Conditioning of Integer Lie Algebras). *Let $\mathfrak{g}$ be a Lie algebra spanned by a subset of the Skew-Hermitian Pauli basis. The Killing form K is an integer matrix with a strictly diagonal structure, and its condition number, taken over the nonzero spectrum, satisfies $\kappa(K|_{\mathfrak{s}}) \leq d$; exponential ill-conditioning is therefore mathematically excluded.*

Proof. The structure constants in the Pauli basis are integers, $f_{ijk} \in \{0, \pm 2\}$. The matrix entries of the Killing form are $K_{ij} = \sum_{k,m} f_{ikm} f_{jmk}$. Due to the property that the product of two Pauli operators is proportional to a unique third Pauli, $P_i P_k \propto P_m$, it follows that $K_{ij} = 0$ for $i \neq j$. The matrix K is strictly diagonal. The diagonal entries are given by $K_{ii} = -\sum_{k,m} (f_{ikm})^2$. Since f_{ikm} are integers, K_{ii} must be an integer multiple of 4. Specifically, for any index i in the semisimple component (where $K_{ii} \neq 0$), we have $|K_{ii}| \geq 4$. This integer spectral gap is critical. Unlike continuous bases where eigenvalues can approach zero arbitrarily closely, the discreteness of the Pauli group enforces a lower bound on the non-zero singular values. For each fixed i at most d structure constants f_{ikm} are nonzero (one m per anticommuting k), each of magnitude 2, so $\max_i |K_{ii}| \leq 4d$. The condition number is thus strictly bounded:

$$\kappa(K|_{\mathfrak{s}}) = \frac{\sigma_{\max}}{\sigma_{\min}} \leq \frac{4d}{4} = d.$$

Combined with $\kappa(D|_{\mathfrak{s}}) \leq O(\sqrt{d})$ and Theorem 4.6, this gives $\kappa(A_{\text{opt}}) \leq O(d^{3/2})$ in the Pauli regime. $\square$

4.2.4 The Optimal Case: Well-Conditioning of $\mathfrak{su}(2^n)$

We now prove that $\mathfrak{su}(2^n)$ is well-conditioned in the Pauli basis.

Theorem 4.11 (Well-Conditioning of $\mathfrak{su}(2^n)$ in the Pauli Basis). *Let $\mathfrak{g} = \mathfrak{su}(2^n)$ be represented in the standard Skew-Hermitian Pauli basis. The operator $A_{\text{opt}} = C^T K$ is well-conditioned, i.e., its condition number $\kappa = O(1)$.*

Proof Sketch. The algebra $\mathfrak{g} = \mathfrak{su}(2^n)$ is simple, so the Killing form is proportional to the Trace form, and the Pauli basis is orthonormal under the Trace form, i.e., $K \propto I$. The squared norms $N_k = \sum_{i,j} |f_{ijk}|^2$ are independent of k by the uniform Clifford group structure of the Pauli basis [27, 4], so $D = \sqrt{N} I$. Both factors are scalar, thus $\kappa(A_{\text{opt}}) = \kappa(DK) = O(1)$ via Theorem B.2. Full proof in Appendix B. $\square$

4.3 Structure-Aware Classical Benchmark

To set the baseline for the quantum advantage, we derive the optimized classical complexity using the same structural parameters s_{adj} and s_{int} that the quantum algorithm exploits. This substantiates the benchmark introduced in Section 1.2. To our knowledge no published classical

algorithm computes the radical faster. The benchmark we derive is a deliberately conservative optimization of the standard de Graaf route [17, 28], so the quantum advantage is set against a classical opponent stronger than off-the-shelf practice.

Theorem 4.12 (Structure-Aware Classical Benchmark). *The complexity of the optimized classical algorithm for computing the radical of a d -dimensional Lie algebra, parameterized by Adjoint Sparsity s_{adj} and Interaction Sparsity s_{int} , assuming access to efficient sparse data structures, is:*

$$T_{C-Opt} = O(d \cdot s_{adj} \cdot s_{int} + d^3). \quad (18)$$

Proof sketch. A four-step analysis tracks (1) Construction of Compressed Sparse Row (CSR) and Compressed Sparse Column (CSC) formats [26] for the structure-constant data, yielding $O(d \cdot s_{adj})$, (2) Computing sparse $K = A^T B$ via SpMM, where the column sparsities of A^T and B are s_{int} and s_{adj} respectively, yielding $O(d \cdot s_{adj} \cdot s_{int})$ for the Killing form, (3) Gaussian elimination to extract a basis of $[\mathfrak{g}, \mathfrak{g}]$, dominated in worst case by the $O(d^3)$ dense bound without low fill-in guarantees, and (4) With M the matrix whose columns form the derived algebra basis from (3), solving the kernel of $M^T K$, again $O(d^3)$ in the worst case. The full derivation is given in Appendix D. $\square$

The Symplectic Classical Limit ($\tilde{O}(d)$ Benchmark). The Pauli basis is an exception to the cubic benchmark. Each basis element B_i has a $2n$ -bit symplectic index $v_i \in \mathbb{F}_2^{2n}$, and the center reduces to the symplectic radical $V \cap V^{\perp_\omega}$ of the subspace $V := \text{span}\{v_1, \dots, v_d\}$, i.e., a basis element lies in $\mathfrak{z}$ exactly when its index is symplectic-orthogonal to every v_j . Gaussian elimination on the $d \times 2n$ index matrix isolates this radical in $O(d \cdot n)$ word operations under bit-packing, equivalently $O(d \cdot n^2)$ bit operations; both absorb into $\tilde{O}(d)$ since $n = O(\log d)$. The Pauli-basis classical benchmark is therefore $T_{C-Symp} = \tilde{O}(d)$. On the implicit Pauli case of Section 3.3 the algebraic projector costs only $T_Q = \tilde{O}(1)$ queries, but the dense state-preparation cost $\tilde{O}(d)$ matches this benchmark (Remark 4.3).

4.4 Performance Summary

The data-access model (Pauli arithmetic oracles versus QRAM) and the spectral conditioning of the algebra are the two axes of the performance picture. The Pauli regime obeys the rigidity ceiling proved in Theorem 4.10 and Corollary 4.7. The QRAM regime admits no such ceiling; Theorem 5.5 forces $\kappa \rightarrow \infty$ at criticality, and the tabulated entry $\kappa(A_{opt}) = O(d)$ marks an operating point at finite distance from critical λ_c .

Worst-case row: operator convention and a conservative bound. The tabulated value depends on which operator is block-encoded. The general $A_{opt} = C^T K$ carries conditioning $\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2} = O(d^{3/2})$ (Lemma C.1); its Pauli block encoding is tight, so Theorem 4.1 gives $T_Q = \tilde{O}(\kappa) = \tilde{O}(d^{3/2})$, the value tabulated. The compact optimization $A'_{opt} = K$ of Corollary 4.2 has the smaller $\kappa(A'_{opt}) = \kappa(K|_{\mathfrak{s}}) = O(d)$, tightening the row to $\tilde{O}(d)$. Both conventions stay at or above the $\tilde{O}(d)$ symplectic benchmark, so the no-advantage verdict holds either way. A direct computation on $\mathfrak{s} = \mathfrak{su}(2) \oplus \mathfrak{su}(2^k)$ fixes the conditioning: there $\kappa(K|_{\mathfrak{s}}) = 4^{k-1} = \Theta(d)$ while $\kappa(C^T K) = 4^{3(k-1)/2} = \Theta(d^{3/2})$, in agreement with $\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}$.

Gell-Mann basis of $\mathfrak{su}(N)$ (intermediate row). The generalised Gell-Mann basis for $\mathfrak{su}(N)$ ($d = N^2 - 1$) hits the intermediate parameter set $s_{adj} = O(d)$, $s_{int} = \Theta(\sqrt{d})$, $\beta = O(1)$, $\kappa = O(1)$, giving $T_Q = \tilde{O}(d^{0.75})$ via the compactness optimization. Against the $O(d^{2.5})$ structure-aware classical benchmark this is an amortised $O(d^{1.75})$ speedup, sitting between the well-conditioned Pauli row ($\tilde{O}(1)$) and the well-conditioned QRAM row ($\tilde{O}(d)$). The full parameter derivation, including the tight $\Theta(\sqrt{d})$ bound on s_{int} via the A_{N-1} root system and the Cartan-matrix conditioning argument, is in Appendix E.

Table 2: Performance summary, derived from Theorems 4.1, 4.12, 4.10, 5.5, 4.11, E.1, Corollary 4.7, and Corollary 4.2. Standardized basis $F = O(1)$ and $s_{adj} = O(d)$ throughout. The Operator column records the block-encoded operator that sets each κ : the general $A_{opt} = C^T K$ or the compact optimization $A'_{opt} = K$ of Corollary 4.2; the worst-case row is tabulated for $C^T K$ as a conservative bound (see below). The Speedup column reports the asymptotic per-call advantage ratio, the Classical baseline column divided by the adjacent Quantum T_Q column; “None” marks the rows where T_Q matches the benchmark. For the QRAM rows the one-time $O(d^3)$, the classical Gauss-elimination kernel step matched by the quantum QRAM setup, is amortized over the $M \geq 2$ shared Hamiltonians and excluded from the per-call Classical baseline column, which quotes the structure-dependent term $d s_{adj} s_{int}$. The Quantum T_Q column reports the corrected query cost $\tilde{O}(\alpha_{opt}/\sigma_{\min})$, tight to $\tilde{O}(\kappa)$ in the Pauli frame; rows 3–5 carry conservative upper bounds under this law. [†]The well-conditioned Pauli projector costs $\tilde{O}(1)$ queries, but the dense state preparation $T_{prep} = \tilde{O}(d)$ then matches the symplectic benchmark and absorbs the advantage (Remark 4.3). [‡]The worst-case Pauli row already exceeds the $\tilde{O}(d)$ symplectic benchmark under both operator conventions, $\tilde{O}(d^{3/2})$ for $C^T K$ and $\tilde{O}(d)$ for the compact K , so it gives no advantage either way.

Basis and conditioning	s_{int}	κ	Operator	Setup	Quantum T_Q	Classical baseline	Speedup
Pauli, well-conditioned	$O(1)$	$O(1)$	K	$\tilde{O}(1)$	$\tilde{O}(1)$	$\tilde{O}(d)$	None [†]
Pauli, worst-case (pushes $\kappa(K _s)$ to its $O(d)$ ceiling)	$O(1)$	$O(d^{3/2})$	$C^T K$	$\tilde{O}(1)$	$\tilde{O}(d^{3/2})$	$\tilde{O}(d)$	None [‡]
Gell-Mann basis of $\mathfrak{su}(N)$, well-conditioned	$\Theta(\sqrt{d})$	$O(1)$	K	$O(d^3)$	$\tilde{O}(d^{0.75})$	$O(d^{2.5})$	$\tilde{O}(d^{1.75})$
Generic dense, well-conditioned (QRAM)	$O(d)$	$O(1)$	K	$O(d^3)$	$\tilde{O}(d)$	$O(d^3)$	$\tilde{O}(d^2)$
Continuous symmetry-adapted near λ_c (tabulated at $\kappa = O(d)$)	$O(d)$	$O(d)$	K	$O(d^3)$	$\tilde{O}(d^2)$	$O(d^3)$	$\tilde{O}(d)$

Symmetry-adapted continuous effective models (near-critical QRAM row). Effective Hamiltonians in a symmetry-adapted basis make κ grow polynomially with the proximity to a quantum phase transition, and Theorem 5.5 forces $\kappa \rightarrow \infty$ at the critical parameter λ_c (Section 5.4). Here κ carries no theorem given upper bound, and the user controls it by working at a finite distance from λ_c . The runtime is governed by the conditioning of the compact operator K : under the corrected cost law $T_Q = \tilde{O}(\alpha'_{opt}/\sigma_{\min})$, the tabulated entry $\tilde{O}(d^2)$ is a conservative bound at the operating point $\kappa = O(d)$, where the algorithm gives a linear speedup over the $O(d^3)$ generic classical benchmark. The speedup degrades smoothly as the operating window tightens around λ_c , and disappears once κ reaches $O(d^2)$.

5 Physical Implications and Typicality of Complexity Parameters

We now analyze the typical behavior of the balance β and the condition number κ for DLAs generated by physically realistic Hamiltonians, characterized by k -locality and potential symmetries. This analysis clarifies which performance classes are prevalent in practice. We assume the DLA is represented in the Pauli basis ($F = O(1)$, $s_{int} = O(1)$).

5.1 Typicality under Physical Constraints

What follows covers balance typicality across the table and conditioning typicality on the QRAM regime.

Typicality of Balance (β). For DLAs generated by generic physical Hamiltonians with d exponential in the qubit count n , the balance parameter β is typically $O(1)$. The argument splits along $\beta = \beta_s \cdot (d/r)$ (Theorem 4.4). A large structural ratio d/r requires center domination, $r \ll d$; in physical systems the number of fundamental symmetries (particle number, total magnetisation, etc.) is at most polynomial in n , so $d - r = O(\text{poly}(n))$ and

$d/r = 1 + O(\text{poly}(n)/\exp(n)) \rightarrow 1$. The intrinsic factor $\beta_{\mathfrak{s}} = O(1)$ follows from the structure of the semisimple core. Within each simple ideal the Weyl group acts transitively on roots of a common length, so the squared norms N_k are uniform up to a bounded root-length ratio, giving $\beta_{\mathfrak{s}} = 1$ exactly for $\mathfrak{su}(2^n)$ and the free-fermion $\mathfrak{so}(2n)$ in the Pauli basis and $\beta_{\mathfrak{s}} = O(1)$ for the generalised Gell-Mann basis of $\mathfrak{su}(N)$ (Appendix E). For a semisimple sum the squared norm N_k is constant on each simple ideal, so $\beta_{\mathfrak{s}}$ stays $O(1)$ whenever the simple factors have comparable rank; even the saturating $\mathfrak{s} = \mathfrak{su}(2) \oplus \mathfrak{su}(2^k)$, where $\kappa(K|_{\mathfrak{s}}) = 4^{k-1} = \Theta(d)$ diverges, keeps $\beta_{\mathfrak{s}} = O(1)$ because the large block sets the average. Imbalance therefore enters only through the structural ratio d/r , that is, through center domination.

Center-dominated DLAs ($\beta = O(d)$) require extensive symmetries with $\dim(\mathfrak{z}) = O(d)$. This is atypical for natural systems but can occur in engineered settings, specific integrable models, or systems with large Decoherence-Free Subspaces.

5.2 Analysis of Specific Physical Models

The Heisenberg and Hubbard Hamiltonians are sums of Pauli strings, but the DLA they generate depends on how the generators are grouped. Treating each Pauli string in the Hamiltonian as an independent generator yields a single-Pauli-spanned DLA that for generic chain lengths equals $\mathfrak{su}(2^n)$ itself, landing the model in the well-conditioned Pauli row of Table 2 via Theorem 4.11. Treating the symmetric coupling operators $\vec{\sigma}_i \cdot \vec{\sigma}_{i+1}$ as generators instead yields the $SU(2)$ -symmetric subalgebra, whose simple summands $\mathfrak{su}(m_J)$ act on multiplicity spaces rather than as Pauli-string subalgebras of $\mathfrak{su}(2^n)$; the integer rigidity of Theorem 4.10 and the Pauli count of Corollary 4.7 do not apply directly, but the isotypic conditioning is fixed instead by Theorem 4.9. The worst-case fallback for the symmetric realization is the Pauli worst-case row of Table 2. For these families the structural computation applies directly and stays well-conditioned in the Pauli regime, yet the end-to-end cost is still absorbed by the $\tilde{O}(d)$ dense state preparation unless a QRAM setup is amortized across many Hamiltonians, exactly as for $\mathfrak{su}(2^n)$.

5.3 Conditioning across compact types: free fermions and symmetry classes

The models above all present a type- A algebra, either $\mathfrak{su}(2^n)$ or a Schur–Weyl sum of $\mathfrak{su}(m_J)$ blocks. Theorem 4.6 holds for every compact simple type, and free-fermion Hamiltonians put types B , C , and D to work.

A quadratic Majorana Hamiltonian on $2n$ modes generates $\mathfrak{so}(2n)$, the dynamical Lie algebra of matchgate and fermionic-linear-optics circuits [35, 52]. An unpaired Majorana mode raises the count to $2n+1$ and gives $\mathfrak{so}(2n+1)$ of type B . Under Jordan–Wigner the Majorana bilinears are Pauli strings, so the integer bound of Theorem 4.10 still holds and the setup cost stays $\tilde{O}(1)$. What moves is the type. A single simple $\mathfrak{so}$ ideal has $K \propto I$, hence $\kappa(A_{\text{opt}}) = O(1)$ and the model sits in the well-conditioned Pauli regime, yet its block scalar reads off the type- D value $h^\vee = 2n - 2$, which the type- A count of Corollary 4.7 does not cover. The conditioning depends on the block scalars $N_l = 2h_l^\vee \nu_l$ alone, and any trace-isometric fermion-to-qubit map scales every ν_l by one common factor, so κ is identical in the Jordan–Wigner and Bravyi–Kitaev frames [50] and only the string-weight prefactors β , s_{int} , and F differ.

The Altland–Zirnbauer classification supplies the same types from one physical family [3, 36]. The Bogoliubov–de Gennes Hamiltonians of the three Cartan classes close into one Lie algebra each: class A into $\mathfrak{u}(n) = \mathfrak{su}(n) \oplus \mathfrak{u}(1)$, the $\mathfrak{u}(1)$ being particle number, class C into the type- C algebra $\mathfrak{usp}(2n)$, and class D into the type- D algebra $\mathfrak{so}(2n)$. The class- A $\mathfrak{u}(1)$ lies in $\ker K$, so it leaves the semisimple conditioning $\kappa(\mathfrak{su}(n)) = O(1)$ untouched while adding the single continuous charge a number-conserving metal is expected to carry (Section 5.1). A sample with a class- C bulk and a class- D Majorana boundary carries the direct sum $\mathfrak{usp}(2n_C) \oplus \mathfrak{so}(2n_D)$, where Remark C.5 applies unchanged: conditioning compares the block scalars $N_l = 2h_l^\vee \nu_l$ alone. The pair $\mathfrak{so}(7) \oplus \mathfrak{usp}(6)$, type B and type C of common dimension 21, has unequal block

scalars $N = 5$ and $N = 8$ and gives $\kappa(A_{opt}) = (8/5)^{3/2}$; a clean class- D with class- C counterpart is $\mathfrak{so}(8) \oplus \mathfrak{usp}(6)$, whose type- D block instead has $h^\vee = 6$.

Two cases need a word of care. Gaussian bosonic dynamics generates $\mathfrak{sp}(2n, \mathbb{R})$, which is noncompact; its Killing form is indefinite, the reduction $CC^T = -K$ of Lemma C.1 loses its sign, and the model falls outside the compact setting of this paper. The type- C realization that does fit is the class- C superconductor, with compact $\mathfrak{usp}(2n)$. At the matched end, the half-filled Hubbard model on a bipartite lattice carries $\mathfrak{so}(4) \cong \mathfrak{su}(2) \oplus \mathfrak{su}(2)$ of spin and η -pairing [56]. The two ideals share a dimension and a normalization, so $N_{\text{spin}} = N_\eta$ and $\kappa(A_{opt}) = 1$, the speedup surviving across both sectors as the matched counterpart of the dimension-split isotypic case.

The radical the algorithm returns is the center, and across these models it takes one of three sizes. The free-fermion class- C and class- D algebras, the cross-type sum $\mathfrak{so} \oplus \mathfrak{usp}$, and the $\mathfrak{so}(4)$ Hubbard algebra are semisimple, so the center is zero and the output certifies that the algebra carries no continuous conserved quantity. The number-conserving class- A algebra $\mathfrak{u}(n)$ has a one-dimensional center, the particle number, and stays well-conditioned. The $SU(2)$ and $SU(N)$ isotypic algebras have a center of dimension equal to the sector count (Theorem 4.9), but their mismatched summands push κ to $\text{poly}(d)$, so a nonzero center and a structural speedup meet only in the number-conserving case. The center here is the conserved structure that lies inside the algebra, and a symmetry that commutes with the dynamics without being generated by it falls outside it. The distinction between a charge in the commutant and one in the center governs what the algorithm can certify.

5.4 Physical Correlates of Conditioning and Criticality

When κ is large, the DLA sits close to the locus where the Killing form loses rank, and that closeness has direct physical meaning. The results below split by how much is proved, from an unconditional bound, through a divergence that holds under stated hypotheses, to connections left for later work.

5.4.1 Structural Distance and Approximate Conserved Quantities

Variety of Lie algebras and the non-semisimple locus. Fix a d -dimensional real vector space V with basis $\{e_i\}_{i=1}^d$. A Lie bracket on V is encoded by structure constants $f = (f_{ijk})_{i,j,k=1}^d \in \mathbb{R}^{d^3}$ through $[e_i, e_j] = \sum_k f_{ijk} e_k$, and the Lie algebra axioms translate into polynomial constraints on f . Antisymmetry gives the linear system $f_{ijk} + f_{jik} = 0$, and the Jacobi identity gives the quadratic system

$$\sum_{\ell=1}^d (f_{ij\ell} f_{\ell km} + f_{jkl} f_{\ell im} + f_{kil} f_{\ell jm}) = 0, \quad \forall i, j, k, m. \quad (19)$$

The common zero set

$$\mathcal{V}_{\text{Lie}}^{(d)} := \{ f \in \mathbb{R}^{d^3} \mid f \text{ satisfies antisymmetry and Jacobi identity} \} \quad (20)$$

is the affine algebraic variety of d -dimensional Lie algebras [32].

The Killing form Equation (6) is a quadratic polynomial in f , and $\det K(f)$ is therefore a polynomial of degree $2d$ on $\mathcal{V}_{\text{Lie}}^{(d)}$. Cartan's criterion identifies its zero locus with the non-semisimple:

$$\mathcal{V}_{\text{deg}} := \{ f \in \mathcal{V}_{\text{Lie}}^{(d)} \mid \det K(f) = 0 \}. \quad (21)$$

This closed subvariety, cut out by the single degree- $2d$ polynomial $\det K(f)$, has codimension one generically, and its points are exactly the non-semisimple Lie algebras of dimension d . The complement $\mathcal{V}_{\text{Lie}}^{(d)} \setminus \mathcal{V}_{\text{deg}}$ is the open stratum of semisimple Lie algebras.

Throughout, $\|\cdot\|_F$ denotes the Frobenius norm on tensors and on matrices, $\|\cdot\|_2$ the spectral norm, and

$$\text{dist}_F(f, \mathcal{V}_{\text{deg}}) := \min_{f' \in \mathcal{V}_{\text{deg}}} \|f' - f\|_F \quad (22)$$

the Frobenius distance from f to the non-semisimple locus inside $\mathbb{R}^{d^3}$.

Structural stability.

Theorem 5.1 (Conditioning controls structural distance). *Let $\mathfrak{s}$ be a semisimple Lie algebra with structure constants $f \in \mathcal{V}_{\text{Lie}}^{(d)} \setminus \mathcal{V}_{\text{deg}}$ and Killing form K . Set $F := \max_{i,j,k} |f_{ijk}|$ and $\delta := \text{dist}_F(f, \mathcal{V}_{\text{deg}})$. Then*

$$\sigma_{\min}(K) \leq C_1 d^{3/2} (F + \delta) \delta, \quad (23)$$

where $C_1 = 3$ is an absolute constant independent of d , F , and f , obtained in the proof from the elementary inequality $(x + y + z)^2 \leq 3(x^2 + y^2 + z^2)$. In the regime $\delta \leq F$ this simplifies to

$$\sigma_{\min}(K) \leq 2C_1 d^{3/2} F \delta. \quad (24)$$

The proof appears in Appendix F, together with a remark (Remark F.1) on the converse direction and the rigidity obstruction tied to Whitehead's second lemma.

Ill-conditioning also forces the appearance of approximate conserved quantities, made precise by the next lemma.

Lemma 5.2 (Approximate conserved quantities from ill-conditioning). *Let $\mathfrak{g} \subset \mathfrak{g}_{\text{amb}}$ be compact with Killing form K and Levi part $\mathfrak{s}$, and let $H \in \mathfrak{g}$ be a Hamiltonian of unit norm. If $\sigma_{\min}(K|_{\mathfrak{s}}) \leq \varepsilon$, there exists a unit-norm element $X \in \mathfrak{s}$ with*

$$\|[H, X]\| \leq C(\mathfrak{g}) \sqrt{\varepsilon}, \quad (25)$$

where $C(\mathfrak{g})$ depends only on the embedding of $\mathfrak{g}$ in $\mathfrak{g}_{\text{amb}}$. The proof is in Appendix F.

5.4.2 Adjoint-gap Closure at Criticality

Emergent symmetry and quantum phase transitions. Structure constants of a DLA are not abstract data. They are read off the Hamiltonian and shift as one tunes couplings or fields, so the whole family $\{f_{ijk}(\lambda)\}$ depends continuously on the control parameter λ . Theorem 5.1 then yields a quantitative statement in one direction: a blow-up of κ at λ keeps the algebra at Frobenius distance at least $\Omega(1/(\kappa\sqrt{d}F))$ from $\mathcal{V}_{\text{deg}}$ in a Pauli basis, set by the spectral scale $\sigma_{\max}(K)$. The bound runs from $\sigma_{\min}(K)$ to a lower bound on that distance, not the reverse; Remark F.1 shows the converse fails at a semisimple point. The gap actually closes as $\lambda \rightarrow \lambda_c$ by Theorem 5.5 alone, without any inversion of the inequality here.¹ For a compact DLA the kernel of K coincides with the center $\mathfrak{z}$, so degeneracy of K forces a nontrivial center on the nearby algebra. For a general Lie algebra the kernel of K sits inside the radical and may differ from the center, so this conclusion is specific to the compact setting that governs the rest of Section 5.4.

A small- δ statement makes sense only along a one-parameter family $\mathfrak{g}(\lambda)$ crossing the stratum boundary, the setting of Hypothesis 5.3 and of Theorem 5.5 below.

This is the algebraic signature of a Quantum Phase Transition (QPT), at which the symmetry content of the ground state changes [21], and the divergence of κ reports proximity to the critical region.

¹Rearranging Equation (24) gives $\delta \geq \sigma_{\min}(K)/(2C_1 d^{3/2} F)$, equivalently $\delta \geq \sigma_{\max}(K)/(2C_1 \kappa d^{3/2} F)$. In a Pauli basis $\sigma_{\max}(K) = O(d)$ (Theorem 4.10), which yields $\delta \geq \Omega(1/(\kappa\sqrt{d} \cdot F))$; in a trace-orthonormal basis of $\mathfrak{su}(N)$ Casimir gives $\sigma_{\max}(K) = \Theta(\sqrt{d})$ and the corresponding bound tightens to $\delta \geq \Omega(1/(\kappa d \cdot F))$.

Stating that the DLA varies with λ requires care: the bracket-closure operation is not lower semicontinuous in its generators, so $\dim \mathfrak{g}(\lambda)$ can jump at isolated parameter values. The next hypothesis fixes the ambient space in which the family may vary, and the lemma after it derives the continuity the divergence theorem needs from constancy of dimension alone.

Hypothesis 5.3 (Constant-dimension algebraic variation in the QRAM regime). *The one-parameter family $\{\mathfrak{g}(\lambda)\}_{\lambda \in I}$, with λ ranging over a real interval $I \subseteq \mathbb{R}$, admits an embedding into a fixed ambient compact Lie algebra $\mathfrak{g}_{\text{amb}}$, the generators of $\mathfrak{g}(\lambda)$, the Hamiltonian terms read off in a fixed frame of $\mathfrak{g}_{\text{amb}}$, depend continuously on λ , and $\dim \mathfrak{g}(\lambda)$ is constant in λ .*

The constancy of $\dim \mathfrak{g}(\lambda)$ is the only substantive restriction, false in general since $\dim \mathfrak{g}(\lambda)$ may jump; the continuity the proof of Theorem 5.5 uses is not a separate hypothesis but a consequence, recorded in the following lemma.

Lemma 5.4 (Grassmannian continuity and the Levi section). *Under Hypothesis 5.3: (i) the map $\lambda \mapsto \mathfrak{g}(\lambda)$ is continuous in the Grassmannian metric on $\text{Gr}_{\dim \mathfrak{g}}(\mathfrak{g}_{\text{amb}})$ and admits a continuous orthonormal frame in which the structure constants vary continuously; and (ii) on each open subset of parameter space where $\dim \mathfrak{z}(\lambda)$ is locally constant, the center $\mathfrak{z}(\lambda)$ and the semisimple Levi part $\mathfrak{s}(\lambda) = [\mathfrak{g}(\lambda), \mathfrak{g}(\lambda)]$ are continuous Grassmannian sections, with $\mathfrak{g}(\lambda) = \mathfrak{s}(\lambda) \oplus \mathfrak{z}(\lambda)$ an orthogonal decomposition. Continuity is not asserted where $\dim \mathfrak{z}(\lambda)$ jumps, in particular not at λ_c . The proof is in Appendix F.*

The notation $\text{Gr}_k(V)$ denotes the Grassmann manifold of k -dimensional linear subspaces $W \subseteq V$ of a finite-dimensional real vector space V . It is a compact smooth manifold.

Theorem 5.5 (Adjoint-gap closure at symmetry-emergent criticality). *Adopt Hypothesis 5.3 and work in the continuous-parameter QRAM regime. Suppose $\mathfrak{g}(\lambda)$ exhibits symmetry emergence at λ_c , in the sense $\dim \mathfrak{z}(\lambda_c) > \dim \mathfrak{z}(\lambda)$ for every λ in some punctured neighborhood of λ_c , and that the critical algebra retains a nontrivial semisimple part, $\mathfrak{s}(\lambda_c) \neq \{0\}$. Then along every sequence $\lambda \rightarrow \lambda_c$ there are unit-norm elements $X(\lambda) \in \mathfrak{s}(\lambda)$ whose Grassmannian limit points at λ_c lie in $\mathfrak{z}(\lambda_c)$, and*

$$\sigma_{\min}(K|_{\mathfrak{s}(\lambda)}) \leq \frac{|\text{tr}(\text{ad}_{X(\lambda)}^2)|}{\|X(\lambda)\|^2} \leq \|\text{ad}_{X(\lambda)}\|_F^2. \quad (26)$$

It follows that $\sigma_{\min}(K|_{\mathfrak{s}(\lambda)}) \rightarrow 0$ as $\lambda \rightarrow \lambda_c$. On a sufficiently small neighborhood of λ_c , the spectral norm $\sigma_{\max}(K|_{\mathfrak{s}(\lambda)})$ stays both bounded above and bounded away from zero, so $\kappa(\lambda) = \sigma_{\max}/\sigma_{\min}$ diverges as $\lambda \rightarrow \lambda_c$.

The proof is given in Appendix F.

Remark 5.6 (Scope). *The QRAM regime carries weight here. In the algorithmic Pauli regime the integer rigidity of Theorem 4.10 rules out any continuous closure of the adjoint gap, so Theorem 5.5 is not a universal divergence statement for all DLAs near a QPT; Case 2 below treats that regime.*

Continuous versus discrete criticality. Interpretation of κ and the adjoint gap splits by regime.

Case 1: continuous-parameter QRAM regime. For systems specified by continuous parameters λ in a fixed symmetry-adapted basis, the adjoint gap $\Delta_{ad}(\lambda)$ of Definition 1.1 plays the role of an algebraic order parameter. Theorem 5.5 forces $\Delta_{ad}(\lambda) \rightarrow 0$ and $\kappa(\lambda) \rightarrow \infty$ as $\lambda \rightarrow \lambda_c$; the rate at which Δ_{ad} closes is captured by the critical exponent ν_{alg} posited in Hypothesis 5.7 below.

Hypothesis 5.7 (Algebraic critical scaling). *In the continuous-parameter QRAM regime the algebraic adjoint gap closes as a power law in the distance to the transition, i.e., there exists an exponent $\nu_{alg} > 0$, the algebraic critical exponent (distinct from the basic-length ν_l of Proposition C.4), with*

$$\Delta_{ad}(\lambda) = A |\lambda - \lambda_c|^{\nu_{alg}} (1 + o(1)) \quad \text{as } \lambda \rightarrow \lambda_c, \quad (27)$$

for some constant $A > 0$.

A compact witness. A six-dimensional family makes these hypotheses concrete. Take $\mathfrak{g}(\lambda) = \mathfrak{su}(2) \oplus \mathfrak{su}(2)_\lambda$ inside the fixed compact ambient $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$, with the first factor fixed and the second carrying the scaled bracket $[Y_i, Y_j] = \lambda \varepsilon_{ijk} Y_k$ and $\lambda_c = 0$. Every member is compact. The dimension stays 6 throughout, while the center grows from $\{0\}$ at $\lambda \neq 0$ to the whole second factor at λ_c , so a symmetry emerges and the Levi part $\mathfrak{su}(2)$ of the first factor survives at criticality. Read in the orthonormal frame of the ambient, the Killing-form block on the contracting factor scales as λ^2 , so the adjoint gap closes as $\Delta_{ad}(\lambda) = \sigma_{\min}(K|_{\mathfrak{s}}) \propto \lambda^2$ while $\sigma_{\max}$ stays fixed by the first factor. The algebraic exponent is therefore $\nu_{alg} = 2$, and $\kappa(K|_{\mathfrak{s}(\lambda)}) \propto \lambda^{-2} \rightarrow \infty$. The closure is an artifact of neither basis nor normalization; it is the contracting factor shrinking against the fixed ambient inner product, and the conditioning law of Theorem 4.6 holds along the whole family. The non-compact contraction $\mathfrak{so}(3) \rightarrow \mathfrak{e}(2)$ falls outside the theorem instead, its Euclidean limit being solvable with no semisimple part.

Case 2: algorithmic Pauli regime, discrete logic. For systems specified by Pauli strings the structure constants are integers in $\{0, \pm 2\}$, and this discreteness changes the criticality at a fundamental level. As Remark 5.6 notes, the integer spectral gap of Theorem 4.10 replaces the continuous-parameter divergence $\kappa \rightarrow \infty$ with algebraic rigidity, so the DLA cannot deform continuously but jumps between distinct subalgebras, and κ stays bounded by $O(d)$ until the exact critical point, at which the rank of K drops abruptly. The adjoint gap is no longer a continuous order parameter, but a discrete indicator of stability of the underlying symmetry group.

5.4.3 Outlook: prethermalization, critical scaling, and numerical validation

Lemma 5.2 connects the proven bound to physics that is less settled. Operators satisfying Equation (25) commute with H up to a controlled residual, and they generate slow dynamics. Under the standard embedding of a compact DLA into $\mathfrak{u}(N)$ the elements of $\mathfrak{g}$ are skew-Hermitian, so the physically relevant Hermitian observable is iX , which inherits the same commutator bound $\|[H, iX]\| = \|[H, X]\| \leq C(\mathfrak{g})\sqrt{\varepsilon}$. Such observables form the substrate behind prethermalization plateaus and behind certain algebraic signatures associated with Many-Body Localization [33]. Running the present algorithm on a system close to symmetry emergence therefore reports the same instabilities that other methods detect only indirectly.

That report carries a sharp caveat. A blow-up of $T_Q \propto \kappa$ as $\lambda \rightarrow \lambda_c$ is necessary for a symmetry-emergent QPT yet falls short of establishing one. Several confounders need ruling out. The spectrum of K in the continuous-parameter regime depends on the choice of symmetry-adapted basis, so a poor choice can manufacture a runtime divergence with no physical content. The subnormalization α of the block encoding can drift upward with λ , and the QSVT polynomial degree at fixed precision can do the same, with either drift inflating T_Q independently of κ . Finite precision arithmetic on the structure constants also produces occasional near degeneracies of K that vanish under refinement.

A quantitative probe of QPT criticality therefore needs more than divergence alone. One must extract a universal exponent from $T_Q(\lambda)$ and match it against an independently measured physical exponent for the same transition. Hypothesis 5.7 posits that $\Delta_{ad}(\lambda) \propto |\lambda - \lambda_c|^{\nu_{alg}}$ provides the testable content. Numerical confirmation on benchmark systems such as the transverse-field Ising chain and the Lipkin–Meshkov–Glick model is left to future work.

6 Discussion

6.1 Limitations

The practical reach of the algorithm is bounded in three ways; the fuller treatment of each follows in the subsections and applications below.

The runtime counts algebraic work only, so end-to-end latency stays bounded below by the state-preparation cost T_{prep} : for a dense Hamiltonian in the well-conditioned QRAM regime it matches T_Q and absorbs the algebraic speedup, while sparse or algorithmically prepared H retain it (Remark 4.3).

The primary output is a block-encoded projector. Recovering a classical description of $\mathfrak{s}$ calls for subspace tomography on the image of $I - P_{\mathfrak{r}}$ at a cost of $O(d_s^2)$ samples; when $d_s = O(d)$, the typical Pauli case, this overhead can cancel the quantum advantage, and the projector then serves coherent simulation (Section 7.1).

Conditioning sets a floor on the achievable speedup. The Pauli regime excludes exponential ill-conditioning (Theorem 4.10), yet its worst case $\tilde{O}(d^{3/2})$ already exceeds the symplectic benchmark, so only the well-conditioned regimes stay competitive; in the QRAM regime κ tracks the adjoint gap and diverges as the algebra nears an emergent symmetry (Section 6.3).

6.2 Data Access: QRAM vs. Arithmetic Oracles

Data access fixes the setup cost across the two regimes of Section 1.4.2. The Pauli arithmetic oracles of Section 3.3 have no $O(d^3)$ bottleneck and give a direct speedup; the QRAM regime instead pays an $O(d^3)$ classical setup that matches the exact benchmark T_{C-Opt} , so its advantage rests on amortization.

For a workflow decomposing M Hamiltonians $H_i \in \mathfrak{g}$, the comparison is $T_{C-Total} = O(Md^3)$ versus $T_{Q-Total} = O(d^3 + MT_Q)$ with $T_Q = \tilde{O}(d)$. Break-even is at $M = 2$, asymptotic throughput advantage $O(d^2)$. Use cases include fixed processor architectures, electronic-structure Hamiltonians, or one lattice geometry scanned over couplings. The setup cost caps the regime to polynomial-dimensioned subspaces: $d = 4^n$ takes $O(64^n)$ to set up, out of reach physically; the exponential case belongs to the Pauli regime instead.

6.3 Handling Ill-Conditioned Systems: Approximate Radical Computation

Continuous parameters in the QRAM regime keep κ as the determining factor. A practical fallback introduces a numerical threshold δ_{th} and defines the Effective Radical

$$\mathfrak{r}_{\text{eff}}(\delta_{th}) = \text{span}\{v_k : \sigma_k(A_{opt}) < \delta_{th}\}. \quad (28)$$

Gap-Relative Thresholding selects δ_{th} without prior knowledge. Low-precision QSVE estimates the lower tail of the spectrum, the index k maximising σ_{k+1}/σ_k inside the target window fixes the threshold, and the QSVT polynomial P_{ker} filters at δ_{th} . The threshold replaces the true κ in the runtime by $\kappa_{eff} = 1/\delta_{th}$, trading exact decomposition for stability.

6.4 Relation to Classical Simulability

A recent line of work draws a sharp boundary around where a quantum advantage for Lie-algebraic problems can live. When the DLA has dimension polynomial in the number of qubits, Lie-algebraic (g-sim) methods simulate the Heisenberg evolution of suitable observables in classical polynomial time [25]. Building on such constructions, Cerezo and coworkers argue, case by case, that the structural features which guarantee the absence of barren plateaus often also supply a classical surrogate, so that provable trainability and a genuine quantum advantage may be hard to secure at once [9]. Their statement is a perspective that collects evidence rather than

a theorem, and it presumes an initial data-acquisition phase on quantum devices; the advantage claimed in the conclusion sits inside the window it leaves open.

Three features separate the present task from what those methods simulate. The end-to-end speedup we claim is the amortized cubic of the well-conditioned QRAM case, which runs in the polynomial-dimensioned regime where g-sim is efficient. Even there g-sim only simulates the Heisenberg evolution of an observable and never returns the radical, so it provides no classical shortcut to the structural computation the speedup performs. The deliverable is a structural object, the radical itself, together with the conditioning law of Theorem 4.6, neither of which a Heisenberg-picture simulation of an observable returns. And in the hardest cases the deliverable is a negative certificate, a statement about the algebra as a whole, independent of any single expectation value. Trainability may also persist in regions with no known classical surrogate [43], so the dichotomy narrows the advantage window without closing it. We therefore rest the contribution on the structure theorem and the certificate, not on a raw speedup that a simulability argument could erode.

7 Applications

For compact DLAs the algorithm identifies the center of the algebra, corresponding to the system’s symmetries. This fixes what “finding the symmetries” can mean. The center is the conserved structure carried inside the algebra; a quantity that commutes with the dynamics but is not generated by it, such as η -pairing in a sparse local model [55], sits in the commutant, outside this center [44]. The algorithm reaches such a charge only when the generating set is enlarged to the full charge-conserving algebra, so the conditioning across compact types (Section 5.3) also bounds when a symmetry is cheap to certify.

7.1 A Hybrid Quantum-Classical Approach to Full Decomposition

The block encoding $U_{P_{\mathfrak{r}}}$ from Section 1.4.2 is the algorithm’s primary output. Applied to a prepared state $|0\rangle \otimes |H\rangle$ encoding a Hamiltonian $H \in \mathfrak{g}$, QSVT produces a controlled projector [23] so that the joint state is, up to precision ϵ in L_2 norm,

$$|0\rangle \otimes P_{\mathfrak{r}} |H\rangle + |1\rangle \otimes (I - P_{\mathfrak{r}}) |H\rangle. \quad (29)$$

A measurement on the ancilla projects onto the radical component $|H_r\rangle$ or the semisimple component $|H_s\rangle$. The preparation cost T_{prep} depends on the sparsity s_H of H in the working basis: with QRAM access to the coefficients of H one has $T_{prep} = O(s_H \text{polylog } d)$, which is efficient whenever H admits a k -local or otherwise sparse representation. A single application of the decomposition circuit costs $T_{prep} + T_Q$. Where the targeted component has norm $\|P_{\mathfrak{r}} |H\rangle\| = \gamma$, amplitude amplification [7] brings the total to $O((T_{prep} + T_Q)/\gamma)$. The application is bottlenecked by T_{prep} only for dense H with $s_H = O(d)$ in the well-conditioned QRAM regime, where $T_{prep} = \tilde{O}(d)$ is comparable to $T_Q = \tilde{O}(d)$ (Remark 4.3).

The algorithm computes the radical but does not return a Levi factor $\mathfrak{s}$; for compact algebras the derived algebra fills that role uniquely. Many applications also require the finer decomposition $\mathfrak{s} = \bigoplus_j \mathfrak{s}_j$ into simple ideals. A hybrid split follows: the quantum computer handles the radical, classical post-processing handles the rest.

7.1.1 The Quantum-Classical Interface Challenge

The goal of this hybrid approach is to extract the structure constants of the quotient algebra $\mathfrak{s}_q = \mathfrak{g}/\mathfrak{r} \cong \mathfrak{s}$. A classical algorithm can then operate on this smaller algebra (of dimension $d_s = \dim(\mathfrak{s})$) to find its decomposition into simple ideals and identify a lifted Levi factor using standard methods [28, 16], which scale as $O(d_s^3)$ (optimized) or $O(d_s^4)$ (standard).

Efficiently extracting a classical description of $\mathfrak{s}$ from the quantum projector $P_{\mathfrak{t}}$ is the hard step. Determining the structure constants of $\mathfrak{s}$ requires a classical basis for the semisimple component, hence quantum subspace tomography on the image of the projector $I - P_{\mathfrak{t}}$.

The overhead of quantum subspace tomography scales quadratically with the dimension of the subspace, requiring $O(d_s^2)$ copies of the projected state [46]. When $d_s = O(d)$, which is typical for the physical models occupying the Pauli situation, the cost may negate the quantum advantage for the specific task of extracting a classical description of $\mathfrak{s}$.

7.1.2 Regimes of Efficiency

Hybrid efficiency requires $\dim \mathfrak{s} = O(\text{poly}(\log d))$, the center-dominated case where tomography overhead is manageable. At $\dim \mathfrak{s} = O(d)$, the typical Pauli scenario, tomography becomes prohibitive, and the algorithm's value reduces to direct coherent use of $P_{\mathfrak{t}}$ for simulation, the use that survives classical extraction (Remark 7.2).

The full-accounting winner. Full decomposition extracts the semisimple part, and the count above makes it efficient only in the atypical small- $\mathfrak{s}$ case. The center deliverable runs the other way. Extracting $\mathfrak{z}$, or merely certifying its dimension, tomographizes only the center, so it stays cheap exactly when the center is small, which is the typical physical regime (Section 5.1). The all-in cost then has a clean form.

Proposition 7.1 (End-to-end cost of the negative certificate). *Take a compact DLA $\mathfrak{g}$ of dimension d accessed through QRAM, well-conditioned with $\kappa = O(1)$, with a center of small expected dimension $\dim \mathfrak{z} = O(\text{poly} \log d)$, and amortize the one-time $O(d^3)$ setup over $M \geq 2$ Hamiltonians sharing $\mathfrak{g}$. Write $\gamma = \|P_{\mathfrak{t}} |H\rangle\|$ for the weight a probe Hamiltonian places on the center. Certifying that the center has exactly its expected dimension, equivalently returning a classical basis of $\mathfrak{z}$, composes the amplitude-amplified single-copy cost $O((T_{\text{prep}} + T_Q)/\gamma)$ of this section with the $O(\dim \mathfrak{z}^2)$ subspace-tomography samples that the image of $P_{\mathfrak{t}}$ requires:*

$$T_{\text{cert}} = O\left(\dim \mathfrak{z}^2 \frac{T_{\text{prep}} + T_Q}{\gamma}\right), \quad T_{\text{prep}} = \tilde{O}(d), \quad T_Q = \tilde{O}(d). \quad (30)$$

With $\dim \mathfrak{z} = O(\text{poly} \log d)$ and a centered probe ($\gamma = \Omega(1)$) the per-Hamiltonian cost is $\tilde{O}(d)$, set against the structure-aware classical benchmark $T_{C\text{-}Opt} = O(d s_{\text{adj}} s_{\text{int}} + d^3) = O(d^3)$ of Theorem 4.12. The marginal advantage is the amortized cubic of Table 2 (row 4), with break-even at $M = 2$.

The certificate clears the tomography barrier of the subsection above for one structural reason: it reconstructs the small center at $O(\dim \mathfrak{z}^2)$ samples and leaves the $O(d)$ -dimensional semisimple part alone; the $O(d_s^2)$ cost of that part is what erases the advantage in a full decomposition. The only tunable quantity outside Table 2 is the probe weight γ ; the center dimension $\dim \mathfrak{z} = O(\text{poly} \log d)$ is the standing assumption on the input algebra. A generic input gives $\gamma = \Omega(1/\sqrt{d})$ and softens the figure to $\tilde{O}(d^{3/2})$, still a polynomial gain over $O(d^3)$, while a probe drawn from the expected center restores $\gamma = \Omega(1)$ and the clean cubic.

7.2 Implications for Exact Dynamical Decoupling and Trotter-Error Reduction

For compact DLAs, the algorithm enables the construction of block encodings for the semisimple and central components of a Hamiltonian $H \in \mathfrak{g}$ via unitary composition: $U_{H_z} \approx U_{P_{\mathfrak{t}}} U_H U_{P_{\mathfrak{t}}}$ and $U_{H_s} \approx U_{I-P_{\mathfrak{t}}} U_H U_{I-P_{\mathfrak{t}}}$. The exact factorization of e^{-iHt} into $e^{-iH_s t} e^{-iH_z t}$ established in Section 1.1 can then be implemented coherently within a qubitization or QSVT pipeline, eliminating all Trotter error between the two components.

The semisimple part itself can decompose into a direct sum of simple ideals, $\mathfrak{s} = \bigoplus_j \mathfrak{s}_j$, if its finer structure is known, $H_s = \sum_j H_{s_j}$. Since components from different ideals commute ($[H_{s_j}, H_{s_l}] = 0$ for $j \neq l$), the evolution of the semisimple part can also be exactly factorized:

$$e^{-iH_s t} = \prod_j e^{-iH_{s_j} t}. \quad (31)$$

The decomposition $\mathfrak{g} = \mathfrak{z} \oplus \mathfrak{s}_1 \oplus \cdots \oplus \mathfrak{s}_k$ splits the dynamics into $k + 1$ commuting parts, reducing circuit depth and complementing commutativity-based techniques [12, 54].

Remark 7.2 (What a small center buys). *The projector has three uses, and none needs the conserved quantity to be unknown. The output is a circuit for the projector P_τ , so it splits $e^{-iHt} = e^{-iH_s t} e^{-iH_z t}$ with zero Trotter error (Equation 2) and drops into a qubitization or QSVT pipeline; knowing that a charge is conserved does not by itself hand you that circuit. The small size of the center is also what keeps the problem well-conditioned: with $r = d - \dim \mathfrak{z}$ and $\dim \mathfrak{z} = O(\text{poly } n)$ against $d = O(\exp n)$, the ratio $d/r \rightarrow 1$ and $\beta = O(1)$ (Section 5.1), while an extensive center would force $\beta = O(d)$. And the smallest singular value of K on the semisimple part measures the distance to an algebra with one more conserved quantity, so a runtime that grows as that gap closes reports proximity to symmetry emergence and to criticality (Theorem 5.5, Lemma 5.2).*

A worked scenario: excluding a hidden charge. Take a number-conserving lattice model whose dynamical Lie algebra is expected to be $\mathfrak{u}(n) = \mathfrak{su}(n) \oplus \mathfrak{u}(1)$, the $\mathfrak{u}(1)$ carrying particle number. The question with physical teeth is whether the dynamics conceals any further conserved charge, an extra central direction that would split the evolution into unannounced superselection sectors. The algorithm settles it by certifying $\dim \mathfrak{z} = 1$ and no more. Two baselines set the comparison. A classical check builds the Killing form and reads its kernel at $O(d^3)$ (Theorem 4.12), which the certificate of Proposition 7.1 beats by the amortized cubic, since it reconstructs only the one-dimensional center. A measurement-based test scales differently in kind. Confirming a single suspected charge Q asks for one commutator norm $\|[H, Q]\|$, but ruling out every hidden charge means probing a basis of the d -dimensional algebra, so a direct non-adaptive sweep spends $\Omega(d)$ commutator measurements and still certifies only the operators it happened to test. The negative certificate closes that gap at the level of the algebra.

8 Conclusion

We have given a quantum algorithm for the radical of a finite-dimensional Lie algebra, with the compact DLAs of closed quantum systems as the main physical target. The algorithm runs on two ingredients, a bilinear factorization $K = A^T B$ that converts the dense Killing form into a sparsity-controlled block encoding, and a QSVT kernel projection that extracts the radical without ever assembling K classically. The structure-aware classical benchmark $T_{C\text{-}Opt} = O(d s_{adj} s_{int} + d^3)$ derived alongside the quantum algorithm keeps the comparison like-for-like.

The runtime $T_Q = \tilde{O}(\alpha_{opt}/\sigma_{\min})$, tight to $\tilde{O}(\kappa)$ in the Pauli frame, lands in one of the rows of Table 2. For $\mathfrak{su}(2^n)$ and k -local DLAs realising it (Theorem 4.11), the well-conditioned Pauli row reduces the algebraic projector to $\tilde{O}(1)$ queries, though dense state preparation caps the full runtime at the symplectic $\tilde{O}(d)$ (Remark 4.3); symmetric Heisenberg/Hubbard variants share this row only when the Levi part stays a single simple summand (Theorem 4.9). A cubic speedup appears in the well-conditioned QRAM row once the $O(d^3)$ setup is amortized over $M \geq 2$ Hamiltonians. Across invariant-orthonormal frames the conditioning obeys one law, $\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}$ with block scalars N_l (Theorem 4.6). The speedup survives just when the simple summands share comparable N_l , which is why a matched $\mathfrak{su}(2^n)$ stays well-conditioned

while a dimension-split symmetric subalgebra does not. The algorithm is accordingly most useful as a negative certificate, confirming that the conserved structure matches expectations; discovering a large hidden symmetry is the task it serves worst, since a richer center is precisely what degrades the conditioning.

A Normalization factor derivations

We derive the normalization factors α_B , α_{A^T} , α_{C^T} of the constituent matrices B , A^T , C^T used in the composite block encoding $U_{A_{opt}}$, using the maximum column L_2 norm definition together with the maximum magnitude F .

1. Scaling of α_B . The column-norm definition gives, for B ,

$$\alpha_B^2 = \max_j \sum_{k,m} |B_{(k,m),j}|^2 = \max_j \sum_{k,m} |f_{jmk}|^2.$$

This expression relates to the Frobenius norm of the adjoint matrices: $\|\text{ad}(B_j)\|_F^2 = \sum_{k,i} |(\text{ad}(B_j))_{ki}|^2 = \sum_{k,i} |f_{jki}|^2$. By Definition 2.5, the adjoint matrix $\text{ad}(B_j)$ has at most s_{adj} non-zero entries. Since each entry's magnitude is bounded by F , the squared Frobenius norm is bounded by $O(F^2 s_{adj})$. Therefore, $\alpha_B^2 = O(F^2 s_{adj})$, i.e. $\alpha_B = O(F \sqrt{s_{adj}})$.

2. Scaling of α_{A^T} . The matrix A^T is wide and row-sparse, so unlike B and C^T its largest column L_2 norm undercounts its spectral norm and cannot serve as a subnormalization on its own. Every block encoding obeys $\alpha \geq \sigma_{\max}$, and the factorization $A^T A = -K$ fixes $\sigma_{\max}(A^T) = \sqrt{\sigma_{\max}(K)} = \Theta(\sqrt{d})$ in the Pauli frame, whereas the maximal column norm is only $O(F \sqrt{s_{int}}) = O(1)$. The sparse-access block encoding therefore carries the geometric mean of the two sparsities, $\alpha_{A^T} = O(F \sqrt{s_r s_c})$, with s_r and s_c the row and column sparsities of A^T [23, Lemma 48]. The column sum over i at fixed (k, m) has at most s_{int} nonzero terms,

$$\max_{(k,m)} \sum_i |f_{ikm}|^2 = O(F^2 s_{int}),$$

while row i of A^T collects the nonzero structure constants of $\text{ad}(B_i)$, hence at most s_{adj} of them. With each entry bounded by F , the valid subnormalization is

$$\alpha_{A^T} = O(F \sqrt{s_{adj} s_{int}}).$$

In the Pauli frame this bound is tight, $\alpha_{A^T} = \sqrt{2(d+1)} = \sigma_{\max}(A^T)$, so the block encoding loses no conditioning.

3. Scaling of α_{C^T} . The same definition gives, for C^T ,

$$\alpha_{C^T}^2 = \max_k \sum_{i,j} |C_{k,(i,j)}|^2 = \max_k \sum_{i,j} |f_{ijk}|^2.$$

This is the maximum squared row norm N_k (Definition 2.7). To bound this maximum, we analyze the average norm $\bar{N}$. The total squared norm of all structure constants is $\sum_k N_k = \sum_{i,j,k} |f_{ijk}|^2$. The total number of non-zero structure constants can be bounded by the total non-zero entries across all d adjoint matrices, i.e. $O(d \cdot s_{adj})$. Since each entry's magnitude is bounded by F , the total squared norm is $O(F^2 \cdot d \cdot s_{adj})$. The average squared row norm is therefore

$$\bar{N} = (1/d) \sum_k N_k = O(F^2 s_{adj}).$$

By the definition of β -balance, the maximum norm is bounded relative to the average: $\alpha_{C^T}^2 = \max_k N_k \leq \beta \cdot \bar{N} = O(F^2 \cdot \beta \cdot s_{adj})$. Therefore, $\alpha_{C^T} = O(F \sqrt{\beta \cdot s_{adj}})$. Combining the three bounds yields Equation (14).

B Pauli-basis structural proofs

The conditioning analysis of Section 4.2.2 specializes to a closed form in the Pauli basis, where the commutator Gram matrix is diagonal. The two statements below record that specialization; both descend from the basis-independent reduction of Appendix C.

Lemma B.1 (Diagonality of CC^T in the Pauli Basis). *For any DLA $\mathfrak{g}$ represented in the standard Skew-Hermitian Pauli basis (where f_{ijk} are real), the Gram matrix CC^T is diagonal: $CC^T = \text{diag}(N_k)$.*

Proof. The elements of the Gram matrix are $(CC^T)_{k,k'} = \sum_{i,j} f_{ijk} f_{ijk'}$.

If this term is non-zero, there must exist a pair (i, j) such that $f_{ijk} \neq 0$ AND $f_{ijk'} \neq 0$. This implies $[B_i, B_j]$ has components along both B_k and $B_{k'}$.

The Pauli basis possesses a structure inherited from the underlying Clifford algebra and the associated finite Pauli group [27]. The commutator of two Pauli operators $[B_i, B_j]$ is proportional to a unique third Pauli operator, or is zero. Due to this algebraic determinism, the result of the commutator is unique. Therefore, we must have $k = k'$.

The diagonal elements are $(CC^T)_{k,k} = \sum_{i,j} f_{ijk}^2 = N_k$. $\square$

This lemma allows for a significant simplification of the condition number analysis, specifically under the constraints of the Pauli basis.

Theorem B.2 (Simplification of $\kappa(A_{\text{opt}})$ in the Pauli Basis). *Let $D = \text{diag}(\sqrt{N_k})$ be the diagonal matrix of the square roots of the row norms. If the DLA $\mathfrak{g}$ is represented in the standard Skew-Hermitian Pauli basis, the relevant condition number of A_{opt} is determined by the operator restricted to the semisimple subspace $\mathfrak{s}$. Specifically:*

$$\kappa(A_{\text{opt}}) = \kappa((DK)|_{\mathfrak{s}}). \quad (32)$$

Proof. We analyze the singular values of A_{opt} via its Gram matrix G . Since the Pauli basis guarantees $f_{ijk} \in \mathbb{R}$, the Gram matrix is $G = A_{\text{opt}}^T A_{\text{opt}} = K C C^T K$. By Lemma B.1, $C C^T = \text{diag}(N_k) = D^2$. Thus, $G = K D^2 K = (DK)^T (DK)$. For central elements $B_k \in \mathfrak{z}$, $N_k = 0$, implying $D_{kk} = 0$. Hence DK vanishes on the center. The non-zero singular values of A_{opt} are therefore the singular values of DK restricted to the semisimple component $\mathfrak{s}$, where D is strictly positive definite. $\square$

Proof of Theorem 4.4. We analyze the distribution of the squared norms $N_k = \sum_{i,j} |f_{ijk}|^2$.

The derived algebra is $[\mathfrak{g}, \mathfrak{g}] = \mathfrak{s}$. If a basis element B_k belongs to the center $\mathfrak{z}$, it cannot be the result of any commutator, because the image of the commutator map is $\mathfrak{s}$, and $\mathfrak{s} \cap \mathfrak{z} = \{0\}$. Therefore, $f_{ijk} = 0$ for all i, j whenever $B_k \in \mathfrak{z}$. This implies $N_k = 0$ if $B_k \in \mathfrak{z}$. The total squared norm $S = \sum_{k=1}^d N_k$ is concentrated entirely on the basis elements belonging to $\mathfrak{s}$, i.e., $S = \sum_{k \in \mathfrak{s}} N_k$. The average norm across the entire algebra $\mathfrak{g}$ is $\bar{N} = S/d$. The average norm within the semisimple part $\mathfrak{s}$ is $\bar{N}_{\mathfrak{s}} = S/r$. The maximum norm must occur within $\mathfrak{s}$. Define the intrinsic balance of $\mathfrak{s}$ as $\beta_{\mathfrak{s}} = (\max_{k \in \mathfrak{s}} N_k) / \bar{N}_{\mathfrak{s}}$. The balance of $\mathfrak{g}$ is

$$\beta = \frac{\max_{k \in \mathfrak{g}} N_k}{\bar{N}} = \frac{\max_{k \in \mathfrak{s}} N_k}{\bar{N}}.$$

Substituting the definitions of the average norms:

$$\beta = \frac{\beta_{\mathfrak{s}} \cdot \bar{N}_{\mathfrak{s}}}{\bar{N}} = \frac{\beta_{\mathfrak{s}} \cdot (S/r)}{S/d} = \beta_{\mathfrak{s}} \cdot \frac{d}{r}. \quad \square$$

Proof of Theorem 4.11. Theorem B.2 reduces the claim to $\kappa(DK)$. Analyze K and D separately.

Killing form K . Here $\mathfrak{g} = \mathfrak{su}(N)$ with $N = 2^n$ is a simple Lie algebra, so the Killing form is proportional to the Trace form. The Pauli basis is orthonormal under the Trace form, so $K \propto I$ and $\kappa(K) = O(1)$.

Norm matrix $D = \text{diag}(\sqrt{N_k})$. The squared norm $N_k = \sum_{i,j} |f_{ijk}|^2$ counts the structure-constant weight that lands on B_k from commutators of basis pairs. The Pauli basis inherits the uniform structure of the Clifford algebra and its associated finite group [27, 4], so N_k is independent of k provided $B_k \neq iI$, which holds on the basis of $\mathfrak{su}(2^n)$. Hence $N_k = \bar{N}$ for all k , $D = \sqrt{\bar{N}} I$, and $\kappa(D) = O(1)$.

Both factors are scalar, so $DK \propto I$ and $\kappa(A_{\text{opt}}) = O(1)$. $\square$

Proof of Corollary 4.7 (direct Pauli count). Fix a Pauli basis of $\mathfrak{g}$ adapted to the direct-sum decomposition $\mathfrak{g} = \mathfrak{s}_1 \oplus \cdots \oplus \mathfrak{s}_m \oplus \mathfrak{z}$. The hypothesis that each $\mathfrak{s}_l$ is itself Pauli-spanned makes such a refinement possible. Distinct simple ideals commute, $[\mathfrak{s}_l, \mathfrak{s}_{l'}] = 0$ for $l \neq l'$, and $[\mathfrak{z}, \mathfrak{g}] = 0$. The defining relation $[B_i, B_j] = \sum_k f_{ijk} B_k$ forces $f_{ijk} = 0$ whenever the indices i, j, k do not all lie in a single simple summand. For $k \in \mathfrak{s}_l$,

$$N_k = \sum_{i,j} f_{ijk}^2 = \sum_{i,j \in \mathfrak{s}_l} f_{ijk}^2. \quad (33)$$

Only pairs internal to $\mathfrak{s}_l$ contribute.

The skew-Hermitian Pauli basis is orthonormal for the inner product $\langle X, Y \rangle = -2^{-n} \text{tr}_{\mathbb{C}^{2^n}}(XY)$, since $\text{tr}_{\mathbb{C}^{2^n}}(P_j P_k) = 2^n \delta_{jk}$, and the form is invariant by cyclicity of the trace. Adapted as above to the splitting, the basis meets every hypothesis of Corollary C.2: on each simple summand the Killing matrix is block-scalar, $K|_{\mathfrak{s}_l} = -N_l I_{d_l}$ with $N_l > 0$. Theorem 4.10 keeps the whole matrix strictly diagonal. The identity (35) evaluates the diagonal as $K_{kk} = -(CC^T)_{kk} = -N_k$, so $N_k = N_l$ for every $k \in \mathfrak{s}_l$.

A direct combinatorial count fixes the numerical value. By hypothesis the Pauli basis of $\mathfrak{s}_l$ corresponds, via symplectic indices, to all non-zero vectors of a $2n_l$ -dimensional non-degenerate symplectic subspace of $\mathbb{F}_2^{2n}$, so the non-identity Paulis spanning $\mathfrak{s}_l$ number exactly $d_l = 4^{n_l} - 1$, and two basis elements anti-commute iff their symplectic inner product equals 1. Fix $B_i \in \mathfrak{s}_l$. Among the $d_l - 1$ other non-identity Paulis of $\mathfrak{s}_l$, the number with symplectic inner product 1 against B_i equals $2^{2n_l-1} = (d_l + 1)/2$; the number with inner product 0 equals $2^{2n_l-1} - 1 = (d_l - 1)/2$, where the off-by-one reflects the fact that B_i itself trivially commutes with B_i . The count of anti-commuting partners is therefore $(d_l + 1)/2$. Each anti-commuting ordered pair (B_i, B_j) produces a unique B_k with $|f_{ijk}| = 2$ by the Pauli product law and the normalization $f_{ijk} \in \{0, \pm 2\}$. Summing,

$$\sum_{i,j,k \in \mathfrak{s}_l} f_{ijk}^2 = d_l \cdot \frac{d_l + 1}{2} \cdot 4 = 2 d_l (d_l + 1).$$

This equals $\sum_{k \in \mathfrak{s}_l} N_k = d_l \cdot N_k$ by the constancy of N_k on $\mathfrak{s}_l$ just established. Division yields

$$N_k = 2(d_l + 1) \quad \text{for every } k \in \mathfrak{s}_l. \quad (34)$$

Substituting into the block-scalar form gives $K|_{\mathfrak{s}_l} = -2(d_l + 1) I_{d_l}$.

Substituting $N_l = 2(d_l + 1)$ into Theorem 4.6 gives $\kappa(A_{\text{opt}}) = ((d_{\max} + 1)/(d_{\min} + 1))^{3/2}$, with $\kappa(D|_{\mathfrak{s}})$ the square root of the same ratio; the saturating case $d_{\min} = O(1)$, $d_{\max} = \Theta(d)$, realised by $\mathfrak{s} = \mathfrak{su}(2) \oplus \mathfrak{su}(2^k)$, attains the Pauli ceiling $\kappa(A_{\text{opt}}) = \Theta(d^{3/2})$. $\square$

C Basis-independent reduction of the conditioning

Lemma B.1 reads the diagonality of CC^T off the Pauli product law, and Theorem B.2 then trades $\kappa(A_{\text{opt}})$ for $\kappa((DK)|_{\mathfrak{s}})$. The diagonality is incidental. What drives the reduction is one identity

between the commutator Gram matrix and the Killing matrix, valid in every basis orthonormal for an invariant inner product and adapted to the splitting $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$. The Gram matrix contains a third power of K , and passing to singular values halves it.

Lemma C.1 (Invariant reduction of $\kappa(A_{opt})$). *Let $\mathfrak{g}$ be a compact Lie algebra with $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$, where $\mathfrak{s} = [\mathfrak{g}, \mathfrak{g}]$ is semisimple and $\mathfrak{z}$ is the center. Let $\langle \cdot, \cdot \rangle$ be an invariant inner product on $\mathfrak{g}$, so that $\langle [Z, X], Y \rangle = -\langle X, [Z, Y] \rangle$ for all $X, Y, Z \in \mathfrak{g}$, and let $\{B_k\}_{k=1}^d$ be orthonormal for it and adapted to the splitting $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$. Then the structure constants are totally antisymmetric, the commutator matrix C and the Killing matrix K satisfy*

$$CC^T = -K, \quad (35)$$

and the Gram matrix of $A_{opt} = C^T K$ is $G = A_{opt}^T A_{opt} = -K^3$. The nonzero singular values of A_{opt} are $|\mu|^{3/2}$ as μ ranges over the eigenvalues of $K|_{\mathfrak{s}}$, so

$$\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}. \quad (36)$$

Proof. Orthonormality identifies the structure constants with inner products. From $[B_i, B_j] = \sum_k f_{ijk} B_k$ and $\langle B_k, B_{k'} \rangle = \delta_{kk'}$,

$$f_{ijk} = \langle [B_i, B_j], B_k \rangle.$$

Antisymmetry under $i \leftrightarrow j$ is the antisymmetry of the bracket. The remaining transposition follows from invariance with $Z = B_i$, which reads $\langle [B_i, B_j], B_k \rangle = -\langle B_j, [B_i, B_k] \rangle = -f_{ikj}$, hence $f_{ijk} = -f_{ikj}$. Adjacent transpositions generate the symmetric group on three letters, so f is totally antisymmetric.

That symmetry is the entire mechanism. Write the commutator Gram matrix entrywise, then move the third index to the front through the cyclic shift $f_{ijk} = f_{kij}$, an even permutation that carries no sign:

$$(CC^T)_{kk'} = \sum_{i,j} f_{ijk} f_{ijk'} = \sum_{i,j} f_{kij} f_{k'ij}.$$

The Killing matrix of Section 3.2 is $K_{kk'} = \sum_{i,j} f_{kij} f_{k'ji}$. Reverse the last two indices of the second factor, $f_{k'ji} = -f_{k'ij}$, and the two sums agree up to a sign:

$$K_{kk'} = -\sum_{i,j} f_{kij} f_{k'ij} = -(CC^T)_{kk'}.$$

This proves (35). On the center the identity is the trivial $0 = 0$, since a central B_k is never the image of a bracket, forcing $f_{ijk} = 0$ there, and K annihilates $\mathfrak{z}$.

The reduction is now pure algebra. With $K^T = K$,

$$G = A_{opt}^T A_{opt} = (C^T K)^T (C^T K) = K (CC^T) K = -K^3.$$

Diagonalize the symmetric matrix $K|_{\mathfrak{s}}$ by the spectral theorem. Its eigenvalues μ are real and strictly negative, because the Killing form of a compact semisimple algebra is negative definite. The matching eigenvalue of G is $-\mu^3 = |\mu|^3 > 0$, so $G|_{\mathfrak{s}}$ is positive definite and the singular values of A_{opt} on $\mathfrak{s}$ are the roots $|\mu|^{3/2}$. The center contributes only zeros. Dividing the largest by the smallest,

$$\kappa(A_{opt}) = \frac{\max_{\mu} |\mu|^{3/2}}{\min_{\mu} |\mu|^{3/2}} = \left(\frac{\max_{\mu} |\mu|}{\min_{\mu} |\mu|} \right)^{3/2} = \kappa(K|_{\mathfrak{s}})^{3/2},$$

the last step using that the singular values of the symmetric matrix $K|_{\mathfrak{s}}$ are the moduli $|\mu|$. $\square$

The Pauli statement of Section 4.2.2 is one corner of this lemma. In the Pauli basis K is diagonal by Theorem 4.10, so (35) forces CC^T diagonal as well, which recovers Lemma B.1 with $N_k = -K_{kk}$; the substitution $D^2 = CC^T = -K$ then collapses $\kappa((DK)|_{\mathfrak{s}})$ to the same $\kappa(K|_{\mathfrak{s}})^{3/2}$. Neither integrality nor the Clifford group entered the argument.

Corollary C.2 (Block-scalar form and the dimensional ratio). *Suppose further that $\mathfrak{s} = \bigoplus_l \mathfrak{s}_l$ with each $\mathfrak{s}_l$ simple, and that the basis is adapted to $\bigoplus_l \mathfrak{s}_l$. Then on the orthonormal basis $K|_{\mathfrak{s}_l} = -N_l I_{d_l}$ for a positive scalar N_l , and*

$$\kappa(A_{opt}) = \left(\frac{\max_l N_l}{\min_l N_l} \right)^{3/2}.$$

Proof. Pick $X, Y \in \mathfrak{s}_l$. The adjoint ad_X respects the decomposition and acts as zero on every $\mathfrak{s}_{l'}$ with $l' \neq l$, since $[X, \mathfrak{s}_{l'}] \subseteq [\mathfrak{s}_l, \mathfrak{s}_{l'}] = 0$. On the center it also vanishes. The same is true of ad_Y . The composition $\text{ad}_X \text{ad}_Y$ therefore vanishes outside $\mathfrak{s}_l$, and the trace decomposes:

$$K_{\mathfrak{g}}(X, Y) = \text{tr}_{\mathfrak{g}}(\text{ad}_X \text{ad}_Y) = \text{tr}_{\mathfrak{s}_l}(\text{ad}_X|_{\mathfrak{s}_l} \text{ad}_Y|_{\mathfrak{s}_l}) = K_{\mathfrak{s}_l}(X, Y). \quad (37)$$

Restricting $K_{\mathfrak{g}}$ to a simple summand reproduces that summand's intrinsic Killing form.

A simple algebra carries a one-dimensional space of invariant symmetric bilinear forms. The restriction $\langle \cdot, \cdot \rangle|_{\mathfrak{s}_l}$ and the Killing form $K_{\mathfrak{s}_l}$ are two such forms, so $K_{\mathfrak{s}_l} = -N_l \langle \cdot, \cdot \rangle|_{\mathfrak{s}_l}$ for a single scalar. Negative definiteness on the compact algebra fixes $N_l > 0$. The restricted Killing matrix in the orthonormal basis is then $-N_l I_{d_l}$, with eigenvalues the constant $-N_l$. Cross terms between distinct summands vanish as well. For $B_i \in \mathfrak{s}_l$ and $B_j \in \mathfrak{s}_{l'}$ with $l' \neq l$, the image of ad_{B_j} lies in $\mathfrak{s}_{l'}$, where ad_{B_i} acts as zero, so $K_{\mathfrak{g}}(B_i, B_j) = \text{tr}_{\mathfrak{g}}(\text{ad}_{B_i} \text{ad}_{B_j}) = 0$ and $K|_{\mathfrak{s}}$ is block-diagonal. Hence $\kappa(K|_{\mathfrak{s}}) = \max_l N_l / \min_l N_l$, and (36) yields the stated ratio. $\square$

Remark C.3 (Orthogonality is necessary, uniform block-scaling is not). *Identity (35) is tied to its hypothesis, and the hypothesis cannot be relaxed to an arbitrary frame. Total antisymmetry is what cancels the cross terms, and it fails as soon as the basis stops being orthonormal. The lowered constants $\langle [B_i, B_j], B_k \rangle$ stay antisymmetric in any basis, yet the raised constants f_{ijk} that assemble C and K acquire metric weights $\langle B_k, B_k \rangle^{-1}$ that no longer agree across the two sides. One freedom is harmless. Rescaling a whole simple block by a constant ν_l feeds the same factor ν_l^{-2} into $CC^T|_{\mathfrak{s}_l}$ and into $K|_{\mathfrak{s}_l}$, where it cancels, so any basis that is orthogonal with block-constant norm still obeys (35). A skew frame does not. A single non-orthogonal shear inside one simple block already breaks the identity by an order-one margin.*

The scalar N_l in Corollary C.2 is not free. Rigidity pins it to a single number attached to the type of $\mathfrak{s}_l$, the dual Coxeter number, times the one normalization that Remark C.3 already isolated. The identification holds for every compact simple type, and the dimensional scaling of the obstruction reads off it.

Proposition C.4 (Casimir dictionary for the block scalar). *Let $\mathfrak{s}_l$ be a compact simple ideal of Cartan type X_r , and let $h_l^\vee$ be its dual Coxeter number. Fix the positive-definite invariant form $(\cdot, \cdot)_l$ on $\mathfrak{s}_l$ by*

$$K_{\mathfrak{s}_l} = -2h_l^\vee (\cdot, \cdot)_l,$$

the basic normalization in which the quadratic Casimir of the adjoint representation equals $2h_l^\vee$ [32]. Then the block scalar of Corollary C.2 is

$$N_l = 2h_l^\vee \nu_l, \quad \nu_l := (B_k, B_k)_l, \quad (38)$$

where ν_l is the squared basic-length shared by the orthonormal generators of the block. The first factor is fixed by the type. The second is the block-rescaling freedom of Remark C.3, and equals one exactly when the orthonormal frame is the basic frame.

Proof. By the one-dimensional space of invariant forms used for Corollary C.2, the chosen inner product $\langle \cdot, \cdot \rangle|_{\mathfrak{s}_l}$, the Killing form $K_{\mathfrak{s}_l}$, and the basic form $(\cdot, \cdot)_l$ are pairwise proportional. That corollary records the first proportionality as $K_{\mathfrak{s}_l} = -N_l \langle \cdot, \cdot \rangle|_{\mathfrak{s}_l}$; the displayed normalization records the second as $K_{\mathfrak{s}_l} = -2h_l^\vee (\cdot, \cdot)_l$. Evaluate both on an orthonormal generator B_k of the block. The Killing values coincide, so $N_l \langle B_k, B_k \rangle = 2h_l^\vee (B_k, B_k)_l$, and orthonormality $\langle B_k, B_k \rangle = 1$ gives (38). Positivity of $(\cdot, \cdot)_l$ on the compact form forces $\nu_l > 0$, and proportionality of the two forms makes $(B_k, B_k)_l$ independent of which $k \in \mathfrak{s}_l$ is taken. $\square$

The dual Coxeter number is tabulated for every simple type. Table 3 sets it beside the dimension $d_l = \dim \mathfrak{s}_l$ across the four classical families and the five exceptional types, the data that turns (38) into an explicit block scalar once a frame is chosen.

Type	Compact algebra	$d_l = \dim \mathfrak{s}_l$	$h_l^\vee$
A_r ($r \geq 1$)	$\mathfrak{su}(r+1)$	$r(r+2)$	$r+1$
B_r ($r \geq 2$)	$\mathfrak{so}(2r+1)$	$r(2r+1)$	$2r-1$
C_r ($r \geq 3$)	$\mathfrak{sp}(2r)$	$r(2r+1)$	$r+1$
D_r ($r \geq 4$)	$\mathfrak{so}(2r)$	$r(2r-1)$	$2r-2$
G_2		14	4
F_4		52	9
E_6		78	12
E_7		133	18
E_8		248	30

Table 3: Dual Coxeter numbers and dimensions of the compact simple types, with the rank ranges that keep the families distinct. The basic-normalization block scalar is $N_l = 2h_l^\vee$, and a general orthonormal frame scales it by ν_l through (38).

Remark C.5 (Type-dependent dimensional scaling). *Equation (38) splits the conditioning into two independent factors. The dual Coxeter number is rigid and depends on the type alone; ν_l depends on how the frame presents the generators. When one uniform frame fixes a common ν_l across the blocks, that factor cancels from the ratio, and Corollary C.2 reads*

$$\kappa(A_{opt}) = \left(\frac{\max_l h_l^\vee}{\min_l h_l^\vee} \right)^{3/2}.$$

Inside one classical family the dual Coxeter number grows as a square root of the dimension: $h^\vee = \sqrt{d+1}$ for A_r , while B_r, C_r, D_r give $h^\vee = \Theta(\sqrt{d})$ with respective constants $\sqrt{2}, 1/\sqrt{2}, \sqrt{2}$. A frame whose generators keep a bounded basic-length, $\nu_l = O(1)$, then leaves $N_l = \Theta(\sqrt{d_l})$, so $\kappa(A_{opt}) = \Theta((d_{\max}/d_{\min})^{3/4})$; the generalized Gell-Mann frame of Theorem E.1, normalized by $\text{Tr}(\lambda_a \lambda_b) = 2$, sits in this case. A full-rank frame whose generators span the block has $\nu_l = \Theta(\sqrt{d_l})$ instead, lifts N_l to $\Theta(d_l)$, and returns the $(d_{\max}/d_{\min})^{3/2}$ ceiling of Corollary 4.7. The exponent belongs to the pair, type together with frame; neither determines it alone. The constant tying $h^\vee$ to $\sqrt{d}$ shifts between families, so a clean power d^p tracks the ratio only inside one type. The invariant that stays faithful across types is N_l , equivalently the pair $(h_l^\vee, \nu_l)$.

The block scalars of Section 5.3 are collected in Table 4, which reads the law $N_l = 2h_l^\vee \nu_l$ of Equation (38) on the free-fermion and symmetry-class models. Each algebra is taken in its defining representation, where $\nu_l = 1/2$ for $\mathfrak{so}$ and $\nu_l = 1$ for $\mathfrak{sp}$ and $\mathfrak{su}$. A single simple ideal has $\kappa(A_{opt}) = 1$ by Corollary C.2, and a direct sum has $\kappa(A_{opt}) = (\max_l N_l / \min_l N_l)^{3/2}$ by Theorem 4.6.

The two frame instances quoted in Section 4.2.2 follow from the same dictionary. The bounded-normalization corollary lowers the exponent to three quarters.

Corollary C.6 (Hilbert–Schmidt frame, type-A family). *Let $\mathfrak{s} = \bigoplus_l \mathfrak{su}(M_l)$ be semisimple of type A, each block carried in the generalized Gell-Mann frame normalized by $\text{tr}(\lambda_a \lambda_b) = 2$. Then $\nu_l = 2$ and $N_l = 2h_l^\vee \nu_l = 4M_l$, so*

$$\kappa(A_{opt}) = \left(\frac{M_{\max}}{M_{\min}} \right)^{3/2} = \left(\frac{d_{\max} + 1}{d_{\min} + 1} \right)^{3/4} = \Theta((d_{\max}/d_{\min})^{3/4}).$$

The Hilbert–Schmidt normalization is the one used for the Gell-Mann analysis of Appendix E.

Physical model	DLA	Type	$h^\vee$	N_l	$\kappa(A_{opt})$	$\dim \mathfrak{z}$
Majorana, matchgate circuit	$\mathfrak{so}(2n)$	D	$2n - 2$	$2n - 2$	1	0
unpaired Majorana mode	$\mathfrak{so}(2n + 1)$	B	$2n - 1$	$2n - 1$	1	0
class- C superconductor	$\mathfrak{usp}(2n)$	C	$n + 1$	$2(n + 1)$	1	0
number-conserving metal	$\mathfrak{su}(n) \oplus \mathfrak{u}(1)$	A	n	$2n$	1	1
half-filled Hubbard	$\mathfrak{so}(4) = \mathfrak{su}(2) \oplus \mathfrak{su}(2)$	$A \oplus A$	2, 2	4, 4	1	0
cross-type sum	$\mathfrak{so}(7) \oplus \mathfrak{usp}(6)$	$B \oplus C$	5, 4	5, 8	$(8/5)^{3/2}$	0
$SU(2)$ Heisenberg, isotypic	$\bigoplus_J \mathfrak{su}(m_J)$	A	m_J	mismatched	$\text{poly}(d)$	sector count

Table 4: Compact dynamical Lie algebras of the free-fermion and symmetry-class models of Section 5.3, with the block scalars that fix the conditioning through $N_l = 2h_l^\vee \nu_l$ in the defining representation. The pair $\mathfrak{so}(7) \oplus \mathfrak{usp}(6)$ shares the dimension 21 across both ideals yet gives $\kappa(A_{opt}) = (8/5)^{3/2}$, since the block scalars differ. The $SU(2)$ isotypic row (Theorem 4.9) carries one central element per spin sector, and its conditioning grows with the spread of the summand dimensions m_J .

Proof. Type A_{M_l-1} has $h_l^\vee = M_l$ (Table 3), and the Gell-Mann normalization fixes the squared basic-length at the bounded value $\nu_l = 2$ of Remark C.5. Proposition C.4 gives $N_l = 4M_l$, and $M_l = \sqrt{d_l + 1}$ turns the ratio of Theorem 4.6 into the three-quarters power. $\square$

The proof of the $SU(2)$ -symmetric obstruction stated in Section 4.2.2 runs through the same dictionary.

Proof of Theorem 4.9. Schur–Weyl duality identifies the commutant of the diagonal $SU(2)$ action with $\bigoplus_J \mathfrak{u}(m_J)$, the Levi splitting $\mathfrak{g} = \mathfrak{s} \oplus \mathfrak{z}$ that Lemma C.1 takes as input, so $\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2}$ and Corollary C.2 attaches a block scalar N_J to each ideal $\mathfrak{su}(m_J)$ of type A_{m_J-1} . Proposition C.4 reads $N_J = 2h^\vee \nu_J = 2m_J \nu_J$ off the type, with $\nu_J = \text{tr}_{M_J}(\lambda_k^2)$ the defining-trace form. The generators sit inside $\mathfrak{su}(2^n)$ as $I_{V_J} \otimes \lambda_k$, so the ambient trace factors as $\text{tr}_{2^n} = (2J + 1) \text{tr}_{M_J}$; the same $2J + 1$ enters the Schur constant and cancels, leaving N_J a function of m_J and ν_J alone. Substituting into Corollary C.2 gives (16). $\square$

D Classical benchmark proof

Proof of Theorem 4.12. We analyze the complexity of each step of the standard classical algorithm, optimized using sparse data structures such as Compressed Sparse Row (CSR) and Compressed Sparse Column (CSC) formats [26].

Step 1: Construction of sparse representations. The algorithm requires access to the structure constants organized for sparse matrix operations. This involves constructing sparse representations of the adjoint matrices $\text{ad}(B_i)$ or, equivalently, the factorization matrices A and B . The cost is proportional to the total number of nonzero structure constants, bounded by $O(d \cdot s_{adj})$.

Step 2: Optimized calculation of the Killing form K . We use the bilinear factorization $K = A^T B$ of Section 3.2, with $A_{(k,m),i} = f_{ikm}$ and $B_{(k,m),j} = f_{jmk}$. The j -th column of B corresponds to the entries of $\text{ad}(B_j)$ (reshaped), so by Definition 2.5 it has at most s_{adj} nonzeros. The (k, m) -th row of A has at most s_{int} nonzeros by Definition 2.6, so the columns of A^T have column sparsity s_{int} . Sparse Matrix Multiplication (SpMM) computes K column-wise: $K_{\cdot j} = A^T B_{\cdot j}$. The vector $B_{\cdot j}$ has at most s_{adj} nonzeros, and each column of A^T has at most s_{int} , yielding $O(s_{adj} \cdot s_{int})$ scalar operations per column [8]. Across all d columns yields $O(d \cdot s_{adj} \cdot s_{int})$.

Step 3: Determination of the derived algebra basis. Finding a basis for $[\mathfrak{g}, \mathfrak{g}]$, i.e. the column space of the commutator matrix C ($d \times d^2$), requires Gaussian elimination or an equivalent rank computation. The matrix is sparse with $O(d \cdot s_{adj})$ nonzeros, but without guarantees on low fill-in, sparse linear algebra reduces to the dense worst case [26]. Thus $O(d^3)$.

Step 4: Kernel of $M^T K$ for the radical. With M the matrix whose columns form the derived algebra basis from Step 3, the radical is the kernel of $M^T K$. Worst case (dense K and fill-in) is again $O(d^3)$.

Combining the four steps gives $T_{C-Opt} = O(d \cdot s_{adj} \cdot s_{int} + d^3)$. $\square$

E Gell-Mann basis analysis

We analyze the generalized Gell-Mann basis for $\mathfrak{su}(N)$ ($d = N^2 - 1$) using the A_{N-1} root system.

Theorem E.1 (Parameters and complexity in the Gell-Mann basis). *For $\mathfrak{su}(N)$ represented in the standard generalized Gell-Mann basis, the parameters are $F = O(1)$, $s_{adj} = O(d)$, $s_{int} = \Theta(\sqrt{d})$, $\beta = O(1)$, and $\kappa = O(1)$. The resulting quantum query complexity is $T_Q = \tilde{O}(d^{0.75})$.*

Proof. We justify each parameter based on the structure of the Gell-Mann basis and the A_{N-1} root system.

Magnitude $F = O(1)$: Standard normalization (e.g. $\text{Tr}(\lambda_a \lambda_b) = 2\delta_{ab}$) bounds the structure constants [22].

Adjoint Sparsity $s_{adj} = O(d)$: Here $\mathfrak{su}(N)$ is a dense algebra.

Interaction Sparsity $s_{int} = \Theta(\sqrt{d})$: The Gell-Mann basis corresponds to a root-space decomposition: Cartan subalgebra $\mathcal{H}$ (dimension $N - 1$) and ladder operators $\mathcal{E}$ associated with roots α . We analyze the constraints on B_i for fixed B_k, B_m .

Lower bound $\Omega(\sqrt{d})$: Set $B_k = B_m = E_\beta$. We seek B_i such that $[B_i, E_\beta]$ has a component along E_β ; this occurs precisely when B_i belongs to $\mathcal{H}$, since $[H_j, E_\beta] \propto E_\beta$. With $\dim(\mathcal{H}) = N - 1$ and $d = N^2 - 1$, this gives $s_{int} \geq N - 1 = \Omega(\sqrt{d})$.

Upper bound $O(\sqrt{d})$: The remaining cases:

1. $B_k, B_m \in \mathcal{E}$ with $B_k = E_\beta, B_m = E_\gamma$.
 - $\gamma = \beta$: count $N - 1$ (handled above).
 - $\gamma \neq \beta$: $[B_i, E_\beta]$ with a component along E_γ forces $B_i \propto E_{\gamma-\beta}$ when $\gamma - \beta$ is a root, otherwise no solution. Count: $O(1)$.
2. $B_k \in \mathcal{E}, B_m \in \mathcal{H}$ (or vice versa): $B_k = E_\beta, B_m = H_j$ forces $B_i \propto E_{-\beta}$. Count: $O(1)$.
3. $B_k, B_m \in \mathcal{H}$: $[B_i, H_k]$ lies entirely in $\mathcal{E}$ or vanishes, so no component along $B_m \in \mathcal{H}$. Count: 0.

The maximum count is $N - 1 = \Theta(\sqrt{d})$.

Balance $\beta = O(1)$: The Weyl group acts transitively on the roots, so the norms N_k on the ladder operators are uniform. The Cartan-generator norms are likewise balanced by root-lattice regularity.

Condition number $\kappa = O(1)$: The algebra $\mathfrak{su}(N)$ is simple, so the Killing form is proportional to the trace form, and the generalized Gell-Mann basis is orthonormal for that (invariant) trace form. Lemma C.1 then applies directly: $K \propto I$ gives $\kappa(K|_{\mathfrak{s}}) = O(1)$, and $\kappa(A_{opt}) = \kappa(K|_{\mathfrak{s}})^{3/2} = O(1)$.

Complexity with compactness optimization. Since $\mathfrak{su}(N)$ is compact, Corollary 4.2 gives the corrected $\alpha'_{opt} = O(F^2 s_{adj} \sqrt{s_{int}})$. Substituting $s_{adj} = O(d)$, $s_{int} = O(\sqrt{d})$ yields $\alpha'_{opt} = O(d^{5/4})$. The Killing form of $\mathfrak{su}(N)$ in the Gell-Mann basis has $\sigma_{\max}(K) = \Theta(\sqrt{d})$ (set by the dual Coxeter number $h^\vee = N$), and at $\kappa = O(1)$ also $\sigma_{\min}(K|_{\mathfrak{s}}) = \Theta(\sqrt{d})$, so the tight cost law gives

$$T_Q = \tilde{O}\left(\frac{\alpha'_{opt}}{\sigma_{\min}(K|_{\mathfrak{s}})}\right) = \tilde{O}\left(\frac{d^{5/4}}{\sqrt{d}}\right) = \tilde{O}(d^{0.75}).$$

Compared with the per-call structure-dependent term of the classical benchmark $T_{C-Opt} = O(d \cdot s_{adj} \cdot s_{int} + d^3)$, namely $O(d \cdot s_{adj} \cdot s_{int}) = O(d^{2.5})$ once the one-time d^3 is amortized over $M \geq 2$ Hamiltonians (Theorem 4.12), the quantum algorithm gives an amortized speedup of order $O(d^{1.75})$. $\square$

The Hilbert–Schmidt normalization $\text{tr}(\lambda_a \lambda_b) = 2$ used here fixes the bounded basic-length $\nu_l = 2$ behind Corollary C.6, which treats a dimension-split type- A sum where the matched single block $\mathfrak{su}(N)$ here keeps $\kappa = O(1)$.

F Adjoint-gap closure proofs

This appendix proves Theorems 5.1 and 5.5, with the rigidity caveat (Remark F.1) attached to the first, and the continuity Lemma 5.4 that feeds the second.

Proof of Theorem 5.1. Choose $f' \in \mathcal{V}_{\text{deg}}$ realizing $\delta = \|f' - f\|_F$ and write $\Delta f := f' - f$. From the bilinear expression in (6),

$$\Delta K_{ij} = \sum_{k,m} (f_{ikm} \Delta f_{jmk} + \Delta f_{ikm} f_{jmk} + \Delta f_{ikm} \Delta f_{jmk}).$$

The three summands are bounded slice by slice. Let f_i denote the slice of f fixing the first index, so $\|f_i\|_F \leq dF$; likewise $\|\Delta f_i\|_F$ is the i -th slice norm of Δf . Applying Cauchy–Schwarz to each of the three summands separately,

$$|\Delta K_{ij}| \leq \|f_i\|_F \|\Delta f_j\|_F + \|\Delta f_i\|_F \|f_j\|_F + \|\Delta f_i\|_F \|\Delta f_j\|_F.$$

Squaring and applying $(x+y+z)^2 \leq 3(x^2+y^2+z^2)$ termwise, then summing over i, j and using $\sum_i \|f_i\|_F^2 = \|f\|_F^2 \leq d^3 F^2$ together with $\sum_i \|\Delta f_i\|_F^2 = \|\Delta f\|_F^2 = \delta^2$,

$$\|\Delta K\|_F^2 \leq 3(2\|f\|_F^2 \delta^2 + \delta^4) \leq 9d^3(F + \delta)^2 \delta^2,$$

the last step using $\|f\|_F^2 \leq d^3 F^2$ and $\delta^2 \leq d^3(F + \delta)^2$. The spectral norm is dominated by the Frobenius norm, $\|\Delta K\|_2 \leq \|\Delta K\|_F \leq 3d^{3/2}(F + \delta)\delta$, so the constant is $C_1 = 3$. Singularity of $K(f')$ gives $\sigma_{\min}(K) \leq \|\Delta K\|_2$, which is Equation (23). The aligned family $f \equiv F$, $\Delta f \equiv g \rightarrow 0$ sends the ratio $\|\Delta K\|_F / (d^{3/2}(F + \delta)\delta)$ to 2, so no absolute constant below 2 is admissible and $C_1 = 3$ sits within a factor 3/2 of optimal. $\square$

Remark F.1 (On the converse direction and Whitehead’s rigidity). *Inverting Equation (23) into a lower bound on δ in terms of $\sigma_{\min}(K)$ runs into a structural obstruction. The Eckart–Young theorem [20] produces a minimal symmetric perturbation ΔK^* with $\|\Delta K^*\|_2 = \sigma_{\min}(K)$ singularizing K . Recovering a structure-constant perturbation requires the singularizing direction itself to lie in $\text{Im}(\text{d}K|_f)$; an orthogonal projection onto $\text{Im}(\text{d}K|_f)$ would yield some image vector, but applying it as a perturbation produces $K + \pi(\Delta K^*)$, which is generically nonsingular.*

For a globally semisimple $\mathfrak{s}$ the obstruction is more severe than a quantitative loss. Whitehead’s second lemma gives $H^2(\mathfrak{s}, \mathfrak{s}) = 0$, so the local deformation space of $\mathfrak{s}$ is trivial, every tangent vector to $\mathcal{V}_{\text{Lie}}^{(d)}$ at f comes from the $\text{GL}(d)$ -orbit through f , and orbit deformations preserve $\text{rank}(K)$. Semisimple algebras therefore form an open stratum of $\mathcal{V}_{\text{Lie}}^{(d)}$, and δ has a uniform positive lower bound at any single semisimple point. A converse statement is meaningful only along a one-parameter family $f(\lambda)$ crossing the stratum boundary, and only at points where the family has already left the semisimple open set. Theorem 5.1 uses only the upper bound Equation (23), which is unconditional.

Proof of Lemma 5.2. Fix an ad-invariant inner product $\langle \cdot, \cdot \rangle$ on $\mathfrak{g}_{\text{amb}}$, with induced norm $\| \cdot \|$; one exists because $\mathfrak{g}_{\text{amb}}$ is compact, and we read unit norm and the singular values of $K|_{\mathfrak{s}}$ against it. Invariance, $\langle [Z, Y_1], Y_2 \rangle + \langle Y_1, [Z, Y_2] \rangle = 0$ for $Z, Y_1, Y_2 \in \mathfrak{g}$, is precisely the statement that every ad_Z with $Z \in \mathfrak{g}$ is skew-adjoint, $\text{ad}_Z^\top = -\text{ad}_Z$.

Choice of X . Represent the restricted form by its Gram operator $\widehat{K} \in \text{End}(\mathfrak{s})$ via $K(Y_1, Y_2) = \langle Y_1, \widehat{K} Y_2 \rangle$. It is self-adjoint, and compactness makes $K|_{\mathfrak{s}}$ negative definite, so every eigenvalue of $\widehat{K}$ is negative and $\sigma_{\min}(K|_{\mathfrak{s}}) = \min_i |\lambda_i(\widehat{K})|$. Pick a unit eigenvector $X \in \mathfrak{s}$ for an eigenvalue μ of smallest modulus; then

$$K(X, X) = \langle X, \widehat{K} X \rangle = \mu \|X\|^2 = \mu, \quad |K(X, X)| = \sigma_{\min}(K|_{\mathfrak{s}}) \leq \varepsilon.$$

From the Killing value to the adjoint norm. Since $X \in \mathfrak{s}$ and $[\mathfrak{s}, \mathfrak{z}] = 0$, the operator ad_X annihilates the center $\mathfrak{z}$ and preserves $\mathfrak{s}$; hence $\text{tr}_{\mathfrak{g}}(\text{ad}_X^2) = \text{tr}_{\mathfrak{s}}((\text{ad}_X|_{\mathfrak{s}})^2)$, so the restriction $K|_{\mathfrak{s}}$ coincides with the intrinsic Killing form of $\mathfrak{s}$ and $K(X, X) = \text{tr}_{\mathfrak{g}}(\text{ad}_X^2)$. Computing the Frobenius norm of ad_X (as an operator on $\mathfrak{g}$) in a $\langle \cdot, \cdot \rangle$ -orthonormal basis and invoking skew-adjointness $\text{ad}_X^\top = -\text{ad}_X$,

$$\|\text{ad}_X\|_F^2 = \text{tr}_{\mathfrak{g}}(\text{ad}_X^\top \text{ad}_X) = -\text{tr}_{\mathfrak{g}}(\text{ad}_X^2) = -K(X, X) = |K(X, X)| \leq \varepsilon.$$

Bracket bound. The operator norm is dominated by the Frobenius norm, so $\|\text{ad}_X\|_{\text{op}} \leq \|\text{ad}_X\|_F \leq \sqrt{\varepsilon}$. With $H \in \mathfrak{g}$ of unit norm and $[H, X] = -\text{ad}_X H$,

$$\|[H, X]\| = \|\text{ad}_X H\| \leq \|\text{ad}_X\|_{\text{op}} \|H\| \leq \sqrt{\varepsilon},$$

which is Equation (25); in the invariant normalization the constant is $C(\mathfrak{g}) = 1$.

The constant $C(\mathfrak{g})$. If unit norm is instead measured in another fixed normalization on the finite-dimensional space $\mathfrak{g}$, for instance the spectral norm of H under the embedding $\mathfrak{g} \subset \mathfrak{u}(N)$, norm equivalence supplies constants $0 < a \leq b$ with $a\|Y\| \leq \|Y\|' \leq b\|Y\|$ for all $Y \in \mathfrak{g}$, depending only on the two inner products and hence only on the embedding $\mathfrak{g} \hookrightarrow \mathfrak{g}_{\text{amb}}$. Propagating them through the three displays replaces the bound by $C(\mathfrak{g})\sqrt{\varepsilon}$. Under the orthonormal normalization fixed in Definition 1.1, which is the meaning of $\sigma_{\min}(K|_{\mathfrak{s}})$ used throughout, one has $C(\mathfrak{g}) = 1$. $\square$

Proof of Lemma 5.4. Fix an ad-invariant inner product on $\mathfrak{g}_{\text{amb}}$, available by compactness. We use the standard fact that a continuous family of matrices of locally constant rank has continuous column space and kernel, equivalently a continuous Moore–Penrose pseudoinverse and continuous orthogonal projectors onto image and kernel [26].

(i) Because $\dim \mathfrak{g}_{\text{amb}}$ is finite, $\mathfrak{g}(\lambda)$ is the span of the iterated brackets of its generators up to a depth bounded by $\dim \mathfrak{g}_{\text{amb}}$. Collect these finitely many bracket words into the columns of a matrix $W(\lambda)$; it is continuous in λ by continuity of the generators (Hypothesis 5.3) and multilinearity of the bracket. Constancy of $\dim \mathfrak{g}(\lambda)$ makes $\text{rank } W(\lambda)$ constant, so $\mathfrak{g}(\lambda) = \text{col } W(\lambda)$ is a continuous Grassmannian section. A continuous orthonormal frame exists because a continuous vector bundle over an interval is trivial, and the structure constants, being bracket coordinates in that frame, vary continuously.

(ii) In such a frame the adjoint representation is a continuous matrix $M(\lambda)$ with $\ker M(\lambda) = \mathfrak{z}(\lambda)$ and nullity $\dim \mathfrak{z}(\lambda)$. On a subset where $\dim \mathfrak{z}(\lambda)$ is locally constant, $\text{rank } M(\lambda)$ is constant, so $\mathfrak{z}(\lambda)$ is a continuous section and so is its orthogonal complement inside $\mathfrak{g}(\lambda)$. Compactness makes $\mathfrak{g}(\lambda)$ reductive, $\mathfrak{g}(\lambda) = \mathfrak{z}(\lambda) \oplus [\mathfrak{g}(\lambda), \mathfrak{g}(\lambda)]$ with orthogonal summands and $[\mathfrak{g}(\lambda), \mathfrak{g}(\lambda)]$ semisimple; that complement is therefore exactly the Levi part $\mathfrak{s}(\lambda)$. $\square$

Proof of Theorem 5.5. Reduction to a single stratum. Since $\sigma_{\min}(K|_{\mathfrak{s}(\lambda)}) \geq 0$, it suffices to show that every sequence $\lambda_n \rightarrow \lambda_c$ has a subsequence along which $\sigma_{\min}(K|_{\mathfrak{s}(\lambda_n)}) \rightarrow 0$; the full limit then follows. By Lemma 5.4(i) the adjoint map of $\mathfrak{g}(\lambda)$ has a continuous matrix, so its nullity $\dim \mathfrak{z}(\lambda)$ is upper semicontinuous and takes finitely many values near λ_c . Pass to a subsequence

with $\dim \mathfrak{z}(\lambda_n) \equiv m$ constant; symmetry emergence forces $m < \dim \mathfrak{z}(\lambda_c)$. Then pass to a further subsequence along which the Levi parts converge in the Grassmannian, $\mathfrak{s}(\lambda_n) \rightarrow V_\star \subset \mathfrak{g}(\lambda_c)$ (compactness of $\text{Gr}_{\dim \mathfrak{g}-m}(\mathfrak{g}_{\text{amb}})$); on the open stratum $\{\dim \mathfrak{z} \equiv m\}$ this section is even continuous by Lemma 5.4(ii), but subsequential compactness is all that is used. Since $\dim \mathfrak{g}(\lambda)$ is constant, $\dim V_\star = \dim \mathfrak{s}(\lambda_n) = \dim \mathfrak{g} - m$ strictly exceeds $\dim \mathfrak{s}(\lambda_c) = \dim \mathfrak{g} - \dim \mathfrak{z}(\lambda_c)$.

The inclusion $\mathfrak{s}(\lambda_c) \subseteq V_\star$ comes from continuity of the bracket. For any generator $z = [Y_1, Y_2]$ of $\mathfrak{s}(\lambda_c) = [\mathfrak{g}(\lambda_c), \mathfrak{g}(\lambda_c)]$, the continuous frame of Lemma 5.4(i) provides lifts $Y_i(\lambda_n) \in \mathfrak{g}(\lambda_n)$ with $Y_i(\lambda_n) \rightarrow Y_i$. The brackets $[Y_1(\lambda_n), Y_2(\lambda_n)] \in \mathfrak{s}(\lambda_n)$ then converge to z inside $\mathfrak{g}_{\text{amb}}$, so z lies in the Grassmannian limit. Spanning gives $\mathfrak{s}(\lambda_c) \subseteq V_\star$, strictly since $\dim V_\star = \dim \mathfrak{g} - m > \dim \mathfrak{s}(\lambda_c)$. By the Grassmann dimension inequality applied inside $\mathfrak{g}(\lambda_c) = \mathfrak{s}(\lambda_c) \oplus \mathfrak{z}(\lambda_c)$,

$$\dim(V_\star \cap \mathfrak{z}(\lambda_c)) \geq \dim V_\star + \dim \mathfrak{z}(\lambda_c) - \dim \mathfrak{g}(\lambda_c) = \dim \mathfrak{z}(\lambda_c) - m > 0,$$

so $V_\star \cap \mathfrak{z}(\lambda_c) \neq \{0\}$.

Pick a unit vector $X_c \in V_\star \cap \mathfrak{z}(\lambda_c)$ and set $X(\lambda_n) := P_{\mathfrak{s}(\lambda_n)} X_c / \|P_{\mathfrak{s}(\lambda_n)} X_c\|$, the normalized orthogonal projection of X_c onto $\mathfrak{s}(\lambda_n)$. Since $\mathfrak{s}(\lambda_n) \rightarrow V_\star \ni X_c$, we have $P_{\mathfrak{s}(\lambda_n)} X_c \rightarrow X_c$, so $X(\lambda_n) \in \mathfrak{s}(\lambda_n)$ is well defined for large n , has unit norm, and $X(\lambda_n) \rightarrow X_c$ in $\mathfrak{g}_{\text{amb}}$. Along this subsequence these unit-norm elements have their only limit point at $X_c \in \mathfrak{z}(\lambda_c)$; the full statement, that along every sequence all limit points are central, is established at the end of the proof.

Upper bound on $\sigma_{\min}$. Ambient compactness of $\mathfrak{g}_{\text{amb}}$ makes the Killing form negative semidefinite, and its restriction $K|_{\mathfrak{s}(\lambda)}$ to the semisimple part is negative definite. For a negative-definite symmetric matrix the Rayleigh quotient $|x^T K x| / \|x\|^2$ is a convex combination of the absolute eigenvalues, so it exceeds $\sigma_{\min}(K)$ for every nonzero x . Applying this to $X(\lambda_n)$, together with the identity $K(X, X) = \text{tr}(\text{ad}_X^2)$ and the inequality $|\text{tr}(A^2)| \leq \|A\|_F^2$, gives the chain (26) evaluated at $X(\lambda_n)$.

The right side vanishes. The limit $X_c \in \mathfrak{z}(\lambda_c)$ is central, so ad_{X_c} vanishes as an operator on $\mathfrak{g}(\lambda_c)$. Take a continuous orthonormal frame $\{e_i(\lambda)\}_{i=1}^{\dim \mathfrak{g}}$ of $\mathfrak{g}(\lambda)$ inside $\mathfrak{g}_{\text{amb}}$, which exists by Lemma 5.4(i). Then

$$\|\text{ad}_{X(\lambda_n)}\|_F^2 = \sum_{i=1}^{\dim \mathfrak{g}} \|[X(\lambda_n), e_i(\lambda_n)]\|^2 \longrightarrow \sum_{i=1}^{\dim \mathfrak{g}} \|[X_c, e_i(\lambda_c)]\|^2 = 0$$

by bilinearity and continuity of the bracket, using $X(\lambda_n) \rightarrow X_c$ and $e_i(\lambda_n) \rightarrow e_i(\lambda_c)$. The chain (26) then forces $\sigma_{\min}(K|_{\mathfrak{s}(\lambda_n)}) \rightarrow 0$ along the subsequence, which completes the reduction and proves $\sigma_{\min}(K|_{\mathfrak{s}(\lambda)}) \rightarrow 0$ as $\lambda \rightarrow \lambda_c$.

The statement's elements, for every sequence. The punctured neighborhood has $\mathfrak{s}(\lambda) \neq \{0\}$ throughout, since $\dim \mathfrak{s}(\lambda) = \dim \mathfrak{g} - \dim \mathfrak{z}(\lambda) > \dim \mathfrak{g} - \dim \mathfrak{z}(\lambda_c) \geq 0$. For each such λ , let $X(\lambda) \in \mathfrak{s}(\lambda)$ be a unit smallest-modulus eigenvector of $K|_{\mathfrak{s}(\lambda)}$, so $|K(X(\lambda), X(\lambda))| = \sigma_{\min}(K|_{\mathfrak{s}(\lambda)})$. Given any sequence $\lambda \rightarrow \lambda_c$ and any Grassmannian limit point $X_\star$ of the $X(\lambda)$, ambient continuity gives $X_\star \in \mathfrak{g}(\lambda_c)$ and $K_{\mathfrak{g}(\lambda_c)}(X_\star, X_\star) = \lim K(X(\lambda), X(\lambda)) = 0$, because $\sigma_{\min}(K|_{\mathfrak{s}(\lambda)}) \rightarrow 0$ was just shown; since $K_{\mathfrak{g}(\lambda_c)}$ is negative semidefinite with radical $\mathfrak{z}(\lambda_c)$, $X_\star \in \mathfrak{z}(\lambda_c)$. These are the unit-norm elements named in the theorem statement.

Lower bound on $\sigma_{\max}$. Here the hypothesis $\mathfrak{s}(\lambda_c) \neq \{0\}$ enters. Every subsequential limit $V_\star$ of $\mathfrak{s}(\lambda)$ as $\lambda \rightarrow \lambda_c$ contains $\mathfrak{s}(\lambda_c)$, since the inclusion argument above applies verbatim to any convergent subsequence; the modular law then gives the orthogonal splitting $V_\star = \mathfrak{s}(\lambda_c) \oplus (V_\star \cap \mathfrak{z}(\lambda_c))$. The center lies in the radical of $K_{\mathfrak{g}(\lambda_c)}$, so on the second summand the form vanishes and is K -orthogonal to the first; hence the nonzero spectrum of $K_{\mathfrak{g}(\lambda_c)}|_{V_\star}$ is exactly that of $K|_{\mathfrak{s}(\lambda_c)}$, and

$$\sigma_{\max}(K_{\mathfrak{g}(\lambda_c)}|_{V_\star}) = \sigma_{\max}(K|_{\mathfrak{s}(\lambda_c)}) > 0,$$

the same value for every $V_\star$. In converging orthonormal frames the Gram matrix of $K|_{\mathfrak{s}(\lambda)}$ tends to that of $K_{\mathfrak{g}(\lambda_c)}|_{V_\star}$ (structure constants continuous, $\mathfrak{s}(\lambda) \rightarrow V_\star$), and $\sigma_{\max}$ is continuous, so

every limit point of $\sigma_{\max}(K|_{\mathfrak{s}(\lambda)})$ as $\lambda \rightarrow \lambda_c$ equals $\sigma_{\max}(K|_{\mathfrak{s}(\lambda_c)}) > 0$; thus $\sigma_{\max}$ is bounded away from zero on a punctured neighborhood of λ_c . Were $\mathfrak{s}(\lambda_c) = \{0\}$, total emergence to an abelian algebra, $\sigma_{\max}$ would vanish in the limit as well and this argument would not control κ ; that case lies outside the theorem.

Upper bound on $\sigma_{\max}$. Entry-wise, $|K_{ij}| = |\text{tr}(\text{ad}_i \text{ad}_j)| \leq \|\text{ad}_i\|_F \|\text{ad}_j\|_F$, uniformly bounded on a compact parameter neighborhood by continuity of the structure constants (Lemma 5.4(i)). Since $K|_{\mathfrak{s}(\lambda)}$ is a matrix of size at most $d \times d$, $\|K\|_F^2 \leq d^2 \max_{ij} |K_{ij}|^2$, and therefore $\sigma_{\max}(K|_{\mathfrak{s}(\lambda)}) \leq \|K\|_F \leq C_2 d$ on the neighborhood, for a constant C_2 depending only on the embedding into $\mathfrak{g}_{\text{amb}}$. Combining the two-sided bound on $\sigma_{\max}$ with the decay of $\sigma_{\min}$ forces $\kappa(\lambda) \rightarrow \infty$. $\square$

Abstract. Fault-tolerant quantum computing requires high-fidelity logical magic states for non-Clifford operations. Magic-state cultivation offers a lower-overhead preparation route, yet early injection-and-cultivation postselection can cause repeated restarts. We propose in-patch multiplexing, which uses idle spacetime inside a single target logical patch to run multiple local cultivation attempts in parallel before the standard escape stage. A surviving candidate is forwarded to the same grafting, decoding, and gap-based acceptance procedure as the single-site baseline. In demonstrations with a $d = 15$ escaped patch, the proposed four-site protocol reduces full-cycle expected attempts by up to 78.69%, reducing cultivation retry overhead while preserving the standard cultivation framework.

Keywords: Magic State Cultivation, Fault Tolerant Quantum Computing, Quantum Error Correction

1 Introduction

Fault-tolerant quantum computing enables reliable universal quantum computation in the presence of physical noise by encoding quantum information into logical qubits and processing it through fault-tolerant logical operations [1, 2]. Universal fault-tolerant computation requires non-Clifford resources, since Clifford operations alone are insufficient for universality and universal transversal gate sets are incompatible with a single quantum error-correcting code [3, 4].

A standard approach to fault-tolerant non-Clifford computation is to prepare and consume logical magic states, such as T -type magic states for implementing T gates [5, 6]. Magic-state distillation is widely used for this purpose, but it requires multiple noisy logical magic states and additional logical circuitry, leading to substantial spacetime overhead [7, 8]. Magic-state cultivation has recently been proposed as a lower-overhead alternative, growing a single local $|T\rangle$ state through injection, cultivation, and escape [9, 10]. However, cultivation remains postselection-based: detector events during the early injection-and-cultivation stages cause the attempt to be discarded and restarted. This work addresses this retry overhead by exploiting idle in-patch spacetime during the early stages of cultivation.

2 Motivation

The motivation of this work comes from the spacetime structure of single-site magic-state cultivation. As shown in Fig. 1, the early injection and cultivation stages use only a limited portion of the final escaped logical patch [9]. In the representative setting considered here, the injection and cultivation stages use local regions associated with $d = 3$ and $d = 5$, whereas the final escape stage uses a $d = 15$ logical patch. Thus, before escape begins, a substantial in-patch spacetime region remains idle.

*youngsun@pknu.ac.kr

Figure 1: Idle spacetime in single-site magic-state cultivation. During the early injection and cultivation stages, only a limited portion of the final $d = 15$ logical patch is actively used, while the remaining in-patch spacetime stays idle until the escape stage begins.

This idle spacetime is important because cultivation is postselection-based. In single-site cultivation, an early detector event rejects the only local trajectory and discards the entire shot. We use the idle early-stage region to create multiple local cultivation opportunities inside the same target patch. If at least one local candidate passes the early detector checks, the protocol can proceed to the standard escape stage. This observation motivates the in-patch multiplexing approach proposed in this work.

3 Proposed Method

We propose an in-patch multiplexing approach that uses the early-stage in-patch spacetime left idle in single-site magic-state cultivation. The proposed protocol places multiple local cultivation sites inside a single target logical patch. As illustrated in Fig. 2, the key idea is to generate multiple local candidates in parallel during the injection-and-cultivation stages and then forward one surviving candidate to the standard escape path.

During injection, four local color-code regions are placed inside a single target logical patch. Each local

Figure 2: Proposed in-patch multiplexed magic-state cultivation protocol. Multiple local color-code regions are initialized in parallel during injection and grown during cultivation inside a common logical patch. After a surviving local candidate is selected, the protocol returns to the standard single escape path through grafting, producing the final $d = 15$ logical patch.

site follows the same local preparation primitive and initializes a local $|T\rangle$ state from a $d = 3$ injection region. Although the four sites are embedded in the same logical patch, they are treated as separate local trajectories. Thus, the proposed protocol creates multiple early-stage cultivation opportunities within a single shot.

During cultivation, each local site grows from a $d = 3$ injection region to a $d = 5$ cultivation region. If a detector event occurs at a particular site, that site is removed from further advancement and is returned to an inactive state. The remaining sites continue through cultivation, and the sites that complete the injection-and-cultivation stages without triggering a detector event form the candidate set. This site-wise rejection rule is the central operational feature of the proposed protocol. The entire shot is discarded only when all local sites fail during the early stages.

Once the candidate set is formed, one surviving candidate is selected and forwarded to the escape stage. The selected candidate is connected to the standard single escape path through grafting, producing the final $d = 15$ escaped logical patch. Candidate selection is performed before escape and does not use post-escape decoder-gap information. The proposed method extends the early injection-and-cultivation stage through in-patch multiplexing, while preserving the final escape stage, decoding pipeline, and gap-based acceptance procedure of the single-site MSC baseline.

$$\left(D_{\text{IC}}^{(1)}\right)^k.$$

Thus, under the independent-site approximation, the early-stage discard probability decreases exponentially

with the number of multiplexed local sites.

$$\frac{1}{1 - D_{\text{IC}}^{(k)}}.$$

Therefore, in-patch multiplexing lowers the early-stage discard probability and reduces the expected number of attempts required to obtain a usable candidate before escape.

4 Results

In this section, we evaluate how much the proposed in-patch multiplexed MSC protocol reduces the expected-attempt cost from a full-cycle perspective. The full cycle includes injection, cultivation, escape, and decoding. In all comparisons, the final escape stage, the desaturation decoder, and the gap-based acceptance procedure are kept identical to those of the single-site MSC baseline. The purpose of this evaluation is therefore to examine how early-stage multiplexing reduces the number of attempts required to obtain one kept logical output under the same escape-stage acceptance framework.

Figure 3 compares the end-to-end cost curves of the single-site MSC baseline and the proposed multiplexed MSC protocol. The horizontal axis shows the expected attempts per kept shot, and the vertical axis shows the logical error rate per kept shot after escape-stage decoding and gap-based acceptance. Solid curves denote the single-site MSC baseline, dashed curves denote the proposed multiplexed protocol, and dotted segments indicate extrapolated estimates in the large-threshold regime where the number of remaining error samples is limited.

The most important feature in Fig. 3 is that the dashed curves of the multiplexed protocol shift toward smaller expected-attempt regions compared with the solid curves

Figure 3: End-to-end cost comparison of the single-site MSC baseline and the proposed in-patch multiplexed MSC protocol. The horizontal axis shows the expected attempts per kept shot, and the vertical axis shows the logical error rate per kept shot after escape-stage decoding and gap-based acceptance. Solid curves denote the single-site baseline, dashed curves denote the multiplexed protocol, and dotted segments indicate extrapolated estimates in the large-threshold regime. The main effect of multiplexing is the shift of the cost curves toward smaller expected attempts.

of the single-site baseline. This shift shows that early-stage multiplexing increases the probability of obtaining a surviving candidate before escape, and that this reduction in retry overhead carries over to the full-cycle evaluation, including escape and decoding. By running multiple local trajectories in parallel during injection and cultivation, the proposed protocol obtains consistent logical outputs with fewer attempts than the single-site baseline.

The reduction becomes more pronounced as the physical error rate and the local cultivation distance increase. For example, at $p = 2 \times 10^{-3}$ with $d_1 = 3$, the full-cycle expected attempts decrease from 3.4288 in the single-site baseline to 1.7473 in the multiplexed protocol, corresponding to a 49.04% reduction. For $d_1 = 5$ at the same physical error rate, the expected attempts decrease from 364.7853 to 77.7446, corresponding to a 78.69% reduction. This behavior indicates that in-patch multiplexing provides a larger retry-reduction benefit in settings where early-stage discard is more frequent.

Overall, the proposed protocol reduces the full-cycle expected-attempt cost while preserving the standard MSC escape-stage decoding and gap-based acceptance procedure. The leftward shift in Fig. 3 demonstrates that early-stage idle spacetime can be used as parallel local cultivation opportunities to reduce the postselection overhead of magic-state cultivation.

5 Conclusion

In this work, we proposed an in-patch multiplexing approach to reduce the early-stage postselection overhead of magic-state cultivation. The proposed protocol uses idle early-stage spacetime inside a single logical patch to create multiple local cultivation opportunities in parallel, and forwards a surviving candidate to the standard escape path. This design preserves the final escape stage, decoding pipeline, and gap-based acceptance procedure of the single-site MSC framework while reducing the retry overhead caused by early-stage discard. In the full-cycle evaluation, the proposed protocol reduces the expected attempts by 49.04% for $d_1 = 3$ and by 78.69% for $d_1 = 5$ at $p = 2 \times 10^{-3}$. These results show that in-patch multiplexing provides an effective protocol-level approach for reducing the postselection overhead of magic-state cultivation.

Abstract. Quantum algorithms for basic numerical linear algebraic tasks have proven essential for translating diverse problems to a unified quantum computational context. Many of these tasks—e.g., applying a function to the spectrum of a matrix embedded in a unitary process (a so-called *block encoding*)—are well-addressed by techniques like quantum singular value transformation (QSVT). However, there exist useful matrix transforms whose realization by quantum algorithms is unclear or inefficient. In this work we construct improved quantum algorithms for some of these transforms, the simplest of which is a *scalar function applied element-wise*. We show the auxiliary space required to compute *quantum element-wise transforms* can be reduced exponentially in the degree of the applied function compared to prior work, and raise and rectify errors in previous constructions. We present these algorithms alongside applications to machine learning, simulation, and signal processing.

Keywords: Quantum algorithms, block encoding, numerical linear algebra, signal processing

1 Overview and main results

The field of classical algorithms relies on a rich substructure of numerical linear algebra [1, 2]. The modern classical numerical linear algebraic toolkit indeed encourages most researchers, as a first attempt, to linearize their problem and determine whether existing methods yield acceptable solutions. The success of this scheme is self-evident; matrix methods pervade signal processing, simulation, statistics, machine learning, and the discrete analogues of huge swaths of functional analysis [3].

The field of quantum algorithms has warmed to a similar scheme. One manifestation is the increasing use of the *block encoding* input model, which embeds a matrix as a sub-block of a larger unitary process. The permissible transformations of block-encodings inform the methods and complexities for mimicking most known quantum algorithms inside a unified, numerically-stable framework [4, 5]. Crucially, for certain transformations and block encodings obeying constraints, these algorithms appear to prepare states and solve discrete problems far more efficiently than their classical cousins.

In this work we expand the quantum numerical linear algebraic toolkit to matrix transformations not easily captured by current block encoding algorithms. Concretely, **we provide quantum algorithms for computing element-wise functions of block encodings using exponentially less space in the degree of the applied function**, compared with prior work. These element-wise matrix functions, while less studied in a quantum context, nevertheless appear ubiquitously in classical signal processing, machine learning, and statistics [6, 7]. Consequently our work provides a new tool, with resource requirements on-par with other practical block encoding algorithms, for computing non-linear transformations of high-dimensional data.

The transformation we consider (the simplest version given in Def. 1) is quite distinct from that of QSVT,

which applies a function to the singular values of a block-encoded matrix, or LCU, which takes linear combinations of block encodings. Our main theorem (Thm. 2) provides the resource complexity of applying an arbitrary polynomial function *element-wise*, and yields an exponential reduction in space use compared with existing work (Tab. 1). We refer to this (and related manipulations) as *quantum element-wise transforms* (QEWTs).

Definition 1 (Element-wise function of a matrix) *Let $M \in \mathbb{C}^{n \times m}$; then the element-wise application of a function $f : \mathbb{C} \rightarrow \mathbb{C}$ to M , denoted $f^\circ(M)$ is simply:*

$$f^\circ(M) \equiv \begin{bmatrix} f(a_{00}) & f(a_{01}) & \cdots & f(a_{0,m-1}) \\ f(a_{10}) & f(a_{11}) & & \vdots \\ \vdots & & \ddots & \\ f(a_{n-1,0}) & \cdots & & f(a_{n-1,m-1}) \end{bmatrix}.$$

Theorem 2 (Quantum element-wise transform)

Let f be a polynomial of degree d with no constant term satisfying $|f| \leq 1$ on $[-1, 1]$, with coefficients $c_k, k \in \{1, \dots, d\}$. Then, given U an (α, a, ε) block encoding of an n -qubit operator A , there is a quantum circuit preparing a (β, b, δ) block encoding of $f^\circ(A/\alpha)$ —the element-wise application of f to A —requiring $\mathcal{O}(d)$ copies of controlled U and $U^\dagger$, and single/two-qubit gates, where (β, b, δ) satisfy

$$\beta = \sum_{k=1}^d |c_k| \alpha^k, \quad b = \mathcal{O}(a + n \log d), \quad (1)$$

$$\delta = \sum_{k=1}^d |c_k| \left[(\alpha + \varepsilon)^k - \alpha^k \right]. \quad (2)$$

The resource complexities of our constructions are compared with prior work in Tab. 1.

Beyond our space-compressed construction of QEWTs, we also provide a comprehensive treatment of prior work,

*zmr@g.ecc.u-tokyo.ac.jp

Method	Query comp.	Aux. space	Notes
Prior work [8]	d	$\mathcal{O}(ad + nd)$	Low depth
Main result (Thm. II.3)	d	$\mathcal{O}(a + n(\log d))$	$\mathcal{O}(d)$ depth
LCU variant (Thm. III.4)	d	$\mathcal{O}(a + n(\log d))$	Reduced space
Approx. variant (Cor. III.5.2)	$\mathcal{O}(d^{\log(\log(d/\varepsilon))})$	$\mathcal{O}(a + n \log(d^{\log(\log(d/\varepsilon))}))$	Input assump.
Half-compressed (Thm. C.1)	d	$\mathcal{O}(a + nd + \log d)$	Low depth

Table 1: High-level overview of the resource complexities of our main result, its variants, and prior work. The problem considered is the element-wise application of a polynomial of degree d given an n -qubit matrix block-encoded using a -qubits of auxiliary space. Our main construction can be further space-compressed by an LCU-based variant, as well as amplified and approximated under certain assumptions on the block-encoded input. The referenced theorems and corollaries provide detailed resource complexities, associated quantum circuits, and error analysis.

raising and rectifying errors which otherwise invalidate previous constructions. This includes an efficient circuit for constructing so-called SELECT unitaries (Prop. C.2):

$$\sum_{k=1}^d |k\rangle\langle k| \otimes U_{A^{\circ k}}, \quad (3)$$

which are required to apply linear combination of unitaries (LCU) [9, 10, 11] techniques to bootstrap element-wise powers of block encodings to arbitrary element-wise functions. We identify and resolve errors in prior work’s SELECT constructions [8], allowing for the recovery of their main statements (with slight changes in gate complexity) as well as a simple hybridization scheme to exchange circuit width and depth for QEWTs (Cor. II.3.1).

Finally, we devote Sec. III to a series of alternative methods for computing exact and approximate QEWTs. This includes a construction for further reducing the auxiliary space required by a constant amount (Thm. III.4), as well as a modification incorporating a variant of robust, oblivious amplitude amplification (ROAA) (Cor. III.5.2) to increase the success probability of applying the resulting transformed block encoding under assumptions on the input.

2 Methods and prior work

The core of our construction depends on the orchestration of well-known and (to the authors’ knowledge) new but simple subroutines for manipulating block encodings. These include (1) a known identity relating the element-wise product of matrices to a principal submatrix of their Kronecker product, (2) a known construction for exponentially reducing the auxiliary space required when *matrix multiplying* many block encodings at once (the *compression gadget* of Low and Wiebe [12, 13]), and (3) a method for cheaply duplicating blocks of block encodings *which themselves have block structure* (which we call a *swap-copy*, Lem. II.1) *as well as* a way to efficiently re-use the auxiliary space required by the swap-copy inside recursively self-composed versions of our protocol, enabling space-efficient computation of high-degree element-wise products (our *weaving lemma*, Lem. II.2).

The primary contribution of our work, beyond constructing (3), is showing that all of (1), (2), and (3) interact while maintaining correctness and $\mathcal{O}(\log d)$ auxiliary

space. Here we briefly describe a condensed version of (3) with associated Figs. 1 and 3.

Lemma 3 (Swap-copy) *Let U block encode $(A \oplus B)$, where $\dim B = (2^n - 1) \dim A$. Then using one query to U , a register of n qubits initialized to $|0^n\rangle$, and $2n$ swap gates, one can deterministically construct a unitary V block encoding $A^{\oplus 2^n}$. Moreover, after applying V , the additional n -qubit register remains in the $|0^n\rangle$ state.*

For expediency we only informally describe (along with Fig. 1) the action of the weaving lemma (Lem. II.2), which allows us to allocate a number of copies of the register r_0 used by the swap-copy operation that scales only with the *depth* of the tree of function-calls that recursively define our element-wise product (Figs. 2, 3). The core observation is that, when working with block encodings with known (+1)-eigensubspaces, we re-use states in this subspace *across sequential applications* of this block encoding by recording each constituent block encoding’s successful application through a compression gadget.

Figure 1: Simplified depiction of our ‘weaving lemma’ (Lem. II.2). Here $(*)$ represents a quantum subroutine catalytically using copies of $|0\rangle_{r_0}$ by swapping the r_0 and r_1 registers. Catalysis here means that $(*)$ is block-diagonal with a known (+1)-eigensubspace. The use by $(*)$ of r_0 is indicated by an allocation (a) and freeing (f). If each $(*)$ itself sequentially calls copies of $(*)$, then the total required copies of r_0 grows with the *depth* of the tree of recursive calls to $(*)$.

To enforce block-diagonality of block encodings, which enables the catalytic re-use of auxiliary space by our nested swap-copy operations, we simultaneously rely on the well-known *compression gadget* [12] which records the

Figure 2: Depiction of the circuit for *clean element-wise products* of block encodings, i.e., block encodings of $I_{r_1} \otimes (A \circ B)_{r_3}$ using auxiliary space r_2r_4 . Note if r_2r_4 is in the all-zeros state, then $|0^n\rangle$ in r_0 is used catalytically by the swap-copy. Here (+) notation indicates projection-controlled addition to r_4 , used for the compression gadget. In our recursive construction each $U_{(I \otimes *)}$ is replaced by an analogous circuit which acquires (1) a new copy of r_0 for each recursive level, and (2) contributes to the size of r_4 , but otherwise acts identically on $r_1r_2r_3$.

success of serial block encoding multiplications in binary on an auxiliary register (denoted r_4 in Fig. 3). In each of our variant constructions, either by interstitial block encoding multiplications, or simple LCUs, we can, conditioned on the register r_4 ending up in the all zeros state, ensure block-diagonality of subroutines. This allows us to take a circuit for block encoding $(A \otimes B)$, which has as a principal sub-matrix $(A \circ B)$ (the element-wise product), and transform it into a block encoding of $I \otimes (A \circ B)$ on the *same registers*, permitting recursive self-composition.

Figure 3: A depiction of the first level of our recursive construction for taking element-wise powers of two block encodings W'_L, W'_R . Note the register used for the compression gadget, r_4 , is not duplicated, and remains the target for the addition gadgets of protocols deeper in the recursion. A new register of size n , r'_0 , is initialized to $|0\rangle$, and a new copy introduced at each level of recursion, though *re-used between swap-copies at the same level*, given the catalytic behavior of the original circuit. This catalysis succeeds under the assumption that all block encodings are successfully applied (equivalently, that the registers r_2 and r_4 both end up in the all zeros state).

To summarize, our construction first identifies our desired element-wise product with a matrix product on an expanded Hilbert space (in this case the Kronecker product of two block encodings), then introduces additional block encoding products to enforce block-diagonality, and then simultaneously applies both (a) our swap-copy operation and (b) the standard compression gadget to a recursively defined construction. Both (a) and (b), albeit for different reasons, require auxiliary space growing only logarithmically in the degree of the element-wise product. We then build an element-wise SELECT unitary,

after which standard LCU techniques yield Thm. 2.

Regarding prior work, beyond the aforementioned direct improvement to the linear-space QEWT of [8], our construction provides an operator extension to state-based non-linear transformation algorithms [14, 15], as well as a non-trivial extension to the widely applied compression gadget to non-standard matrix products [12, 13]. By bringing the space, query, and gate complexity of our algorithm in line with other widely-applied matrix functions of block encodings, we enable the practical investigation of running our construction on near-term devices, and incorporating element-wise transforms, which appear widely in classical signal processing, machine learning, and simulation, into the quantum algorithmic toolkit.

3 Discussion, applications, and impact

Our work constructs a new **quantum algorithm for computing element-wise functions of block encodings whose space use scales logarithmically rather than linearly in the degree of the applied function**—this scaling, matching that of methods for applying spectral maps to (QSVT; [4]) or taking linear combinations of (LCU; [9]) block encodings, represents a new and practically implementable subroutine within the block encoding toolkit. Moreover, we rectify errors in previous work, establishing a robust foundation for the theory of *quantum element-wise transforms* (QEWTs).

Beyond introducing a class of improved quantum algorithms, we devote Sec. IV of our work to specific applications across (1) machine learning inference, (2) multi-dimensional signal processing, and (3) generalized matrix products. For (1) we apply our main construction to reduce the space requirements for computing the element-wise softmax function of block encoding products (appearing in the self-attention step of transformer model inference), improving prior constructions in [8, 16]. In (2) we show multidimensional analogues of the well-known convolution theorem allow us to space- and time-efficiently compute 2D convolutions of block encodings. Finally in (3) we provide quantum algorithms for well-known block-matrix products (the *Tracy-Singh* and *Khatri-Rao* products [17, 18]) whose algorithms follow (space-efficiently) from our main theorem.

Our work suggests numerous extensions, including the use of randomized/approximative techniques to further improve performance under architectural constraints, as is widely applied to other block encoding algorithms [19, 20, 21]. We expect that additional knowledge of the input (e.g., low rank or well-conditioned) can be leveraged for performance, and that variants of our swap-copy and weaving lemma can yield independently interesting methods for manipulating block encodings with block structure or known eigensubspaces.

Our aim is that quantum algorithms for core numerical linear algebraic subroutines can be efficiently and interpretably combined and generalized to (1) more easily incorporate sophisticated classical techniques and (2) admit the practical application of numerical tools for compilation/verification/optimization of quantum subroutines.

Quantum algorithms for basic numerical linear algebraic tasks have proven essential for translating diverse problems to a unified quantum computational context. Many of these tasks—e.g., applying a function to the spectrum of a matrix embedded in a unitary process (a so-called *block encoding*), or taking linear combinations of these block encodings—are well-addressed by techniques like quantum singular value transformation (QSVT) or linear combination of unitaries (LCU). However, there exist useful matrix transforms whose realization by existing quantum algorithms is unclear or inefficient. In this work we construct improved quantum algorithms for some of these transforms, the simplest of which is a *scalar function applied element-wise*. We show the auxiliary space required to compute *quantum element-wise transforms* can be reduced exponentially in the degree of the applied function compared to prior work, and raise and rectify errors in previous constructions. We present these algorithms alongside applications to machine learning, simulation, and signal processing.

I. Introduction

The field of classical algorithms—and the art of running these algorithms on real-world devices—reveals, wherever one stoops to flip over a rock, a rich sub-structure of numerical linear algebra [Tre19, TB22]. The modern classical numerical linear algebraic toolkit indeed encourages most researchers, as a first attempt, to linearize their problem and quickly determine whether existing methods yield acceptable solutions or useful insights. The success of this scheme is self-evident; matrix methods pervade signal processing, differential equations, statistics, machine learning, and the discrete (and thus classically computable) analogues of huge swaths of functional analysis.

The field of quantum algorithms has warmed to a similar scheme. One manifestation of this is the increasing use of the *block encoding* (Def. II.1) input model, which embeds a matrix as a sub-block of a larger unitary process run on a quantum computer. The permissible transformations of these block-encoded matrices (which represent non-linear subsystem dynamics) inform both the methods and resource complexities for mimicking a diverse family of previously known quantum algorithms inside a unified, numerically-well-understood framework [GSLW19, MRTC21]. Crucially, for certain common transformations, and for block-encoded matrices obeying certain constraints, these algorithms appear to be able to prepare states, sample from distributions, and solve discrete problems far more efficiently than their classical cousins (e.g., for certain N -dimensional problems, the required space or time for a quantum algorithm can scale as $\text{polylog}(N)$).

In this work we expand the quantum numerical linear algebraic toolkit to matrix transformations not easily captured by current block encoding algorithms. Concretely, we provide simple and improved circuits for computing non-standard matrix products, permitting exponential space reductions compared with previous work. These non-standard products (e.g., the *element-wise* product), while less studied in a quantum context, nevertheless appear ubiquitously in classical signal processing, machine learning, and statistics (see Sec. IB). This provides a new tool, with resource requirements on par with other block encoding algorithms, for efficiently computing non-linear transformations of high-dimensional data.

We will construct and explicate multiple quantum algorithms for computing various matrix products under differing input assumptions, but use the rest of this section to define the simplest example (Sec. IC introduces some of the relevant used notation), highlighting how our matrix transformations differ from those usually considered for algorithms like quantum singular value transformation (QSVT) [GSLW19]; a brief introduction to the suite of previously known block-encoding-based quantum algorithms (many of whose methods appear in our work) appears in Sec. IIA.

Definition I.1 (Singular-value transformation of a matrix). Let $M \in \mathbb{C}^{n \times n}$ a matrix with $\|M\| \leq 1$; then the *singular-value transformation* (SVT) of M according to a function (typically continuous) $f : [0, 1] \rightarrow [0, 1]$ is:

$$f^{(\text{SV})}(M) \equiv U f(\Sigma) V^\dagger = U \begin{bmatrix} f(\xi_0) & & \\ & \ddots & \\ & & f(\xi_{n-1}) \end{bmatrix} V^\dagger, \quad \Sigma = \text{diag}(\xi_0, \xi_1, \dots, \xi_{n-1}), \quad (1)$$

where $M = U \Sigma V^\dagger$ is the singular value decomposition (SVD), and where we have restricted to the square case (otherwise one can pad Σ with additional rows or columns of zeros, and increase the dimensions of the unitary U and V to keep the product conformable).

QSVT, whose main results are introduced and employed in Sec. II, provides a method to compute the SVT of exponentially large matrices using simple circuits whose depth scales as the degree of a polynomial approximating f to a desired precision. In our work we will instead focus on a well-defined, commonly applied, but comparatively less well-studied matrix transformation wherein a function is applied *element-wise* to M . Before defining this transformation we quickly disambiguate between two types of matrix product.

Definition I.2 (The matrix and element-wise products). Throughout this work we will refer to a number of non-standard products between matrices (a table for our notational choices is given in Sec. IC). The most well-known of these is the standard *matrix product*, which takes $A \in \mathbb{C}^{n \times m}$ and $B \in \mathbb{C}^{m \times p}$ and returns $C = AB \in \mathbb{C}^{n \times p}$ following $C_{ij} = A_{ik}B_{kj}$, where repeated indices are summed over. Less commonly, and here referred to as the *element-wise product*, one can take two matrices A and B of identical shape and compute $C_{ij} = A_{ij}B_{ij}$, denoted¹ $C = A \circ B$.

The element-wise product, like its matrix product cousin, is associative and distributes over matrix addition; moreover, it is also commutative and an inverse for $\circ$ exists for a matrix A if and only if all of its elements are non-zero. These properties, among numerous related ones, are given treatment in Ch. 5 of the standard reference [HJ91]. Definitions or results we make heavy use of related to element-wise products are glossed in Appx. B. This product can be immediately extended, given its pleasant properties, to the notion of an *element-wise function* applied to a matrix.

Definition I.3 (Element-wise function of a matrix). Let $M \in \mathbb{C}^{n \times m}$; then the element-wise application of a function $f : \mathbb{C} \rightarrow \mathbb{C}$ to M , often denoted $f^\circ(M)$, is simply:

$$\begin{bmatrix} a_{00} & a_{01} & \cdots & a_{0,m-1} \\ a_{10} & a_{11} & & \vdots \\ \vdots & & \ddots & \\ a_{n-1,0} & \cdots & & a_{n-1,m-1} \end{bmatrix} \mapsto \begin{bmatrix} f(a_{00}) & f(a_{01}) & \cdots & f(a_{0,m-1}) \\ f(a_{10}) & f(a_{11}) & & \vdots \\ \vdots & & \ddots & \\ f(a_{n-1,0}) & \cdots & & f(a_{n-1,m-1}) \end{bmatrix}. \quad (2)$$

Equivalently, we could express this element-wise function using index notation: $a_{ij} \mapsto f(a_{ij})$.

It is this transformation (and its constituent operations and extensions) that will be the main subject of this work. We will generically refer to quantum algorithms achieving this and related transforms of block-encoded matrices *quantum element-wise transforms* (QEWTs),² joining an already-large family of acronyms and initialisms for block-encoding based algorithms (see Sec. IB).

Unlike singular value transformations (and related eigenvalue or Jordan-block transformations), which have been the focus of previous quantum algorithms research, these element-wise transformations exhibit numerous unusual properties, including basis-dependence and non-obvious effect on the matrix norm (and rank, positive-definiteness, condition number, etc.). Correspondingly the space-, query-, and gate-complexities, as well as success probability upper- and lower-bounds for quantum algorithms computing element-wise functions of matrices remain incompletely characterized. In the following section we provide an overview of our main results (Sec. IA), discussion of prior work on adjacent topics and related quantum algorithms (Sec. IB), and finally a quick-start guide to our notation, which for this topic especially is inhomogeneous across literature (Sec. IC).

A. Main results

We construct a quantum circuit that uses d copies of a unitary block encoding of a matrix and produces a block encoding of a desired function applied element-wise (in a chosen basis) to that matrix. The cost of this transformation (as in previous work) can be measured along multiple axes, including query complexity, gate complexity, auxiliary space use, block encoding subnormalization, and success probability.

For brevity we present a table (Tab. I) comparing our construction to the prior work in terms of query complexity and auxiliary space use, and leave detailed discussion of our

¹ Here, and confusingly across literature, the repeated indices i, j are *not* summed over, but merely denote component-wise access. Where possible we try to avoid Einstein summation notation.

² Pronounced like *newt* 🐸.

Method	Query comp.	Aux. space	Notes
Prior work [GYC ⁺ 25]	d	$\mathcal{O}(ad + nd)$	Low depth
Main result (Thm. II.3)	d	$\mathcal{O}(a + n(\log d))$	$\mathcal{O}(d)$ depth
LCU variant (Thm. III.4)	d	$\mathcal{O}(a + n(\log d))$	Reduced space
Approx. variant (Cor. III.5.2)	$\mathcal{O}(d^{\log(\log(d/\varepsilon))})$	$\mathcal{O}(a + n \log(d^{\log(\log(d/\varepsilon))}))$	Input assump.
Half-compressed (Thm. C.1)	d	$\mathcal{O}(a + nd + \log d)$	Low depth

TABLE I. High-level overview of the resource complexities of our main result, its variants, and prior work. The problem considered is the element-wise application of a polynomial of degree d given an n -qubit matrix block-encoded using a -qubits of auxiliary space. The simplest construction we provide (Thm. II.3) can be further space-compressed by an LCU-based variant, as well as amplified and approximated under certain assumptions on the block-encoded input. The referenced theorems and corollaries provide detailed (i.e., non-asymptotic) resource complexities, associated quantum circuits, and error analysis.

construction’s full attributes to the main text. We also note that while our work and prior work give constructions of a ‘sequential’ and ‘parallel’ flavor respectively, both have success probability that can decrease (at worst) exponentially in d . This is a generic feature of quantum algorithms that multiply d (possibly ill-conditioned) block encodings, and we enumerate and investigate the minimal sufficient assumptions (common in prior work using similar subroutines [LW19, FLT23, VG25]) to avoid worst-case behavior.

Theorem I.1 (Quantum element-wise transform; *condensed*). Let f be a polynomial of degree d with no constant term satisfying $|f| \leq 1$ on $[-1, 1]$, with coefficients $c_k, k \in \{1, \dots, d\}$. Then, given access to controlled U and controlled $U^\dagger$, where U is an (α, a, ε) block encoding of an n -qubit operator A , there exists a quantum circuit preparing a (β, b, δ) block encoding of $f^\circ(A)$ —the *element-wise application of f to A* —which requires $\mathcal{O}(d)$ copies of controlled U and $U^\dagger$, and single/two-qubit gates, where (β, b, δ) satisfy

$$\beta = \sum_{k=1}^d |c_k| \alpha^k, \quad b = a + n \lceil \log d \rceil, \quad \delta = \sum_{k=1}^d |c_k| \left[(\alpha + \varepsilon)^k - \alpha^k \right]. \quad (3)$$

While the top-line result of this work is an improved method for quantum element-wise transformation of block encodings, our construction comprises numerous subroutines that may be of independent interest. Principally these are (1) a novel technique for introducing a small amount of additional space when processing block encodings with block structure to cheaply copy sub-blocks in fixed bases (which we call the ‘weaving lemma’ for its multi-time use of known, catalytic quantum states that can be ‘woven’ through a quantum circuit), (2) the modification of quantum circuits for element-wise products such that we can apply previously-known ‘compression gadgets’ for reducing space requirements when computing matrix products of block encodings, and (3) the use of simple, LCU-based subroutines and variants of amplitude amplification to improve success probability and gate complexity simultaneously. These techniques prove remarkably flexible, and we devote a section (Sec. III) to their modification and improvement under specific assumptions.

None of the individual techniques in this work is particularly complex, though their assemblage introduces a bit of index bookkeeping. To build intuition for our construction we provide an overview of salient block encoding manipulation techniques (Sec. II A), then cover a small-scale example introducing the intended action of each subroutine (without their realizing circuit) (Sec. II B), followed by a sequential construction of element-wise products followed by element-wise functions (Secs. II C and II D). Finally we discuss the quantum element-wise transform in generality, introducing more involved variant constructions with improved properties in special cases (Sec. III). Along the way we clarify some subtleties under-emphasized in previous work, toward a thorough treatment of the theory of these *quantum element-wise transforms*, as well as their application to existing classical and quantum problems (Sec. IV).

B. Prior work

Below we introduce some work related to our construction along the following axes: (1) the theory and common uses of element-wise products and functions of matrices/tensors, (2) existing techniques for realizing element-wise transformations with quantum algorithms (and their application), and finally (3) parallel work in quantum algorithms for computing other non-standard matrix functions (or functions restricted to sub-classes of matrices allowing for significant resource improvements).

An accessible treatment of the theory of element-wise products can be found in the well-known textbook of Horn and Johnson [HJ85] (which uses the term *Hadamard product*); this product is also given its own chapter (Ch. 5) in their topics textbook [HJ91], which sketches its common uses, e.g., for computing convolutions among periodic functions, when studying integral equation kernels (with applications to Mercer’s theorem), as related to the weak minimum principle in PDEs, and in the study of characteristic functions (related to Bochner’s theorem). Horn and Johnson also gloss applications to combinatorics (e.g., association schemes), computing covariance matrices, control theory (e.g., the study of the relative gain array), and analyzing solutions to various generalized matrix equations (e.g., the Lyapunov equation). The study of fundamental analytic properties of the element-wise product (and its block-matrix variants [Joh74, KR68, TJ89, Liu99, HC89]) applied to structured families of matrices is active and ongoing, though these technical treatments are beyond the scope of this work.

The element-wise product appears commonly throughout classical signal processing, statistics [MN99, Sty73, KNW91], the analysis of certain matrix and integral equations [KR68, TS72], as well as ubiquitously in machine learning and tensor arithmetic [KB09, CWP⁺25]. Much of these latter applications center on this product’s ability to cheaply introduce nonlinearities into tensor manipulations, as well as compute useful approximations to certain tensors (e.g., the canonical polyadic decomposition: CPD). From this standpoint the element-wise product could be seen as an essential sub-routine for tensorial algorithmic analogues to singular value decomposition/transformation (noting, to temper this analogy, that many problems in the computation of useful tensorial properties are known to be extremely difficult [HL13]). In any event, at a practical level, the cheap computation element-wise transforms in a dimension-efficient way by quantum computers offers numerous doors into the study of wide sub-fields of applied numerical linear algebra.

The problem of computing element-wise products between representations of linear operators encoded in quantum processes has been considered previously [ZZRF21, GYC⁺25, DLX25, LTLF26] in varying access models, and has some connection to the related problem of applying non-linear functions to quantum state amplitudes [GMF24, RR23, HCSS23]. In general the work of applying element-wise functions to block encodings, as noted in [RR23] is incomparable to the state case, which relies on a crucial coincidence between various matrix products under diagonality assumptions. Simultaneous work has also considered numerous applications downstream of these transforms, e.g., the computation of convolutions [RHG⁺25]. Nevertheless, the constructions given in these works (by-and-large un-optimized and treated only in passing) leave the study of element-wise transformations quite open and, as we show, subject to significant improvement and generalization.

More generally the theory of (and accompanying numerical tools for) block-encoding quantum algorithms has expanded rapidly over the past ten years. This includes quantum signal processing (QSP) [LYC14, LYC16, LC17, LC19] and its lifted version quantum singular value transformation (QSVT) [GSLW19], which have been the main focuses of pedagogical introductions³ to the subfield [MRTC21, TT24], and whose numerical properties (e.g., results on the convergence of classical algorithms for computing the *QSP phases*) have received extensive treatment⁴ with accompanying public software [Haa19, CDG⁺20, WDL22, DMWL21, DLNW24]. QSP and QSVT have themselves spawned a complex landscape of

³ For the basic results we use in this work, see the treatment of Sec. II A.

⁴ Including recent work tethering the theory of QSP/QSVT and their variants to beautiful methods in the comparatively niche subfield of *non-linear Fourier analysis* [AMT24, ALM⁺26].

variants and extensions, including the multivariable setting (M-QSP) [RC22], the indefinite parity setting (G-QSP) [MW24], methods for eigenvalue transformations [LS26, GLS26], modular versions [RCC25], extensions to continuous variables [RBM23, BW26], and the practical use of randomization [MR25] and parallelization [MRC⁺25]. Moreover, beyond QSP and QSVT, which transform block encoding spectra, other algorithms for block encoding arithmetic have found diverse success, including linear combination of unitaries (LCU) for Hamiltonian simulation [CW12, BCC⁺14, BCK15], linear combination of Hamiltonian simulation (LCHS) for simulating general PDEs [ALL23, ACL26, LS25], and the combined use of QSVT and LCU for algorithms approximating contour integrals as applied to simulation and linear systems solving [SLBB25, SBS26].

The constructions above have also yielded independently interesting and widely applicable methods for reducing space use in block encoding algorithms [LW19, VG25], increasing success probability, and leveraging known problem structure to improve resource requirements both above the block-encoding layer [ZS24, LKB⁺25, Yua25] and for compiling desired block encodings down to the gate-level [NKL22, CVB22, SCC24, CLVBY24]. Together these improvements compose a growing toolkit of flexible, fungible quantum algorithms for the manipulation of linear operators, with great potential (as we begin to implement these sub-routines on real devices with specific architectural constraints) in hybridization, heuristic-led optimization, and approximate or ‘fuzzy’ extensions.

C. Notation and terminology

We denote the set of positive integers as $\mathbb{N}$, the set of positive real numbers as $\mathbb{R}_+$, and $\log$ will always denote logarithm base 2, unless stated otherwise. The complex Hilbert space associated with n qubits has dimension 2^n ; any linear operator acting on this Hilbert space is called an n -qubit operator, following the convention of [GSLW19], and is represented by a $2^n \times 2^n$ matrix over $\mathbb{C}$. All matrices and tensors, when their shape or dimension is given, are taken over $\mathbb{C}$ unless otherwise noted; we sometimes use the notation M_n or $M_{n,m}$ for matrices of size $n \times n$ or $n \times m$ over $\mathbb{C}$. For a vector $v \in \mathbb{C}^m$ we index its components $v_0, \dots, v_{m-1}$, and denote the vector and matrix p -norms by $\|v\|_p$ and $\|A\|_p$ respectively for all $p \geq 1$. We often use the operator norm induced by the vector 2-norm (the *spectral norm*) which we denote $\|A\|$. Where specific notation is required, it will be introduced *in situ*.

A focus of this work is the efficient computation of various matrix and vector products by quantum algorithms. The names and notation of these products is hopelessly inconsistent across prior work, both across and within disciplines. Below we provide a legend for the notational convention we follow in this work (all standard with the $\text{\LaTeX}$ `amssymb` package):

$$\otimes \quad \text{\code\otimes} \quad (\text{Kronecker/tensor product}), \quad (4)$$

$$\circ \quad \text{\code\circ} \quad (\text{Element-wise product}), \quad (5)$$

$$\boxtimes \quad \text{\code\boxtimes} \quad (\text{Tracy–Singh product; Def. IV.3}), \quad (6)$$

$$\odot \quad \text{\code\odot} \quad (\text{Khatri–Rao product; Def. IV.4}), \quad (7)$$

$$\ast \quad \text{\code\ast} \quad (\text{Convolution}), \quad (8)$$

$$\cdot / \times \quad \text{\code\cdot} / \text{\code\times} \quad (\text{Matrix product/block-encoded product}). \quad (9)$$

For the usual matrix product we will usually use no symbol at all, and the non-standard use of $\times$ for the matrix product of *block encoded* matrices is repeated explicitly where relevant to avoid confusion.

We exclusively employ the term *element-wise product* to refer to the operation in Def. I.2, which is elsewhere variously referred to as the *Hadamard*, *Schur*, *entry-wise*, or *point-wise* product, which we do not use given their collision with common constructions in quantum information. For the products mentioned above we will provide further in-line notes when defining related variants.

Remark I.1 (On matrix subscript conventions). We often make reference to unitary matrices that encode other matrices as sub-blocks, where these sub-blocks themselves have

special block structure. This introduces a necessity for non-standard subscript uses, e.g., we may refer to a block encoding unitary (Def. II.1) as U_{A,ij,r_1r_3} .

In this case we will always use upper-case Latin letters to denote the block encoded operator, doubled lower-case Latin indices to denote matrix elements, and r_k subscripts to denote the qubit registers on which a linear operator acts. Sometimes we will also use single Latin indices to denote lists of operators, e.g., U_k for $k \in \{0, 1, \dots, n\}$.

As expected, the tensor product of two unitaries on two registers acts on their concatenation: $W_{r_1r_2} \equiv U_{r_1} \otimes V_{r_2}$; for non-unitary matrices (e.g., a linear combination of unitaries all acting on a set of registers) we use the same subscript conventions. In all cases we follow the standard practice in quantum information where tensor products are considered equal up to the canonical isomorphism induced by re-ordering registers.

We take liberties when denoting operations where the registers on which they act are obvious, e.g., following common conventions we sometimes denote the all-zeros state on n qubits as $|0^n\rangle$, or even simply $|0\rangle$, and the n -qubit identity matrix as I_n . Additionally, when only a subset of the indices given in Rem. I.1 is provided, we will sometimes insert additional commas for clarity.

II. Main construction

The core contribution of our work involves the interaction of straightforward but carefully defined subroutines for transforming matrices that have been *block-encoded* as sub-blocks of unitary processes. To smoothly introduce these subroutines (and the subtleties of their composition) we briefly review basic facts and methods related to block encodings (Sec. II A), followed by the aforementioned small-scale example of the *action* of our construction (Sec. II B). We then motivate and explicate, in isolation, constructions enabling these *actions* in the general case (Sec. II C). These constructions comprise most of the novelty of this work, and are bootstrapped to our full *quantum element-wise transform* (Sec. II D) mainly through the application of well-known block encoding techniques. Throughout this section we discuss quirks of element-wise products (and the quantum algorithms realizing them), raising and rectifying gaps in previous work on the subject.

A. Block encoding basics

Before continuing to our main construction we briefly outline some common definitions and constructions for quantum algorithms manipulating block encodings; we focus on concision, covering only those techniques that appear in this work. For general, accessible references to this class of quantum algorithms we refer to the reader to standard entry-points [GSLW19, MRTC21, TT24].

Definition II.1 (Block encoding; cf. [GSLW19]). Let A be an n -qubit operator, $\alpha, \varepsilon \in \mathbb{R}_+$, and $a \in \mathbb{N}$. We say an $(n + a)$ -qubit unitary U is an (α, a, ε) *block encoding* of A if

$$\|A - \alpha(\langle 0^a | \otimes I_n)U(|0^a\rangle \otimes I_n)\| \leq \varepsilon. \quad (10)$$

Note that as $\|U\| \leq 1$, we have $\|A\| \leq \alpha + \varepsilon$, by the triangle inequality: equivalently, that the top-left block of U contains an $(\varepsilon$ -approximate) α -subnormalized copy $\tilde{A}$ of A :

$$U = \begin{bmatrix} \tilde{A}/\alpha & * \\ * & * \end{bmatrix} \implies \tilde{A} = \alpha(\langle 0^a | \otimes I_n)U(|0^a\rangle \otimes I_n), \quad (11)$$

with $\|\tilde{A} - A\| \leq \varepsilon$. The quantity α in (10) is known as the *subnormalization factor*. In the case that A is non-square (or has dimensions not a power-of-two), this definition can be recovered by padding the rows and columns of A with zeros.

A natural question is whether the class of efficiently constructable block encodings is interesting, as generically specifying exponentially-many matrix elements is prohibitively expensive. The originating reference [GSLW19] enumerates multiple settings (e.g., sparse oracles, state preparation unitaries, free Hamiltonian evolution) where block encoding access is natural and efficient.

Moreover, block encodings, by merit of encoding non-unitary behavior within a larger unitary process, turn out to be incredibly useful for subsuming diverse techniques in numerical linear algebra and quantum algorithms generally. In what follows we enumerate common operations and transformations of block encodings.

Definition II.2 (Block encoding multiplication). Let U and V be (α, a, ε) and (β, b, δ) block encodings of n -qubit operators A and B , respectively. Then $(I_{r_1} \otimes U_{r_2 r_3})(I_{r_2} \otimes V_{r_1 r_3})$ is a $(\alpha\beta, a+b, \alpha\delta + \beta\varepsilon + \varepsilon\delta)$ block encoding of the *matrix product* AB . Here we have defined qubit registers r_1, r_2, r_3 , which are respectively of size b, a, n . The additional space (register) used by one block encoding unitary (either a or b qubits, contained in r_2 or r_1) is left alone by the other.

Definition II.3 (State preparation pair). Let $y \in \mathbb{C}^m$ and $\|y\|_1 \leq \beta$. For $b \geq \log m$, a pair of b -qubit unitaries P_L, P_R is called a (β, b, ε) *state preparation pair* for y if

$$P_L|0^b\rangle = \sum_{k=0}^{2^b-1} c_k|k\rangle, \quad P_R|0^b\rangle = \sum_{k=0}^{2^b-1} d_k|k\rangle, \quad \text{and} \quad \sum_{k=0}^{m-1} |\beta(c_k^* d_k) - y_k| \leq \varepsilon, \quad (12)$$

where for all $k \in \{m, \dots, 2^b - 1\}$, $c_k^* d_k = 0$.

Theorem II.1 (Linear combination of unitaries; from [GSLW19]). Let $A = \sum_{k=0}^{m-1} y_k A_k$ be a weighted sum of n -qubit operators A_k , for some $y \in \mathbb{C}^m$ and $\|y\|_1 \leq \beta$. Then given a (β, b, ε) state preparation pair (Def. II.3) (P_L, P_R) for y , and access to U_k for $k \in \{0, \dots, m-1\}$ respectively $(\alpha, a, \varepsilon')$ block encodings of the A_k , we can implement a $(\alpha\beta, a+b, \alpha\varepsilon + \beta\varepsilon')$ block encoding of A with a single use of P_L, P_R , and a SELECT unitary W of the form

$$W = \sum_{k=0}^{m-1} |k\rangle\langle k|_{r_1} \otimes (U_k)_{r_2 r_3} + \left[\left(I - \sum_{k=0}^{m-1} |k\rangle\langle k| \right)_{r_1} \otimes I_{r_2} \otimes I_{r_3} \right]. \quad (13)$$

Note here that we have notated by subscripts the registers on which our operators act, where r_1, r_2, r_3 have size $b = \lceil \log m \rceil, a, n$ respectively. The unitary product achieving this block encoding has the simple form $W' = ([P_L^\dagger]_{r_1} \otimes I_{r_2 r_3}) W_{r_1 r_2 r_3} ([P_R]_{r_1} \otimes I_{r_2 r_3})$.

It turns out that we can do even better than LCU for a certain class of matrix transformations described by spectral maps. The most prominent of these algorithms, quantum singular value transformation (QSVT), has proven remarkably useful in unifying, simplifying, and improving the performance of previously disparate quantum information processing tasks [MRTC21]. We reproduce the main statement of QSVT below, towards presenting a few common applications that will appear as subroutines in our later constructions. This statement is adapted and simplified from various presentations (e.g., Thms. 17 and 18 in [GSLW19], Ch. 13 of [LW26]), and we refer interested readers to pedagogically-oriented and streamlined introductions to this useful class of quantum algorithms [MRTC21, TT24, LW26].

Definition II.4 (Quantum singular value transformation). Let U an $(1, a, 0)$ block encoding of an n -qubit operator A according to orthogonal projectors $\Pi, \tilde{\Pi}$:

$$\tilde{\Pi} U \Pi = A. \quad (14)$$

Moreover, let $P \in \mathbb{R}[x]$ (a polynomial with real coefficients) and $\Phi \in \mathbb{R}^d$, where P has parity $(n \bmod 2)$ and satisfies $|P(x)| \leq 1$ for $x \in [-1, 1]$. Then we can build a circuit that block

encodes (parameterized by Φ) the *singular value transformation* of A according to P (taking d odd for the moment):

$$P^{(SV)}(A) \equiv \sum_{k=1}^{\text{rank}(A)} P(\xi_k) |\ell_k\rangle\langle r_k| = \tilde{\Pi} U_{\Phi} \Pi, \quad (15)$$

which uses $\mathcal{O}(d)$ copies of U , $U^\dagger$, Π , $\tilde{\Pi}$ -controlled-NOT, and single- and two-qubit gates. Here $|\ell_k\rangle, |r_k\rangle$ are the left and right singular vectors of A , and their respective spans are the images of $\tilde{\Pi}$ and Π . This block encoding, referred to as U_{Φ} , has the following form:

$$U_{\Phi} \equiv e^{i\phi_1(2\tilde{\Pi}-I)} U \prod_{j=1}^{n/2} \left[e^{i\phi_{2j}(2\Pi-I)} U^\dagger e^{i\phi_{2j+1}(2\tilde{\Pi}-I)} U \right]. \quad (16)$$

Here the *phases* $\Phi = \{\phi_1, \phi_2, \dots, \phi_d\}$ are precisely the same as those used by the quantum signal processing (QSP) protocol achieving the polynomial P . In the even-parity case the final application of U and the $\tilde{\Pi}$ -controlled single-qubit rotation is removed.

The purpose of the exposition of the main QSVT theorem (Thm. II.4) is not to provide deep insight into the mechanism and circuits of these transformations, but instead to communicate that applying spectral maps to block encoded linear operators is well-understood, associated with simple quantum circuits, and comes with tight resource complexity bounds. As above, we refer the interested reader to the numerous recent pedagogically-slanted treatments of the subject, which cleanly lay out competing notational conventions, definitional variants, and circuit shortcuts in special cases.

The workflow of applying QSVT is remarkably straightforward: once a block encoding has been built, the query and space complexity of the desired transformation relates simply to functional analytic properties of polynomial approximations, which are well understood. Moreover, through substantial functional analytic and numerical linear algebraic work, the classical algorithms used to compute the QSVT phases for a given transformation are known to be both efficient and stable, with associated public computational packages [Haa19, CDG⁺20, DMWL21, WDL22, DLNW24]. In our main construction we will introduce some explicit functions (and their corresponding QSVT subroutines) useful for our purposes, including variants of amplitude amplification and certain thresholding protocols. Wherever possible we will indicate the reason for using a particular block encoding technique over another, highlighting the benefits, limitations, and various trade-offs among the most common block encoding methods.

B. A minimal example

We quickly run through an explicit, small example of our eventual construction in the computational basis. The circuits for realizing each subroutine, and other unique aspects of the general case, are the subject of later sections. It is intended that this acts as an extrapolatable template plainly laying out the logic of the full algorithm.

A distinguishing aspect of the QEWT is that it cannot be simply described as a matrix product, linear combination, or spectral map applied among input block encodings. This necessitates a few additional steps and notational amendments. As in prior work, our construction is rooted in the well-known observation that the element-wise product of two matrices is a principal submatrix of their Kronecker product.

Proposition II.1 (Relation between element-wise and Kronecker products). The element-wise (variously referred to as the *Hadamard* or *Schur* or *pointwise*) product of two matrices A, B is a principal submatrix⁵ of their Kronecker product ($A \otimes B$). For A and B both 2×2

⁵ I.e., a submatrix obtained by deleting any k rows and the correspondingly indexed k columns.

we can see this concretely.⁶ Given block encodings of $(A \otimes I)$ and $(I \otimes B)$

$$U_{A \otimes I} = \left[\begin{array}{cc|c} a_0 & a_1 & * \\ & a_0 & a_1 \\ a_2 & & a_3 \\ & a_2 & a_3 \\ \hline & * & * \end{array} \right], \quad U_{I \otimes B} = \left[\begin{array}{cc|c} b_0 & b_1 & * \\ b_2 & b_3 & \\ & b_0 & b_1 \\ & b_2 & b_3 \\ \hline * & & * \end{array} \right], \quad (17)$$

we can permute rows and columns of their matrix product⁷ to recover $A \circ B$ in the upper left corner:

$$U_{A \otimes B} = \left[\begin{array}{cc|cc|c} a_0 b_0 & * & * & a_1 b_1 & * \\ * & * & * & * & \\ * & * & * & * & \\ a_2 b_2 & * & * & a_3 b_3 & \\ \hline & * & & & * \end{array} \right] \mapsto U_{P(A \otimes B)P^\dagger} = \left[\begin{array}{cc|cc|c} a_0 b_0 & a_1 b_1 & * & * & \\ a_2 b_2 & a_3 b_3 & * & * & \\ * & * & * & * & \\ * & * & * & * & \\ \hline & * & & & * \end{array} \right]. \quad (18)$$

This identity is well-known [HJ85, GVL13] and generalizes simply to larger A and B .

The problem we encounter after this product is that we cannot simply repeat this process, as we have not achieved a block encoding of $(A \circ B) \otimes I$, but rather a *block encoding whose sub-block* is $(A \circ B)$. One way of remedying this (for which there will be multiple methods of varying performance discussed later) is to *mask out* the undesired elements $*$ in the top-left block of (18), followed by *copying* the remaining desired sub-block $A \circ B$. The simplest way one could think to do this is again by matrix multiplication on the left and right:

$$V \equiv \left[\begin{array}{ccc} 1 & & \\ & 1 & \\ & & 0 \end{array} \right] \Rightarrow V[P(A \otimes B)P^\dagger]V = \left[\begin{array}{cc} a_0 b_0 & a_1 b_1 \\ a_2 b_2 & a_3 b_3 \end{array} \right], \quad (19)$$

where we denote zeros in these matrices where otherwise obvious by blank space, and where we've switched to focusing only on the top-left block of the overall block encoding unitaries. It turns out, as we show in the next section, that *copying blocks of block-diagonal block encodings*⁸ is comparatively simple, i.e., computing the following:

$$\left[\begin{array}{cc|cc} a_0 b_0 & a_1 b_1 & & \\ a_2 b_2 & a_3 b_3 & & \\ & & * & * \\ & & * & * \end{array} \right] \rightarrow \left[\begin{array}{cc|cc} a_0 b_0 & a_1 b_1 & & \\ a_2 b_2 & a_3 b_3 & & \\ & & a_0 b_0 & a_1 b_1 \\ & & a_2 b_2 & a_3 b_3 \end{array} \right] = I \otimes (A \circ B). \quad (20)$$

If we can perform each of the above steps efficiently, then we have returned to the case that our block encoded matrix is indeed the desired⁹ $(A \circ B) \otimes I$. The main business of this work is showing that each of these steps, for general A and B , is both possible, efficient under certain restrictions on A, B , and uses less space than existing methods (i.e., logarithmic versus linear in the degree of the desired element-wise product).

Finally, we briefly distinguish between element-wise products between matrices and a derived transform: element-wise functions of a single matrix. The constructions in the following section discuss costs primarily for computing block encodings of $A^{\circ k}$ given a block encoding of A , after which linear combination of unitaries (LCU) methods¹⁰ can be used to compute arbitrary linear combinations of these element-wise monomials. It turns out that our methods extend to a much wider class of generalized matrix products and functions, though their core mechanism follows from techniques in Sec. IIC.

⁶ For later consistency assuming we depict these matrices as block encoded inside larger unitaries, but the matrix products/Kronecker products are taking place among the *block encoded* matrices.

⁷ I.e., $(A \otimes I)(I \otimes B) = (A \otimes B)$.

⁸ It is important to distinguish that we will be constantly working with unitaries whose sub-blocks are matrices that themselves have block structure.

⁹ Up to a swap on the two registers required to receive the action $A \otimes B$.

¹⁰ We note here that it is non-trivial to properly prepare the SELECT unitary in our setting; see Lem. II.4.

C. Swap-copy and the weaving lemma

We now motivate and construct a few of the core mechanisms of this work, which will allow us to reduce the auxiliary space usage for element-wise functions of block encoding from linear to logarithmic in the degree of the applied function. This ability will stem from two compatible constructions: the first operation, named *swap-copy* (Lem. II.1), allows us to cheaply copy blocks of block-diagonal block encodings at the cost of a small amount of additional space, while the second, a technique we call the *weaving lemma* (Lem. II.2) allows us to recursively apply the swap-copy operation in a space-efficient way. Together these techniques allow us to build quantum circuits for element-wise products that much more closely resemble circuits for matrix products, which in turn will enable us, in the following Sec. IID, to apply existing (in a compatible way) space-compression techniques (i.e., the compression gadget presented again in Appx. A) for high-degree matrix products of block encodings.

Definition II.5 (Registers for block encodings with block structure). For most of this work we will consider block-encoded matrices which *themselves* have block structure. For block encodings acting on qubits, we can ascribe this block structure (in a given basis) to sub-registers of qubits. A common definition of a block encoding explicitly indicates a ‘flag qubit’ whose state identifies the location of the block-encoded matrix:

$$(|0\rangle_{r_1} \otimes I_{r_2})U(|0\rangle_{r_1} \otimes I_{r_2}) = A_{r_2}. \quad (21)$$

Here the register r_1 labels the four blocks of U , the top-left of which is A , while r_2 is the register on which A acts. Where obvious register subscripts may be omitted for brevity.

We will commonly work with three registers r_1, r_2, r_3 (not necessarily single qubits), which define respectively (1) the block-structure of the block-encoded matrix, (2) the block structure of the overall unitary, and (3) the register on which the block-encoded matrix acts; i.e., (1) defines the *inner blocks*, while (2) defines the *outer blocks*. Moreover, registers of the same size as r_1, r_2 , or r_3 may be instantiated, and joint registers are notated simply (e.g., $r_1 r_2$). The input state for our transform will *almost always be* loaded into the r_3 register.

Lemma II.1 (Swap-copy). Let U block encode $(A \oplus B)$, where $\dim B = (2^n - 1) \dim A$. Then using one query to U , a register of n qubits initialized to $|0^n\rangle$, and $2n$ swap gates, one can deterministically construct a unitary V block encoding $A^{\oplus 2^n}$. Moreover, after applying this block encoding, the additional n -qubit register remains in the $|0^n\rangle$ state.

Proof. The generic form of the block encoding unitary can be written (suppressing labels giving the sizes of the registers):

$$U_{A \oplus B} = |0\rangle\langle 0|_{r_2} \otimes \left[|0\rangle\langle 0|_{r_1} \otimes A_{r_3} + \left(\sum_{j,k=1}^{2^n-1} |j\rangle\langle k| \right) \otimes [B_{j,k}]_{r_3} \right] + \dots \quad (22)$$

Introducing a new register r_0 of n qubits (the same size as r_1), the action of $U_{A \oplus B}$ under conjugation by the register-wise swap gate S_{r_0, r_1} (under the assumption that the register r_0 is initialized to $|0\rangle_{r_0}$) is

$$\begin{aligned} & S_{r_0, r_1} [U_{A \oplus B}] S_{r_0, r_1} \\ &= \left[\sum_{i=0}^{2^n-1} |0\rangle\langle i|_{r_0} \otimes |i\rangle\langle 0|_{r_1} + \dots \right] [U_{A \oplus B}] \left[\sum_{i=0}^{2^n-1} |i\rangle\langle 0|_{r_0} \otimes |0\rangle\langle i|_{r_1} + \dots \right] \end{aligned} \quad (23)$$

$$= |0\rangle\langle 0|_{r_2} \otimes \left[|0\rangle\langle 0|_{r_0} \otimes I_{r_1} \otimes A_{r_3} + \sum_{\substack{p,q=1 \\ j,k=0}}^{2^n-1} |p\rangle\langle q|_{r_0} \otimes |j\rangle\langle k|_{r_1} \otimes [*]_{r_3} \right] + \dots \quad (24)$$

We have dropped those terms that (1) appear outside the top left block of the block encoding unitary (labeled by r_2), or (2) appear if the register r_0 were initialized to some other state

FIG. 1. Circuit for swap-copy (Lem. II.1). The catalytically used state $|0\rangle$ in r_0 (the *weaving state*; see Lem. II.2) allows a block encoding of $A \oplus *$ to be used as a block encoding of $I_{r_1} \otimes A$, consuming only a single call to the block encoding, requiring single-qubit swap gates, and catalytically using a small amount of additional space. On the left is the applied circuit, while on the right is an equivalent circuit, given the assumed block diagonal structure of the block-encoded input.

than $|0\rangle$, or (3) vanish given the block diagonal nature of the block encoded matrix. This is a block encoding of $A^{\oplus 2^n}$ on $r_1 r_3$ when the register r_0 is initialized to the $|0\rangle$ state, and the state in r_0 is used catalytically given the second sum over p, q . Recall that r_2 indexes the *outer block* structure of our *block encoding unitary*, while r_1 index the *inner block* structure of our *block encoded* matrix. A depiction of this circuit is given in Fig. 1. $\square$

As an example of the above lemma, in the $n = 1$ case¹¹, when A and B are both 2×2 matrices, this conversion can be written

$$U = \left[\begin{array}{c|c} A & \dots \\ \hline B & \ddots \\ \vdots & \end{array} \right] \mapsto V = \left[\begin{array}{c|c} A & \dots \\ \hline A & \ddots \\ \vdots & \end{array} \right], \quad (25)$$

and this process catalytically uses a single qubit initialized to $|0\rangle$, one query to U , and two swap gates.

Definition II.6 (Submatrix permutation unitary). We define the *submatrix permutation* to be the unitary on $2n$ qubits applying CNOTs between respective pairs of qubits in each n -qubit half. This has form:

$$P = \sum_{j,k=0}^{2^n-1} |j\rangle\langle j| \otimes |j \oplus k\rangle\langle k|. \quad (26)$$

As was observed in [GYC⁺25], this is precisely the permutation required to relocate the sub-matrix of $(A \otimes B)$ equal to the element-wise product $(A \circ B)$ to the top left corner, i.e.,

$$(I_n \otimes \langle 0^n|) P (A \otimes B) P^\dagger (I_n \otimes |0^n\rangle) = A \circ B. \quad (27)$$

Here the CNOTs span the two n -qubit registers implicit in the tensor product $(A \otimes B)$.

Definition II.7 (Mask unitary). We define the *mask* as the unitary on registers r_1, r_2 , and r_3 that block encodes the following operation on $r_1 r_2$:

$$M = \frac{1}{2} \left(I_{r_1} \otimes I_{r_2} + [2|0\rangle\langle 0|_{r_1} - I_{r_1}] \otimes I_{r_2} \right) = |0\rangle\langle 0|_{r_1} \otimes I_{r_2}. \quad (28)$$

Such a block encoding can be simply constructed through an LCU [CW12, BCC⁺14, BCK15] of state-dependent reflections. Here $|0\rangle$ indicates the all-zeros state on the labeled register.

¹¹ Note the general case results in 2^n copies of A along the diagonal, denoted $A^{\oplus 2^n}$.

Lemma II.2 (Recursive composition of unitary-valued functions; *weaving lemma*). Let $W(*_1, *_2)$ a function which takes as input two operators and returns a unitary. Moreover, let S a set of pairs of operators and R, T sets of quantum states such that for all $(V_1, V_2) \in S$, all $|r\rangle \in R$, and all $|t\rangle \in T$, the following holds:

$$W(V_1, V_2)|r\rangle_{r_0}|t\rangle_{r_1} = |r\rangle_{r_0}|*\rangle_{r_1}, \quad \text{equivalently,} \quad (29)$$

$$W(V_1, V_2) = |r\rangle\langle r|_{r_0} \otimes U(V_1, V_2)_{r_1} + \sum_{r', r'' \neq r} |r'\rangle\langle r''|_{r_0} \otimes [*]. \quad (30)$$

Here $|*\rangle$ is some generally unknown pure state, and $U(V_1, V_2)$ is the operator induced by initializing the r_0 register to the state $|r\rangle$. I.e., W returns unitaries that catalytically consume $|r\rangle$ (provided in the r_0 register), given oracle access to operators coming from pairs in S , and is thus block-diagonal in the computational basis of the r_0 register.

We consider the following question: given an operator on a register r_1 described by a composition of many such $U_k(*_1, *_2)$, all of which are induced by some W_k for the same $|r\rangle$, how many copies of $|r\rangle$ total across an auxiliary register of what size are required to implement this composition on r_1 *using only access to the W_k* ? Here all W_k share S, R, T , and we assume $V_1 = U_{k'}, V_2 = U_{k''}$ is a sufficient condition for $(V_1, V_2) \in S$.

We claim that the number of copies of $|r\rangle$ is equal to the *depth of the tree representing the desired composition* of the U_k , and provide a brief proof of this fact. We will refer to this result from now on as the *weaving lemma*.¹²

Proof. Proof is by casework, noting that physically implementable compositions among the U_k correspond to binary trees. If $U_k(*_1, *_2)$ is a leaf (i.e., applied only to pairs $(V_{1,k}, V_{2,k})$, then it can be implemented using W_k and consuming a single copy of $|r\rangle$, by definition. Alternatively, $U_k(*_1, *_2)$ might instead be a node:

$$U_k = U_k(U_{k'}(*_1, *_2), U_{k''}(*_3, *_4)), \quad \text{or} \quad (31)$$

$$= U_k(V_1, U_{k'}(*_1, *_2)), \quad \text{or} \quad (32)$$

$$= U_k(U_{k'}(*_1, *_2), V_2). \quad (33)$$

In any case, as each of the $U_{k'}, U_{k''}$ are used sequentially, U_k can be implemented using two copies of $|r\rangle$ in tandem with $W_k, W_{k'}$, and possibly $W_{k''}$ (plus any copies required by the *arguments* of $W_{k'}$ or $W_{k''}$). I.e., an additional layer of recursion necessitates only a single fresh copy of the state $|r\rangle$ to convert each W (across r_1 and some auxiliary register) to its respective U (only on r_1), where the sequential form of the circuit and the catalytic use of $|r\rangle$ allow $*_1$ and $*_2$ to share the same auxiliary $|r\rangle$ state. This immediately yields $|r\rangle$ copy- and space-complexity that is linear in the depth of the tree. A depiction of this construction for a complete binary tree is given in Fig. 2. $\square$

Proposition II.2 (Block encoding the element-wise product). Given oracle access to unitaries U_A and U_B , respectively $(1, a, 0)$ and $(1, b, 0)$ block encodings of A and B (square matrices of equal dimension), we can block encode their element-wise product

$$(|0\rangle_{r_2} \otimes I_{r_3})(P')_{r_1 r_3}(I_{r_1} \otimes U_{A, r_3})(I_{r_3} \otimes U_{B, r_1})(P')_{r_1 r_3}^\dagger(|0\rangle_{r_2} \otimes I_{r_1 r_3}) \quad (34)$$

$$= (|0\rangle_{r_2} \otimes I_{r_1 r_3})U_{P(A \otimes B)P^\dagger, r_1 r_3}(|0\rangle_{r_2} \otimes I_{r_1 r_3}) \quad (35)$$

$$= |0\rangle\langle 0|_{r_1} \otimes (A \circ B)_{r_3} + \dots \quad (36)$$

using a single query to each of U_A and U_B . Here (P') (Def. II.6) is the unitary comprising n -CNOT gates permuting rows and columns of $(A \otimes B)$ to move $(A \circ B)$ to the top-left block. This unitary, which acts only on r_1 and r_3 , can thus be taken into the block encoding unitary's subscript, denoted here $P(A \otimes B)P^\dagger$. For brevity from here on we will simply use P to denote *both* this qubit-wise CNOT gate and the induced permutation matrix.

¹² As copies of $|r\rangle$ will be re-used by ‘weaving’ them through applications of the W_k to induce U_k .

FIG. 2. Simplified depiction of the application of the weaving lemma (Lem. II.2). Here $(*)$ represents some quantum process which catalytically uses copies of $|0\rangle$ (possibly on many qubits) in a register r_0 by swapping the contents of r_0 with this process' r_1 register. The use by $(*)$ of the contents of r_0 is indicated by an allocation operation (a) followed by a freeing operation (f). If this process itself can sequentially call copies of $(*)$, then the total required copies of register r_0 , here denoted by $r_0, r_0', \dots$, grows with the depth of the tree induced by recursive function calls (seen by the re-use of r_0 across protocols at the same depth).

Proof. This result is known and its proof reproduced in multiple prior works [ZZRF21, GYC⁺25], essentially following from the known identity that the element-wise product is a sub-matrix of the tensor product [HJ85]. $\square$

Important to note in Prop. II.2 is that r_1 now labels *blocks* of the *block encoded matrix* $P(A \otimes B)P^\dagger$, and that the other blocks contain related (but undesirable) products of elements A, B . Consequently there is no easy way to feed this block encoding back into another element-wise product protocol without the instantiation of additional space—in the following Prop. II.3 we discuss one method of *cleaning* this block encoding (i.e., removing these undesirable blocks outside of $(A \circ B)$ and performing a swap-copy operation; see Lem. II.1) to make alternative methods for auxiliary space reduction applicable. This results in a block encoding which not only has $(A \circ B)$ as its top-left block, but which has the form $I_{r_1} \otimes (A \circ B)_{r_3}$, which satisfies the input assumption of our tensor-product to element-wise product gadget in Prop. II.2.

Proposition II.3 (Block encoding the clean element-wise product). Let U_A and U_B block encoding unitaries for square matrices A, B of equal dimension. Then the clean block encoding of their element-wise product $(A \circ B)$ can be written as a product¹³ of three *block-encoded matrices* (U_M , $U_{P(A \otimes B)P^\dagger}$, and $U_M^\dagger$) interspersed with unitaries. Here we denote this as an operator-valued function W on r_0, r_1, r_3 of the block encodings of A and B :

$$W_{r_0 r_1 r_3}(U_A, U_B) \equiv \quad (37)$$

$$(\langle 0|_{r_2, \text{mult}} \otimes I_{r_1 r_3}) S_{r_0 r_1} [U_M \times U_{P(A \otimes B)P^\dagger} \times U_M^\dagger] S_{r_0 r_1} (|0\rangle_{r_2, \text{mult}} \otimes I_{r_1 r_3}) \quad (38)$$

$$= |0\rangle\langle 0|_{r_0} \otimes U_{I_{r_1} \otimes (A \circ B)_{r_3}}. \quad (39)$$

Note that there can be two different swap operations (denoted S), one between the two registers originally holding A and B , i.e., $(A_{r_1} \otimes B_{r_3})$, as well as one between r_0 and r_1 (used for the weaving lemma; Lem. II.2). This product uses one copy each of the block encoding unitaries for A and B , a constant amount of additional space, and ultimately frees

¹³ That is, this product, denoted where relevant by $\times$, is not between the block encoding unitaries but *between the matrices they block encode*. Achieving this requires a block-encoding multiplication subroutine (e.g., Def. II.2 or Lem. A.1) and the use of additional space, discussed later and here denoted by the register label ‘mult.’

the register r_0 initialized to $|0\rangle_{r_0}$. Finally, note the (here suppressed) register labeled *mult* (later referred to as r_4 and explicated along with compression techniques in Sec. IID), which are used to multiply the block encoded input matrices and mask matrices, and which return to the state $|0\rangle$ precisely when this multiplication is successful.

Proof. The proof of this statement follows directly from the action of the mask unitary multiplication, which selects out only the $|0\rangle\langle 0|_{r_1}$ sub-block of the block encoded $P(A \otimes B)P^\dagger$, followed by the swap-copy operation that ensures that all computational basis states in r_3 are acted on *as if* r_1 had been in the state $|0\rangle$ (as this state is indeed swapped in from r_0), resulting in the overall action of $I_{r_1} \otimes (A \circ B)_{r_3}$, *under the assumption* that r_2 begins and ends in the state $|0\rangle$. $\square$

Remark II.1 (On error in block encoding inputs). The main theorems in this section are presented in the case that the input block encodings have no error, i.e., are of the form $(\alpha_k, a_k, 0)$ for some set of permissible k . This has been done both for brevity, and because the calculations involved in the generic case of $(\alpha_k, a_k, \varepsilon_k)$ are well known in the context of common arithmetic operations among block encodings. Given the close relationships we rely on between the element-wise and more common matrix products, and the linearity of this error with respect to the outer loop of LCU (see the main Thm. II.3),¹⁴ error propagation in our results will go through almost identically (and will always have a simple upper bound) in terms of these previous results. We include detailed discussion of these error-propagation techniques/known results in the dedicated Appx. D.

The statement of Prop. II.3 immediately suggests a definition for the unitary-valued function (39) used in the weaving lemma (Lem. II.2). In the following proposition we give this function explicitly, before discussing how it interacts with other space-compression techniques in block encoding manipulation towards the formal statement of our main result in the following Sec. IID.

Proposition II.4 (Unitary function for element-wise products). As hinted in the statement of Prop. II.3, the operator-valued function to which we'll apply Lem. II.2 is the same as that given by (37), which has the form required by the weaving lemma when considered as a function of its block encoding inputs, i.e.:

$$W(*_1, *_2)_{r_0 r_1 r_3} \equiv |0\rangle\langle 0|_{r_0} \otimes U(*_1, *_2)_{r_1 r_3} + \sum_{r', r'' \neq r} |r'\rangle\langle r''|_{r_0} \otimes [*]_{r_1 r_3}. \quad (40)$$

In this case the sets S, R, T comprise respectively, (1) block encodings of square operators of the same dimension, (2) the quantum state $|0\rangle$ on a register of n qubits, and (3) any quantum state on a register of $2n$ qubits.

Note for now that the registers r_2, r_4 , which handle our outer block selection and block encoded matrix multiplication respectively, are assumed to begin in and return to the state $|0\rangle$ to ensure the success of our protocol (i.e., respectively ensuring we correctly end up in the top-left outer block of our block encoding, and that the masking operation succeeded). In other words, the full $W_{r_0 r_1 r_2 r_3 r_4}$ unitary-valued function itself has block structure, the $|0\rangle\langle 0|_{r_2 r_4}$ block of which is the expression in (40). In the following sections we further explicate how these registers function, their required sizes, the success probability of the resulting protocol, and how this action interacts with the swap-copy operation, the weaving lemma, and recursively defined higher-degree protocols.

To summarize our progress before the full construction, we have created a gadget in Lem. II.2 that recursively applies the swap-copy operation of Lem. II.1; in turn this allows quantum circuits whose unitaries have nested block-structure to be composed in a space-efficient way *up to assumptions that we can post-select on a subset of auxiliary qubits and end*

¹⁴ For the curious reader we note that when applying QSVT this error propagation becomes slightly more complex, as the relation between the operator norm of the difference of two linear operators, and the difference between a chosen function applied to those operators, depends on the function's modulus of continuity (see Sec. 13.7 of [LW26]).

up in critical blocks.¹⁵ In the next section we build on top of these lemmas to provide explicit circuits for both element-wise powers and linear combinations of these element-wise powers (the latter of which is not trivial, and exposes oversights in prior work that we rectify). An important aspect of these extensions is that we maintain logarithmic space auxiliary usage in the degree of the applied polynomial element-wise function, which requires us to keep track of both (1) the usual compression gadget accumulation register as well as (2) the recursively-applied swap-copy register. While we leave this discussion to the later section on alternative constructions (Sec. III) and the final Sec. V, it is an interesting research direction to explore improved block encoding manipulation subroutines under assumptions of block structure or other side information.

D. Full construction

We build on the construction of the previous section (which used the weaving lemma, Lem. II.2, to convert a circuit computing element-wise products into one computing matrix products) and apply a series of known techniques for space reduction (so-called *compression gadgets*, see Appx. A) in block encoding algorithms for computing matrix products. Most of the remaining work thus lies in showing these existing methods are compatible with our previous constructions, as well as examining their behavior under small errors in the input block encoding, ultimately showing we can achieve exponential space reduction in the degree of the applied element-wise function.

We first discuss the basic properties of these *compression gadgets*, followed by an explicit circuit for the recursively-defined self-element-wise product (Thm. II.2), which can be bootstrapped through LCU techniques (with an important detour to correct an omission in prior work, covered in Appx. C) to yield our main result (Thm. II.3) characterizing the space and query complexity of applying element-wise functions to block encodings. Along the way we introduce a variety of block encoding manipulation techniques, indicating where they require modification.

The compression gadget, introduced in [LW19] in the context of Hamiltonian simulation, applied widely in dynamical systems simulation [FLT23], and recently extended in [VG25], allows for dramatic space-savings when block encoding high-degree *matrix products* of block encodings. The core idea is to encode the success or failure of intermediate block encoding applications in binary on an auxiliary register, rather than unary; this exchanges unimportant information on which intermediate block encoding application failed in event of an out-of-block measurement for exponential space savings in the degree of the product. We restate this result more casually below, and refer interested readers to its formal statement and associated circuit in Appx. A (which also points toward tangential but interesting developments of related space-saving gadgets).

Lemma II.3 (Compression gadget; *informal*). Let U_k for $k \in [K]$ a series of unitaries respectively block encoding (square) A_k . Then we can construct a unitary using one copy each of the U_k and $\log(K)$ auxiliary qubits that block encodes the product

$$B = A_1 A_2 \cdots A_K, \quad (41)$$

whereas naïve repetition of the usual product gadget would require $\mathcal{O}(K)$ auxiliary qubits. The success probability for applying B to the input quantum state depends on the norm-squared of the resulting state.

Our aim is to apply compression gadget techniques to higher-degree variants of the construction of Prop. II.3. In that section we provided a ‘clean’ (i.e., ready for repeated self-composition) circuit computing element-wise products in terms of matrix products. Successfully combining this construction with the compression gadget requires addressing the following questions:

¹⁵ I.e., the same assumptions that are usually made in block-encoding algorithms, though careful analysis of the success probability of these post-selections is required, and the subject of both Secs. IID and III.

FIG. 3. Depiction of the circuit for *clean element-wise products* of block encodings, i.e., block encodings of $I_{r_1} \otimes (A \circ B)_{r_3}$ using auxiliary space r_4r_2 . Note if r_4r_2 is in the all-zeros state, then the state $|0^n\rangle$ in r_0 is necessarily used catalytically. Here the (+) notation indicates projection-controlled addition with target register r_4 used for the compression gadget (see Lem. A.1); when r_2 is not a single qubit, this is a Π -controlled addition on r_4 for Π a projector with form $(I - |0\rangle\langle 0|_{r_2})$. Note also the non-standard ordering of registers to make depiction easier. In our recursive construction, each $U_{(I \otimes *)}$ is replaced by an analogous circuit which acquires (1) a new copy of r_0 for each recursive level, and (2) contributes to the size of r_4 to multiply all block encodings, but otherwise acts identically on r_1 , r_3 , and r_2 (depictions of this composition is given across Figs. 4 and 5). Finally, recall if the registers r_2 and r_4 are measured in the all-zeros state, then the r_0 and r_1 registers experience only the identity operation, and $(A \circ B)$ is applied to r_3 .

Q1: We have multiple sources of auxiliary space including (a) the registers used by the swap-copy operations/weaving lemma, (b) the accumulation register used by the compression gadget, and (c) the auxiliary space used by each input block encoding. Does the resulting unitary have sensible block structure with respect to these registers?¹⁶

Q2: The log-space use of our protocol relies critically on the re-use of the weaving state from Lem. II.2 across each recursive level (i.e., that this state is catalytic); is this compatible with the compression gadget, and what is the effect on the protocol's overall success probability?

We address the first question by careful bookkeeping of the registers involved, which are depicted across multiple stages of our construction in Figs. 3 (our ‘cleaned’ matrix product to element-wise product construction), 4 (a reduced form of this construction as an operator-valued function), and 5 (the second level of our recursive construction for the iterated self element-wise product). The second question, which we address after the statement of our main result, follows from basic calculations on the success of each constituent block encoding.

Theorem II.2 (Iterated element-wise product; *formal*). Let U_A a $(1, a, 0)$ block encoding of an n -qubit operator A . Then a $(1, \mathcal{O}(a + n \log d), 0)$ block encoding of the d -th iterated element-wise product of A , denoted A^{c^d} , can be exactly constructed using d copies of U_A .

Proof. Proof follows directly from an application of the *compression gadget* of Low and Wiebe [LW19] (see Lem. A.1) to the recursively-defined product of (40) in Lem. II.2, along with the following two observations. The first is that unrolling our $\log d$ -level recursion gives a matrix product of block encodings of length $\mathcal{O}(d)$ (in this case $3d + 1$) interspersed with known unitaries (which have no bearing on the operation of the compression gadget). The second is that, under the condition that the compression gadget succeeds (i.e., the auxiliary register is measured in the $|0\rangle_{\text{comp}}$ state), the weaving lemma (Lem. II.2) ensures that all $\mathcal{O}(\log d)$ initial $|0\rangle_{r_0^{(m)}}$ states, one for each recursion level, are used catalytically, as $r_1r_2r_3$, assuming the mask unitaries’ successful application (kept track of by the compression gadget accumulation register), encounter only *block-diagonal block encodings*, for which the $|0\rangle_{r_0^{(m)}}$ is a $(+1)$ -eigenstate. The overall space use is thus simply that which is required for the

¹⁶ I.e., we need to ensure, under the assumption that the auxiliary qubits all begin and end in the $|0\rangle$ state, that the desired element-wise function is applied to the input block encoding.

FIG. 4. Two equivalent, simplified depictions of the circuit in Fig. 3. On the left the unitary-valued function W takes two unitary-valued inputs, here denoted $(*_L)$ and $(*_R)$, which in our setting will both be block encoding unitaries of matrices that have the form $(I \otimes M)$ for some square matrix M . This unitary-valued function (i.e., a circuit with holes) is further condensed on the right, where the free arguments (or holes) are suppressed. Note that wires with slashes represent multi-qubit registers, between which swap gates denote qubit-wise swaps. Additionally, the projection controlled addition operators (see Lem. A.1), here with their targets denoted with $(+)$, have their controls absorbed into W ; on the left-hand side, the sequence of such addition operators are represented all together by a dotted line.

FIG. 5. A depiction of the first level of the recursive use of the circuit form of Fig. 3 by itself, making use of both forms of the condensed notation introduced in Fig. 4. Note here that the register used for the compression gadget, r_4 , is not duplicated, and remains the target for the addition gadgets of protocols deeper in the recursive construction. A new register of size n , namely r'_0 , is however initialized to $|0\rangle$, with a new copy introduced at each level of recursion, though *re-used between subroutines at the same level*, given the catalytic behavior of the original circuit. This catalysis succeeds under the assumption that all block encodings are successfully applied (equivalently, that the registers r_2 and r_4 both end up in the all zeros state). Note that all of the swaps have the same target register, r_1 , and thus for each level of the recursion subroutines receive ‘fresh’ copies of $|0^n\rangle$ to correctly carry out the swap-copy operation (Lem. II.1); this allows both W_L and W_R to be ‘seen’ by the outer protocol W as block encodings of the form that W expects, as discussed in the weaving lemma (Lem. II.2).

input block encoding, a , plus the $\log d$ copies of $|0\rangle_{r_0}$, plus the $\mathcal{O}(\log d)$ qubits required for the compression gadget. More precisely we end up with a $(1, a + (n + 1) \log 3d + 1, 0)$ block encoding of $A^{\odot d}$. $\square$

Having constructed block encodings of the d -th element-wise product of a block-encoded matrix with itself in Thm. II.2, we can now work towards applying a desired *element-wise polynomial function* by taking linear combinations of these unitaries. As indicated in the basic statement of LCU (Thm. II.1), this requires us to construct a so-called SELECT unitary, which applies an indexed unitary U_k coherently when an auxiliary register is in the state labeled $|k\rangle$ (i.e., a quantum state labeled by a binary encoding of the integer k). Here we merely give our lemma characterizing the cost of building SELECT given access to *controlled block encodings* of a desired matrix A . While this construction ‘sits above’ our technique for taking element-wise powers of matrices, we emphasize that the technique used the prior work [GYC⁺25] to build SELECT is under-specified and (as implied) insufficient/incorrect.

We take time to raise and rectify this gap in the dedicated Appx. C, which also includes the constructive proof of Lem. II.4.

Lemma II.4 (Building SELECT for the element-wise product). Let U_A a $(1, a, 0)$ block encoding of an n -qubit linear operator A and $d \in \mathbb{N}$. Then the SELECT unitary for element-wise powers of A up to degree d , i.e.,

$$U_{\text{SELECT}} \equiv \sum_{k=0}^d |k\rangle\langle k| \otimes U_{A^{\circ k}}, \quad (42)$$

can be built using d copies of *controlled* U_A , $\log d$ qubits of additional space, and $\mathcal{O}(d \log d)$ single and two qubit gates. Note here that the notation $A^{\circ 0}$ is taken to be the *usual identity matrix* on n qubits. For a proof of this statement see Lem. C.2 in Appx. C.

Theorem II.3 (Quantum element-wise transform; *formal*). Let f be a polynomial (with a trivial constant term) of degree d satisfying $|f| \leq 1$ on $[-1, 1]$, with coefficients $c_k, k \in \{0, \dots, d\}$, $c_0 = 0$. Then, given access to controlled- U and controlled- $U^\dagger$, where U is an (α, a, ε) block encoding of an n -qubit operator A , there exists a quantum circuit preparing a (β, b, δ) block encoding of $f^\circ(A)$ —the *element-wise application of f to A* —that requires $\mathcal{O}(d)$ copies of controlled- U and controlled- $U^\dagger$, as well as $\mathcal{O}(d)$ single/two-qubit gates, where (β, b, δ) satisfy

$$\beta = \sum_{k=1}^d |c_k| \alpha^k, \quad b = a + n \lceil \log d \rceil, \quad \delta = \sum_{k=1}^d |c_k| \left[(\alpha + \varepsilon)^k - \alpha^k \right]. \quad (43)$$

Proof. Applying LCU to our element-wise product gadget (Thm. II.2) requires us to construct the SELECT unitary as mentioned previously and discussed variously in foundational work on LCU [CW12, BCC⁺14, BCK15, GSLW19]. The ultimate result, presented in condensed form in the previous Thm. II.1, is the following:

$$V = \sum_{k=1}^d |k\rangle\langle k|_{r_5} \otimes [U_{A^{\circ k}}]_{r_0 r_1 r_2 r_3 r_4} + \left[I_{r_5} - \sum_{k=1}^d |k\rangle\langle k|_{r_5} \right] \otimes I_{r_0 r_1 r_2 r_3 r_4}. \quad (44)$$

Notably, we cannot, as incorrectly implied by previous work, simply matrix multiply together element-wise products $A^{\circ 2^j}$ per Lem. C.1 from [CKS17]); instead we construct projection-controlled versions of controlled U and $U^\dagger$ per Lem. II.4, before applying our element-wise power construction (Thm. II.2. This requires an additional register r_5 of size $\mathcal{O}(\log d)$, as is expected, and gives the block encoding parameters quoted in the theorem statement. Note that the form of δ follows from the linear relation between input and output error in both (1) each element-wise power k and (2) each coefficient c_k ; a detailed calculation of this error is provided in the dedicated Appx. D (specifically Prop. D.2), where we identify a few errors in extant literature. $\square$

The astute reader might notice that the depth of our log-space protocol is larger than that of the previous linear-space one, here due to our inclusion of mask unitaries. Consequently, the overall success probability of our protocol depends in some complex way on the successful application of all of these $\mathcal{O}(d)$ masks. This success probability is dependent on both the initial quantum state and the input block encodings, and thus just as in the application of the standard compression gadget (as well as prior constructions for element-wise products, which also multiply $\mathcal{O}(d)$ block encodings), there may exist initial states and input block encodings which can suppress this success probability arbitrarily (e.g., when block encoding the all zeros matrix). In the following Sec. III we address this problem in specific contexts where this success probability can be bounded usefully from below, and show that for a variety of non-trivial block encoding inputs (e.g., the near-identity setting, as also investigated in [VG25]) our log-space construction succeeds with good probability. In general the study of the success probability of these basis-dependent matrix transforms is quite rich, as unlike in

FIG. 6. The application of the standard LCU circuit to generate the full quantum element-wise transform of Thm. II.3; unpacking this figure through previous definitions and circuits gives the full transform. I.e., here SEL denotes the SELECT unitary (42) constructed in Lem. II.4 (whose proof and discussion is contained in Appx. C) for the element-wise product circuit of Thm. II.2 (depicted in Fig. 5). Here $b = \mathcal{O}(n \log d)$ denotes the number of qubits (copies of the register r_0) required to recursively apply the weaving lemma (Lem. II.2), and the new register r_5 on $\mathcal{O}(\log d)$ qubits has been instantiated large enough to encode d terms using standard LCU techniques (see Thm. II.1).

QSP/QSVT, or other spectral mapping techniques, the relation between the chosen function and the resultant effect on the input's spectrum is only cursorily understood in theory [HJ91] (e.g., among the most celebrated results in the study of element-wise products is that they preserve the cone of PSD matrices). Consequently we expect the utility of the QEWT will be quite dependent on known properties of the input.

As a small addendum on this topic, we can show a simple corollary regarding space-time trade-offs for algorithms computing element-wise functions. I.e., as the inputs to our compression scheme are arbitrary block encodings we can easily hybridize the standard and compressed approach to iterated element-wise products. Such hybrid methods may be of independent interest under experimental/architectural resource constraints, or for known instance sizes, and allow for flexibility in compilation.

Corollary II.3.1 (QEWT time-space tradeoff). Let f of degree d defined as in the main Thm. II.3. Then given some $q \in \mathbb{N}$ we can compute the QEWT according to any division of $\mathcal{O}(d)$ element-wise product gadgets into at most $\lceil d^{1/q} \rceil$ blocks of size at most $\lceil d^{(q-1)/q} \rceil$, where the blocks are computed using our logarithmic-space method and element-wise multiplied using the standard linear-space method. Then the overall protocol for computing the same element-wise transform uses an auxiliary register of size b' (using the same conventions as the main theorem):

$$b = \mathcal{O}\left(a + n \left[1 - \frac{1}{q}\right] \log d\right), \quad b' = \mathcal{O}\left(b d^{1/q} + n d^{1/q}\right), \quad (45)$$

where we have computed the intermediate space complexity b for the inner logarithmic-space protocol, which gives a total auxiliary space complexity b' of the composition of the linear- and logarithmic-space protocols:

$$b' = \mathcal{O}\left(a d^{1/q} + n \left[2 - \frac{1}{q}\right] d^{1/q} \log d\right). \quad (46)$$

Moreover, the depth of the resulting circuit is based on the depth of the largest sequentially-computed block, which is $\mathcal{O}(d^{(q-1)/q})$, which approaches $\mathcal{O}(d)$ as expected for large q .

Proof. The proof, which we do not provide in detail, follows straightforwardly from the generic input assumptions of both the logarithmic-space and linear-space element-wise product gadgets; i.e., the inner protocol (logarithmic-space) is treated as a black box by the outer protocol (linear-space), meaning we can compute the overall asymptotic auxiliary space complexity purely from the block size and sum the results. $\square$

As an example of Cor. II.3.1, for $q = 2$ we have, for each element-wise product, at most $\sqrt{d}$ blocks of size at most $\sqrt{d}$, yielding an intermediate auxiliary space register of

size $\mathcal{O}([a+n]\sqrt{d}\log d)$ and circuit depth $\mathcal{O}(\sqrt{d})$. For $q \gg 1$ (i.e., where each block is of size at most one) this hybrid approach reduces to our logarithmic-space construction. While beyond the scope of this work, this division of a single element-wise transform between these linear- and logarithmic-space methods is quite generic, does not require uniform block size, and offers wide opportunity for optimizations given side-information about the input block encoding. At first glance (beyond circuit depth reduction), the merit of this hybridization is not obvious; however, as is discussed in the alternative constructions of the next Sec. III, as well as in the appendix devoted to properties of the element-wise product (Appx. B), the behavior of basic properties of linear operators under element-wise products (e.g., rank, condition number, spectral norm), and thus the success probability of the result block encoding circuits, is much more erratic than in the usual matrix multiplication setting—complicating questions of optimal resource complexity.

III. Alternative constructions and special cases

The main construction of the previous section was presented piece-wise to clarify the interaction between its components—here the compression gadget, weaving lemma, and relation between the Kronecker, matrix, and element-wise products. Here we provide an alternative construction for computing the same element-wise transform, as well as identify common settings/assumptions under which these alternative constructions allow further performance improvements. The high-level action is that we dispense with the ‘masking unitaries’ (Def. II.7) and instead employ LCU techniques to achieve the block-diagonality that our swap-copy operation requires. These LCU methods also allows us to employ a few common block encoding manipulation techniques (namely, oblivious and fixed-point amplitude amplification, defined briefly below) to further improve the success probability of our protocol when certain preconditions on the input are met.

Theorem III.1 (Fixed-point amplitude amplification; Thm. 27 from [GSLW19]). Let U a unitary and Π an orthogonal projector such that $\alpha|\psi_G\rangle = \Pi U|\psi_0\rangle$ and $\alpha > \eta > 0$. Then there is a unitary U' such that $\| |\psi_G\rangle - U'|\psi_0\rangle \| \leq \varepsilon$ which uses a single auxiliary qubit, and comprises $\mathcal{O}((1/\eta)\log(1/\varepsilon))$ copies of the following gates: U , $U^\dagger$, $C_{\Pi}\text{NOT}$, $C_{|\psi\rangle\langle\psi|}\text{NOT}$, and single-qubit rotations.

Theorem III.2 (Robust, fixed-point, oblivious amplitude amplification; modified from Thm. 28 of [GSLW19]). Let U a unitary and Π, Π' orthogonal projectors such that

$$\|\alpha W - \Pi' U\| \leq \varepsilon, \quad (47)$$

for $\alpha > \eta > 0$ and where W is an isometry ($W : \text{img}(\Pi) \rightarrow \text{img}(\Pi')$). Then we can construct a unitary U' such that for all $|\psi\rangle \in \text{img}(\Pi)$:

$$\|W|\psi\rangle - \Pi' U'|\psi\rangle\| \leq \varepsilon/\alpha, \quad (48)$$

which uses a single auxiliary qubit and $\mathcal{O}((1/\eta)\log(1/\varepsilon))$ copies of the following gates: U , $U^\dagger$, $C_{\Pi}\text{NOT}$, $C_{\Pi'}\text{NOT}$, and single-qubit rotations.

Theorem III.3 (Uniform singular value amplification; modified from Thm. 30 of [GSLW19]). Let U an $(\alpha, a, 0)$ -block encoding of A . Then we can construct a $(\|A\|_1/(1-\eta), a+1, \varepsilon\|A\|_1)$ -block encoding of A using $\mathcal{O}((\gamma\eta)^{-1}\log[(\gamma\varepsilon)^{-1}])$ queries to U , $U^\dagger$, where $\gamma \equiv \|A\|_1/\alpha$.

One of the ways we will modify our initial element-wise product algorithm is through using, at each level of our recursive construction, multiple copies of the input block encodings. It is thus necessary to establish how this additional processing affects the total query, gate, and space complexity of the full algorithm. We give a remark below on this topic before providing a few more helper-lemmata and propositions before explicitly providing our LCU- and amplitude-amplification-dependent constructions.

Remark III.1 (Query complexity for alternative protocols). In our recursively defined quantum element-wise product the query complexity of our ‘base case’ (e.g., the circuit in Fig. 5) completely defines the query complexity of the general protocol. Computing this query complexity in the two-argument case is simple: if in the base case each argument, $(*_1)$ and $(*_2)$, requires m copies, then the k -th recursive level yields a degree 2^k product at a cost of $(2m)^k$. Consequently achieving a degree d product requires $k = \log d$, for a total query complexity of $\mathcal{O}((2m)^{\log d}) = \mathcal{O}(d^{1+\log m})$. For constant m this is polynomial in d .

Moreover, we will also investigate the approximate setting (e.g., Thm. III.5) where m is not constant but depends weakly on the approximation error, i.e., $m = \mathcal{O}((1/\delta) \log(1/\varepsilon))$ for δ bounded below by some constant. Here the total query complexity to achieve error ε would scale instead as $d^{\log((1/\delta) \log(d/\varepsilon))}$, which is quasi-polynomial in d .

The key observation toward our construction is that the application of the swap-copy operation (Lem. II.1) does not require that the block encoding be zero outside of the copied block, but only *block diagonal*. An easier way to achieve this instead of masking unitaries U_M depicted in Fig. 3, is through the use of linear combination of unitary (LCU) techniques (Thm. II.1). In our case the LCU which achieves the required block diagonal structure is quite simple (see Fig. 7), and does not required controlled access to nor multiple copies of the input block encodings. In what follows we give the circuit for this LCU (Fig. 7), recovering a new statement for the complexity of computing element-wise powers (Lem. III.1) and thus transforms (Thm. III.4). We then investigate means of increasing the success probability through amplitude amplification subroutines (Thm. III.5) followed by analysis in special cases (Cors. III.5.1 and III.5.2). For simplicity we first state a fact on the success probability of generic LCU protocols.

Proposition III.1 (LCU protocol success probability). Let a non-unitary V be expressible as the sum of K unitaries according to coefficients c_k for $k \in \{0, \dots, K-1\}$. Then the standard LCU technique to apply V to some initial state $|\psi\rangle$ uses an auxiliary register of $\lceil \log K \rceil$ qubits and succeeds with probability

$$p_{\text{succ}} = \|V|\psi\rangle\|^2 \left(\sum_k |c_k| \right)^{-2}. \quad (49)$$

I.e., the success probability is affected by both (1) the non-unitarity of the desired operator, and (2) the ℓ_1 norm of the coefficients of the linear combination. Note that the spectral norm of the constituent unitaries ensures this success probability of between zero and one.

We can investigate this generic statement in the specific setting of using LCU to achieve the self-element-wise product of a block encoding with itself. Here we will use a simple, two-coefficient LCU subroutine (depicted in Fig. 7) to recover the preconditions for the application of our swap-copy operation.

Lemma III.1 (LCU-based element-wise product). Let U_A be $(1, a, 0)$ block encoding of an n -qubit operator A . Then we can construct a $(1, a + n[2 \log d + 1], 0)$ block encoding of the d -th order element-wise product of A with itself ($A^{\circ d}$) using d copies of U_A and $\mathcal{O}(d)$ additional quantum gates. Moreover, the probability of successfully applying this element-wise product depends on both A and the initial state $|\psi\rangle$:

$$p_{\text{succ}} = \|A^{\circ d}|\psi\rangle\|^2. \quad (50)$$

Proof. In this alternative construction, rather than applying masking unitaries, we use a simple LCU to zero-out the off-diagonal blocks of our input, such that the swap-copy (Lem. II.1) can be applied. The key observation is applying a sign to the off-diagonal (non-square) blocks of our block encoding of $P(A \otimes B)P^\dagger$ can be achieved by a unitary that acts like a Z gate on subspaces, where denoted by the unitary $Z^\perp$:

$$Z^\perp \equiv \left(-|0\rangle\langle 0|_{r_1} + \sum_{j=1}^{2^n-1} |j\rangle\langle j|_{r_1} \right) \otimes \sum_{k=0}^{2^n-1} |k\rangle\langle k|_{r_3} = (I_{r_1} - 2\Pi_{|0\rangle\langle 0|_{r_1}}) \otimes I_{r_3}, \quad (51)$$

FIG. 7. Alternative circuit for constructing a block encoding unitary V of the cleaned element-wise product (Prop. II.3) of two block encoded matrices. Here we use the same reduced notation for W' as in Fig. 4, where here W' does not contain the masking unitaries of Fig. 3, and where recursive self-composition proceeds the same as in Fig. 5, save that r_5 (a single-qubit register) also becomes the control of a projector-controlled addition to r_4 , and is re-used across the same recursive level. Here $Z^\perp$ is a controlled reflection about the $|0^n\rangle$ state in r_1 , as defined in Lem. III.1.

which is just a reflection about the state $|0\rangle$ in the r_1 register. When applied to a block matrix (taking for the moment $A \in \mathbb{C}^{2^n \times 2^n}$ and $D \in \mathbb{C}^{(2^{2n}-2^n) \times (2^{2n}-2^n)}$ and B, C such that the entire matrix is square) this appends a sign to only the off-diagonal (non-square) blocks:

$$Z^\perp \equiv \begin{bmatrix} -I_{2^n} & \\ & I_{(2^{2n}-2^n)} \end{bmatrix}_{r_1 r_3} \implies Z^\perp \begin{bmatrix} A & B \\ C & D \end{bmatrix} Z^\perp = \begin{bmatrix} A & -B \\ -C & D \end{bmatrix}. \quad (52)$$

We can now use standard LCU techniques to take the linear combination of U_A and $Z^\perp U_A Z^\perp$, weighted by coefficients $c_0 = c_1 = 1/\sqrt{2}$. A circuit for this unitary is given in Fig. 7, uses only a single copy of U_A , and can be recursively self-composed almost identically to our original circuit in Fig. 5, save with our new single-qubit LCU register r_5 , and a controlled addition operation from this register to the compression gadget register r_4 after each pair of Hadamard gates, at each recursive level. This requires a single additional qubit, and succeeds with probability sub-normalized by the squared one-norm of the LCU coefficients $(|c_0| + |c_1|)^2 = 2$. $\square$

Remark III.2 (On the difference between Lem. III.1 and Thm. II.2). Looking closer at the circuit in Fig. 7, we can see that if one were to insert a pair of Hadamard gates on r_5 , split the wire between them, and create two qubits experiencing the first and second half of the original gates interacting with r_5 , they would recover the construction in our original Thm. II.2. The saving here stems from the fact that we only require *block-diagonality* for the swap-copy operation, and not all zeros outside the top left block. This allows us to apply an XOR rather than a true sum to the register r_5 , resulting in saving an additional qubit per recursive self-composition of our circuit.

Once we have a protocol for the element-wise product we can use the same techniques as in Thm. II.3 to build out the full element-wise transform. We give this extension in Thm. III.4, followed by further discussion of the success probability, and select instances in which it can be improved by amplitude amplification techniques.

Theorem III.4 (LCU-based element-wise function). Let f be a polynomial (with a trivial constant term) of degree d satisfying $|f| \leq 1$ on $[-1, 1]$, with coefficients $c_k, k \in \{0, \dots, d\}$, $c_0 = 0$. Then, given access to controlled- U and controlled- $U^\dagger$, where U is an (α, a, ε) block encoding of an n -qubit operator A , there exists a quantum circuit preparing a (β, b, δ) block encoding of $f^\circ(A)$ —the *element-wise application of f to A* —that requires $\mathcal{O}(d)$ copies of controlled- U and $U^\dagger$, as well as $\mathcal{O}(d)$ single/two-qubit gates, where (β, b, δ) satisfy

$$\beta = \alpha \sum_{k=1}^d |c_k|, \quad b = a + n \log d, \quad \delta = (\varepsilon/\alpha) \sum_{k=1}^d k |c_k|. \quad (53)$$

Moreover, the probability of successfully applying this element-wise function has the following form, dependent on f , A , and the initial state:

$$p_{\text{succ}} = \left(\sum_k |c_k| \right)^{-2} \|f^\circ(A)|\psi\rangle\|^2. \quad (54)$$

Proof. Proof of this statement follows immediately from the term-wise complexity of the element-wise power subroutine in Lem. III.1 and the previous construction of the full element-wise transform in Thm. II.3 using standard LCU techniques as depicted in Fig. 6. $\square$

A drawback of the constructions we have given thus far is that in the worst case (both for the log-space and linear-space protocols for element-wise products and functions) the probability of successfully applying the transformed block encoding can decrease exponentially¹⁷ in the degree of the applied polynomial function. In what follows we discuss a few techniques by which (under certain conditioning assumptions) this problem can be mitigated. For the most part these problems have been encountered in prior work for taking long matrix products of block encodings, which can be modified to apply to our Kronecker-to-element-wise product identities.

Restricting ourselves to the usual matrix product compression gadget, we first deal with the possibility that each input $(\alpha_k, a_k, \varepsilon_k)$ block encoding for some linear operator A has some non-optimal subnormalization $\alpha_k \geq \|A\|$. In the following lemma, adapted from Thm. 4 of [FLT23], it can be shown that uniform singular value amplification (Thm. III.3) can be used to multiply this subnormalization by a factor of $\gamma \equiv \alpha(1 - \delta)/\|A\|$, up to precision ε , in turn mitigating the effect of these α_k when they appear in long products of block encoded linear operators.

Lemma III.2 (Amplified compression gadget; adapted from [FLT23]). Let U_{A_k} be $(\alpha_k, a_k, \varepsilon_k \|A_k\|)$ block encodings of (possibly non-unitary) A_k for $k \in \{0, 1, \dots, K-1\}$ and $\sum_k \varepsilon_k \leq 1/2$. Then for any $0 < \varepsilon < 1/2K$ we can construct an $(\alpha', a', \varepsilon')$ block encoding of the matrix product $A_{K-1} \cdots A_1 A_0$, where α' satisfies

$$\frac{1}{2}(1 - \delta)^{-L} \prod_k \|A_k\| \leq \alpha' \leq e^{1/2}(1 - \delta)^{-L} \prod_k \|A_k\|, \quad (55)$$

and a' and ε' satisfy

$$a' = \max a_k + \log(K) + 2, \quad \varepsilon' = e^{1/2} \left[K\varepsilon + \sum_k \varepsilon_k \right] \prod_k \|A_k\|. \quad (56)$$

Moreover, this amplification procedure uses $\mathcal{O}(\alpha_k/(\delta\|A_k\|) \log(\alpha_k/(\varepsilon\|A_k\|)))$ copies of each controlled- U_k and its inverse.

The point of the provided Lem. III.2, e.g., choosing $\delta = \mathcal{O}(1/K)$, is that it modifies the success probability of the compression gadget to near its best possible value:

$$\frac{\|A_{K-1}A_{K-1} \cdots A_0|\psi\rangle\|^2}{\|A_{K-1}\|^2 \cdots \|A_1\|^2 \|A_0\|^2}, \quad (57)$$

i.e., up to the chosen error ε , on which the query complexity depends only weakly. Consequently if we have good knowledge of an upper bound on the spectral norm of the element-wise products at each level of our recursion, we improve our success probability at the cost of query complexity. In the next statement we apply the results of Lem. III.2 to our compressed element-wise product gadget (Thm. II.2); as mentioned this improves the success

¹⁷ Note this is distinct from the separate but similarly thorny problem that if an initial state is nearly annihilated by the block encoding, i.e., that $\|A|\psi\rangle\|^2$ is small, which can generically occur if A is far from unitary, then our protocol can also fail with high probability.

probability of our protocol in terms of the subnormalization factors of the input block encodings at the cost of additional query complexity (and thus a small amount of additional space) as well as an introduced approximation error.

Theorem III.5 (Amplified element-wise product). Let U_A an (α, a, ε) block encoding of an n -qubit operator A . Then we can construct an $(\gamma, a + n \log d, \varepsilon')$ block encoding of the d -th element-wise product of A with itself, denoted $A^{\odot d}$ using $Q = \mathcal{O}(d^{\log(\eta/\delta) \log(\eta/\varepsilon)})$ queries to U_A , where these block encoding parameters have the form

$$\gamma = \mathcal{O}\left(\alpha^{d^{\log(d \log(1/\varepsilon))}}\right), \quad \varepsilon' = \mathcal{O}\left([\alpha + \varepsilon]^{d^{\log(d \log(1/\varepsilon))}} - \alpha^{d^{\log(d \log(1/\varepsilon))}}\right), \quad (58)$$

and $\eta \equiv \alpha/\|A\| \geq 1$. Moreover, the lower bound on the success probability of the resulting protocol (p_{succ}), compared to that of the construction in Thm. II.2 (p'_{succ}), is improved:

$$p'_{\text{succ}} = \alpha^{-2d} \|A^{\odot d}|\psi\rangle\|^2 \mapsto p_{\text{succ}} = (1 - \varepsilon)(1 - \delta)^{-2d} \|A^{\odot d}|\psi\rangle\|^2. \quad (59)$$

Proof. The query complexity of this amplification at any given recursive level is the quoted

$$\mathcal{O}(\alpha/(\delta\|A\|) \log(\alpha/(\varepsilon\|A\|))) \equiv \mathcal{O}(\eta/\delta \log(\eta/\varepsilon)), \quad (60)$$

where $\eta = \alpha/\|A\| \geq 1$. Using the general relation worked out in Rem. III.1 we can compute the asymptotic scaling of the total query complexity for achieving a degree- d element-wise product of amplified block encodings

$$Q = \mathcal{O}\left(d^{\log([\eta/\delta] \log(\eta/\varepsilon))}\right). \quad (61)$$

The choice of δ required to bring the success probability to within a $\Omega(1)$ multiplicative factor of $\|A^{\odot d}|\psi\rangle\|$ is $\delta = \mathcal{O}(1/d)$, which shows that our resulting query complexity is quasipolynomial in d . $\square$

It is well-known in literature (albeit often misquoted¹⁸) that techniques like fixed-point, oblivious amplitude amplification (see Thm. III.2) rely crucially on the block encoded linear operator being (close to) an isometry. When given a general block encoding, as shown in the previous Thm. III.5, the success probability cannot generally be driven close to one for all input states (i.e., obliviously). In the following few statements we will consider the much stronger assumption that our input block encoding (and indeed, its element-wise powers) is close to an isometry. Note for element-wise powers this means our block encoding is close to the (matrix product) identity, which while restrictive is analogous to assumptions made in previous work on compression gadgets [LW19, VG25, FLT23], and allows us to apply robust, oblivious amplitude amplification (ROAA). Following these statements we will discuss a few additional reasonable and useful input assumptions for the QEWT.

Definition III.1 (Near-identity block encodings). Let $U_A(k)$ a k -parameterized family of (α, a, ε) block encodings for $k \in \mathbb{N}$. Then we say that $U_A(k)$ is k -near-identity if

$$\|U_A(k) - I\| = \mathcal{O}(1/k), \quad (62)$$

equivalently that the maximum singular value of the difference between $U_A(k)$ (the entire block encoding unitary) and the identity matrix of the same dimension scales as $1/k$.

While the condition of Def. III.1 appears quite restrictive, we argue, as is also noted in [VG25], that similar bounds appear in a wide array of block encoding applications including Hamiltonian simulation and generic differential equation solvers (e.g., for short time evolutions e^{iHt} can yield near-identity block encodings). As in the cited prior work and here, we are interested in this property as it provides a lower bound on the success probability of the (element-wise) multiplication of multiple near-identity block encodings.

¹⁸ For a good explanation of why this is, see the discussion given in the pedagogical [LW26]

Proposition III.2 (Element-wise multiplication of near-identity block encodings). Let $U_{A_k}(K)$ for $k \in \{0, 1, \dots, K-1\}$ each K -near-identity. Then the element-wise product of all of the A_k succeeds with probability $p_{\text{succ}} = \Omega(1)$, and moreover the product $B = (A_0 \circ A_1 \circ \dots \circ A_{K-1})$ satisfies $\|B - I\| = \mathcal{O}(1)$.

Proof. It can easily be checked that the success probability for a K -near-identity block encoding scales as $\text{tr}(\rho|A|^2) = \Omega(1 - 1/K)$ for any fixed initial state ρ , and consequently the overall success probability scales as $\Omega((1 - 1/K)^K)$ or $\Omega(e^{-1}) = \Omega(1)$. The bound on the difference between the element-wise product and the identity follows from the submultiplicativity of the element-wise product in the operator norm (see Appx. B). $\square$

Corollary III.5.1 (Element-wise products between operators near the identity). Let U_A an (α, a, ε) block encoding of some n -qubit A , and moreover let U_A d -near-identity. Then we can construct a (β, b, δ) block encoding of the d -th element-wise product of A with itself, denoted $A^{\circ d}$ using d queries to U_A , and where β, b, δ satisfy

$$\beta = \Omega(1), \quad b = \mathcal{O}(a + n \log d), \quad \delta = (\alpha + \varepsilon)^d - \alpha^d. \quad (63)$$

Moreover the probability of successfully applying $A^{\circ d}$ to $|\psi\rangle$ scales as $\Omega(1)$.

Proof. Proof follows immediate by restricting of our previous amplified element-wise product (Thm. III.5) to the case that A is d -near-identity, which constrains both α and thus provides the $\Omega(1)$ lower bound on both β and the overall success probability. $\square$

Corollary III.5.2 (Approximate element-wise transform). Let U_A as in the main Thm. II.3, with the additional assumption that U_A is d -near-identity. Then we can create a block encoding of $f^{\circ}(A)$, the element-wise application of f to A , with block encoding parameters

$$\beta = (1 - \varepsilon) \sum_{k=1}^d |c_k|, \quad b = \mathcal{O}(a + n(\log d) \log(\log(1/\varepsilon))), \quad (64)$$

$$\delta = (1 - \varepsilon) \sum_{k=1}^d |c_k| \left[(\alpha + \varepsilon)^k - \alpha^k \right]. \quad (65)$$

where the query complexity to the input block encoding is d , and the probability of successfully applying $f^{\circ}(A)$ to the input state is given by $\|f^{\circ}(A)\|^2 / \|f\|_1^2$, where $\|*\|_1$ refers to the ℓ_1 norm of the coefficients of f .

Before moving on to the following Sec. IV, where we construct and discuss some applications of the quantum element-wise transform, we briefly summarize what the above calculations express regarding the conditions under which applying element-wise functions is expected to be efficient/succeed with high probability. In the general setting the best we can do is uniformly amplify all singular values of the input block encoding, which in general costs, at each level of our recursive construction, queries proportional to $\alpha/\|A\| \geq 1$ (as well as logarithmically on the inverse approximation error), and for non-isometric A can still permit success probability for certain input states to decay exponentially in d . Being able to arbitrarily drive the success probability to one requires *both* that A is a near-isometry and that the element-wise product preserves this near-isometric property, which restricts us to the near-identity¹⁹ setting.

While beyond the scope of this work (and briefly expanded on in our discussion of open directions in Sec. VB), it is easy to enumerate assumptions which may allow more efficient application of the QEWT. These include cases where the input matrices have known block-structure, non-trivial null-space, or known/easily preparable eigenvectors, which may either

¹⁹ More generally to near-permutation matrices where each element is free up to a complex phase; these are sometimes referred to as *monomial matrices*, and are a representation of a *wreath product* $\mathbb{T} \wr S_{2^n}$. These turn out to be the largest class of matrices preserved under element-wise powers.

obviate the need to allocate additional space or to apply a masking step before performing a swap-copy operation. We also note the recent explosion of randomized/parallelized/Trotterized techniques in block encoding algorithms [Cam19, CST⁺21, Cha24, MR25], which may provide practical benefit when running these algorithms on constrained devices.

IV. Applications

The original impetus for this work is rooted in the ubiquitous appearance of element-wise products and functions in applied numerical linear algebra. In this section we cover a few of these applications and the induced resource complexity for quantum algorithms addressing them; a few of these, for instance the section on quantum algorithms for common subroutines in machine learning inference (Sec. IV A), e.g., computing attention by way of an element-wise softmax, are in direct comparison to prior work. We also examine more generic applications to computing derived transforms common in classical signal processing, e.g., matrix convolutions (Sec. IV B) and block generalizations of the Kronecker and element-wise products (Sec. IV C), each of which inherits the space-savings of our main construction.

A. Machine learning inference

Here we focus on a key subroutine of a previous work on (linear-space) element-wise transforms [GYC⁺25] which involves applying an element-wise function to a product of block encodings as part of a critical subroutine (self-attention) in transformer model inference [VSP⁺17]. Our construction provides immediate improvements to Thms. S6, S8, and S9 of [GYC⁺25], which we exposit briefly below along with a few critical definitions. We note that our construction specifically applies to the block encoding input model, which subsumes the related *state encoding* (Def. IV.1) model, which should be thought of as a block encoding where only the first column (possibly subnormalized) is specified and transformed. The benefit of our method, as noted also in the cited work, is that element-wise transforms of block encodings are in general much more difficult to achieve than element-wise transforms of state encodings, given the ability in the latter to reduce to the diagonal case where the matrix and element-wise products coincide.

Definition IV.1 (State encoding; Def. 2 in [GYC⁺25]). A unitary U_ϕ is a (α, a, ε) *state encoding* of an n qubit quantum state $|\phi\rangle$ if

$$\| |\phi\rangle - \alpha(|0^a\rangle \otimes I_n)U_\phi(|0^{a+n}\rangle) \|_\infty \leq \varepsilon. \quad (66)$$

In other words the unitary U prepares, when applied to the all zeros state, a quantum state $|\phi'\rangle$ that ε -approximates a state with $1/\alpha$ overlap²⁰ with the desired $|\phi\rangle$:

$$U_\phi|0^{a+n}\rangle = \alpha^{-1}|0^a\rangle|\phi'\rangle + (1 - \alpha^{-2})^{1/2}|\phi^\perp\rangle, \quad (67)$$

where $|\phi^\perp\rangle$ is some unknown quantum state orthogonal to $|\phi\rangle$ (and whose first a qubits have zero support on $|0^a\rangle$). Here (and in the referenced work) error is taken in the ℓ_∞ -norm, as the interest is in element-wise transformations.

Theorem IV.1 (Block encoding softmax; extension of Thm. S8 in [GYC⁺25]). Let U_A an (α, a, ε) block encoding of a square matrix $A \in \mathbb{C}^{N \times N}$ for $N = 2^n$, $d \in \mathbb{N}$, and $0 \leq j \leq N$ an integer. Then one can prepare a $(1, \mathcal{O}(a + n \log \ell), \mathcal{O}(\sqrt{\varepsilon \sqrt{N/Z_j}}))$ state encoding of the softmax of the j -th column of A :

$$|A_j\rangle \equiv \frac{1}{\sqrt{Z_j}} \sum_{k=1}^N f^\circ(A_{jk}/2\alpha)|k\rangle, \quad (68)$$

²⁰ In this equation and through the rest of the definition, we correct an improper normalization/under-specification of the orthogonal component of the state given in [GYC⁺25].

where $f(*) = \exp(*)$ is the exponential function, and Z_j is the sum of $f^\circ(A_{jk})$ over all k . This requires using $\mathcal{O}(\ell\sqrt{N/Z_j})$ copies of controlled U_A , where $\ell = \mathcal{O}(n \log(1/\varepsilon))$.

Problem IV.1 (Defining block encoding self-attention). Let $n, d \in \mathbb{N}$ and $N = 2^n$, and assume access to the unitary U_S which is an $(\alpha_s, a_s, \varepsilon_s)$ block encoding of $S \in \mathbb{R}^{N \times d}$. Moreover, for matrices W_q, W_k , and W_v all in $\mathbb{R}^d$, assume access to unitaries U_{W_*} which are $(\alpha_w, a_w, \varepsilon_w)$ block encoding of each respectively. Then define $Q = SW_q$, $K = SW_k$, and $V = SW_v$. Given an index $j \in \{1, 2, \dots, N\}$, computing the self attention according to Q, K, V requires preparing a block encoding of $G_{j,*}$ with the form

$$G_{j,*} = (\text{softmax}(QK/\alpha_0) V)_{j,*}. \quad (69)$$

Theorem IV.2 (Block encoding self-attention; extension of Thm. S9 in [GYC⁺25]). Let $j \in \{0, 1, \dots, N\}$ and $\alpha_0 \equiv \alpha_s^2 \alpha_w^2$, and consider the objects/conventions established in Prob. IV.1. Then we can construct an

$$(\alpha_s \alpha_w, \mathcal{O}(a_s + a_w + n \log \ell), \mathcal{O}(\alpha_s \alpha_w \sqrt{(\varepsilon_s + \varepsilon_w)N/Z_j})) \quad (70)$$

block encoding of a matrix G where $G_{j,*}$ has the form

$$G_{j,*} = (\text{softmax}(QK/\alpha_0) V)_{j,*}, \quad (71)$$

using $\mathcal{O}(\ell\sqrt{N/Z_j})$ queries to U_S, U_{W_q}, U_{W_k} and U_{W_v} , where Z_j is the has the form

$$Z_j \equiv \sum_{k=1}^N (e^\circ(QK^\top)/\alpha_0)_{j,k}, \quad (72)$$

and $\ell = \mathcal{O}(n \log(\varepsilon_s + \varepsilon_w)^{-1})$, where we've used the notation $e^\circ(*)$ to denote the element-wise application of the exponential function.

We note again that the application of our construction to the softmax and self-attention subroutines presented above applies primarily in the block encoding input model; as noted in [GYC⁺25, RR23], if our goal instead is to just compute non-linear transformations of state encodings, then we can appeal to other methods that can convert our problem to one involving diagonal block encodings for which even more space efficient QSVT methods can apply. In this sense our method, while not necessary for certain state preparation problems, is strictly more powerful, and does not necessarily acquire the exponential (in dimension, or subnormalization) overhead that column-wise application of non-linear state transformation methods would accrue.

B. Matrix convolutions

Among the most straightforward application of element-wise transforms of block encodings appears in multi-dimensional signal processing generally [CWP⁺25, HJ91], which has also been a recent focus of other block encoding-based quantum algorithms [RHG⁺25, MW24]. Concretely for discrete signals of finite support the element-wise product has a well-known and particularly nice interpretation as a certain convolution in Fourier space. In this section we define these convolutions in the two-dimensional setting and provide a simple quantum algorithm (Thm. IV.3) based in our previous construction for computing them; this provides an immediate extension to the one-dimensional or vectorized convolution algorithms of previous work [RHG⁺25, MW24], and suggests a wealth of further applications based on performing variant quantum element-wise transforms in the Fourier basis.

Definition IV.2 (Discrete 2D convolutions). Let $h(k_1, k_2)$ and $g(k_1, k_2)$ two discrete signals of finite extent, where $0 \leq k_1, k_2 \leq K - 1$.²¹ Then the *linear convolution* of h, g is given by

$$(h * g)_{\text{lin}}(k_1, k_2) \equiv \sum_{j_1} \sum_{j_2} h(j_1, j_2) g(k_1 - j_1, k_2 - j_2). \quad (73)$$

The region over which j_1, j_2 are summed is left unspecified here, though can be bounded if h, g have finite support; regardless, it can be shown that the region of support for the resulting convolution is $0 \leq k_1, k_2 \leq 2K - 1$. If we instead wanted to compute the *circular convolution*, we simply treat the finite signals in a periodic way:

$$(h * g)_{\text{circ}}(k_1, k_2) \equiv \sum_{j_1=0}^{K-1} \sum_{j_2=0}^{K-1} h(j_1, j_2) g(k_1 - j_1 \pmod{K}, k_2 - j_2 \pmod{K}), \quad (74)$$

which has support on $0 \leq k_1, k_2 \leq K - 1$. It is this *circular convolution* that corresponds to element-wise multiplication of the 2D discrete Fourier transforms of our signals (see Lem. IV.1). Finally, note that the linear convolution can be recovered using the circular convolution by padding the signals with zeros until they are of length $2K - 1$.

Lemma IV.1 (Discrete 2D convolution theorem). Let $h(k_1, k_2)$ and $g(k_1, k_2)$ two discrete signals of finite extent, where $0 \leq k_1, k_2 \leq K - 1$. Then the 2D circular convolution of h and g can be written as the inverse Fourier transform applied to the element-wise product of the Fourier transforms H, G of h, g :

$$(h * g)_{\text{circ}}(k_1, k_2) = \mathcal{F}^{-1}(H \circ G) = \mathcal{F}^{-1}(\mathcal{F}(h) \circ \mathcal{F}(g)), \quad (75)$$

where the 2D Fourier transform is defined in the expected way,

$$H(k_1, k_2) \equiv \sum_{j_1=0}^{K-1} \sum_{j_2=0}^{K-1} h(j_1, j_2) e^{-2\pi i(j_1 k_1 + j_2 k_2)/K}, \quad (76)$$

and the element-wise product in the discrete 2D setting is the usual one (Def. I.3). Note that while this definition (and the convolution in Def. IV.2) are presented in the 2D setting, a similar relation extends simply to higher dimensions.

In the 2D setting, however, we have the particularly nice relation that the 2D DFT of a matrix can be written as the composition of the row-wise and column-wise 1D DFTs of the matrix, i.e.,

$$\text{DFT}_{2D}(A) = F A F^T \implies \text{DFT}_{2D}(A)_{jm} = \sum_{k, \ell} F_{jk} A_{k\ell} F_{m\ell}, \quad (77)$$

where $F_{jk} = \omega^{jk}/\sqrt{K}$ and $\omega = e^{-2\pi i/K}$ is the usual DFT matrix. This implies that our 2D circular convolution can be written as a series of matrix and element-wise products:

$$(h * g)_{\text{circ}} = F^\dagger([F h F^T] \circ [F g F^T]) F^* = F^\dagger([F h F] \circ [F g F]) F^\dagger, \quad (78)$$

where we've treated all among F, g, h as K -dimensional matrices, and made the additional simplification given that the DFT matrix F is both symmetric and unitary. Note crucially that the element-wise product and matrix products are not mutually associative.

Having defined the discrete 2D circular convolution, as well as the associated convolution theorem, a quantum algorithm for block encoding such convolutions is almost immediate from our previous constructions. Note also that if one wishes to take the convolution of d total block encodings on n qubits, our methods yield a quantum algorithm which uses only $\mathcal{O}(n \log d)$ additional space, as it would for any combination of matrix and element-wise products of $\mathcal{O}(d)$ total block encodings.

²¹ In general the domains of support can be different in each index for each signal, but we keep the support domain square for simplicity.

Theorem IV.3 (Block encoding the 2D convolution). Let U_A and U_B be (α, a, ε) and (β, b, δ) block encodings of square n -qubit operators A, B respectively. Then we can construct a $(\alpha\beta, \max(a, b) + 1, \alpha\varepsilon + \beta\delta + \varepsilon\delta)$ block encoding of the circular convolution of A and B , denoted $(A * B)$ using a single query to each of U_A and U_B , $\mathcal{O}(n^2 \log n)$ single and two-qubit gates, and $\mathcal{O}(\max(a + b))$ additional space.

Proof. Proof follows directly from constructing the quantum circuit achieving the block encoding of the product in Lem. IV.1, which involves conjugating an element-wise product of two block encodings in the Fourier basis with a quantum Fourier transform (whose gate complexity goes as $\mathcal{O}(n^2 \log n)$). The error propagation follows from the fact that the element-wise product is a principal sub-matrix of the Kronecker product, and that the quantum Fourier transform is unitary. $\square$

C. Non-standard block matrix products

It turns out the constructions of Sec. II yield quantum algorithms for computing other non-standard matrix products and functions. In this section we define, discuss, and build quantum algorithms for realizing various block-matrix generalizations to the Kronecker and element-wise products. These products appear in statistical physics, the analysis of linear systems, and control theory [TS72, KR68], and have been subjected to extensive study both through applied [TJ89, HC89] and foundational matrix analytic lenses [MN79, Liu99].

Definition IV.3 (Tracy–Singh product [TS72]). Let $A \in \mathbb{C}^{m \times n}$ and $B \in \mathbb{C}^{p \times q}$ where A can be decomposed into $(m_i \times n_j)$ -sized blocks, and B can be decomposed into $(p_k \times q_\ell)$ -sized blocks. Then the *Tracy–Singh product* (or TS product) of A and B , often denoted $(A \boxtimes B)$ has the form²²

$$(A \boxtimes B) \equiv ((A_{ij} \otimes B_{k\ell})_{k\ell})_{ij}, \quad (79)$$

which should be interpreted as the pair-wise *Kronecker product* according to the partitions of the two input block matrices. Note the shape of the resulting matrix is $(mp \times nq)$.

Proposition IV.1 (Relation between the Kronecker and TS product; adapted from [Cho25]). Let the *commutation matrix* $K_{m,n}$ have the form (written suggestively in bracket notation)

$$K_{m,n} = \sum_{i,j}^{m,n} |i\rangle\langle j| \otimes |j\rangle\langle i|. \quad (80)$$

Then the TS product $(A \boxtimes B)$ between square A and B of size n^2 and m^2 respectively (with square sub-blocks of dimension n and m respectively) is related to the Kronecker product $(A \otimes B)$ by the commutation matrix:

$$A \boxtimes B = (I_n \otimes K_{m,n} \otimes I_m)(A \otimes B)(I_n \otimes K_{n,m} \otimes I_m). \quad (81)$$

Note also that the commutation matrix is named as such given the related identity $K_{m^2, n^2}(A \otimes B)K_{m^2, n^2} = (B \otimes A)$. I.e., the commutation matrix in (80), interpreted as a quantum gate, is just the swap operation (taking the dimensions of A, B equal). Evidently it is also its own inverse, and the Kronecker and TS products are related by a simple *block-wise swap*, which can easily be computed quantum mechanically as in Thm. IV.4.

²² Here what is meant by the nested indices is that the ij -th sub-block of the $(mp \times nq)$ matrix is itself divided into blocks, the $k\ell$ -th of which is the Kronecker product $A_{ij} \otimes B_{k\ell}$.

Definition IV.4 (Khatri–Rao product [KR68]). Let $A \in \mathbb{C}^{m \times n}$ and $B \in \mathbb{C}^{p \times q}$ where A can be decomposed into $(m_i \times n_j)$ -sized blocks, and B can be decomposed into $(p_k \times q_\ell)$ -sized blocks, where i, k and j, ℓ range over the same sets respectively. Then the *Khatri–Rao product* (or KR product) of A and B , denoted $(A \odot B)$, has the form

$$(A \odot B) \equiv (A_{ij} \otimes B_{ij})_{ij}, \quad (82)$$

which should be interpreted as a block-wise (as in between blocks indexed by the same index pair (i, j)) Kronecker product between the two block matrices. Unlike the TS product (Def. IV.3), Kronecker products between sub-blocks of A and B do not cover all pairs of index pairs $(ij, k\ell)$, but only one set of indices (ij) . The shape of the resulting matrix is $(m_i p_i) \times (n_j q_j)$, where sums over i, j are implicitly taken *inside* their encompassing parentheses.

In the case that A, B in the above products have only trivial (i.e., scalar) sub-blocks, the TS and KR products reduce to the usual Kronecker and element-wise products. Moreover, the TS product shares many desirable properties with the Kronecker product, including associativity, distribution over sums, and that $(A \boxtimes B)^{-1} = A^{-1} \boxtimes B^{-1}$. In what follows we make the correspondence between these pairs of products more concrete by giving quantum algorithms to compute the TS and KR products between block encoded matrices. For simplicity we work in a qubit-adapted setting, though standard methods in matrix padding (see discussion in [GSLW19]) can be used to achieve these non-standard products between block matrices of arbitrary (conformable) shape and dimension.

Example IV.1 (TS and KR products; minimal examples). For the visual reader we include brief, explicit examples of the Tracy–Singh (Def. IV.3) and Khatri–Rao (Def. IV.4) products between (2×2) block matrices. Note that defining these products in principles requires no additional assumptions on the block sizes beyond their mutual compatibility to constitute a rectangular M_1, M_2 , defined below:

$$M_1 = \left[\begin{array}{c|c} A_{00} & A_{01} \\ \hline A_{10} & A_{11} \end{array} \right], \quad M_2 = \left[\begin{array}{c|c} B_{00} & B_{01} \\ \hline B_{10} & B_{11} \end{array} \right]. \quad (83)$$

In this case the (4×4) block matrix TS product can be expressed as the following:

$$(M_1 \boxtimes M_2) \equiv \left[\begin{array}{cc|cc} A_{00} \otimes B_{00} & A_{00} \otimes B_{01} & A_{01} \otimes B_{00} & A_{01} \otimes B_{01} \\ A_{00} \otimes B_{10} & A_{00} \otimes B_{11} & A_{01} \otimes B_{10} & A_{01} \otimes B_{11} \\ \hline A_{10} \otimes B_{00} & A_{10} \otimes B_{01} & A_{11} \otimes B_{00} & A_{11} \otimes B_{01} \\ A_{10} \otimes B_{10} & A_{10} \otimes B_{11} & A_{11} \otimes B_{10} & A_{11} \otimes B_{11} \end{array} \right], \quad (84)$$

where we see that the larger 2×2 blocks (each containing four sub-blocks) are each indexed by the same block A_{ij} entering into the left argument of a Kronecker product. Just as in the usual Kronecker product, we can see that the four corner blocks of this block matrix contain Kronecker products between sub-blocks of M_1 and M_2 with the same index. Permuting these blocks and post-selecting on the resulting top-left sub-matrix yields the KR product, summarized (dropping indices for now) below:

$$(M_1 \odot M_2) \equiv (\langle 0| \otimes I) P \left[\begin{array}{cc|cc} A_{00} \otimes B_{00} & * & * & A_{01} \otimes B_{01} \\ * & * & * & * \\ \hline * & * & * & * \\ A_{10} \otimes B_{10} & * & * & A_{11} \otimes B_{11} \end{array} \right] P^\dagger (|0\rangle \otimes I), \quad (85)$$

$$= \left[\begin{array}{c|c} A_{00} \otimes B_{00} & A_{01} \otimes B_{01} \\ \hline A_{10} \otimes B_{10} & A_{11} \otimes B_{11} \end{array} \right]. \quad (86)$$

From this it can be seen, at least at a moral level, that the quantum algorithms to compute these products involve applying our previously constructed algorithms to sub-registers of block-encoded matrices with block structure.

Theorem IV.4 (Tracy–Singh product between block encodings). Let U_A and U_B be $(\alpha, a, 0)$ and $(\beta, b, 0)$ block encodings of $(n + m)$ -qubit operators A and B respectively.

Moreover, consider A and B as each divided into 2^n square blocks of size 2^m , and that matrix elements within these blocks are indexed by computational basis states for qubits over disjoint registers, e.g., $A_{r_1 r_2}$ where r_1 (labeling the blocks) has size n , while r_2 has size m . Then we can construct a unitary V that is a $(\alpha\beta, a+b, 0)$ -block encoding of the Tracy–Singh product $(A \boxtimes B)$ using one query to each of U_A and U_B and $\max(m, n)$ two-qubit swap gates. Here $(A \boxtimes B)$ is a square matrix of dimension $2^{2(n+m)}$.

Proof. The construction in this qubit setting follows from the identity in Prop. IV.1, as the TS product is not only a block-wise analogue of the Kronecker product, but also its row- and column-permutation. I.e., ignoring the unitaries U_A and U_B for the moment, the TS product satisfies, modifying the notation of (81):

$$(A \boxtimes B)_{r_1 r_2 r_3 r_4} = S_{r_2 r_3} (A_{r_1 r_2} \otimes B_{r_3 r_4}) S_{r_2 r_3}. \quad (87)$$

As the Kronecker product of two block encoded operators is a simple construction (and indeed is a subroutine in our element-wise product circuit, using only the union of the auxiliary space required by each input), the only addition is that the conjugating qubit-wise swap gates on the n - and m -qubit registers r_2 and r_3 (here denoted S with the registers swapped in the subscript). Note that here the swap is performed in-place between registers of different sizes, n, m , and thus requires $\max(m, n)$ two-qubit swap gates. Finally, as this product is just a permutation of the Kronecker product, error propagation is identical to that case, yielding an $(\alpha\beta, a+b, \alpha\delta + \beta\varepsilon + \delta\varepsilon)$ block encoding of $(A \boxtimes B)$ in the case that the input block encodings have error ε and δ respectively. $\square$

Theorem IV.5 (Khatri–Rao product between block encodings). Let U_A and U_B as in Thm. IV.4. Then we can construct a unitary V that is a $(\alpha\beta, a+b, 0)$ -block encoding of the Khatri–Rao product $(A \odot B)$ using one query to each of U_A and U_B and $\max(m, n)$ swap gates. Here $(A \odot B)$ is a square matrix of dimension $2^{(n+m)}$ (the same as A and B).

Proof. Proof follows from the observation that the KR product is a submatrix of the TS product analogously to how the element-wise product is a submatrix of the Kronecker product. I.e., we conjugate by the same permutation employed in our original element-wise construction, save here only on the block-labeling register of the first block encoding.

$$(A \odot B)_{r_3 r_4} = (\langle 0 |_{r_1 r_2} \otimes I_{r_3 r_4}) P_{r_1 r_3} (A \boxtimes B)_{r_1 r_2 r_3 r_4} P_{r_1 r_3}^\dagger (|0\rangle_{r_1 r_2} \otimes I_{r_3 r_4}). \quad (88)$$

As in our construction of the TS product, error propagation here for block encodings of A and B with error ε and δ respectively is exactly analogous to the standard element-wise product, i.e., the result is an $(\alpha\beta, a+b, \alpha\delta + \beta\varepsilon + \delta\varepsilon)$ block encoding of $(A \odot B)$. $\square$

V. Discussion

In this work we construct a family of quantum algorithms for computing element-wise functions of block encodings, whose space use scales logarithmically rather than linearly in the degree of the applied function—this scaling, matching that of existing methods for applying spectral maps to or taking linear combinations of block encodings, thus represents a new and practically-implementable subroutine in the block encoding toolkit. Moreover, we raise and rectify errors in previous constructions (Appx. C), establishing a robust foundation for the general theory of *quantum element-wise transforms* (QEWTs).

The core of our construction depends on the orchestration of both well-known and (to the authors’ knowledge) new but simple subroutines for manipulating block encodings. These include (1) a known identity relating the element-wise product of matrices to a principal submatrix of their Kronecker product, (2) a known construction for exponentially reducing the auxiliary space required when *matrix multiplying* many block encodings at once (the so-called *compression gadget* of Low and Wiebe [LW19, VG25]), and (3) a method for cheaply duplicating blocks of block encodings *which themselves have block structure* (which we call a *swap-copy*, Lem. II.1) *as well as* a way to efficiently re-use the auxiliary space required by this

swap-copy within recursively self-composed versions of our protocol, enabling space-efficient computation of high-degree element-wise products (our *weaving lemma*, Lem. II.2). These, together with our corrected scheme for constructing LCU SELECT unitaries (Lem. II.4), and application of various amplitude amplification/uniform singular value amplification techniques (Sec. III), compose our central contribution. Crucially, beyond merely introducing (1-3) above, we show that these techniques can be made to interact while maintaining both correctness and $\mathcal{O}(\log d)$ auxiliary space.

Beyond introducing a class of improved quantum algorithms, we devote Sec. IV to specific applications across machine learning inference, multidimensional signal processing, and the computation of generalized block-matrix products. These applications are partly direct improvements to existing constructions [GYC⁺25], as well as strict generalizations [RR23, RHG⁺25, MW24], and novel quantum algorithms for existing, classically useful matrix/tensor functions [TS72, KR68]. In addition to applications, however, a tandem aim of this work is the development of quantum algorithms for core numerical linear algebraic subroutines that can be *efficiently and interpretably combined*, as well as modified to (1) more easily incorporate classical techniques and (2) admit the use of numerical tools for compilation/verification/optimization long common in classical computing.

A. On space and query lower bounds

While the primary focus of this work is showing large space improvements and explicit quantum circuits for computing element-wise functions of block encodings, it is worth investigating the ultimate performance limitations of any quantum algorithm for this task. As for many other aspects of this work, the element-wise product, given its strange character, does not immediately permit the known circuit depth, space, and query lower bounds for matrix products. Nevertheless, we can establish a few such bounds, and leave the remaining gap to future work.

1. Most simply the element-wise product and matrix product coincide for diagonal block encodings, which establishes an Ωd query complexity lower bound, as well as (in the multivariable setting) an $\Omega \log d$ space lower bound (following from the space lower bound of exact compression gadgets shown in [VG25]).
2. Secondly, while the linear-space protocol identifies the d -th element-wise product as a sub-matrix of the Kronecker product $A^{\otimes d}$, which can be implemented in constant depth given block encodings of A , the full circuit including permutations requires linear depth, as is expected from standard results in circuit depth lower bounds for Hamiltonian simulation and phase estimation.

Consequently room for improvement to this work exists for the case of (1) element-wise functions of a single block encoding, where the known gap is logarithmic in the degree of the applied function, and (2) depth improvements under special structural assumptions on the input block encoding, where the gap is linear in the degree of the applied function. Moreover, while not investigated in this work, we expect there exist hardness assumptions for certain element-wise transforms based on the accrued subnormalization factor, e.g., in the case where one uniformly amplifies or else applies a thresholding function element-wise.

B. Open directions

Our work suggests numerous near-term extensions, including the use of randomized/approximative techniques to further improve performance under architectural constraints, as is widely applied to other block encoding algorithms [MR25, MRC⁺25, RCC25]. We expect that additional knowledge of the input (e.g., low rank or well-conditioned) can also be leveraged for performance, and that variants of our the swap-copy and weaving lemma can yield independently interesting methods for manipulating block encodings with block structure or

known eigensubspaces. Here we briefly enumerate a few concrete directions and associated questions related to this work.

At a high level these are clustered around (a) direct performance improvements for the subroutines presented in the main text under reasonable assumptions on the input, (b) the extension of our methods to other common but under-studied (in a quantum computing context) matrix/tensor functions, (c) fundamental questions on resource lower bounds, and finally (d) the proposal of concrete applications with reasonable instance sizes.

- (a) As discussed in the main text, various assumptions on the input block encoding (the most trivializing being the diagonal case) can change the space cost of implementing QEWTs or their approximate versions. Promising assumptions include the near-diagonal setting (or their Fourier-space equivalents of matrices with displacement-structure, including Toeplitz, Hankel, and their block-variants). Moreover, there exist matrices whose block diagonalization (after which a swap-copy can be applied) can be accomplished in other ways than our masking procedure (e.g., block-triangular matrices in [SLBB25] in the context of solving linear matrix equations).
- (b) While our construction works given black-box block encodings, there exist assumptions stronger than block encodings (e.g., sparse element-wise oracles) under which computing QEWTs becomes significantly easier. Do there exist less trivial access assumptions, stronger than black box access, which permit even more space-efficient QEWTs? Are any of these *de-quantizable* by existing matrix sketching methods?
- (c) While we can show space and query lower bounds for generic multivariable element-wise transforms (e.g., by reducing to the diagonal case where matrix multiplication and element-wise products coincide, which requires $\mathcal{O}(\log d)$ auxiliary space generically [VG25]), this argument *does not* apply to an element-wise function of a *single* block encoding. How can we show space and query lower bounds in this restricted setting?
- (d) While the element-wise product appears ubiquitously in machine learning [CWP⁺25], control theory [JS86], the study of the stability of dynamical systems, and classical signal processing [HJ91], this work does not study the interaction between common conditioning/rank assumptions for these problems and the subnormalizations/success probabilities of our QEWT. Under what assumptions on the input block encoding should we expect, e.g., the polynomial advantages in [GYC⁺25] to be preserved?

VI. Acknowledgments

The authors are grateful to John Martyn, Isaac Chuang, and Mark Wilde for discussions on the topic of this work. ZMR acknowledges funding from the Japan Society for the Promotion of Science (JSPS) Postdoctoral Fellowship for Research in Japan (KAKENHI 24KF0136).

On LLM use: The planning, main results and constructions, composition, and reference compilation for this document were completed *without* the use of a large language model (LLM). In the final stages of this work’s composition LLMs were consulted asynchronously and without edit permissions to identify typos, obvious errors, redundancies, or notational deficiencies; any suggestions were reviewed and implemented serially and by-hand if correct.

A. The compression gadget

A key component of the main construction of Sec. II is a method for reducing auxiliary space usage when taking high-degree matrix products of block encodings. Here we briefly review the background, main statement, and variants of these *compression gadgets* (introduced in [LW19]).

The basic conceit of these methods is that, while the gadget for multiplying two block

encodings involves the instantiation of disjoint auxiliary qubit registers, e.g.,

$$(\langle 0|_{r_1} \otimes I_{r_2})(U_A)_{r_1 r_2}(|0\rangle_{r_1} \otimes I_{r_2}) = A_{r_2}, \quad (\text{A1})$$

$$(\langle 0|_{r'_1} \otimes I_{r_2})(U_B)_{r'_1 r_2}(|0\rangle_{r'_1} \otimes I_{r_2}) = B_{r_2}, \quad (\text{A2})$$

$$(\langle 0|_{r'_1 r_1} \otimes I_{r_2})(U_A)_{r_1 r_2}(U_B)_{r'_1 r_2}(|0\rangle_{r'_1 r_1} \otimes I_{r_2}) = (AB)_{r_2}, \quad (\text{A3})$$

when we are multiplying many matrices at once we can instantiate a smaller auxiliary register which records only vital information about the successful application of each constituent block encoding. This reduces the auxiliary space usage from linear (i.e., copying $r_1, r'_1, r''_1, \dots$ according to the example above) to logarithmic in the degree of the product. This improvement is captured by the formal statement of the compression gadget below (depicted in Fig. 8).

Lemma A.1 (Compression gadget; Lemma 13 in [LW19], generalized in [VG25]). Let U_k for $k \in [K]$ be a series of unitaries respectively block encoding (square) A_k ,

$$(\langle 0|_a \otimes I_s)U_k(|0\rangle_a \otimes I_s) = A_k, \quad \|A_k\| \leq 1, \quad (\text{A4})$$

where each A_k acts on n_s qubits and each block encoding uses n_a additional qubits of space. Then there exists a quantum circuit V with form

$$(\langle 0|_{ac} \otimes I_s)V(|0\rangle_{ac} \otimes I_s) = |0\rangle\langle 0|_b \otimes I_s + \sum_{k=1}^K |k\rangle\langle k|_b \otimes \left[\prod_{j=1}^k A_j \right]_s, \quad (\text{A5})$$

where $n_b \in \mathcal{O}(n_c) = \mathcal{O}(\log K)$, and the cost of V is one query to controlled-controlled- U_k and $\mathcal{O}(K(n_a + \log K))$ additional single qubit gates. I.e., V is a $(1, n_a + n_c, 0)$ block encoding of the block diagonal matrix

$$W = I_s \oplus \bigoplus_{k=1}^K \left[\prod_{j=1}^k A_j \right]_s, \quad (\text{A6})$$

which can be converted to a block encoding of the product of all A_k by selecting only the $k = K$ block, i.e., V is a $(1, n_a + n_b + n_c, 0) = (1, n_a + \mathcal{O}(\log K), 0)$ block encoding this product. Fig. 8 depicts the circuit for this block encoding.

While we give only asymptotic space and query complexities in Lem. A.1, quick examination of the circuit in Fig. 8 reveals that the pre-factors involved are quite reasonable, and further optimizations are readily made (e.g., dropping the last projection-controlled addition, given the definition of a block encoding). Indeed, as we discuss a little below, one can define a whole class of related circuits which use coherently applied mid-circuit gates to transduce information about the successful application/transformation of intermediate block encoding unitaries. In the case that the input block encodings are approximate, the error propagation is handled in precisely the same way as the usual, linear-space product method, which we reproduce in Appx. D (Rem. D.1).

Since its introduction the compression gadget has been widely employed [LW19, FLT23] as well as extended to a general class of techniques for space-saving when manipulating many block encodings simultaneously. These extensions, which may offer interesting avenues to extend techniques of this work, and pivot on the following common assumptions. Concretely, in [VG25] they consider the possibility of moving from an exact compression gadget to an approximate one, allowing for even further reduction in space use. They enumerate the conditions under which this further compression succeeds and fails, and identify key assumptions (e.g., that the inputs are near-identity) where this approximate scheme is practically relevant. Analogously, when the input model is not merely block encodings but access to free Hamiltonian evolution for arbitrary (polynomial) time [KS26], there exist further approximate protocols for matrix arithmetic that are space-efficient compared to naïve methods for multiplying/adding. These methods, in addition to hybrid techniques involving Trotterization and product formulas, as well as the incorporation of randomness, offer exciting avenues for future work further optimizing our construction in special cases.

FIG. 8. Circuit form of the standard compression gadget (Lem. A.1) introduced and generalized in [LW19] and [VG25] respectively. Here we have suppressed multiple qubit wires with a slash, and compute the block encoding of the matrix product of $\{A_1, \dots, A_K\}$, given access to their block encoding unitaries, which use r_1 as their auxiliary register. We also compress notation for our projection-controlled addition (modulo 2^m) operations, whose controls here are notated by $(\perp)$ and whose targets are notated by $(+)$ (i.e., if r_1 is not in the all zeros state, then a modular addition is performed on r_0). If r_0 and r_1 are measured at the end in the all zeroes state, then the desired matrix product is applied to $|\psi\rangle$.

B. Properties of the element-wise product

Here we briefly collect a few known, useful properties of the element-wise product of matrices obeying certain constraints. While our main results do not depend explicitly on nor take advantage of the more involved of these properties, we briefly gloss the most important as there exist numerous other block encoding algorithms (e.g., linear combination of Hamiltonian simulation: LCHS [ACL26, LS25, SLBB25]) whose resource complexity depends strongly on the spectral properties of their input, and thus these results may have bearing on the efficiency block encoding methods applied post-QEWT. We also expect (especially through some of the non-trivial spectral lower bounds of Prop. B.2 that one might be able to prove useful lower bounds on success probability and amplitude amplification requirements for specific classes of block encodings.

Theorem B.1 (Schur product theorem; Thm. 5.2.1 in [HJ91]). If $A, B \in M_n$ are positive semi-definite (PSD), then so is their element-wise product $A \circ B$. Moreover, if B is PSD and A has no diagonal entry equal to zero, then $A \circ B$ is also PSD. Furthermore, if A and B are both positive definite (PD), then so is $A \circ B$. As a corollary, note that element-wise polynomials of PSD/PD matrices with positive real coefficients are also PSD/PD.

Proposition B.1 (Submultiplicativity of element-wise product; Thm. 5.5.1 of [HJ91]). For any $A, B \in M_{m,n}$ ($m \times n$ matrices with complex coefficients), $\|(A \circ B)\| \leq \|A\| \|B\|$, where $\|A\|$ is the spectral norm, or largest singular value of A . We also have the following chain of inequalities:

$$\|(A \circ B)\| \leq r(A) c(B) \leq \|A\| \|B\|, \quad (\text{B1})$$

where $r(A)$, $c(A)$ are the maximum ℓ_2 norms among rows and columns of A or B . The commutativity of the element-wise product establishes the statement with row and column maximum ℓ_2 -norms flipped. Moreover, the (element-wise product) submultiplicativity of the spectral norm given here can be extended to all *unitarily-invariant* norms.

Proposition B.2 (Spectral properties of the element-wise product; variously [HJ85, HJ91]). Let $A, B \in M_n$ be positive definite. Then $AB = A \circ B$ iff both A and B are diagonal. Moreover, $\det(A \circ B) \geq \det B \prod_k A_{kk}$ (this is called *Oppenheim's inequality*). For A, B PSD, we thus also have $\det(A \circ B) \geq (\det A)(\det B)$. Finally, as a relatively weak statement, recalling that the element-wise product is a principal submatrix of the Kronecker product, we have the following spectral bounds:

$$\lambda_{\min}(A \circ B) \geq \lambda_{\min}(A) \lambda_{\min}(B), \quad \lambda_{\max}(A \circ B) \leq \lambda_{\max}(A) \lambda_{\max}(B), \quad (\text{B2})$$

whenever A, B are PSD. A stronger statement can be made (Thm. 5.3.1 of [HJ91]) for PSD Hermitian A, B :

$$\lambda_{\min}(A \circ B) \geq \lambda_{\min}(AB^T), \quad \lambda_{\min}(A \circ B) \geq \lambda_{\min}(AB). \quad (\text{B3})$$

In the interest of concision we stop here, but refer the interested reader to the in-depth treatment of the element-wise or Hadamard product in [HJ85, HJ91] (specifically Ch. 5 of the latter and its references), which provides a huge variety of useful statements, including in the block-matrix case, the study of the relative gain array, stronger constraints than PSD on the input matrices, and the interaction between the element-wise product and so-called ‘ordinary functions’ of matrices, which generalize spectral mappings like QSVT.

C. LCU for non-standard matrix products

In the main text we stated a lemma (Lem. II.4) confirming that the SELECT unitary for the element-wise product up to a degree d could be built, just as for the usual matrix product, using a d copies of a controlled block encoding of the desired matrix, as well as $\mathcal{O}(\log d)$ additional space and $\mathcal{O}(d \log d)$ single- and two-qubit gates. In this section we both give a constructive proof of this Lem. II.4, and discuss the insufficiency of a brief argument given in prior work for constructing the same unitary.²³

We provide a brief summary of the oversights in prior work on this topic (Rem. C.1), which can be roughly grouped into questions of access model, properties of the element-wise product, and block encoding properties. We also provide an auxiliary figure (Fig. 9) which illustrates, at a minimal size, the modifications that can recover the desired construction. Following these discussions we provide the statement and accompanying proof of the main text’s Lem. II.4.

Remark C.1 (Subtleties non-standard SELECT unitaries). The proof of Thm. S6 in [GYC⁺25] makes only passing reference to a construction which takes as input block-encoded element-wise powers of a given matrix, and produces the SELECT unitary which coherently applies these powers according to the quantum state of an auxiliary register. The core argument of this work is that the usual construction of SELECT for matrix products (reproduced below in Lem. C.1) suffices. We point out three complications in this statement.

- (a) The construction of SELECT, toward applying LCU among block encodings, requires *controlled access* to the block encoding unitaries. If a circuit description of these block encodings is known this controllization can be straightforward, while for black-box unitaries controllization can be extremely expensive. Regardless, the controlled access assumption should be noted explicitly where relevant.
- (b) The application of Lem. C.1 (e.g., in the cited [CKS17]) involves the sequential application of 2^j -th *matrix powers* of a block encoding according to the j -th bit b_j of the control register. This sequential application necessarily induces *matrix powers* among these block encodings, leading (by the associativity of matrix multiplication) to the desired total power:

$$\prod_{j=0}^{\log d} A^{b_j 2^j} = A^{\sum_{j=0}^{\log d} b_j 2^j} = A^k \text{ where } k \equiv b_{\lceil \log d \rceil} \cdots b_1 b_0. \quad (\text{C1})$$

The issue immediately encountered when trying to apply this to the element-wise product is that the matrix and element-wise products are *incompatible*, meaning that the matrix multiplication of bit-wise controlled element-wise products is simply incorrect:

$$(A^{\circ b_0 2^0})(A^{\circ b_1 2^1}) \cdots (A^{\circ b_{\log d} d}) \neq A^{\circ (b_0 2^0 + b_1 2^1 + \dots b_{\log d} d)}. \quad (\text{C2})$$

- (c) Finally, as implied in the previous point it is not even clear how we should define $A^{\circ 0}$, as the identity element for the standard matrix product and the element-wise

²³ We emphasize that, as our construction occurs above the element-wise power subroutine, we remedy and leave (mostly) unchanged the quoted complexities in the prior [GYC⁺25].

FIG. 9. The quantum circuit to apply, controlled on the single-qubit register r_5 , either $A = A^{\circ 1}$ or $(A \circ A) = A^{\circ 2}$ to the register $r_1 r_3$ (assuming successful post-selection of $r_0 r_2 r_4$ in the all-zeros state). Note that if the permutations were *not controlled* that this would apply either $(A \circ I)$ or $(A \circ A)$ for $r_5 = |0\rangle, |1\rangle$ respectively, which is equivalent iff A is diagonal. In the controlled version of our recursive construction these controlled permutations, at each level, would become *multi-controlled permutations* applied only when *not all* of the inputs A, B are the identity matrix.

product are not identical. Consequently, *even if* the scheme of sequentially applying bit-wise controlled element-wise powers worked, we could not use standard controlled block encodings without further modification. As a small example (the circuit for the correct version of which is given in (Fig. 9)) one can compare the following two SELECT unitaries, where the first computes the desired bit-wise-controlled element-wise product with the matrix product identity, and the second with the element-wise product identity.

$$V = |0\rangle\langle 0|_{r_5} \otimes (A \circ I)_{r_1 r_3} + |1\rangle\langle 1|_{r_5} \otimes (A^{\circ 2})_{r_1 r_3}, \quad (\text{C3})$$

$$V' = |0\rangle\langle 0|_{r_5} \otimes (A^{\circ 1})_{r_1 r_3} + |1\rangle\langle 1|_{r_5} \otimes (A^{\circ 2})_{r_1 r_3}. \quad (\text{C4})$$

I.e., we have to make sure that in the case that a control bit for a constituent block encoding unitary is zero that we *either* apply an element-wise product with the element-wise identity, or a matrix product with the matrix product identity, such that the overall effect on the product is null. It turns out (as block encoding the element-wise identity incurs a bad subnormalization) that we can do the former comparatively simply as discussed in the proof of Lem. C.2.

Lemma C.1 (Gate cost for controlled matrix product gadgets; Lem. 8 from [CKS17]). Let $U = \sum_{k=0}^N |k\rangle\langle k| \otimes Y^k$, where Y is a unitary with gate complexity G . Let the gate complexity of Y^{2^j} be $G_j \leq 2^j G$. Then the gate complexity of U is $\mathcal{O}(NG)$.

Proof. Let $n = \lfloor \log N \rfloor$, and note that the unitaries Y^{2^j} for $j \in \{0, \dots, n\}$, which have query complexity G_j , also have controllized versions with query complexity G_j . The desired unitary U is just the sequential application of controlled- Y^{2^j} to the j -th qubit of a register of size n encoding $k \in \{0, \dots, N-1\}$ in binary. The total gate complexity is thus

$$\mathcal{O}\left(\sum_{j=0}^n G_j\right) \leq \mathcal{O}\left(\sum_{j=0}^n 2^j G\right) = \mathcal{O}(NG), \quad (\text{C5})$$

which is evidently linear in both the maximum degree and the cost of Y . $\square$

The morals of Lem. C.1 are clear: the gate cost of coherently computing controlled matrix products of a desired unitary is not much larger than the gate cost of computing the highest degree constituent matrix product, and the realizing circuit needs access only to certain (sufficiently cheap) controlled powers of this matrix product. This result, while referred to in the LCU construction of Thm. S6 of [GYC+25], is not sufficient to establish a similar construction in the case of *element-wise* powers for the reasons discussed in Rem. C.1. Here we clarify and remedy these problems by providing a modified version of Lem. C.1. The key

enabling factor is that our desired matrix function has a uniform circuit which, viewed as a function of (multiple copies of) the block encoding input, doesn't depend on their order. Moreover, given the known identity that the element-wise product is a sub-matrix of the Kronecker product (which is itself a matrix product) we have a cheap way of (coherently) ensuring that matrix-product identities rather than element-wise product identities can be applied, simply by controllizing the permutations used to realize this identity. It is an interesting open question whether other SELECT unitaries for indexed matrix functions can be built in a similar way.

Lemma C.2 (Building SELECT for the element-wise product). Let U_A a $(1, a, 0)$ block encoding of an n -qubit linear operator A and $d \in \mathbb{N}$. Then the SELECT unitary for element-wise powers of A up to degree d , i.e.,

$$U_{\text{SELECT}} \equiv \sum_{k=0}^d |k\rangle\langle k| \otimes U_{A^{\circ k}}, \quad (\text{C6})$$

can be built using d copies of *controlled* U_A , $\log d$ qubits of additional space, and $\mathcal{O}(d \log d)$ single and two qubit gates. Note here that the notation $A^{\circ 0}$ is taken to be the *usual identity matrix* on n qubits.

Proof. The statement follows from the assumption that the circuit for the unitary-valued function we want to coherently apply $g(k, A) = A^{\circ k}$ is uniform, i.e., that it depends only on the number of copies of (block encodings of) A it is provided. If this is the case, we can build our select from copies of controlled- U_A by the same bit-wise control scheme with a few addenda. I.e., assuming for now that d is a power of 2,²⁴ we fill the first $d/2$ slots of our uniform circuit with copies of controlled- U_A , where the control qubit is the most significant bit of the additional register (r_5) of size $\log d$, and the target is the usual registers ($r_1 r_2 r_3$) for our block encoding. The next $d/4$ slots are then controlled by the second-most significant bit, and so on. This ensures that, coherently, when $|k\rangle$ is encountered in the control register (encoded in binary with consistent endianness), that k total copies of U_A are provided to the uniform circuit, yielding the desired $g(k, Y)$.

What remains is then to argue that we can also simultaneously enforce the matrix product identity (which is seen by the circuit instead of A when a given U_A 's control qubit is in the state $|0\rangle$) to act like the element-wise product identity. The simplest of example of this was given in Fig. 9, e.g., at the lowest level of our recursion the *permutation unitaries* $P, P^\dagger$ are controlled by our register r_5 such that, whenever *either of the control qubits* for the two inputs $U_{(I \otimes A)}$ or $U_{(I \otimes B)}$ (as in Fig. 3) are in the state $|0\rangle$, then neither of $P, P^\dagger$ is applied. For higher levels of recursion these $P, P^\dagger$ are turned off only when *all control qubits* contributing to *either input block encoding* from lower levels are zero. These are simply multi-qubit controlled permutations, which catalytically use at most an additional $\log d$ -qubits of additional space an access to a qubit-controlled permutation (e.g., see Sec. 4.3 of the standard [NC11]).

The total gate complexity of our construction is thus $\mathcal{O}(d \log d)$, as there are d total slots in our uniform circuit, and each controlled U_A comes paired with a constant depth circuit acting over at most $\mathcal{O}(\log d)$ qubits. $\square$

The mechanisms of Lem. C.2 can be used to amend the error in prior work raised when trying to build an element-wise SELECT only from an application of Lem. C.1 (taken from [CKS17]). We give this amendment in the dedicated Prop. C.1; note that in this statement we are building a bit-wise-controlled element-wise product under the assumption of access to block encodings of $A^{\circ 2^j}$ for varying j . For ease of visualization we also provide a figure of the circuit corresponding to our construction in the two bit case in Fig. 10. In our main construction we assume only access to block encodings of $A = A^{\circ 1}$, and show that it is not strictly necessary to go through an intermediate bit-wise construction like the one below.

²⁴ If not we can pad our construction to the next largest power of two and simply truncate our LCU, as is common in prior work [CW12].

Proposition C.1 (Amended construction for bit-wise element-wise SELECT). Let U_A an $(1, a, 0)$ block encoding of an n -qubit operator A , and $U_{A^{\circ k}}$ an $(1, a_k, 0)$ block encoding of the k -th element-wise product of A with itself. Then given query access to $U_{A^{\circ 2^j}}$ for $j \in \{0, 1, \dots, m\}$ we can construct the bit-wise SELECT unitary for the element-wise product:

$$\sum_{b_0, b_1, \dots, b_m=0}^1 |b_0 b_1 \dots b_m\rangle \langle b_0 b_1 \dots b_m| \otimes U_{A^{\circ(2^0 b_0 + 2^1 b_1 + \dots + 2^m b_m)}}, \quad (C7)$$

Proof. Merely controllizing all of the unitaries in the original element-wise product construction is not sufficient to achieve our desired SELECT unitary, due to the problems brought up in Rem. C.1. Consequently we also need to controllize the permutations used to bring the element-wise product to the top-left block of our block encodings, *as well as* the swap operation used to turn a block encoding of $(I_{r_1} \otimes A_{r_3})$ to one of $(A_{r_1} \otimes I_{r_3})$. Moreover, this controlization needs to be such that it occurs whenever *either* of the input bit-wise controlled block encodings is trivial, which is accomplished by introducing an additional qubit of space and the use of Toffoli gates to achieve an bit-wise XOR. For the two bit case this is depicted in Fig. 10, from which the general circuit follows simply. We note that the additional space used²⁵ scales only in the bit-length m (multiplied by the size of the register containing the action of A , n), yielding the quoted $\mathcal{O}(nm)$ qubit and gate complexities. $\square$

²⁵ Here the additional space is logarithmic in the maximum degree $(2^{m+1} - 1)$ of the element-wise product only because we have assumed low-space block encodings for each 2^k -th element-wise power of A .

Lemma C.3 (Block encoding Kronecker products). Let U_A an (α, a, ε) block encoding of an n -qubit operator A . Then we can construct an $(\alpha^d, a + \log d, \delta)$ block encoding of $A^{\otimes d}$ (the d -th order Kronecker product of A with itself) using d queries to U_A and total space $nd + a + \log d$.

Proof. The construction follows simply from recognition that $A^{\otimes d}$ is the matrix product of $B_k \equiv I_0 \otimes \cdots \otimes A_k \otimes \cdots \otimes I_{d-1}$, where A appears in the k -th register and the identity matrices are on n -qubits. Moreover, block encoding the Kronecker product of an operator and the identity matrix is trivial, and requires only allocating additional unused qubits on which the identity matrix ‘acts.’ Once we have reduced to the matrix product setting, the usual compression gadget (Lem. A.1) applies, reducing auxiliary space usage from the naïve ad to $a + \log d$ qubits. $\square$

Theorem C.1 (Half-compressed QEWT). Let U_A an (α, a, ε) block encoding of an n -qubit operator A . Then we can construct an $(\alpha^d, a + n(d-1) + \log d, \delta)$ block encoding of $A^{\odot d}$ (the d -th order element-wise product of A with itself) using d queries to U_A .

Proof. For element-wise powers, the result follows from Lem. C.3, to which we apply the $\mathcal{O}(d)$ pairs of n -qubit qubit-wise CNOT gates to locate the copy of A^d inside the d -th order Kronecker product. Absorbing the unused $(n-1)d$ qubits into the auxiliary space of the final block encoding completes the construction. Proof for the general QEWT then follows by direct application of Thm. II.3 to our half-compressed element-wise product gadgets (built into a SELECT unitary by the methods of Lem. C.2). This immediately improves the space complexity in d , albeit not exponentially as in our fully compressed construction. $\square$

D. Error propagation in block encodings

This appendix has been reserved to offload repetitive proofs in the main paper regarding the handling of errors in input block encodings. We take some time to discuss how handling this error propagation changes with respect to the matrix functions we consider, and rectify some common oversights in prior work. Where appropriate we have referred results quoted in the main theorems to their respective proofs here.

Remark D.1 (Error propagation in various block encoding products). We take a brief detour to summarize (and in some places rectify) standard arguments used to propagate error from the input block encodings to a quantum algorithm and its output block encoding.

Let U_A and U_B respectively (α, a, ε) and (β, b, δ) block encodings of matrices A and B square and of the same dimension. Recall that this means, wlog for U_A , that the unitary contains an $\alpha \geq 1$ sub-normalized ε -approximation (in the operator norm²⁶) to A , i.e.

$$\|A - (\langle 0^a | \otimes I)U_A(|0^a\rangle \otimes I)\| \leq \varepsilon. \quad (\text{D1})$$

It is well known how to propagate error with respect to the equipped associative algebra (here sums and products)²⁷

$$(\alpha, a, \varepsilon), (\beta, b, \delta) \mapsto (\alpha + \beta, \max(a, b) + 1, \delta + \varepsilon) \quad (\text{sum, } A + B) \quad (\text{D2})$$

$$(\alpha, a, \varepsilon), (\beta, b, \delta) \mapsto (\alpha\beta, a + b, \alpha\delta + \beta\varepsilon + \varepsilon\delta) \quad (\text{matrix product, } AB) \quad (\text{D3})$$

It turns out that these two rules (and their iterated variants, captured by LCU and the compression gadget respectively) tell us most of what we need to know, as the other common

²⁶ We discuss elsewhere in the text that, in the context of element-wise products it may sometimes make more sense to use element-wise max norms, or variant Frobenius norms.

²⁷ We note here that the auxiliary space use for the sum operation involves padding the smaller register among a, b , and that for multiplication we can reduce $a + b$ to 1 using the compression gadget.

matrix products we consider are mainly sub-matrices, block-versions, or basis-transformed variants of the above manipulations. We recall a subset of the products covered in this work:

$$\otimes \quad \backslash \text{otimes} \quad (\text{Kronecker/tensor product}), \quad (\text{D4})$$

$$\circ \quad \backslash \text{circ} \quad (\text{Element-wise product}), \quad (\text{D5})$$

$$\boxtimes \quad \backslash \text{boxtimes} \quad (\text{Tracy–Singh product; Def. IV.3}), \quad (\text{D6})$$

$$\odot \quad \backslash \text{odot} \quad (\text{Khatri-Rao product; Def. IV.4}), \quad (\text{D7})$$

$$* \quad \backslash \text{ast} \quad (\text{Convolution}). \quad (\text{D8})$$

Note that the Kronecker product $(A \otimes B)$ is simply the matrix product of $(A \otimes I)$ and $(I \otimes B)$, which can be built from (α, a, ε) and (β, b, δ) block encodings of A and B respectively as $\|M \otimes N\| \leq \|M\| \|N\|$, and thus propagates error in the same way as the matrix product. Likewise, given that the element-wise product is a sub-matrix of the Kronecker product, its accrued propagation can be no-worse, and thus we can also use the usual matrix product error propagation formula. Moreover, as the TS product is a row- and column-permutation of the Kronecker product, and the KR product is a submatrix of the TS product, these also obey the matrix product error propagation formula. Finally, the 2D cyclic convolution we consider is a basis transformation of the element-wise product, and thus does not change the operator norm.

To belabor one more point, we explicitly reproduce the error propagation formula in the case of multiplying together K block encoded matrices at once. This treatment has been the subject of a small error since early publications, and spans both of [GSLW19, GYC⁺25] (separated by at least six years). Here we consider a collection of K block encoded matrices $A_0, A_1, \dots, A_{K-1}$, assumed conformable to matrix multiplication, and with respective block encoding parameters $(\alpha_k, a_k, \varepsilon_k)$; then we can achieve a block encoding of their product $A_0 A_1 \cdots A_{K-1}$ with the following parameters:

$$(\alpha_k, a_k, \varepsilon_k)_{k \in \{0, \dots, K-1\}} \mapsto \left(\prod_{k=0}^{K-1} \alpha_k, [*], \prod_{k=0}^{K-1} (\alpha_k + \varepsilon_k) - \prod_{k=0}^{K-1} \alpha_k \right), \quad (\text{D9})$$

where the auxiliary space usage is denoted $[*]$ as it depends on whether a compression scheme is used. A full derivation of this result is contained in Prop. 9.12 of the developing, public lecture notes [LW26]. Assuming that $\varepsilon_k \ll \alpha_j$ for all j, k , the leading order terms of the approximation error of this expression is what is supplied by a large fraction of extant literature.

In the interest of a self-contained appendix, we calculate the propagated error in our element-wise product subroutine (Thm. II.2) in the following Prop. D.1, and then the error in our full quantum element-wise transform (Thm. II.3) in the following Prop. D.2. These are different from the error quoted in the non-compressed Thm. S6 of [GYC⁺25] for the reasons quoted in Rem. D.1.

Proposition D.1 (Error in iterated element-wise product of block encodings). Let $A \in \mathbb{C}^{N \times N}$ for $N = 2^n$ and U_A a (α, a, ε) block encoding of A . Then we can construct a $(\alpha^d, da + (d-1)n, \gamma)$ block encoding of A^{o^d} , where $\gamma = (\alpha + \varepsilon)^d - \alpha^d$ (approximately $d\alpha\varepsilon$ in the case of large α and small ε).

Proof. The linear-space result is given in [GYC⁺25], and we reproduce their brief argument here. Let $A' = \alpha \langle 0^a | U_A | 0^a \rangle$ and $E \equiv A - A'$, which by definition must satisfy $\|E\| \leq \varepsilon$. Then the error δ between the ideal element-wise self-product and the achieved one is bounded

above according to (in the $d = 2$ case)

$$\delta \leq \|A \circ A - \langle 0^n | P(A' \otimes A') P^\dagger | 0^n \rangle\|, \quad (\text{D10})$$

$$\leq \|A \circ A - \langle 0^n | P(A' \otimes A - A' \otimes A + A' \otimes A') P^\dagger | 0^n \rangle\|, \quad (\text{D11})$$

$$\leq \|A \circ A - \langle 0^n | P(A' \otimes A) P^\dagger | 0^n \rangle\| + \|\langle 0^n | P(A' \otimes A - A' \otimes A') P^\dagger | 0^n \rangle\|, \quad (\text{D12})$$

$$\leq \|\langle 0^n | P(A \otimes E) P^\dagger | 0^n \rangle\| + \|\langle 0^n | P(E \otimes A') P^\dagger | 0^n \rangle\|, \quad (\text{D13})$$

$$\leq (\alpha + \varepsilon)\varepsilon + \alpha\varepsilon, \quad (\text{D14})$$

$$= 2\alpha\varepsilon + \varepsilon^2, \quad (\text{D15})$$

where we have just applied the triangle inequality, the definition of E , and that the error is invariant under the swap of the tensor product order. Note carefully²⁸ that we have $\|A\| \leq \alpha + \varepsilon$, and *not* $\|A\| \leq \alpha$, as our target operator is allowed to violate our block encoding subnormalization constraint by a additive factor of ε . The case for general d follows immediately by an inductive argument, identical to that of Prop. 9.12 in [LW19], or reproduced in Rem. D.1. $\square$

Proposition D.2 (Error in LCU of element-wise products of block encodings). Let U_A an (α, a, ε) block encoding of a square matrix A on n qubits. Then the LCU according to a polynomial function f with complex coefficients c_k , for $k \in \{1, 2, \dots, d\}$ applied to element-wise powers of A yields a block encoding unitary $U_{f \circ (A)}$ with the following transformed parameters:

$$(\alpha, a, \varepsilon) \mapsto \left(\gamma, a + n \log d, \sum_{k=1}^d \varepsilon_k \right), \quad (\text{D16})$$

$$\gamma \equiv \sum_{k=1}^d |c_k|, \quad \varepsilon_k \equiv |c_k| \left[(\alpha + \varepsilon)^k - \alpha^k \right]. \quad (\text{D17})$$

Proof. The sub-normalization according to the ℓ_1 -norm γ of the coefficients of f is a basic consequence of the LCU construction and the unitarity of $U_{f \circ (A)}$. For each individual element-wise power we have computed ε_k directly from Prop. D.1 and the observations in Rem. D.1; these errors accrete linearly in the LCU, leading to the resulting total error. The auxiliary space usage follows from our recursive construction in the main Thm. II.3. $\square$

²⁸ This is an oversight that appears in the exposition of error propagation for block encoding multiplication in both [GSLW19, GYC⁺25], and is carefully amended in the recent (and in-progress) lecture notes of Lin and Wiebe [LW26].

Lean-Quantum: Toward AI-Assisted Formalization of Quantum Information

Abstract. Quantum information theory relies centrally on entropic quantities. Among them, the sandwiched Rényi relative entropy is a fundamental divergence with applications to hypothesis testing, strong converses, and entropic inequalities, and its data processing inequality under quantum channels is a cornerstone result. In this work, we present a Lean 4 formalization of this inequality for positive definite operators on finite-dimensional quantum systems. The formalization uses a basis-independent operator-theoretic framework compatible with the standard mathematical library *Mathlib*. It builds reusable analytic tools, including operator monotonicity and convexity through the real continuous functional calculus, block-operator positivity, Hilbert–Schmidt operator spaces, Jensen’s operator inequality, generalized perspective functions, operator power means, and Lieb–Ando trace inequalities. On top of this framework, we formalize the entropy-specific ingredients needed for the data processing inequality: variational formulas for the sandwiched quasi-entropy via trace Young and reverse-Young inequalities, tensor-product compatibility of real power functions, and Haar measures on unitary groups. Together, these results give a Lean formalization of the data processing inequality, yield strong subadditivity as a corollary, and provide the missing component needed to complete the Lean formalization of the generalized quantum Stein’s lemma. More broadly, the development provides reusable infrastructure for formalized quantum information theory and machine-checkable foundations for future AI-assisted theoretical research.

Keywords: Lean formalization, formalization-friendly proof, data processing inequality, sandwiched Rényi relative entropy, strong subadditivity, generalized quantum Stein’s lemma

0.1 Background

Quantum information theory provides a mathematical framework for characterizing the optimal performance and fundamental limitations of quantum information processing [1]. Entropic quantities play a central role in this framework: they quantify distinguishability, uncertainty, correlations, channel capacities, error exponents, and security parameters. Their structural properties often determine whether an information-processing theorem has a physically meaningful interpretation. Among these properties, the monotonicity of quantum divergences under quantum channels is particularly fundamental. If a quantum channel represents a physically realizable processing of quantum systems, then a physically consistent measure of distinguishability should not increase under the action of the channel.

The sandwiched Rényi relative entropy [2–4] is a central quantum divergence satisfying this principle. For positive semidefinite operators ρ and σ and for $\alpha \in (0, 1) \cup (1, \infty)$, the sandwiched Rényi relative entropy $D_\alpha(\rho \parallel \sigma)$ is defined by

$$Q_\alpha(\rho \parallel \sigma) = \text{Tr} \left[\left(\sigma^{\frac{1-\alpha}{2\alpha}} \rho \sigma^{\frac{1-\alpha}{2\alpha}} \right)^\alpha \right], \quad (1)$$

$$D_\alpha(\rho \parallel \sigma) = \frac{1}{\alpha - 1} \log \left[\frac{Q_\alpha(\rho \parallel \sigma)}{\text{Tr}[\rho]} \right], \quad (2)$$

whenever $0 < \alpha < 1$, and whenever $\alpha > 1$ and $\text{supp}[\rho] \subseteq \text{supp}[\sigma]$; otherwise the standard extended-real convention sets the divergence to $+\infty$ for $\alpha > 1$. For normalized states, $\text{Tr}[\rho] = 1$. This quantity interpolates and extends several operationally meaningful divergences and has become a standard tool in quantum hypothesis testing, strong converse analysis, one-shot information theory, and the study of quantum channel capacities. Its data processing inequality (DPI) states that, for every completely positive trace-preserving map Φ ,

$$D_\alpha(\Phi[\rho] \parallel \Phi[\sigma]) \leq D_\alpha(\rho \parallel \sigma), \quad \alpha \in [1/2, 1) \cup (1, \infty). \quad (3)$$

The inequality was shown for $\alpha \in (1, 2]$ by Refs. [2, 3] and then established in its full valid range $\alpha \geq 1/2$ by Frank and Lieb in Ref. [5], while Ref. [6] also provided an alternative proof for $\alpha \in (1, \infty)$. The proof in Ref. [5] reduces the DPI to joint convexity or concavity of Q_α , which is proved using Lieb–Ando trace inequalities together with variational formula; the passage from these convexity properties to channel monotonicity uses Stinespring dilation, normalized Haar averaging over a unitary group, Jensen’s inequality, tensor-product additivity, and monotonicity of the logarithm. Thus, the DPI for the sandwiched Rényi relative entropy is not only a cornerstone theorem of quantum information theory, but also a representative example of the analytic and operator-

theoretic complexity that modern quantum information theory involves.

The development of quantum information theory has also increasingly relied on software infrastructure. Numerical and symbolic software tools, including *Qiskit* [7], *Qulacs* [8], and *Stim* [9], are widely used for designing, simulating, and testing quantum circuits, quantum algorithms, and quantum protocols. These tools have expanded the scale and reliability of computational exploration in quantum information science, but they do not, by themselves, verify the proofs of the theorems being used. As quantum information theory becomes more intricate, and as AI systems begin to assist in conjecture generation, proof search, and formal manipulation, it becomes increasingly important to develop infrastructure that can verify logical correctness directly.

Interactive theorem provers provide such infrastructure. Lean 4 [10] is a proof assistant in which every theorem is checked by a small trusted kernel, and every logical dependency must ultimately be reduced to previously verified definitions and theorems. Its mathematical library, *Mathlib* [11], already contains extensive formalized material in algebra, topology, measure theory, functional analysis, operator theory, C^* -algebras, and continuous functional calculus. A Lean formalization is therefore not only a machine-checked record of a single proof. It is also a reusable mathematical interface: a precise library of definitions, lemmas, and proof methods that can be searched, combined, and extended without ambiguity. Such libraries are particularly important for AI-assisted theoretical research. AI systems can generate plausible definitions, proof sketches, and code fragments, but plausibility alone does not establish logical correctness. A Lean library provides a machine-checkable reference point: just as a compiler checks that a program is well typed, Lean’s kernel checks that each accepted proof term has the claimed theorem as its type, using only explicit definitions and previously verified results. It therefore makes it possible to distinguish heuristic reasoning suggested by AI from reasoning that has been certified as a formal proof.

0.2 Main Results

In this work, we present a Lean 4 formalization of the data processing inequality for the sandwiched Rényi relative entropy for positive definite operators on finite-dimensional quantum systems. The formalization is organized as a reusable software library [12] rather than as a monolithic proof. It contains a basis-independent framework for finite-dimensional quantum systems and channels, a hierarchy of operator and trace inequalities, and a mechanized proof architecture for the DPI based on the proof strategy of Frank and Lieb [5] with modifications and simplifications suitable for the Lean formalization, as summarized in the following. (See also the section “Design choices and formalization methodology” in the Technical Version for details of these contributions.)

1. Our first contribution is a basis-independent formulation of finite-dimensional quantum informa-

tion theory in Lean, without relying on matrix representations. In our codebase, quantum systems are represented as finite-dimensional complex Hilbert spaces, operators as linear endomorphisms, states as positive trace-one operators, and channels as completely positive trace-preserving maps. Building on this framework, we formalize tensor-product systems, partial traces, vectorization, Choi operators, Kraus representations, Stinespring representations, and the standard equivalences among complete positivity, positivity of ampliations, Choi positivity, Kraus representations, and Stinespring representations. Rather than forcing all arguments into explicit $d \times d$ matrices, this formulation aligns the development with the operator-algebraic structures used in *Mathlib* and allows the formalization to use its infrastructure for continuous linear maps, ordered star structures, C^* -algebras, spectra, and continuous functional calculus.
